About the Book

About The Authors

- Michael G. Newman, DDS, FACD
- Henry H. Takei, DDS, MS, FACD
- Perry R. Klokkevold, DDS, MS, FACD
- Fermin A. Carranza, DR ODONT, FACD

Preface

Acknowledgments

Video Contents

Introduction: The Historical Background of Periodontology

- Chapter Outline
- Early Civilizations
- The Classical World
- The Middle Ages
- The Renaissance
- The Eighteenth Century
- The Nineteenth Century
- The Twentieth Century
- The History of This Book
- References

Part 1 Evidence-Based Practice

Chapter 1 Evidence-Based Decision Making

- Background and Definition
- Principles of Evidence-Based Decision Making
- Evidence-Based Decision-Making Process and Skills
- Conclusion
- References

Chapter 2 Critical Thinking

Twelve Tools for Assessing Evidence

Conclusion

References

Part 2 Biologic Basis of Periodontology

Section I Normal Periodontium

Chapter 3 Anatomy, Structure, and Function of the Periodontium

Oral Mucosa

Gingiva

Periodontal Ligament

Cementum

Alveolar Process

Development of the Attachment Apparatus

External Forces and the Periodontium

Vascularization of the Supporting Structures

References

Chapter 4 Aging and the Periodontium

Effects of Aging on the Periodontium

Effects of Aging on the Progression of Periodontal Diseases

Aging and the Response to Treatment of the Periodontium

References

Section II Classification and Epidemiology of Periodontal Diseases

Chapter 5 Classification of Diseases and Conditions Affecting the Periodontium

- Gingival Diseases
- Periodontitis
- Medication-Related Osteonecrosis of the Jaw
- Necrotizing Periodontal Diseases
- Abscesses of the Periodontium
- Periodontitis Associated With Endodontic Lesions
- Developmental or Acquired Deformities and Conditions
- References

Chapter 6 Fundamentals in the Methods of Periodontal Disease Epidemiology

- The Need for Epidemiology
- Epidemiologic Study Designs
- Causes
- Diagnosis
- References

Section III Etiology of Periodontal Disease

Chapter 7 Periodontal Disease Pathogenesis

Histopathology of Periodontal Disease

Inflammatory Responses in the Periodontium

Linking Pathogenesis to Clinical Signs of Disease

Resolution of Inflammation

Immune Responses in Periodontal Pathogenesis

Concept of Host Susceptibility

References

Chapter 8 Biofilm and Periodontal Microbiology

The Oral Cavity From a Microbe's Perspective

Bacteria and Their Biofilm Mode of Living

Characteristics of Biofilm Bacteria (Life in “Slime City”)

Bacterial Transmission and Translocation

Nonbacterial Inhabitants of the Oral Cavity

Microbiologic Specificity of Periodontal Diseases

The Transition From Health to Disease

Virulence Factors of Periodontopathogens

Future Advances in Periodontal Microbiology

References

Chapter 9 Practical Molecular Biology of Host–Microbe Interactions

Microbe-Associated Molecular Patterns

Toll-Like Receptors

Nucleotide-Binding Oligomerization Domain–Like Receptors

Complement System

Antimicrobial Peptides

Immunomodulatory Therapies

References

Chapter 10 Resolution of Inflammation

Inflammation

Acute Inflammation Is Self-Limited

Unresolved Chronic Inflammation in Periodontal Diseases

Systemic Link

Therapeutic Actions of Resolution Mediators

Final Remarks

References

Chapter 11 Precision Dentistry

Genomic Advances in the 21st Century

Genetic Basis for Individual Differences in Disease Risk

Precision Dentistry: Using Genetics for Personalized Treatment

Acknowledgments

References

Chapter 12 Smoking and Periodontal Disease

The Smoking Epidemic

Effects of Smoking on the Prevalence and Severity of Periodontal Diseases

Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease

Effects of Smoking on the Response to Periodontal Therapy

Effects of Smoking Cessation on Periodontal Treatment Outcomes

References

Chapter 13 The Role of Dental Calculus and Other Local Predisposing Factors

Calculus

Other Predisposing Factors

References

Section IV Relationship between Periodontal Disease and Systemic Heath

Chapter 14 Influence of Systemic Conditions

Endocrine Disorders and Hormonal Changes

Hematologic Disorders and Immune Deficiencies

Genetic Disorders

Stress and Psychosomatic Disorders

Nutritional Influences

Medications

Other Systemic Conditions

Conclusion

References

Chapter 15 Impact of Periodontal Infection on Systemic Health

Pathobiology of Periodontitis

Focal Infection Theory Revisited

Evidence-Based Clinical Practice

Subgingival Environment as a Reservoir for Bacteria

Periodontal Disease and Mortality

Periodontal Disease, Coronary Heart Disease, and Atherosclerosis

Periodontal Disease and Stroke

Periodontal Disease and Diabetes Mellitus

Periodontal Disease and Pregnancy Outcome

Periodontal Disease and Chronic Obstructive Pulmonary Disease

Periodontal Disease and Acute Respiratory Infections

Periodontal Disease and Asthma

Periodontal Medicine in Clinical Practice

Conclusions

References

Section V Gingival Pathology

Chapter 16 Defense Mechanisms of the Gingiva

Sulcular Fluid

Leukocytes in the Dentogingival Area

Saliva

References

Chapter 17 Gingival Inflammation

Stage I Gingival Inflammation: The Initial Lesion

Stage II Gingival Inflammation: The Early Lesion

Stage III Gingival Inflammation: The Established Lesion

Stage IV Gingival Inflammation: The Advanced Lesion

References

Chapter 18 Clinical Features of Gingivitis

Course and Duration

Description

Clinical Findings

References

Chapter 19 Gingival Enlargement

Terminology and Classification

Diagnosis

Types of Gingival Enlargement

Other Forms of Gingival Enlargement

References

Chapter 20 Acute Gingival Infections

Necrotizing Ulcerative Gingivitis

Primary Herpetic Gingivostomatitis

Pericoronitis

Conclusions

References

Chapter 21 Gingival Disease in Childhood

Periodontium of the Primary Dentition

Periodontal Changes Associated With Normal Development

Gingival Diseases of Childhood

Periodontal Diseases of Childhood

Gingival Manifestation of Systemic Disease in Children

Oral Mucosa in Childhood Diseases

Therapeutic Considerations for Pediatric Patients

Conclusions

References

Chapter 22 Desquamative Gingivitis

Chronic Desquamative Gingivitis

Diagnosis of Desquamative Gingivitis: A Systematic Approach

Diseases That Can Manifest as Desquamative Gingivitis

Drug-Related Eruptions

Miscellaneous Conditions That Mimic Desquamative Gingivitis

References

Section VI Periodontal Pathology

Chapter 23 The Periodontal Pocket

Classification

Clinical Features

Pathogenesis

Histopathology

Periodontal Disease Activity

Site Specificity

Pulp Changes Associated With Periodontal Pockets

Relationship of Attachment Loss and Bone Loss to Pocket Depth

Area Between Base of Pocket and Alveolar Bone

Relationship of Pocket to Bone

Periodontal Abscess

Lateral Periodontal Cyst

References

Chapter 24 Bone Loss and Patterns of Bone Destruction

Bone Destruction Caused by the Extension of Gingival Inflammation

Bone Destruction Caused by Trauma From Occlusion

Bone Destruction Caused by Systemic Disorders

Factors Determining Bone Morphology in Periodontal Disease

Bone Destruction Patterns in Periodontal Disease

Conclusion

References

Chapter 25 Periodontal Response to External Forces

Adaptive Capacity of the Periodontium to Occlusal Forces

Trauma From Occlusion

Stages of Tissue Response to Increased Occlusal Forces

Effects of Insufficient Occlusal Force

Reversibility of Traumatic Lesions

Effects of Excessive Occlusal Forces on Dental Pulp

Relationship Between Plaque-Induced Periodontal Diseases and Trauma From Occlusion

Pathologic Tooth Migration

Summary

References

Chapter 26 Masticatory System Disorders That Influence the Periodontium

Temporomandibular Joint

Muscles and Nerves of the Masticatory System

Centric Relation

Biomechanics of the Masticatory System

Dysfunction and Deterioration

Orofacial Pain

Comprehensive Evaluation

Diagnostic Decision Making

Acknowledgments

References

Chapter 27 Chronic Periodontitis

Clinical Features

Risk Factors for Disease

References

References

References

Chapter 28 Aggressive Periodontitis

Overview

Historical Background

Classification and Clinical Characteristics

Epidemiology

Pathobiology and Risk Factors

Therapeutic Considerations in Aggressive Periodontitis Patients

References

Chapter 29 Necrotizing Ulcerative Periodontitis

Clinical Features

Microscopic Findings

Patients With HIV/AIDS

Etiology of Necrotizing Ulcerative Periodontitis

Malnutrition

Conclusion

References

Chapter 30 Pathology and Management of Periodontal Problems in Patients With Human Immunodeficiency Virus Infection

Pathogenesis

Epidemiology and Demographics

Classification and Staging

Oral and Periodontal Manifestations of Human Immunodeficiency Virus Infection

Dental Treatment Complications

Gingival and Periodontal Diseases

Periodontal Treatment Protocol

References

Part 3 Clinical Periodontics

Section I Diagnosis, Prognosis, and Treatment Plan

Chapter 31 Levels of Clinical Significance

Tangible Versus Intangible Benefits

Size of the Treatment Effect

Defining Four Levels of Clinical Significance

Summary

References

Chapter 32 Periodontal Examination and Diagnosis

Overall Appraisal of the Patient

Health History

Dental History

Photographic Documentation

Clinical Examination

Tactile Periodontal Examination

Periodontal Charting

Examination of the Teeth and Implants

Radiographic Examination

Laboratory Aids to Clinical Diagnosis

Periodontal Diagnosis

Assessment of Biofilm Control and Patient Education

Conclusion

References

Chapter 33 Radiographic Aids in the Diagnosis of Periodontal Disease

Normal Interdental Bone

Radiographic Techniques

Bone Destruction in Periodontal Disease

Radiographic Appearance of Periodontal Disease

Digital Intraoral Radiography

Advanced Imaging Modalities

Conclusion

References

Chapter 34 Clinical Risk Assessment

Definitions

Risk Factors for Periodontal Disease

Risk Determinants/Background Characteristics for Periodontal Disease

Risk Indicators for Periodontal Disease

Risk Markers/Predictors for Periodontal Disease

Clinical Risk Assessment for Periodontal Disease

Conclusion

References

Chapter 35 Determination of Prognosis

Definitions

Types of Prognosis

Factors in Determination of Prognosis

Prognosis of Specific Periodontal Diseases

Determination and Reassessment of Prognosis

Conclusion

References

Chapter 36 The Treatment Plan

Overall Treatment Plan

Sequence of Therapy

Explaining the Treatment Plan to the Patient

Conclusion

Chapter 37 Electronic Dental Records and Decision Support Systems

Functionalities and Components Available in Electronic Dental Records

Electronic Dental Record Use in Dental Practices

Future of Electronic Dental Records and Decision Support Systems in Dentistry

References

Section II Management of Patients with Special Needs

Chapter 38 Conscious Sedation

- Rationale for Sedation During Periodontal and Implant Surgical Procedures
- American Dental Association Policy Statement and Guidelines for Conscious Sedation
- Definitions and Levels of Sedation
- Minimal Sedation and Anxiolysis
- Moderate Sedation
- Sedation Failures
- Emergency Preparedness
- Conclusions
- References

Chapter 39 Periodontal Treatment of Medically Compromised Patients

- Cardiovascular Diseases
- Endocrine Disorders
- Hemorrhagic Disorders
- Renal Diseases
- Liver Diseases
- Pulmonary Diseases
- Medications and Cancer Therapies
- Prosthetic Joint Replacement

Pregnancy

Infectious Diseases

References

Chapter 40 Sleep-Disordered Breathing

New and Evolving Role of the Dentist

Sleep-Related Breathing Disorders and the Periodontium

Dental Identification of Signs and Symptoms

Sleep, Breathing, and Apnea

Diagnosis of Obstructive Sleep Apnea

Treatment Options for Obstructive Sleep Apnea

Oral Devices for Mandibular Repositioning

Device Design and Compliance

Conclusions

References

Chapter 41 Periodontal Therapy in the Female Patient

Puberty

Menses

Pregnancy

Oral Contraceptives

Menopause

Conclusions

References

Chapter 42 Periodontal Treatment for Older Adults

The Aging Periodontium

Demographics

Dental and Medical Assessments

Periodontal Diseases in Older Adults

Periodontal Treatment Planning

Conclusions

References

Chapter 43 Treatment of Aggressive and Atypical Forms of Periodontitis

Aggressive Periodontitis

Periodontitis Refractory to Treatment

Necrotizing Ulcerative Periodontitis

Conclusions

References

Section III Diagnosis and Treatment of Periodontal Emergencies

Chapter 44 Treatment of Acute Gingival Disease

Necrotizing Ulcerative Gingivitis

Primary Herpetic Gingivostomatitis

Pericoronitis

Conclusion

References

Chapter 45 Treatment of Periodontal Abscess

Classification of Abscesses

Specific Treatment Approaches

References

Chapter 46 Endodontic-Periodontic Lesions

Factors Initiating Pulpal and Apical Diseases

Classification of Pulpal and Apical Diseases

Biologic Effects of Pulpal Infection on Periodontal Tissues

Biologic Effects of Periodontal Infection on the Dental Pulp

Effects of Endodontic Pathosis on Development of Retrograde Peri-implantitis

Interactions Between Extraradicular Infection and the Periodontium

Differential Diagnosis of Pulpal and Periodontal Infection

Treatment Considerations

Summary

References

Section IV Nonsurgical Treatment

Chapter 47 Phase I Periodontal Therapy

Rationale

Treatment Sessions

Sequence of Procedures

Results

Healing

Decision to Refer for Specialist Treatment

Conclusion

References

Chapter 48 Plaque Biofilm Control for the Periodontal Patient

The Toothbrush

Powered Toothbrushes

Dentifrices

Toothbrushing Methods

Interdental Cleaning Aids

Gingival Massage

Oral Irrigation

Caries Control

Chemical Plaque Biofilm Control With Oral Rinses

Disclosing Agents

Frequency of Plaque Biofilm Removal

Patient Motivation and Education

Conclusion

References

Chapter 49 Breath Malodor

Semantics and Classification

Epidemiology

Etiology

Fundamentals of Malodor Detection

Diagnosis of Malodor

Treatment of Oral Malodor

Conclusion

References

Chapter 50 Scaling and Root Planing*

Classification of Periodontal Instruments

General Principles of Instrumentation

Principles of Scaling and Root Planing

Instrument Sharpening

References

Chapter 51 Sonic and Ultrasonic Instrumentation and Irrigation

Power-Driven Instruments: Overview

Mechanism of Action of Power Scalers

Type and Benefit of Power Instruments

Clinical Outcomes of Power-Driven Instruments

Principles of Instrumentation

Home and Self-Applied Irrigation

Mechanism of Action of Irrigation

Clinical Outcomes of Irrigation

Individuals With Special Considerations

Action of a Tip With Filaments Cleaning Around an Implant

Conclusion

References

Chapter 52 Systemic Anti-infective Therapy for Periodontal Diseases

Definitions

Systemic Administration of Antibiotics

Serial and Combination Antibiotic Therapy

Conclusion

References

Chapter 53 Locally Delivered, Controlled-Release Antimicrobials

Background and Objectives

Drug Development and Registration

Clinical Use

Case Reports

Conclusions

References

Chapter 54 Host Modulation

Introduction

Systemically Administered Agents

Locally Administered Agents

Host Modulation and Comprehensive Periodontal Management

Sub-antimicrobial–Dose Doxycycline

Emerging Host Modulatory Therapies

Host Modulation Factors in Systemic Disorders

Summary

References

Chapter 55 Occlusal Evaluation and Therapy

Pathogenesis

Evidence-Based Decision Making

Terminology

Occlusal Function and Dysfunction

Parafunction

Clinical Examination

Occlusal Therapy

Conclusions

References

Chapter 56 Orthodontics

Abstract

Keywords

Chapter Outline

Benefits of Orthodontic Therapy

Preorthodontic Osseous Surgery

Orthodontic Treatment of Osseous Defects

Orthodontic Treatment of Gingival Discrepancies

Conclusion

References

Abstract

Keywords

Chapter Outline

Introduction

Implant Interactions in Orthodontics

Conclusion

References

Section V Surgical Treatment

Chapter 57 Phase II Periodontal Therapy

Objectives of the Surgical Phase

Pocket Elimination Versus Pocket Maintenance

Reevaluation After Phase I Therapy

Critical Zones in Pocket Surgery

Indications for Periodontal Surgery

Methods of Pocket Therapy

Conclusions

References

Chapter 58 Periodontal and Peri-Implant Surgical Anatomy

Mandible

Maxilla

Exostoses

Muscles

Anatomic Spaces

Conclusion

References

Chapter 59 General Principles of Periodontal Surgery

Outpatient Surgery

Hospital Periodontal Surgery

Surgical Instruments

Conclusion

References

Chapter 60 Periodontal Surgical Therapy

Rationale for Periodontal Access Surgery

Fundamentals of Periodontal Surgery

Periodontal Surgical Techniques

Conclusion

References

Chapter 61 Treatment of Gingival Enlargement

Chronic Inflammatory Enlargement

Periodontal and Gingival Abscesses

Drug-Induced Gingival Enlargement

Leukemic Gingival Enlargement

Gingival Enlargement During Pregnancy

Gingival Enlargement During Puberty

References

Chapter 62 Resective Osseous Surgery

Selection of Treatment Technique

Rationale

Normal Alveolar Bone Morphology

Terminology

Factors in Selection of Resective Osseous Surgery

Examination and Treatment Planning

Methods of Resective Osseous Surgery

Osseous Resection Technique

Flap Placement and Closure

Postoperative Maintenance

Specific Osseous Reshaping Situations

Conclusion

References

Chapter 63 Periodontal Regeneration and Reconstructive Surgery

Assessment of Periodontal Wound Healing

Reconstructive Surgical Techniques

Factors That Influence Therapeutic Success

Future Directions for Periodontal Regeneration

Conclusion

References

Chapter 64 Furcation

Etiologic Factors

Diagnosis and Classification of Furcation Defects

Local Anatomic Factors

Anatomy of the Bony Lesions

Indices of Furcation Involvement

Treatment

Nonsurgical Therapy

Surgical Therapy

Prognosis

References

Chapter 65 Periodontal Plastic and Aesthetic Surgery

Terminology

Objectives

Cause of Marginal Tissue Recession

Factors That Affect Surgical Outcome

Techniques to Increase Attached Gingiva

Techniques to Deepen the Vestibule

Techniques to Remove the Frenum

Techniques to Improve Aesthetics

Tissue Engineering

Criteria for Selection of Techniques

Conclusions

References

Chapter 66 Leukocyte- and Platelet-Rich Fibrin

Introduction

General Characteristics of L-PRF Membranes

Extraoral Applications of L-PRF

L-PRF in the Treatment of Periodontal Bony Defects

L-PRF for Ridge Preservation

L-PRF and Sinus Floor Elevation

L-PRF and Implant Surgery

L-PRF for Periodontal Mucogingival Surgery

L-PRF and Medication-Related Osteonecrosis of the Jawbone

Initial Observations on the PRF-Block

Conclusions

References

Chapter 67 Periodontal Microsurgery

Philosophy of Periodontal Microsurgery

Advantages of Microsurgery

Magnification Systems

Microsurgical Sutures

Aesthetic Periodontal Microsurgery

Microsurgical Knots

Conclusions

References

Chapter 68 Lasers in Periodontal and Peri-implant Therapy

Laser Physics and Biologic Interactions

Laser Applications in Periodontics

Lasers in the Management of Periodontitis

Lasers in the Management of Peri-implantitis

Complications and Risks of Laser Therapy

Conclusion

References

Section VI Periodontal-Restorative Interrelationships

Chapter 69 Preparation of the Periodontium for Restorative Dentistry

Rationale for Therapy

Sequence of Treatment

Control of Active Disease

Preprosthetic Surgery

Conclusion

References

Chapter 70 Restorative Interrelationships

Biologic Considerations

Aesthetic Tissue Management

Occlusal Considerations in Restorative Therapy

Special Restorative Considerations

References

Chapter 71 Multidisciplinary Versus Interdisciplinary Approaches to Dental and Periodontal Problems

Educational Trends Toward Multidisciplinary Specialist Education in Implant Treatment

The Future

Section VII Supportive Care and Results of Periodontal Treatment

Chapter 72 Supportive Periodontal Treatment

Rationale for Supportive Periodontal Treatment

Maintenance Program

Classification of Posttreatment Patients and Risk Assessment

Referral of Patients to the Periodontist

Tests for Disease Activity

Conclusion

References

Chapter 73 Results of Periodontal Treatment

Prevention and Treatment of Gingivitis

Prevention and Treatment of Loss of Attachment

Tooth Mortality

Conclusion

References

Part 4 Oral Implantology

Section I Biology, Diagnosis, Biomechanics, and Treatment Plan

---

Chapter 74 Peri-implant Anatomy, Biology, and Function

Implant Geometry (Macrodesign)

Implant Surface Characteristics (Microdesign)

Hard Tissue Interface

Soft Tissue Interface

Clinical Comparison of Teeth and Implants

Conclusion

References

Chapter 75 Clinical Evaluation of the Implant Patient

Case Types and Indications

Pretreatment Evaluation

Risk Factors and Contraindications

Posttreatment Evaluation

Conclusion

References

Chapter 76 Diagnostic Imaging for the Implant Patient

Standard Projections

Cross-Sectional Imaging

Interactive “Simulation” Software Programs

Patient Evaluation

Clinical Selection of Diagnostic Imaging

Conclusion

References

Chapter 77 Prosthetic Considerations for Implant Treatment

Implant Considerations

Abutment/Prosthesis Considerations for Single Units

Management of Partially Edentulous Implant Treatment in the Aesthetic Zone

Fully Edentulous: Prosthetic Considerations

Conclusion

References

Section II Surgical Procedures

Chapter 78 Basic Implant Surgical Procedures

General Principles of Implant Surgery

Two-Stage “Submerged” Implant Placement

One-Stage “Nonsubmerged” Implant Placement

Conclusion

References

Chapter 79 Localized Bone Augmentation and Implant Site Development

Guided Bone Regeneration

Localized Ridge Augmentation

Alveolar Ridge Preservation/Management of Extractions

Conclusion

References

Chapter 80 Advanced Implant Surgical Procedures

Maxillary Sinus Elevation and Bone Augmentation

Supracrestal/Vertical Bone Augmentation

Growth Factors in Bone Augmentation

Conclusion

References

Chapter 81 Aesthetic Management of Difficult Cases (Minimally Invasive Approach)

Surgical Strategy for Predictable Aesthetics

Immediate Implant Placement for Predictability and Aesthetics

Surgical Management of Difficult Cases (Minimally Invasive Approach)

Conclusion

References

Chapter 82 Dental Implant Microsurgery

Conclusion

References

Chapter 83 Piezoelectric Bone Surgery

Clinical Characteristics of Ultrasonic Cutting

Clinical Applications

Advanced Clinical Applications

Conclusion

References

Chapter 84 Digitally Assisted Implant Surgery

Digitally Assisted Implant Surgery

Conclusion

References

Section III Complications

Chapter 85 Implant-Related Complications and Failures

Definitions of Implant Survival and Success

Types and Prevalence of Implant Complications

Types of Dental Implants

Surgical Complications

Biologic Complications

Complications Related to Augmentation Procedures

Complications Related to Placement and Loading Protocols

Prosthetic or Mechanical Complications

Aesthetic and Phonetic Complications

Conclusions

References

Section IV Supportive Care and Results of Implant Treatment

Chapter 86 Supportive Implant Treatment

Rationale for Supportive Implant Treatment

Examination of Implants

Assessment of Peri-Implant Health

Implant Maintenance

Treatment of Peri-Implant Diseases

Referral of Patients to the Periodontist

References

Chapter 87 Results of Implant Treatment

Defining Implant Outcomes

Factors That Influence Implant Outcomes

Aesthetic Results and Patient Satisfaction

Conclusions

References

Part 5 Atlas of Periodontal Diseases

Chapter 88 Atlas of Periodontal Diseases

Plaque-Induced Gingival Diseases

Causes of Periodontal Diseases

Gingival Diseases Modified by Systemic Factors

Gingival Diseases Associated With Blood Dyscrasias

Drug-Induced Gingival Diseases

Non–Plaque-Induced Gingival Lesions

Gingival Lesions of Genetic Origin

Gingival Manifestations of Systemic Conditions

Traumatic Lesions: Factitious, Iatrogenic, and Accidental

Cysts and Tumors

Chronic Periodontitis

Aggressive Periodontitis

Periodontitis as a Manifestation of Systemic Diseases

Genetic Disorders

Necrotizing Periodontal Diseases

Abscesses of Periodontium

Index

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.
Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods, they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.
With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

About the Book

Newman and Carranza's Clinical Periodontology, thirteenth edition, is the definitive global reference text in periodontics. Edited by Drs. Michael G. Newman, Henry H. Takei, Perry R. Klokkevold, editor emeritus Fermin A. Carranza, and associate editor Satheesh Elangovan, this book provides the highest quality information for students, residents, and practitioners.

The thirteenth edition is truly transformational. It fully engages modern information technology while maintaining and refining its decades of educational excellence. This edition improves on the previous one by more accurately reflecting the essential core information of periodontology and state-of-the-art methods in both the science and clinical knowledge base. Experts from more countries than ever have contributed to reflect a unifying view of the basic information related to the science and technology of modern periodontics.

The content on Expert Consult site is much improved in every aspect, including better speed, quality, functionality, access, and linking. There are more animations, videos, and case reports and one of the most comprehensive image libraries on periodontal pathology ever assembled. New case scenarios offer readers the opportunity to challenge their knowledge of integrated information in much more "real-life" patient encounters.

The print book is a complete and thorough presentation of periodontology essentials while retaining the style and quality that makes *Newman and Carranza's Clinical Periodontology* the number one periodontal textbook in the world. Advances in printing and

digital technology make this edition more “readable” than ever before.

About The Authors

Michael G. Newman, DDS, FACD

Dr. Michael G. Newman graduated from the University of California, Los Angeles (UCLA), College of Letters and Sciences with a degree in psychology. He completed his dental training at the UCLA School of Dentistry in 1972. Dr. Newman received a Certificate in Periodontics and Oral Medicine at the Harvard School of Dental Medicine and a Certificate in Oral Microbiology from the Forsyth Dental Institute under the mentorship of Dr. Sigmund Socransky. He is a Diplomate of the American Board of Periodontology and is Professor Emeritus of Periodontics at the UCLA School of Dentistry. Dr. Newman is a fellow and past

president of the American Academy of Periodontology. In 1975, he won the Balint Orban Memorial Prize from the American Academy of Periodontology. He has been in private practice of periodontics for more than 25 years. In 2007, Dr. Newman received the Gold Medal, the highest honor bestowed by the American Academy of Periodontology.

Dr. Newman has published more than 260 abstracts, journal articles, and book chapters and has co-edited nine textbooks. He has served as an ad-hoc reviewer for the National Institute of Dental and Craniofacial Research, was a consultant to the Council on Scientific Affairs of the American Dental Association, and is a reviewer for numerous scientific and professional journals and governmental research organizations.

Professor Newman has lectured throughout the world on microbiology, antimicrobials, evidence-based methodology, risk factors, and diagnostic strategies for periodontal disease. He has a strong interest in applied science and the transfer of new technology for practical use. Dr. Newman is a consultant to major dental and pharmaceutical companies throughout the world. He is the founding editor-in-chief of the *Journal of Evidence-Based Dental Practice (JEBDP)* and *The JEBDP Annual Report Series* and was the associate editor of the *International Journal of Oral and Maxillofacial Implants*.

Henry H. Takei, DDS, MS, FACD

Dr. Henry H. Takei graduated in 1965 from the Marquette University School of Dentistry in Milwaukee, Wisconsin. He completed his Periodontics Certificate and Master of Science degree in 1967 at Marquette University and the Veterans Administration Hospital in Wood, Wisconsin.

Presently, Dr. Takei is a Distinguished Clinical Professor of Periodontics and Consultant in Periodontics at the University of California, Los Angeles (UCLA), School of Dentistry and a consultant in periodontics at the Veterans Administration Hospital in Los Angeles. In addition to his educational activities, he maintains a private practice limited to periodontics and implant surgery.

Dr. Takei has published numerous clinical and scientific articles on periodontal surgery and has contributed chapters to five textbooks. He has been actively involved in continuing education and has lectured throughout the world on clinical periodontology and implant surgery.

Dr. Takei has been honored nationally and internationally with awards from numerous periodontal organizations, universities, and study clubs for his contributions to education. He is also a Fellow of both the American College of Dentists and the International College of Dentists and has been elected into Omicron Kappa Upsilon.

He received the Distinguished Alumnus Award from Marquette

University in 2001 and the Honorary Distinguished Alumnus Award from UCLA in 1998. The American Academy of Periodontology has honored Dr. Takei with the prestigious Master Clinician Award in 2006. This award is the highest clinical recognition from this national periodontal organization. In 2016, two universities in Japan, Meikai University and Asahi University, presented Dr. Takei with the Honorary Doctorate Degree for many years of academic and clinical collaboration.

Perry R. Klokkevold, DDS, MS, FACD

Dr. Perry R. Klokkevold graduated from the University of California, San Francisco, School of Dentistry in 1986. His postdoctoral clinical training includes a General Practice Residency in Hospital Dentistry completed in 1987, a Postgraduate Periodontal Residency completed in 1994, and a Surgical Implant Fellowship completed in 1995. All of his postgraduate training was completed at the University of California, Los Angeles (UCLA), School of Dentistry. He earned a Master of Science degree in Oral Biology at UCLA in 1995.

Dr. Klokkevold is a Diplomate of the American Board of Periodontology and a Fellow of the American College of Dentists.

He is an Associate Professor in the Division of Constitutive and Regenerative Sciences, Section of Periodontics, at the UCLA School of Dentistry and Program Director of the UCLA Postgraduate Periodontics Residency program. Dr. Klokkevold served as Clinical Director and Program Director of the General Practice Residency program in Hospital Dentistry at the UCLA School of Dentistry from 1987 to 1992. He has maintained a faculty practice limited to the specialty of periodontics and dental implant surgery at UCLA since 1995.

Dr. Klokkevold has published more than 60 articles for international peer-reviewed journals and has written more than 100 book chapters for 13 books, including five editions of *Clinical Periodontology,* on topics including periodontal medicine, influence of systemic disease and risk factors on periodontitis to bone regeneration, and dental implants. He has served as a reviewer for several journals, among them the *Journal of Periodontology* and the *International Journal of Oral and Maxillofacial Implants*. Dr. Klokkevold lectures nationally and internationally on many periodontal and implant-related topics. He has been invited to serve as an expert consultant/reviewer for five international conferences organized by the American Academy of Periodontology and the Academy of Osseointegration on topics that include implant therapy, bone augmentation and implant site development, periodontal regeneration, and lasers in periodontal therapy.

Fermin A. Carranza, DR ODONT, FACD

Dr. Fermin A. Carranza graduated from the University of Buenos Aires School of Dentistry in Argentina in 1948 and completed his postdoctoral training in periodontics at Tufts University School of Dental Medicine in 1952 under the mentorship of Dr. Irving Glickman.

Dr. Carranza is Professor Emeritus of Periodontology at the University of California, Los Angeles (UCLA), School of Dentistry. He was head of the Department of Periodontics at the University of Buenos Aires from 1966 to 1974 and at UCLA from 1974 until his retirement in 1994.

Dr. Carranza has published more than 218 scientific papers and abstracts on basic and applied aspects of periodontics and 18 books, including the past five editions of *Clinical Periodontology.* He has received numerous awards and recognition for his work, including the IADR Science Award in Periodontal Disease and the Gies Award of the American Academy of Periodontology.

Dr. Carranza has lectured throughout the world on clinical periodontology, pathology, and therapy.

Preface

With the help of Elsevier's advanced technology and high standards of quality, an international team of editors and contributors have developed the most comprehensive periodontal resource available, *Newman and Carranza's Clinical Periodontology*, thirteenth edition. The book's companion website is rich with images, animations, videos, question sets, case reports, PowerPoint slides, audio slides, virtual microscope, multidisciplinary case scenarios, and more. No other resource offers such a comprehensive approach to providing high quality content.

Since publication of the first edition of this book in 1953, periodontology has made tremendous advancements. Scientific analysis of periodontal tissues and the elucidation of mechanisms and causes of disease have extended far beyond histology and physiology into the realm of cellular and molecular biologic understanding.

Implant dentistry has become a major component of periodontology, and this book offers a wide coverage of important treatment modalities.

New therapeutic goals and clinical techniques, based on an improved understanding of disease and healing, have facilitated better outcomes and brought us closer to achieving the ultimate goal of optimal periodontal health and function. Today, reconstruction and regeneration of lost periodontal structures, replacement of compromised teeth with implants, and creation of aesthetic results are integral parts of clinical practice.

The multifaceted, complex task of producing the thirteenth edition required the collaboration of numerous experts from

various fields, and their contributions are invaluable. We know that this new edition will continue to be a useful resource for to dentists, dental hygienists, periodontists, students, educators, and researchers.

Having this resource available will contribute to the continuous progress of our profession.

Michael G. Newman

Henry H. Takei

Perry R. Klokkevold

Fermin A. Carranza

Acknowledgments

Clinical Periodontology has been a trusted and valuable periodontics resource for students, residents, academicians, scientists, and clinicians since the early 1950s. Dr. Irving Glickman was the originator and author of *Clinical Periodontology* for the first four editions, which were published in 1953, 1958, 1964, and 1972. Dr. Glickman was professor and chairman of the Department of Periodontology at Tufts University School of Dental Medicine, in Boston, Massachusetts.

Dr. Fermin A. Carranza, once a student of and collaborator with Dr. Glickman, assumed responsibility to author and continue the book after Dr. Glickman's death in 1972 at age 58. Dr. Carranza was professor and chairman of periodontics at the University of California, Los Angeles (UCLA), School of Dentistry. The subsequent four editions were published in 1979, 1984, 1990, and 1996 under the leadership and guidance of Dr. Carranza.

Dr. Michael G. Newman joined Dr. Carranza in 1996 as co-editor of the eighth edition. Dr. Newman was adjunct professor of periodontics at the UCLA School of Dentistry. Dr. Carranza retired to become professor emeritus at UCLA, and the responsibility of maintaining the book's tradition of almost half a century changed hands once again, this time to Dr. Newman. The subsequent four editions were published in 2002, 2006, 2012, and 2015 under the direction of Dr. Newman. The title of the ninth edition was changed from *Clinical Periodontology* to *Carranza's Clinical Periodontology* to acknowledge and honor Dr. Carranza for his leadership and dedication to this renowned resource.

Dr. Henry H. Takei joined Dr. Newman and Dr. Carranza in 2002 as co-editor of the ninth edition. Dr. Takei was clinical professor of periodontics at the UCLA School of Dentistry. Dr. Takei currently holds the title of Distinguished Clinical Professor of Periodontics at UCLA School of Dentistry.

Dr. Perry R. Klokkevold joined Drs. Newman, Takei, and Carranza in 2006 as co-editor of the tenth edition. Dr. Klokkevold is an associate professor and the program director of Postgraduate Periodontics at the UCLA School of Dentistry. Dr. Carranza became editor emeritus for the tenth and subsequent editions.

The title of the thirteenth edition has been changed to *Newman and Carranza's Clinical Periodontology* to acknowledge and recognize Dr. Newman's leadership in maintaining the book's reputation as a high-quality and forward-looking resource for those who practice periodontology and implant dentistry.

The level of understanding and the practice of clinical periodontics have evolved tremendously since the mid-20th century. Advances in basic science and clinical techniques have increased the knowledge base so dramatically that it is virtually impossible for individuals to master and retain all the information.

It is also certain that the task of researching, preparing, and assembling the enormous amount periodontology-related content necessary for this book had to be borne by many experts who shared their experience and knowledge. We express our deep gratitude to all the contributors whose expertise, ideas, and efforts built this valuable resource over the years. Many scientists and clinicians have shared their wisdom and expertise in previous editions of *Carranza's Clinical Periodontology*, as associate editors, section editors, and contributors, though some of their names no longer appear.

Our appreciation is given to Elsevier and particularly to Jennifer Flynn-Briggs and Lucia Gunzel. Their expertise and detailed attention to every word and every concept contributed greatly to producing a quality book and a truly useful website.

We also express appreciation to Dr. Satheesh Elangovan who joined the team for the thirteenth edition as associate editor. The

online version of the book continues to assume greater importance to our readers. Elsevier's electronic capabilities provide a rich, useful, and complete resource and are directed by Dr. Elangovan.

We express gratitude to our parents, colleagues, friends, and mentors who have always been so tolerant, encouraging, and understanding and who guided our first steps in our profession and helped us develop our ideas in the field.

Dr. Newman: My family, Susan, Andrea, Kara, Callahan and Natalie, Scott, Zoey and Eleanor; my parents, Paul, Rose, John, and Inez. Sigmund S. Socransky, Fermin A. Carranza, Jr., and Henry H. Takei. My gratitude to my co-editors and contributors whose expertise and willingness to participate in this work have made this book an excellent educational standard.

Dr. Takei: My wife, June; my children, Scott and Akemi; their spouses, Kozue and David; my grandchildren, Hana, Markus, Carter, and Arden. My graditude to my mentors Dr. Fermin A. Carranza, Jr., Dr. Donald Van Scotter, Dr. Delbert Nachazel, and Dr. John Pfeiffer. Thank you to my three co-editors and friends Michael G. Newman, Fermin A. Carranza, Jr., and Perry R. Klokkevold. Special gratitude to Laura Miyabe for her professional support. I would like to acknowledge and thank all of my periodontal postdoctoral students at UCLA for their help and support throughout the preparation of this classic textbook. Another note of thank you to Dr. Sasan Garakani for the many hours of collaboration and help that he provided in the review of literature and organizing the references for numerous chapters.

Dr. Klokkevold: My wife, Angie; my daughters, Ashley and Brianna; my parents Carl and Loretta; my gratitude and appreciation to my mentors Dr. Henry H. Takei, Dr. John Beumer III, Dr. Bradley G. Seto, Dr. Charles N. Bertolami, and Dr. Thomas Han. I am grateful to the many talented residents who matriculated through UCLA Postgraduate Periodontics for the passion and inspiration they bring to me as an educator and clinician. Finally, I give special thanks to my co-editors, Dr. Michael G. Newman, Dr. Henry H. Takei, and Dr. Fermin A. Carranza, Jr., for their friendship, support, and encouragement.

Dr. Carranza: My wife, Rita; my children, Fermin, Patricia, and Laura; and my grandchildren, Irving Glickman, Fermin Carranza, Sr., and Romulo L. Cabrini. My gratitude also to my co-editors, who will continue the tradition of this book.

Video Contents

Chapter 8 **Biofilm and Periodontal Microbiology**

- Video 8.1 Bacteria compete with their neighbors by secreting antibacterial molecules such as inhibitory peptides (bacteriocins) or hydrogen peroxide (H_2O_2)
- Video 8.2 Plaque growth
- Video 8.3 Difference in plaque growth between heavy and light plaque former
- Video 8.4 Colonization inhibition
- Video 8.5 Phase contrast

Chapter 24 **Bone Loss and Patterns of Bone Destruction**

- Video 24.1 Vertical bone loss animation

Chapter 46 **Endodontic-Periodontic Lesions: Pathogenesis, Diagnosis, and Treatment Considerations**

- Video 46.1 Fractured teeth slide show

Chapter 51 **Sonic and Ultrasonic Instrumentation and Irrigation**

- Video 51.1 Ultrasonic debridement
- Video 51.2 Ultrasonic debridement

Video 51.3 Pulsating action of a jet tip
Video 51.4 Depth of penetration with a dental water jet
Video 51.5 Action of a tip with bristles around orthodontic brackets
Video 51.6 Action of a tip with filaments cleaning around an implant
Video 51.7 Action of the site-specific tip into a pocket
Chapter 64 **Furcation: Involvement and Treatment**
Video 64.1 Bone loss with furcation slide show
Chapter 65 **Periodontal Plastic and Aesthetic Surgery**
Video 65.1 Periodontal plastic and aesthetic surgery
Chapter 69 **Preparation of the Periodontium for Restorative Dentistry**
Video 69.1 Effects of single tooth loss
Chapter 70 **Restorative Interrelationships**
Video 70.1 Smile design principles animation
Chapter 75 **Clinical Evaluation of the Implant Patient**
Video 75.1 Single aesthetic implant slide show
Chapter 78 **Basic Implant Surgical Procedures**
Video 78.1 Single tooth implant video
Video 78.2 Dental implant case presentation

Introduction: The Historical Background of Periodontology

Gerald Shklar [†], *Fermin A. Carranza*

Chapter Outline

Early Civilizations
The Classical World
The Middle Ages
The Renaissance
The Eighteenth Century
The Nineteenth Century
The Twentieth Century
The History of This Book

Gingival and periodontal diseases have afflicted humans since the dawn of history. Studies in paleopathology have indicated that destructive periodontal disease, as evidenced by bone loss, affected early humans in such diverse cultures as ancient Egypt and early

pre-Columbian America. The earliest historical records that involve medical topics reveal an awareness of periodontal disease and the need for treatment. Almost all early writings that have been preserved have sections or chapters dealing with oral diseases, and periodontal problems comprise a significant amount of space in these writings. Calculus and systemic disease were frequently postulated as causes of periodontal disorders.

However, methodic and carefully reasoned therapeutic discussions did not exist until the Arabic surgical treatises of the Middle Ages. Modern treatment, with illustrated text and sophisticated instrumentation, did not develop until the time of Pierre Fauchard during the eighteenth century.

Early Civilizations

Oral hygiene was practiced by the Sumerians, the Babylonians, and the Assyrians; this included gingival massage in combination with various herbal medications.[25,33]

Periodontal disease was the most common of all diseases found in the embalmed bodies of the ancient Egyptians.[7,44] The Ebers papyrus contains many references to gingival disease and offers a number of prescriptions for strengthening the teeth and gums.[14]

The medical works of ancient India and China devote significant space to oral and periodontal problems and oral hygiene,[47] and they describe gingival inflammations, periodontal abscesses, and gingival ulcerations.[12,21] The early Hebrews also recognized the importance of oral hygiene. Many pathologic conditions of the teeth and their surrounding structures are described in the Talmudic writings.

The Classical World

Among the ancient Greeks, Hippocrates of Cos (460 BC-377 BC), the father of modern medicine, discussed the function and eruption of the teeth and the etiology of periodontal disease. He believed that inflammation of the gums could be caused by accumulations of "pituita" or calculus, with gingival hemorrhage occurring in cases of persistent splenic maladies.[10,27]

Among the Romans, Aulus Cornelius Celsus (25 BC-50 AD) referred to diseases that affect the soft parts of the mouth and their treatment, including oral hygiene. Paul of Aegina (625 AD-690 AD) wrote that tartar deposits must be removed with either scrapers or a small file and that the teeth should be carefully cleaned after the last meal of the day.[41]

The Middle Ages

The decline and fall of the Roman Empire that plunged Europe into an age of darkness was accompanied by the rise of Islam and the golden age of Arabic science and medicine. The Arabic treatises derived their information from Greek medical treatises, but many refinements and novel approaches were added, particularly in surgical specialties.[45]

Albucasis (936-1013) was born and lived in Moorish Spain. His 30-volume medical encyclopedia, called *al-Tasrif,* was translated into Latin during the twelfth century, and it was the medical text used in European universities until the seventeenth century. The contributions of Albucasis to dentistry and periodontology were outstanding achievements.[1] He had a clear understanding of the major etiologic role of calculus deposits, and he described the techniques of scaling the teeth with the use of a set of instruments that he developed (Fig. I.1), splinting loose teeth with gold wire, and filing gross occlusal abnormalities.

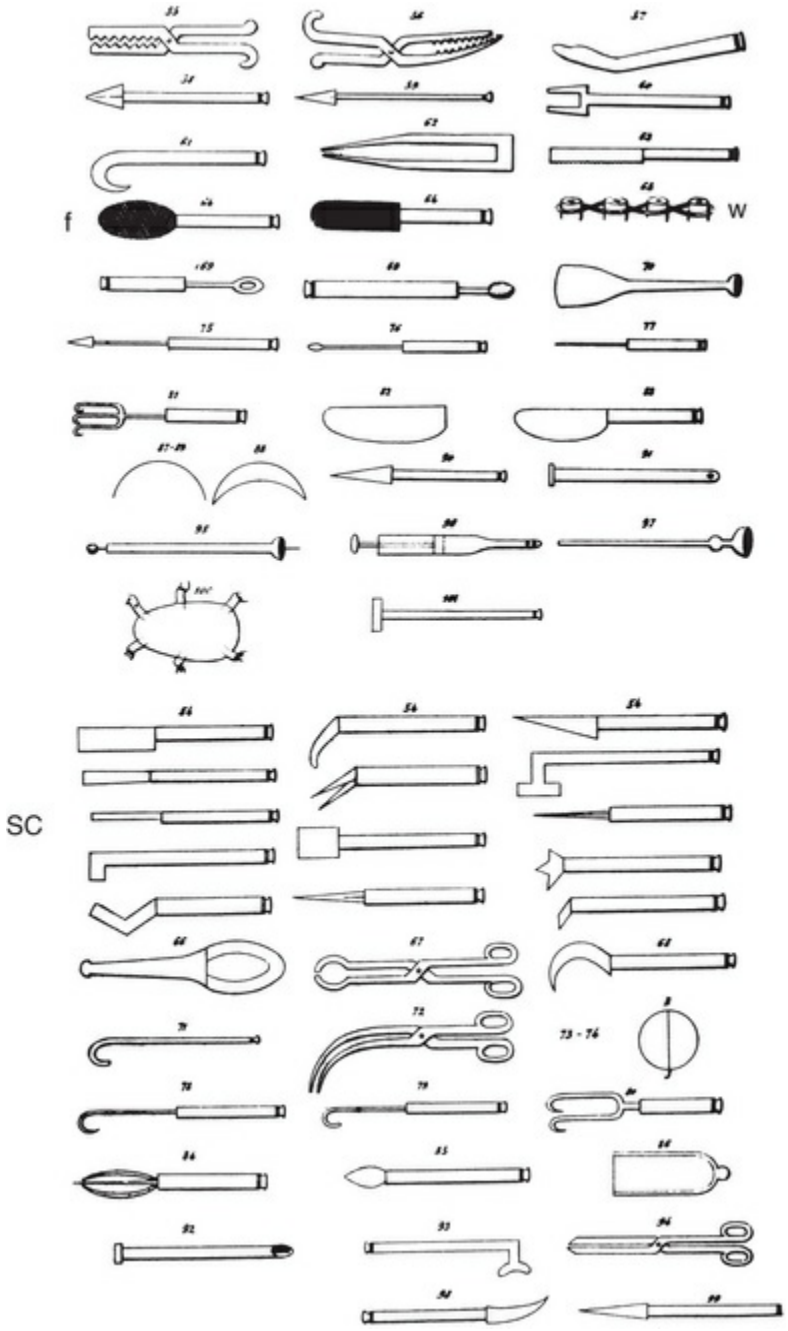

FIG. I.1 Illustration of Albucasis' periodontal instruments, showing scalers *(sc),* files *(f),* and the wiring of loose teeth *(w).*

Avicenna (980-1037) was possibly the greatest of the Persian physicians. His *Canon,* a comprehensive treatise on medicine, was in continuous use for almost 600 years. Avicenna used an extensive "materia medica" for oral and periodontal diseases and rarely resorted to surgery.[3]

The Renaissance

During the Renaissance—with the rebirth of classical scholarship, the development of scientific thought and medical knowledge, and the flowering of art, music, and literature—significant contributions were made to anatomy and surgery.

Albucasis' work was expanded during the fifteenth century by the Turkish author Serefeddin Sabuncuoglu (1385-1468), who included illustrations of the surgical removal of hypertrophic and swollen gingiva and lingual frenum (Fig. I.2). Drug treatment should be initiated if there are swollen gums, mobile teeth, and pus formation. If there is no response, surgical treatment should be performed. A tube is placed on the gums. A hot cautery is inserted into the cannula, and the gingival tissue is cauterized. If this is correctly applied, the adjacent teeth will be warm.

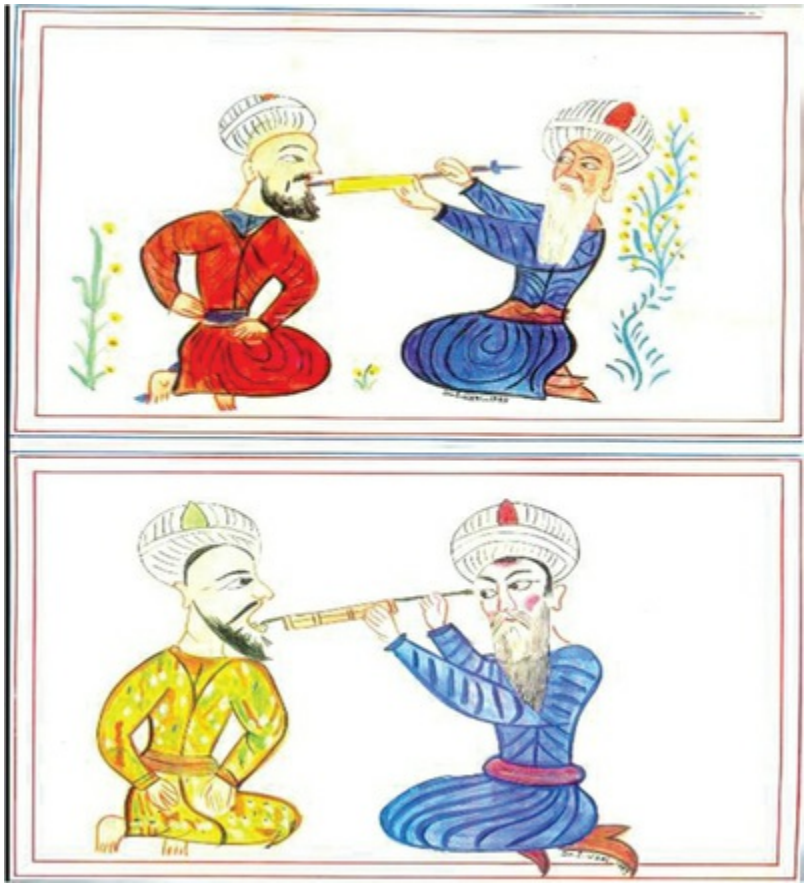

FIG. I.2 Illustration by Serefeddin Sabuncuoglu showing gingival cauterization. (From Abulcasis and redrawn by Professor Ilter Uzel, Turkey.)

Paracelsus (1493-1541) developed an interesting and unusual theory of disease: the doctrine of calculus. Paracelsus recognized the extensive formation of tartar on the teeth and related this to toothache. He considered toothache to be comparable to the pain produced by calculus in other organs, such as the kidneys.[39]

Andreas Vesalius (1514-1564), who was born in Brussels, taught at the University of Padua and wrote a magnificent book about anatomy that included many excellent illustrations.[48] Bartholomeus Eustachius (1520-1574) of Rome was another outstanding anatomist who wrote a small book about dentistry, *Libellus de Dentibus* ("A Little Treatise on the Teeth"), which contained 30 chapters.[16] This was the first original book about the teeth, and it included a description of the periodontal tissues as well as information about the diseases of the mouth, their treatment modalities, and the rationale for treatment. For the treatment of periodontitis, Eustachius recommended both the scaling of calculus and the curettage of granulation tissue so that actual reattachment of the gingival and periodontal tissues could take place.

The Frenchman Ambroise Paré (1509-1590) was the outstanding surgeon of the Renaissance, and his contributions to dental surgery included gingivectomy for hyperplastic gingival tissues.[40] He also understood the etiologic significance of calculus and used a set of scalers to remove the hard deposits on the teeth.

The first book in the common language of German and specifically devoted to dental practice, which was entitled *Artzney Buchlein* or *Zene Artzney* ("Medicine of the Teeth"), was published in Leipzig in 1530.[2] It contains three chapters devoted to periodontal problems, including a crude concept of systemic and local factors in the etiology of periodontal disease. The presence of local infective agents or "worms" is also mentioned.

A variety of ointments, which are often astringent in nature, is suggested, and the binding of loose teeth to sound ones with silk or gold thread is recommended. Cauterizing the gingiva with a hot iron is mentioned.

The Italian physician, mathematician, and philosopher Girolamo Cardano (1501-1576) appears to have been the first to differentiate among the types of periodontal disease. In a publication dated 1562, he mentions one type of disease that occurs with advancing age and

leads to progressive loosening and loss of teeth as well as a second very aggressive type that occurs in younger patients.[26] It was not until late in the twentieth century that this classification was rediscovered and became widely accepted.

Anton van Leeuwenhoek (1632-1723) of Delft, Holland, was a layman, but he had an inquisitive mind and a hobby of grinding lenses that allowed him to develop the microscope. He used it to discover microorganisms, cellular structure, blood cells, sperm, and various other microscopic structures, including the tubular structure of dentin.[9,13] Using material from his own mouth, Leeuwenhoek first described oral bacterial flora, and his drawings offered a reasonably good presentation of oral spirochetes and bacilli (Fig. I.3). He even performed antiplaque experiments involving the use of strong vinegar in his own mouth and in vitro on bacteria in a dish.[13]

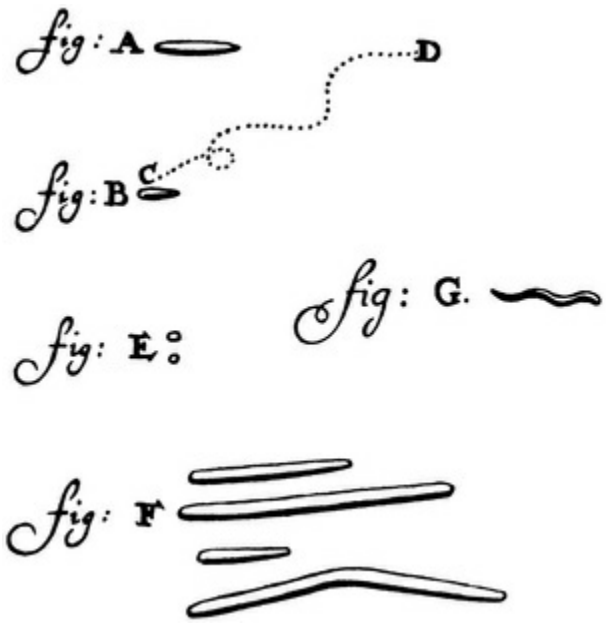

FIG. I.3 Leeuwenhoek's drawing of oral spirochetes, bacilli, and other microorganisms.

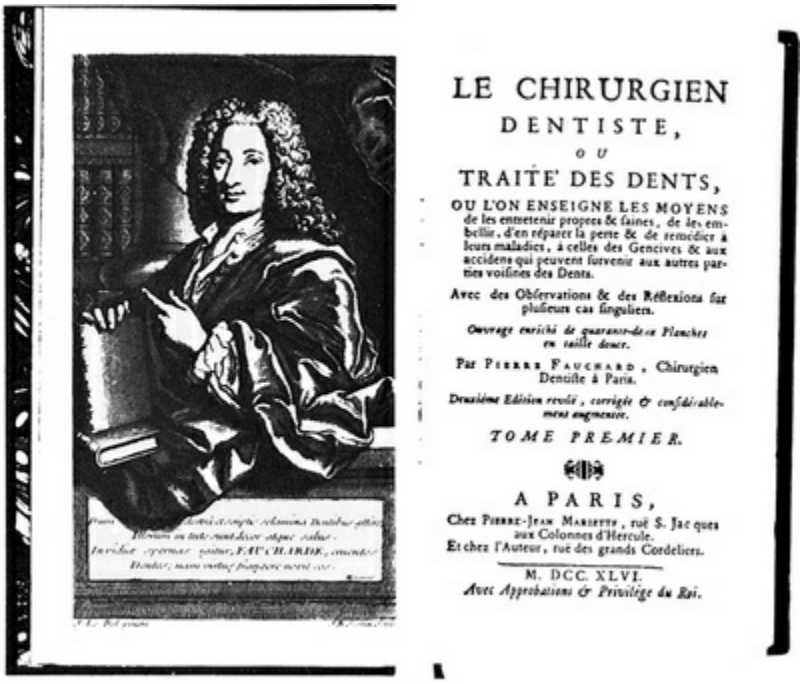
The Eighteenth Century

Modern dentistry essentially developed in eighteenth century Europe, particularly France and England. Pierre Fauchard, who was

born in Brittany in 1678, is rightly regarded as the father of the dental profession as we know it. His book, *The Surgeon Dentist,* which was published in 1728, covered all aspects of dental practice, including restorative dentistry, prosthodontics, oral surgery, periodontics, and orthodontics[17] (Fig. I.4). Fauchard described in detail his periodontal instruments and the scaling technique for using them (Fig. I.5).



LE CHIRURGIEN
DENTISTE,
OU
TRAITÉ DES DENTS,
OU L'ON ENSEIGNE LES MOYENS de les entretenir propres & saines, de les embellir, d'en réparer la perte & de remédier à leurs maladies, à celles des Gencives & aux accidens qui peuvent survenir aux autres parties voisines des Dents.
Avec des Observations & des Réflexions sur plusieurs cas singuliers.
Ouvrage enrichi de quarante-deux Planches en taille douce.
Par PIERRE FAUCHARD, Chirurgien Dentiste à Paris.
Deuxième Edition revûë, corrigée & considérablement augmentée.
TOME PREMIER.
A PARIS,
Chez PIERRE-JEAN MARIETTE, rue S. Jacques aux Colonnes d'Hercule.
Et chez l'Auteur, rue des grands Cordeliers.
M. DCC. XLVI.
Avec Approbation & Privilége du Roi.

FIG. I.4 Frontispiece of Fauchard's book entitled *The Surgeon Dentist* (1746 edition).

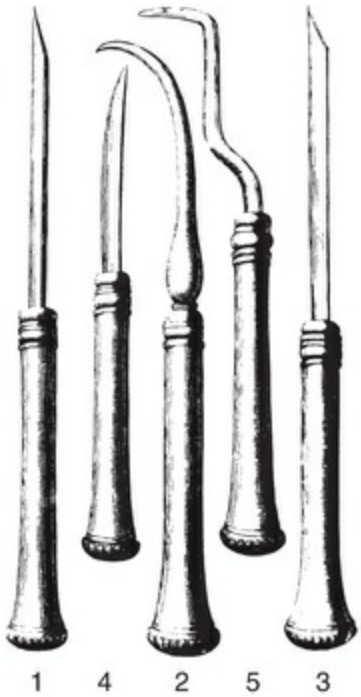


FIG. I.5 The five types of instruments used by Fauchard for detaching tartar from the teeth: *1*, chisel; *2*, parrot beak; *3*, graver; *4*, convex blade; and *5*, Z-shaped hook.

John Hunter (1728-1793), who was the most distinguished anatomist, surgeon, and pathologist of eighteenth-century England, wrote an excellent treatise on dentistry entitled *The Natural History of the Human Teeth.*[30] He offered remarkably clear illustrations of the anatomy of the teeth and their supporting structures, and he described the features of periodontal diseases.

A contemporary of Hunter, Thomas Berdmore (1740-1785), was considered the outstanding dentist in England. In 1770, he published a book that had several chapters devoted to periodontal problems.[4]

The Nineteenth Century

Leonard Koecker (1785-1850) was a German-born dentist who practiced in Baltimore. In a paper in 1821, he mentioned the careful removal of tartar and the need for oral hygiene by the patient, recommending that it be performed in the morning and after every meal with the use of an astringent powder and a toothbrush, with care taken to place "the bristles … into the spaces of the teeth."

Koecker was an early advocate of the "odontogenic focal infection" theory, and he recommended the extraction of all severely involved teeth and roots, including all unopposed molars, to prevent systemic infections.[35]

Levi Spear Parmly (1790-1859) was a New Orleans, Louisiana, dentist who is considered the father of oral hygiene and the inventor of dental floss.[11,18]

During the mid-nineteenth century, John W. Riggs (1811-1885) was the leading authority on periodontal disease and its treatment in the United States; in fact, at the time, periodontitis was known as "Riggs' disease" (Fig. I.6). Riggs graduated from the Baltimore College of Dental Surgery in 1854 and practiced in Hartford, Connecticut, where he died on November 11, 1885. Riggs seems to have been the first individual to limit his practice to periodontics and therefore can be considered the first specialist in this field. Riggs' publications, however, are limited. In an 1876 paper, Riggs was a strong proponent of the so-called conservative approach to periodontal therapy; he developed the concept of oral prophylaxis and prevention, advocated for the cleanliness of the mouth, and opposed surgery, which at the time consisted of gingival resection.[43]

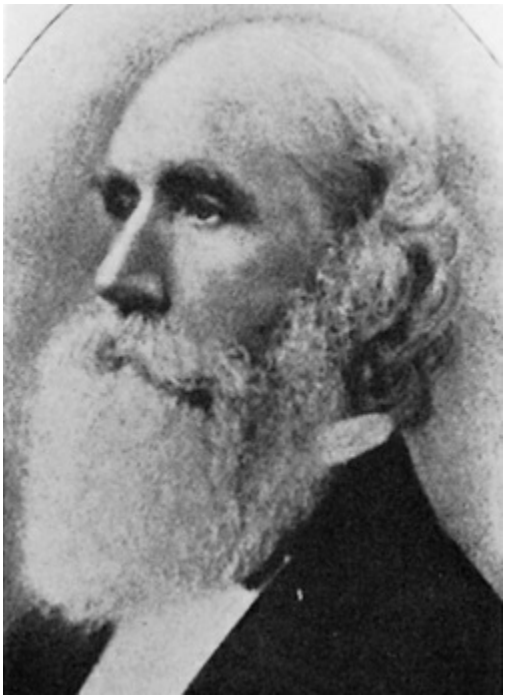

FIG. I.6 John W. Riggs (1811-1885). (From Hoffman-Axthelm W: *History of dentistry,* Chicago, 1981, Quintessence.)

Riggs and his disciples had great influence on the dental profession. Among Riggs' followers were L. Taylor, D.D. Smith, R.B. Adair, and W.J. Younger. The instruments designed by Younger[57] and later modified by his student Robert Good were used widely until well beyond the middle of the twentieth century.

Several major developments in medical science occurred during the second half of the nineteenth century and started the era that can be called *modern medicine,* which includes dentistry.[9,36] The first was the discovery of anesthesia by Horace Wells (1813-1848) of Hartford, Connecticut, in 1845 and by William Morton (1819-1868) of Boston, Massachusetts, in 1846, who discovered the general anesthetic effects of nitrous oxide and ether, respectively. *Local anesthesia* was developed by the Vienna ophthalmologist Carl Köller (1857-1944), who produced anesthesia of the eye with drops of cocaine. Procaine (Novocaine) was developed in 1905 by the Munich chemists Alfred Einhorn and Richard Willstädter. Later, with the addition of adrenaline, which was discovered separately in the United States by Jokichi Takamine and Thomas Bell Aldrich, local anesthesia was born.[29]

The second scientific breakthrough was made by the French chemist Louis Pasteur (1822-1895), who established the *germ theory of disease.* Subsequently, the German physician Robert Koch (1843-1910), in a series of brilliant investigations, discovered the microorganism that causes the cattle disease anthrax and the bacterial etiology of tuberculosis and cholera.

The concepts of Pasteur were transferred to clinical and surgical practice by Joseph Lister (1827-1912) of England, and thus the era of antisepsis—and later, asepsis—in surgery was born. Anesthesia and antisepsis made possible extraordinary advances in surgical techniques.

Pasteur, Koch, and their collaborators and followers—Elie Metchnikoff, Emile Roux, Paul Ehrlich, Emil von Behring, Shibasaburo Kitasato, and many others—discovered the bacterial etiologies of numerous diseases (e.g., pneumonia, puerperal fever, diphtheria, meningitis, plague, dysentery, syphilis) and gave birth to two sciences that became basic to periodontics: bacteriology and immunology.

A third scientific finding that changed the practice of dentistry in

general and of periodontics in particular was the *discovery of radiographs* by the German physicist Wilhelm Röntgen (1845-1923; also written as *Roentgen*). Röntgen's discovery was made in 1895 at the University of Würzburg and was purely a basic science finding, but it was immediately taken up by physicians and dentists, and it proved to be a crucial development in periodontics and many other areas of medicine and dentistry.

Also during the late nineteenth century, studies by Rudolph Virchow (1821-1902), Julius Cohnhein (1839-1884), Elie Metchnikoff (1845-1916), and others had started to reveal the microscopic changes that occur during inflammation.[8,9] This resulted in an understanding of the pathogenesis of periodontal disease on the basis of histopathologic studies. The Russian N.N. Znamensky described the complex interaction of local and systemic factors in the etiology of periodontal disease. His observations and concepts were summarized in 1902 in a classic paper in which he described the presence in inflamed gingivae of a cellular infiltrate that extends deeper as the disease progresses, thereby causing the bone resorption associated with multinucleated cells (osteoclasts) and Howship lacunae[58] (Fig. I.7).

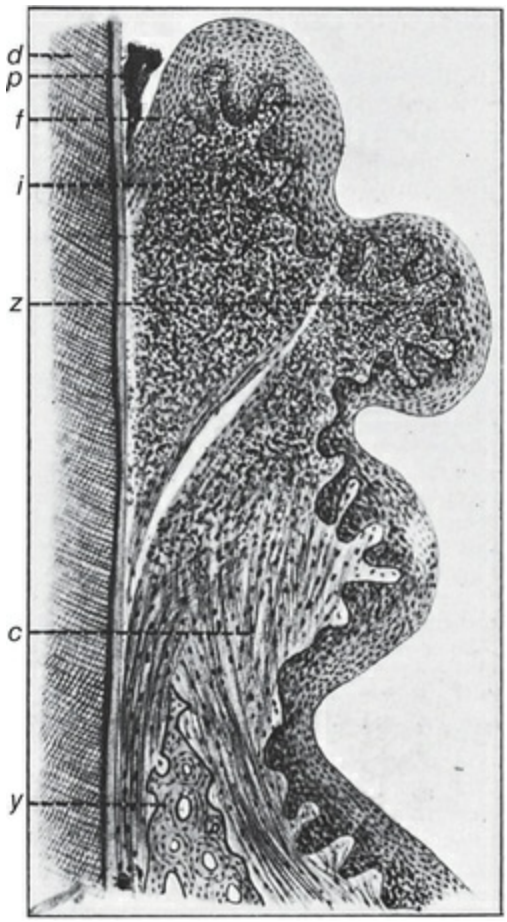

FIG. I.7 Microscopic features of periodontal disease as presented by Znamensky.

The first individual to identify bacteria as the cause of periodontal disease appears to have been the German dentist Adolph Witzel (1847-1906).[23,56] The first true oral microbiologist, however, was the American Willoughby D. Miller (1853-1907), whose professional activities took place in Berlin, where he embarked on a research career that introduced modern bacteriology principles to dentistry. Although his greatest accomplishments were in caries research, in his classic book, *The Microorganisms of the Human Mouth,* which was published in 1890, he described the features of periodontal disease and considered the role of predisposing factors, irritational factors, and bacteria in its etiology. He believed that the disease was not caused by a specific bacterium but by a complex array of various bacteria that are normally present in the oral cavity. This constitutes what was later known as the *nonspecific plaque hypothesis,* which went unchallenged for seven decades.[23,37]

Bacterial plaque was described by J. Leon Williams (1852-1932), an American dentist who practiced in London and who in 1897 described a gelatinous accumulation of bacteria adherent to the enamel surface in relation to caries.[55] In 1899, G.V. Black (1836-1915) coined the term *gelatinous microbic plaque*.[5]

Salomon Robicsek (1845-1928) was born in Hungary and practiced dentistry in Vienna. He developed a surgical technique that consisted of a scalloped, continuous gingivectomy excision that exposed the marginal bone for subsequent curettage and remodeling.[46]

The first description in 1901 of a possible role of trauma from occlusion and bruxism in periodontal disease is generally attributed to the Austrian dentist Moritz Karolyi (1865-1945), who also recommended its correction by grinding occlusal surfaces and preparing bite plates.[34]

Necrotizing Ulcerative Gingivitis

Necrotizing ulcerative gingivitis had been recognized during the fourth century BC by Xenophon, who mentioned that Greek soldiers were affected with "sore mouth and foul-smelling breath." In 1778, Hunter described the clinical features of this disease and differentiated it from scurvy and chronic periodontitis.

Hyacinthe Jean Vincent (1862-1950),[23,49] a French physician working at the Pasteur Institute in Paris, and Hugo Carl Plaut (1858-1928)[42] in Germany described the spirillum and fusiform bacilli associated with what later became known as *Vincent's angina*. In 1904, Vincent described the presence of these organisms in ulceronecrotic gingivitis.[50]

The Twentieth Century

During the first third of the twentieth century, periodontics flourished in central Europe, with two major centers of excellence: Vienna and Berlin.[22]

Vienna

The Vienna school developed the basic histopathologic concepts on which modern periodontics was built. The major representative from this group was Bernhard Gottlieb (1885-1950), who published extensive microscopic studies of periodontal disease in human autopsy specimens (Fig. I.8).[19] His major contributions appeared in the German literature during the 1920s, and they described the attachment of the gingival epithelium to the tooth, the histopathology of inflammatory and degenerative periodontal disease, the biology of the cementum, active and passive tooth eruption, and traumatic occlusion. A book published in 1938 by Gottlieb and Orban presented a complete review in English of the concepts developed by Gottlieb and his coworkers in Vienna.[24]

FIG. I.8 Bernhard Gottlieb (1885-1950). (From Gold SI: *J Clin Periodontol* 12:171, 1985.)

A younger contemporary of Gottlieb's in Vienna was Balint J. Orban (1899-1960) (Fig. I.9), who carried out extensive histologic studies on periodontal tissues. These studies serve as the basis for much of current therapy. Other members of the Viennese school were Rudolph Kronfeld (1901-1940), Joseph P. Weinmann (1889-1960), and Harry Sicher (1889-1974). All of these scientists emigrated to the United States during the 1930s and contributed

greatly to the progress of American dentistry.

FIG. I.9 Balint J. Orban (1899-1960). (From *J Periodontol* 31:266, 1960.)

Berlin

The Berlin group consisted mostly of clinical scientists who developed and refined the surgical approach to periodontal therapy. Prominent in this group were Oskar Weski (Fig. I.10) and Robert Neumann (Fig. I.11).

FIG. I.10 Oskar Weski (1879-1952). (From Hoffman-Axthelm W: *History of dentistry,* Chicago, 1981, Quintessence.)

FIG. I.11 Robert Neumann (1882-1958). (Courtesy Dr. Steven I. Gold, New York.)

Weski (1879-1952) carried out pioneering studies that correlated radiographic and histopathologic changes in patients with periodontal disease.[53] He also conceptualized the periodontium as being formed by the cementum, gingiva, periodontal ligament, and bone, and he gave it the name *paradentium;* this was later changed for etymologic reasons to *parodontium,* which is a term that is still used in Europe.

Neumann (1882-1958), in a book published in 1912[38] (with new editions in 1915, 1920, and 1924), described the principles of periodontal flap surgery, including osseous recontouring as it is currently known[20] (Fig. I.12). Other clinicians who described flap surgery at the beginning of the twentieth century were Leonard Widman of Sweden (1871-1956)[54] and A. Cieszynski of Poland. A bitter controversy developed among Widman, Cieszynski, and Neumann during the 1920s with regard to the priority of describing the periodontal flap.

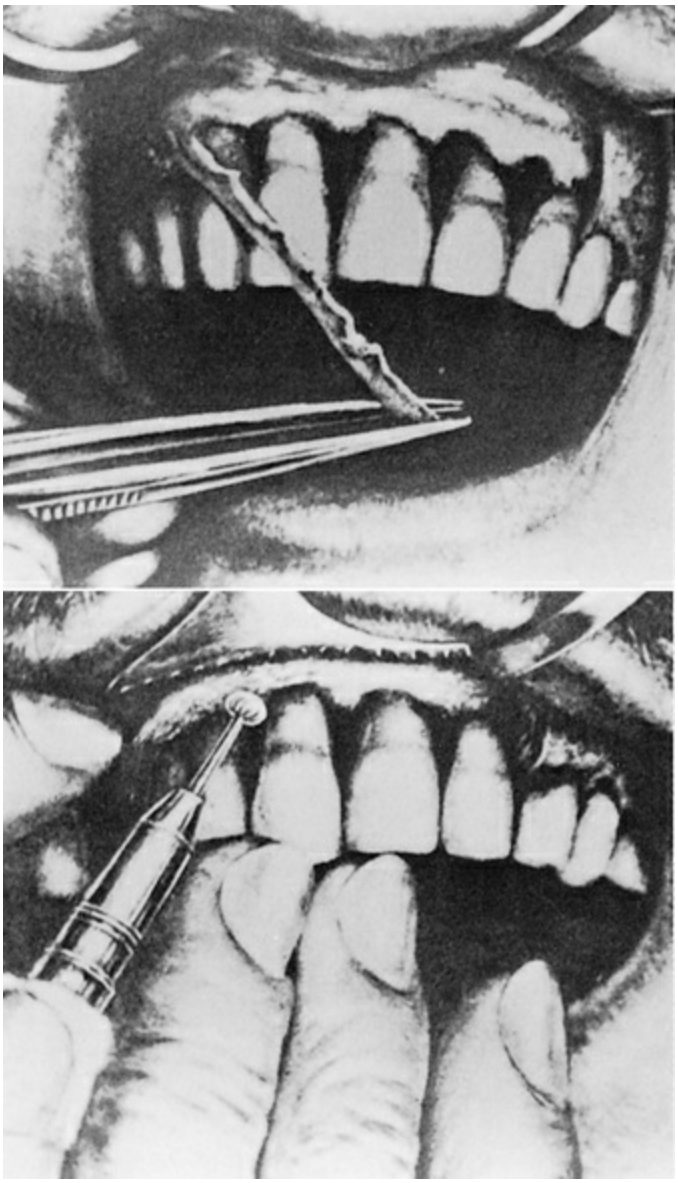

FIG. I.12 Surgical procedure advocated by Robert Neumann during the early part of the twentieth century. *Top,* After raising a mucoperiosteal flap, its edge is trimmed with scissors to leave a scalloped outline. *Bottom,* Osseous recontouring with burs. (From Gold SI: *J Periodontol* 53:456, 1982.)

The United States and Other Countries

In the United States, before World War II, important contributions to periodontal surgery were made by A. Zentler, J. Zemsky, G.V. Black, O. Kirkland, A.W. Ward, A.B. Crane, H. Kaplan, and others. In 1923, Ward introduced the surgical pack under the trade name Wondr-Pak.[51]

The nonsurgical approach was championed by Isadore Hirschfeld (1882-1965) of New York, who wrote classic papers about oral hygiene,[28] local factors, and other topics. In 1913, Alfred Fones (1869-1938) opened the first school for dental hygienists in Bridgeport, Connecticut.[9]

In other countries, H.K. Box (Canada); M. Roy and R. Vincent (France); R. Jaccard and A.-J. Held (Switzerland); F.A. Carranza, Sr, and R. Erausquin (Argentina); W.W. James, A. Counsell, and E.W. Fish (Great Britain); and A. Leng (Chile) are well known for their important contributions. Probably the most comprehensive book about periodontics published during the first half of the twentieth century was *El Paradencio, Su Patologia y Tratamiento,* which was written by the Uruguayan F.M. Pucci in 1939.

Focal Infection

The concept of systemic diseases originating in dental and oral infections had been mentioned in the Assyrian clay tablets (seventh century BC), by Hippocrates (460-370 BC), in the Babylonian Talmud (third century AD), and by Girolamo Cardano and the German Walter Hermann Ryff during the sixteenth century.[29,52] During the nineteenth century, Benjamin Rush (a famous physician and one of the signers of the American Declaration of Independence) in 1818 and Leonard Koecker in 1828 recognized the role of oral sepsis in rheumatic and other diseases. Later during the nineteenth century, W.D. Miller also mentioned oral infections as the cause of many diseases.[37]

In a paper published in 1900[31] and a decade later in a lecture at McGill University in Montreal, Quebec, Canada,[32] William Hunter (1861-1937), a British physician, indicted dentistry as being the cause of oral sepsis, which in turn caused rheumatic and other chronic diseases. This idea was taken up by Billings, Rosenow, and many others, who advocated the extraction of all teeth with periodontal or periapical infections to prevent systemic diseases. This led to the wholesale extraction of teeth and the removal of the tonsils.

The focal infection theory fell into disrepute when it was found that extractions failed to eliminate or reduce the systemic diseases

to which the infected teeth were supposed to be linked.[15] However, the concept was revisited during the 1990s, this time with a more solid research foundation.

Dental Implants

The replacement of human teeth with implants has been attempted for centuries. Skulls with metal or stone implants have been found in a Gallo-Roman necropolis in France and dated from the second century AD; they were also found in a mandible of Mayan origin dated about 600 AD.[9]

In 1806, the Italian M. Maggiolo attempted to place solid-gold roots in human jaws. Later during the nineteenth century, several other investigators used porcelain and metallic implants. During the first half of the twentieth century, several attempts were made to use elaborate surgical techniques and complicated constructs of gold and other precious metals. Microscopic investigations were begun to address the tissue response to various metals.

In 1939, A.E. Strock of Harvard University started implanting cobalt–chromium (Vitallium) screws into tooth sockets. After World War II, numerous attempts were made with different materials and shapes of implants, including tantalum twisted spiral (Formiggini), Vitallium tree shaped (Lee), acrylic tooth root replica (Hodosh), Vitallium double helical spiral (Chércheve), tantalum tripodal pins (Scialom), tantalum vent-plant and titanium blade (Linkow), and vitreous carbon.[9]

During the 1950s, the Swedish orthopedic surgeon Per-Ingvar Bränemark developed a technique that involved the use of titanium screw-shaped intraosseous implants. This proved to be quite successful, and it was gradually adopted by the dental profession after the 1982 international conference in Toronto, Ontario, Canada. The success and predictability of Bränemark's technique are attributed to the achievement of direct contact between vital bone and the implant surface without intervening soft tissue; this phenomenon was later termed *osseointegration*.[6] Numerous variations of the Bränemark concept were presented by A. Kirsch, G.A. Niznick, A. Schroeder, and others, and they are widely used at present.

After World War II

The United States and Scandinavia took leading roles in basic and clinical periodontal research during and after the 1950s, with major advances made in the fields of experimental pathology, microbiology, immunology, and therapy.

In the United States, five individuals led the efforts to advance our understanding of disease processes and the technical approaches needed to address them: Irving Glickman (1914-1972) (Fig. I.13), Henry M. Goldman (1911-1991), Balint J. Orban (1899-1960) (see Fig. I.8), Sigurd P. Ramfjord (1911-1997), and Helmut A. Zander (1912-1991). In the clinical area, the influence of John Prichard (1907-1990) and Saul Schluger (1908-1990) led to new concepts and new directions in the pursuit of clinical success and excellence.

FIG. I.13 Irving Glickman (1914-1972).

The leading figure of the Scandinavian group was Jens Waerhaug (1907-1980) (Fig. I.14) of Oslo, Norway, whose dissertation entitled *The Gingival Pocket* (1952) and whose lifetime of research opened a new era in the understanding of the biology of the periodontium and the management of periodontal problems.

FIG. I.14 Jens Waerhaug (1907-1980). (From *J Clin Periodontol* 7:534, 1980.)

The next generations centered their attention more on the role of microorganisms and the host response, including its defensive and its destructive aspects. Their contributions, as well as those of their predecessors, are documented in this book.

Several workshops and international conferences have summarized existing knowledge regarding the biologic and clinical aspects of periodontology. Worthy of mention are those that were conducted in 1951, 1966, 1977, 1989, 1996, 1999, and 2008, which were cosponsored and published by the American Academy of Periodontology.

The American Academy of Periodontology, which was founded in 1914 by two female periodontists, Grace Rogers Spalding (1881-1953) and Gillette Hayden (1880-1929), has become the leader in organized periodontics. Its monthly scientific publication, *Journal of Periodontology,* presents all current advances in this discipline. In Europe, the periodontal societies have joined to form the European Federation of Periodontology, which meets regularly at the Europerio meeting. Their official publication is *Journal of Clinical Periodontology.* Other scientific periodontal journals in English include *Journal of Periodontal Research, Periodontology 2000,* and

International Journal of Periodontics and Restorative Dentistry. With regard to journals in other languages, *Journal de Parodontologie* (France), *Periodoncia* (Spain), and *Journal of the Japanese Association of Periodontology* deserve mention.

Periodontal education in the United States also has grown during the second half of the twentieth century, and most dental schools have separate and independent units for teaching and research in this discipline. Periodontics was recognized as a specialty of dentistry by the American Dental Association in 1947. The first university-based programs for the training of specialists in periodontics were begun in several universities (e.g., Columbia, Michigan, Tufts) during the late 1940s; these 1-year programs expanded to 2-year programs about 10 years later. In 1995, the American Academy of Periodontology mandated that all postgraduate periodontal programs increase to a 3-year curriculum because of the increased knowledge in periodontics and the expansion of the scope of periodontics to include the placement of dental implants and the administration of conscious sedation. Currently in the United States, more than 50 periodontal graduate programs are based in universities and hospitals.

The History of This Book

The originator of this book and the author of its first four editions, which were published in 1953, 1958, 1964, and 1972, was Dr. Irving Glickman (see Fig. I.13), professor and chairman of the Department of Periodontology at Tufts University School of Dental Medicine in Boston, Massachusetts.

Dr. Glickman was an outstanding researcher, a superb educator, and a gifted speaker and writer whose concepts shaped periodontal thinking for many years. His style of writing, his ideas, and his philosophy of dental practice can still be found in many areas of this book.

After Dr. Glickman's death in 1972 at age 58, responsibility for continuing this book moved to Dr. Fermin A. Carranza, who had been a student and collaborator of Dr. Glickman. At the time, Dr. Carranza was professor and chairman of periodontics at the School of Dentistry of the University of California, Los Angeles. The

following four editions were published in 1979, 1984, 1990, and 1996 under the guidance of Dr. Carranza, who is now professor emeritus at the University of California, Los Angeles.

In 2002, the task of maintaining the book's tradition of almost half a century changed hands once again. Drs. Michael G. Newman and Henry H. Takei joined Dr. Carranza to take major responsibility for the ninth edition. Starting with the tenth (2006) edition, they were joined by Dr. Perry Klokkevold.

CHAPTER OUTLINE

Background and Definition
Principles of Evidence-Based Decision Making
Evidence-Based Decision-Making Process and Skills
Conclusion

Each day, dental care professionals make decisions about clinical care. It is important that these decisions incorporate the best available scientific evidence to maximize the potential for successful patient care outcomes. It is also important for readers of this book to have the background and skills necessary to evaluate information they read and hear about. These evaluative skills are as important as learning facts and clinical procedures. *The ability to find, discriminate, evaluate, and use information is the most important skill that can be learned as a professional and lifelong learner.* Becoming

excellent at this skill will provide a rewarding and fulfilling professional career.

Background and Definition

Using evidence from the medical literature to answer questions, direct clinical action, and guide practice was pioneered at McMaster University, Ontario, Canada, in the 1980s. As clinical research and the publication of findings increased, so did the need to use the medical literature to guide practice. The traditional clinical problem-solving model based on individual experience or the use of information gained by consulting authorities (colleagues or textbooks) gave way to a new methodology for practice and restructured the way in which more effective clinical problem solving should be conducted. This new methodology was termed *evidence-based medicine* (EBM).[12]

Key Definitions

Evidence: Evidence is considered the synthesis of all valid research that answers a specific question and that, in most cases, distinguishes it from a single research study.[2]

Evidence-based medicine: The integration of the best research evidence with our clinical expertise and our patient's unique values and circumstances.[31]

Evidence-based dentistry: An approach to oral health care that requires the judicious integration of systematic assessments of clinically relevant scientific evidence, relating to the patient's oral and medical condition and history, with the dentist's clinical expertise and the patient's treatment needs and preferences.[4]

The use of evidence to help guide clinical decisions is not new. However, the following aspects of EBM are new:

- The methods of generating high-quality

evidence, such as randomized controlled trials (RCTs) and other well-designed methods
• The statistical tools for synthesizing and analyzing the evidence (systematic reviews [SRs] and meta-analysis [MA])
• The ways for accessing the evidence (electronic databases) and applying it (evidence-based decision making [EBDM] and practice guidelines)[9,10]

These changes have evolved along with the understanding of what constitutes the evidence and how to minimize sources of bias, quantify the magnitude of benefits and risks, and incorporate patient values.[13] "In other words, evidence-based practice is not just a new term for an old concept and as a result of advances, practitioners need (1) more efficient and effective online searching skills to find relevant evidence and (2) critical appraisal skills to rapidly evaluate and sort out what is valid and useful and what is not."[28]

EBDM is the formalized process and structure for learning and using the skills for identifying, searching for, and interpreting the results of the best scientific evidence, which is considered in conjunction with the clinician's experience and judgment, the patient's preferences and values, and the clinical and patient circumstances when making patient care decisions. Translating the EBDM process into action is based on the abilities and skills identified in Box 1.1.[31]

Box 1.1

Skills and Abilities Needed to Apply an Evidence-Based Decision-Making Process[31]

1. Convert information needs and problems into clinical questions so that they can be answered.

2. Conduct a computerized search with maximum efficiency for finding the best external evidence with which to answer the question.
3. Critically appraise the evidence for its validity and usefulness (clinical applicability).
4. Apply the results of the appraisal, or evidence, in clinical practice.
5. Evaluate the process and your performance.

Principles of Evidence-Based Decision Making

The use of current best evidence does not replace clinical expertise or input from the patient, but rather provides another dimension to the decision-making process,[11,16,19] which is also placed in context with the patient's clinical circumstances (Fig. 1.1). It is this decision-making process that we refer to as "evidence-based decision making" and is not unique to medicine or any specific health discipline; it represents a concise way of referring to the application of evidence to clinical decision making.

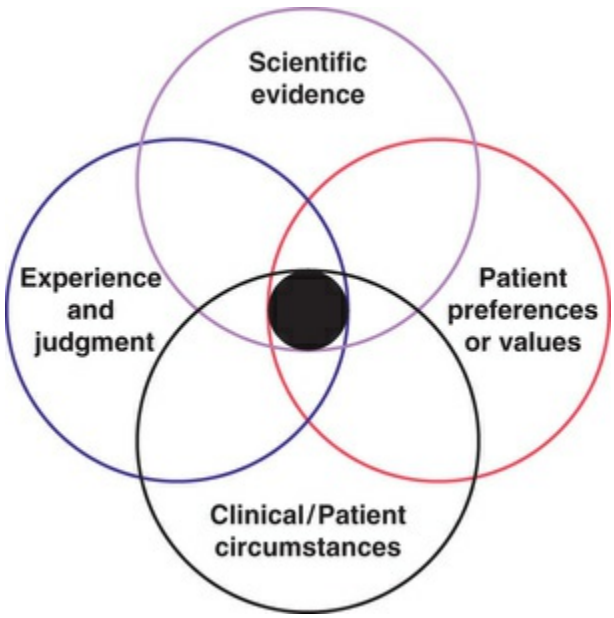

FIG. 1.1 Evidence-based decision making. (Copyright Jane L. Forrest, reprinted with permission.)

EBDM focuses on solving clinical problems and involves two fundamental principles, as follows[13]:

1. Evidence alone is never sufficient to make a clinical decision.
2. Hierarchies of quality and applicability of evidence exist to guide clinical decision making.

EBDM is a structured process that incorporates a formal set of rules for interpreting the results of clinical research and places a lower value on authority or custom. In contrast to EBDM, traditional decision making relies more on intuition, unsystematic clinical experience, and pathophysiologic rationale.[13]

Evidence-Based Dentistry

Since the 1990s, the evidence-based movement has continued to advance and is widely accepted among the health care professions, with some refining the definition to make it more specific to their area of health care. The American Dental Association (ADA) has defined evidence-based dentistry (EBD) as "an approach to oral health care that requires the judicious integration of systematic assessments of clinically relevant scientific evidence, relating to the patient's oral and medical condition and history, with the dentist's clinical expertise and the patient's treatment needs and preferences."[4] They also have established the ADA Center for Evidence-Based Dentistry (ebd.ada.org) to facilitate the integration of EBD into clinical practice.

The ADA's definition is now incorporated in the Accreditation Standards for Dental Education Programs.[3] Dental schools are expected to develop specific core competencies that focus on the need for graduates to become critical thinkers, problem solvers, and consumers of current research findings to enable them to become lifelong learners. The accreditation standards require learning EBDM skills so that graduates are competent in being able to find, evaluate, and incorporate current evidence into their decision making.[3]

Key Fact

PICO

The first step in evidence-based decision making is asking the right question. The key is to frame a question that is simple and at the same time highly specific to the clinical scenario. Dissecting the question you want to ask into its components—problem or population (P), intervention (I), comparison group (C) and outcomes (O)—and then combining them will facilitate a thorough and precise evidence search.[31]

Evidence-Based Decision-Making Process and Skills

The growth of evidence-based practice has been made possible through the development of online scientific databases such as MEDLINE (PubMed) and Internet-based software, along with the use of computers and mobile devices, for example, smart phones, that enable users to quickly access relevant clinical evidence from almost anywhere. This combination of *technology* and *good evidence* allows health care professionals to apply the benefits from clinical research to patient care.[29] EBDM recognizes that clinicians can never be completely current with all conditions, medications, materials, or available products, and it provides a mechanism for assimilating current research findings into everyday practice to answer questions and to stay current with innovations in dentistry. Translating the EBDM process into action is based on the abilities and skills identified in Box 1.1.[31] This is illustrated clearly in a real patient case scenario (management of a patient with trauma-related avulsion and luxation of teeth) that is introduced in Case Scenario 1.1 (Figs. 1.2 and 1.3) and used throughout the chapter.

Case Scenario 1.1

Clinical Application of Evidence-Based Decision Making

The clinician received a call from the parents of a 13-year-old

female patient who had been struck in the face with a softball. She was being examined by paramedics in a town 30 minutes north of the dental office. The paramedics cleared the patient of any head or neck injury and other medical issues and informed the dentist that dental trauma was her primary injury. The dentist and his assistant met the parents and the patient at the office 45 minutes following the dental trauma. The patient's teeth remained in her mouth following the incident. Fig. 1.2A shows the initial examination of the patient. The preference of the patient and her parents was to "do anything to keep the teeth." After the site was cleaned and irrigated, it was apparent that there was complete avulsion of the maxillary right central incisor from the socket and lateral luxation of the maxillary left central and lateral incisors. In addition, there was alveolar bone fracture partially encasing the roots of the maxillary left central and lateral incisors (Fig. 1.2B.) The clinician replanted the teeth and reapproximated the gingival tissue with sutures (Fig. 1.2C). A stable and accurate ribbond and flowable composite splint were placed (Fig. 1.2D), and a radiograph was taken (Fig. 1.2E).

Radiographic Examination

The radiograph shows reimplantation of maxillary central incisors and left lateral incisor in correct socket location and confirmed proper reapproximation of the alveolar bone that was fractured with maxillary left central and lateral incisors. The stent also is apparent in this radiograph showing the splinting of the displaced teeth.

Due to the difficulty of splint placement and not wanting to risk displacing the teeth or breaking the splint prematurely, the clinician was hesitant to proceed with endodontic treatment until he had access to dependable information. The dentist had two questions regarding the treatment of the patient. He needed to determine the optimal timing of the pulp extirpation and splinting that would result in the best outcome and prognosis for healing. Fig. 1.3 diagrams the decision-making pathway from telephone call to resolution.[24]

Asking Good Questions: The PICO Process

Converting information needs and problems into clinical questions is a difficult skill to learn, but it is fundamental to evidence-based practice. The EBDM process almost always begins with a patient question or problem. A "well-built" question should include four parts that identify the patient problem or population *(P)*, intervention *(I)*, comparison *(C)*, and outcome(s) *(O)*, referred to as PICO.[31] Once these four components are clearly and succinctly identified, the following format can be used to structure the question:

"For a patient with _____ (P), will _____ (I) as compared with _____ (C) increase/decrease/provide better/in doing _____ (O)?"

The formality of using PICO to frame the question serves two key purposes, as follows:

1. PICO forces the clinician to focus on what he or she and the patient believe to be the most important single issue and outcome.
2. PICO facilitates the next step in the process, the computerized search, by identifying key terms that will be used in the search.[31]

The conversion of information needs into a clinical question is demonstrated using Case Scenario 1.1 Two separate PICO questions were written as follows:

1. For a patient with replanted avulsed and luxated teeth (P), will early pulp extirpation (10 to 14 days) (I) as compared with late pulp extirpation (past 14 days) (C) increase the likelihood of successful tooth integration and functional periodontal healing and decrease the likelihood of resorption and ankylosis (O)?
2. For a patient with replanted avulsed and luxated teeth (P), will short-term splinting (7 to 14 days) (I) as compared with long-term splinting (2 to 4 weeks) (C) increase the likelihood of successful tooth integration and functional periodontal healing and decrease the development of resorption and ankylosis (O)?

PICO directs the clinician to identify clearly the problem, the results, and the outcomes related to the specific care provided to that patient. This, in turn, helps identify the search terms that should be used to conduct an efficient search. It also allows identification of the type of evidence and information required to solve the problem, as well as considerations for measuring the effectiveness of the intervention and the application of the EBDM process. Thus EBDM supports continuous quality improvements through measuring outcomes of care and self-reflection.

Before conducting a computerized search, it is important to have an understanding of the types of research study methodologies and

the appropriate methodology that relates to different types of clinical questions. The methodology, in turn, relates to the levels of evidence. Table 1.1 shows these relationships.

TABLE 1.1

Type of Question Related to Type of Methodology and Levels of Evidence

Type of Question	Methodology of Choice[27]	Question Focus[22]
Therapy, prevention	MA or SR of randomized controlled trials SR of cohort studies	Study effect of therapy or test on real patients; allows for comparison between intervention and control groups; largest volume of evidence-based literature
Diagnosis	MA or SR of controlled trials (prospective cohort study) *Controlled trial* (Prospective: compare tests with a reference or "gold standard" test)	Measures reliability of a particular diagnostic measure for a disease against the "gold standard" diagnostic measure for the same disease
Etiology, causation, harm	MA or SR of cohort studies *Cohort study* (Prospective data collection with formal control group)	Compares a group exposed to a particular agent with an unexposed group; important for understanding prevention and control of disease
Prognosis	MA or SR of inception cohort studies *Inception cohort study* (All have disease but free of the outcome of interest) *Retrospective cohort*	Follows progression of a group with a particular disease and compares with a group without the disease

MA, Meta-analysis; *SR*, systematic review.

Becoming a Competent Consumer of the Evidence

Evidence typically comes from studies related to questions about treatment and prevention, diagnosis, etiology and harm, and prognosis of disease, as well as from questions about the quality and economics of care. Evidence is considered the synthesis of all valid research that answers a specific question and that, in most

cases, distinguishes it from a single research study.[15] Once synthesized, evidence can help inform decisions about whether a method of diagnosis or a treatment is effective relative to other methods of diagnoses or to other treatments and under what circumstances. The challenge in using EBDM arises when only one research study is available on a particular topic. In these cases, individuals should be cautious in relying on the study because it can be contradicted by another study and it may test only efficacy and not effectiveness. This underscores the importance of staying current with the scientific literature because the body of evidence evolves over time as more research is conducted. Another challenge in using EBDM occurs when the limited research available is weak in quality or poorly conducted. In these cases, one may rely more heavily on clinical experience and patients' preferences and values than the scientific evidence (see Fig. 1.1).

Sources of Evidence

The two types of evidence-based sources are primary and secondary, as follows:

- *Primary sources* are original research studies and publications that have not been filtered or synthesized, such as an RCT or a cohort study.
- *Secondary sources* are synthesized studies and publications of the already conducted primary research. These include clinical practice guidelines (CPGs), SRs, MAs, and evidence-based article reviews and protocols. This terminology is often confusing to individuals new to the EBDM approach because, although SRs are *secondary* sources of evidence, they are considered a higher level of evidence than a *primary* source, such as an individual RCT.

Both primary and secondary sources can be found by conducting

a search using such biomedical databases as MEDLINE (accessed through PubMed), EMBASE, and Database of Abstracts of Review of Effectiveness (DARE). Other sources of secondary evidence, such as CPGs, clinical recommendations, parameters of care, position papers, academy statements, and critical summaries related to dental practice can be found on the websites of professional organizations and journals as listed in Table 1.2.

Levels of Evidence

As previously mentioned, one principle of EBDM is that hierarchies of evidence exist to guide decision making. At the top of the hierarchy for therapy are CPGs (Fig. 1.4). These are systematically developed statements to assist clinicians and patients about appropriate health care for specific clinical circumstances.[8] CPGs should be based on the best available scientific evidence typically

from MAs and SRs, which put together all that is known about a topic in an objective manner. The level and quality of the evidence are then analyzed by a panel of experts who formulate the CPGs. Thus, guidelines are intended to translate the research into practical application.

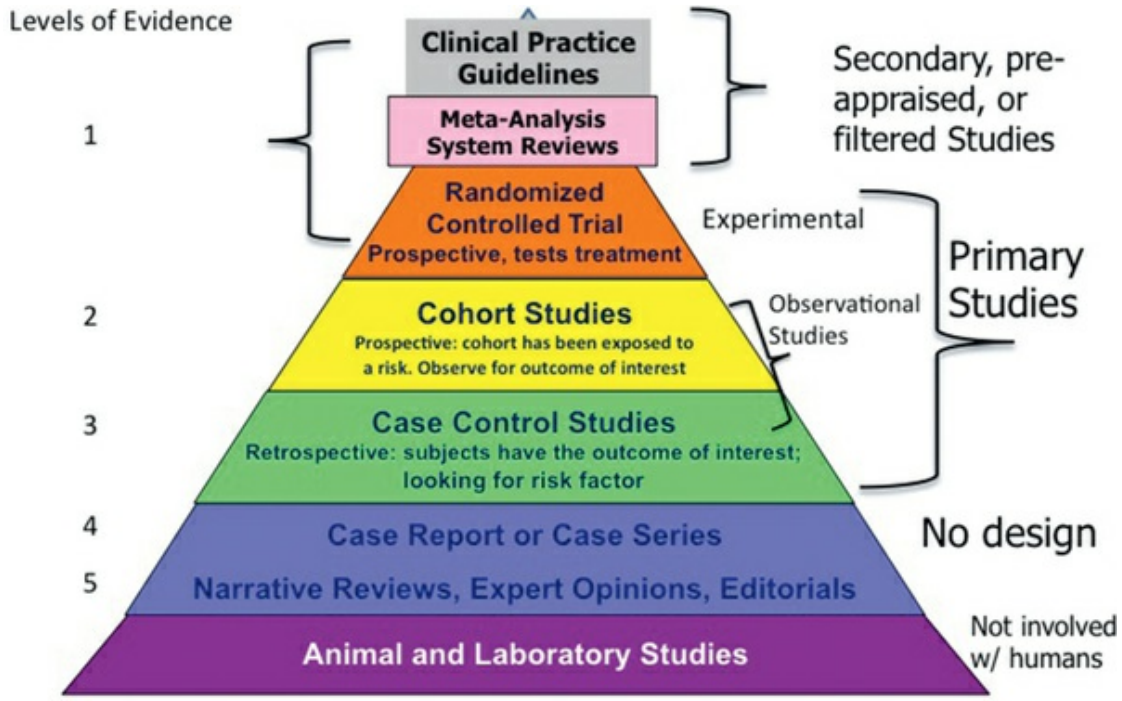

FIG. 1.4 Hierarchy of research and levels of clinical evidence. (Image Copyright 2012 JL Forrest, SA Miller: National Center for Dental Hygiene Research & Practice.)

Guidelines also will change over time as the evidence evolves, thereby underscoring the importance of keeping current with the scientific literature. One example of this is the change in the American Heart Association guidelines for the prevention of infective endocarditis related to the need for premedication before dental and dental hygiene procedures.[5] Before the 2007 guidelines, the last update was in 1997, and before then, eight updates were added to the primary regimens for dental procedures since the original guideline was first published in 1955. In the 2007 update, the rationale for revising the 1997 document was provided, notably that the prior guidelines were largely based on expert opinion and a few case-controlled studies. With more research conducted, the ability now existed to synthesize those findings to provide a more objective body of evidence on which to base recommendations.[5]

If a CPG does not exist, other sources of preappraised evidence (critical summaries, critically appraised topics [CATs], SRs, MAs, or reviews of individual research studies) are available to help stay current. MAs and SRs have strict protocols to reduce bias and the synthesis of research from more than one study. These reviews provide a summary of multiple research studies that have investigated the same specific question. SRs use explicit criteria for retrieval, assessment, and synthesis of evidence from individual RCTs and other well-controlled methods. SRs facilitate decision making by providing a clear summary of the current state of the existing evidence on a specific topic. SRs provide a way of managing large quantities of information,[25] thus making it easier to keep current with new research.

MA is a statistical process used when the data from the individual studies in the SR can be combined into one analysis. When data from these studies are pooled, the sample size and power usually increase. As a result, the combined effect can increase the precision of estimates of treatment effects and exposure risks.[25]

SRs and MAs are followed respectively by individual RCT studies, cohort studies, case–control studies, and then studies not involving human subjects.[27] In the absence of scientific evidence, the consensus opinion of experts in appropriate fields of research and clinical practice is used (see Fig. 1.4). This hierarchy of evidence is based on the concept of causation and the need to control bias.[21,22] Although each level may contribute to the total body of knowledge, "not all levels are equally useful for making patient care decisions."[22] In progressing up the pyramid, the number of studies and, correspondingly, the amount of available literature decrease, while at the same time their relevance to answering clinical questions increases.

Evidence is judged on its rigor of methodology, and the level of evidence is directly related to the type of question asked, such as those derived from issues of therapy or prevention, diagnosis, etiology, and prognosis (see Table 1.1). For example, the highest level of evidence associated with questions about therapy or prevention is from CPGs based on MAs and/or SRs of RCT studies. However, the highest level of evidence associated with questions

about prognosis is from CPGs based on MAs and/or SRs of inception cohort studies.[27] Because the two case scenario questions are related to prognosis, the highest level of evidence for them is a CPG based on MAs and/or SRs of inception cohort studies. If no CPG is found, then the next highest level would be a critical summary of an MA or SR of cohort studies. In the event that a critical summary is not found, MAs or SRs of cohort studies followed by individual cohort studies provide the next highest levels of evidence.

Knowing what constitutes the highest levels of evidence and knowing how to apply evidence-based filters are necessary skills to search the literature with maximum efficiency.[22] By using filters, one can refine the search to limit the citations to publication types such as practice guidelines, MAs, SRs, RCTs, and clinical trials, the highest levels of evidence.

Searching for and Acquiring the Evidence

PubMed is designed to provide access to both primary and secondary research from the biomedical literature. PubMed provides free access to MEDLINE, the National Library of Medicine's premier bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health care system, and the preclinical sciences. MEDLINE contains bibliographic citations and author abstracts from more than 5200 biomedical journals published in the United States and 80 other countries. The database contains more than 22 million citations dating back to 1966, and it adds more than 520,000 new citations each year.[26]

It is often helpful to identify the appropriate terminology when searching PubMed. This is done by using the Medical Subject Heading (MeSH) database. It provides the definition of terms and illustrates how the terms are indexed in MEDLINE. The PICO terms from the question can be typed into the MeSH database to maximize searching efficiency. For example, by typing “avulsed tooth” into the MeSH database, a term from the case scenario, it is learned that the MeSH term is “tooth avulsion.” It is defined as partial or complete displacement of a tooth from its alveolar

support. It is commonly the result of trauma. It also is learned that "tooth luxation" links to the MeSH term "tooth avulsion." This informs the searcher that "tooth avulsion" is the best term to use for the search because it encompasses both avulsed and luxated teeth.[23]

Using PubMed's Clinical Queries feature, one can quickly pinpoint a set of citations that will potentially provide an answer to the question being posed. Although online databases provide quicker access to the literature, knowing how databases filter information and having an understanding of how to use search terms and database features allow a more efficient search to be conducted.

Because two focused clinical (PICO) questions were generated from the clinical case, two separate searches were conducted, one for each PICO question. In addition to PubMed, several other databases were used to find high levels of evidence. These included the Database of Abstracts of Reviews of Effects (https://www.crd.york.ac.uk/CRDWeb/), the National Guideline Clearinghouse (http://www.guideline.gov), the ADA Center for Evidence-Based Dentistry website (http://ebd.ada.org), the American Academy of Pediatric Dentistry website (www.aapd.org), and the American Association of Endodontists (www.aae.org), resulting in several relevant references.

When searching for evidence, the PICO question guides the search[4,6] (Table 1.3). By using key terms identified in the PICO question and combining them using the Boolean operators "OR" and "AND," relevant articles can be narrowed to a manageable number.

TABLE 1.3

Search Terms for Each PICO Question

PICO Question 1 Search Terms		PICO Question 2 Search Terms
Tooth avulsion (MeSH)[23] OR Tooth replantation (MeSH)[23]	**P**	Tooth avulsion (MeSH)[23] OR Tooth replantation (MeSH)[23]
Pulp extirpation OR Root canal therapy (MeSH)[23]	**I**	Splints (MeSH)[23]
(Same intervention as	**C**	(Same intervention as

above, however, timing is the real comparison so that is the factor in the final article selection.)		above, however, timing is the real comparison so that is the factor in the final article selection)
Tooth integration OR Functional periodontal healing OR Root resorption (MeSH)[23] OR Tooth ankylosis (MeSH)[23]	**O** These terms were used as inclusion criteria and were not used when searching PubMed because only a few number of systematic reviews and guidelines were found just using the P, I, and C terms	Tooth integration OR Functional periodontal healing OR Root resorption (MeSH)[23] OR Tooth ankylosis (MeSH)[23]

MeSH, Medical Subject Heading (database); *PICO*, patient problem or population, intervention, comparison, and outcome(s).

The first search used the terms "(tooth avulsion OR tooth replantation) AND (pulp extirpation OR root canal therapy)." This resulted in 590 papers. Studies were limited to practice guidelines, MAs, and SRs by using each of these three filters separately so that each of these types of studies could be identified. The findings included four practice guidelines including those of the American Association of Endodontists and the International Association of Dental Traumatology, one critical summary of an SR, and one SR. The second search used the terms "(tooth avulsion OR tooth replantation) AND splints." This resulted in 340 papers. Again, studies were limited to practice guidelines, MAs, and SRs by using the filter for each publication type separately. Relevant results included four practice guidelines from the International Association of Dental Traumatology and Pediatric Dentistry, one MA, and one SR. Fig. 1.3 provides a detailed review of the decision-making steps in this case and the outcomes.[24]

The articles that were selected as relevant research included each aspect of the PICO question. Inclusion criteria included the following: The patient population studied had to have replanted avulsed or luxated teeth; the research studied the intervention for each of the two PICO questions, pulp extirpation and splint duration, respectively; and the research measured at least one of the outcomes of tooth integration, functional periodontal healing, or the levels of resorption or ankylosis. To reduce the requirement of critical appraisal, the search also looked for critical summaries of the SRs that were found.

Appraising the Evidence

After identifying the evidence gathered to answer a question, it is important to have the skills to understand the evidence found. In all cases, it is necessary to review the evidence, whether it is a CPG, MA, SR, or an original study, to determine whether the methods were conducted rigorously and appropriately. International evidence-based groups have made this easier by developing appraisal forms and checklists that guide the user through a structured series of "YES/NO" questions to determine the validity of the individual study or SR. Table 1.4 provides the names and websites of three different guides that can be used for critical analysis.

RCTs, Randomized controlled trials; *SRs*, systematic reviews.

Common Ways Used to Report Results

Once the results are determined to be valid, the next step is to determine whether the results and potential benefits (or harms) are important. Straus and colleagues[31] identified the clinically useful measures for each type of study. For example, in determining the magnitude of therapy results, we would expect articles to report the control event rate (CER), the experimental event rate (EER), the absolute and relative risk reduction (ARR or RRR), and number needed to treat (NNT). The NNT provides the number of patients (e.g., surfaces, periodontal pockets) who would need to be treated with the experimental treatment or intervention to achieve one additional patient (surfaces, periodontal pockets) who has a

favorable response. Another way of assessing evidence is presented in Chapter 2, which introduces 12 tools that may be useful in assessing causality in clinical sciences.

In appraising the evidence found for the case scenario, the first research study retrieved that answered the first PICO question was a well-conducted SR published in *Dental Traumatology* in 2009.[17] Results indicated an association between pulp extirpations performed after 14 days following replantation and the development of inflammatory resorption. A corresponding critical summary also was found.[30] This evidence was consistent with the 2007 clinical guidelines from the International Association of Dental Traumatology for pulp extirpation within 10 to 14 days of replantation.[14]

The Practice Guideline on the Management of Acute Dental Trauma from the American Academy of Pediatric Dentistry answered the second PICO question. It recommended a "flexible splint for 1 week" for avulsed teeth. However, for lateral luxation, an additional 2 to 4 weeks may be needed when there is breakdown of marginal bone.[2] In addition, a well-conducted SR about splinting duration reported inconclusive evidence of an association between short-term splinting and an increased likelihood of functional periodontal healing, acceptable healing, or decreased development of replacement resorption.[18] The study found no evidence to contraindicate the current guidelines and suggested that the likelihood of successful periodontal healing after replantation was unaffected by splinting duration. Although this SR excluded studies of luxated teeth, this SR is still applicable to the patient. It concluded that dentists should continue to use the currently recommended splinting periods when replanting avulsed permanent teeth, pending future research to the contrary.[18] Consistent with previous reviews, another SR on splinting luxated, avulsed, and root-fractured teeth reported that "the types of splint and the fixation period are generally not significant variables when related to healing outcomes."[20] These two SRs were appraised using the Critical Appraisal Skills Program (CASP) form for appraising reviews (see Table 1.4).

Applying the Evidence: Evidence-Based

Dentistry in Action

Throughout this chapter, the EBDM process has illustrated the application of evidence in clinical decision making. The clinician used the EBDM process to answer two clinical questions. Several relevant resources were incorporated into the decision-making process and the treatment of the patient. The clinician performed pulp extirpations on the avulsed and luxated teeth within the recommended time period of 10 to 14 days (Fig. 1.5A). Healing at 2 weeks post trauma is seen in Fig. 1.5B. The clinician also removed the splint within the recommended time frame for luxated teeth of 2 to 4 weeks. The evidence, in combination with clinical experience, helped provide care for this patient that resulted in the best possible prognosis given the extent of the patient's dental trauma. It also allowed the patient to keep her own teeth, which incorporated the patient preferences aspect of the EBDM process. Fig. 1.5C shows the patient at 4 weeks post trauma; Fig. 1.5D shows the patient at 12 weeks; and Fig. 1.5E shows the patient 2 years post trauma.

FIG. 1.5 (A) Periapical radiograph following pulp extirpations. (B) Healing at 2 weeks post trauma. (C)

Evaluating the Outcomes

The final steps in the EBDM process are to evaluate the effectiveness of the intervention and clinical outcomes and to determine how effectively the EBDM process was applied. For example, one question to ask in evaluating the effectiveness of the intervention is, "Did the selected intervention or treatment achieve the desired result?" In this specific case, the answer is yes.

EBDM is a valuable tool that guides practice decisions to achieve optimal results. In the case of tooth avulsion, the key PICO questions were established to identify research that studied the outcomes of reducing the risk of root resorption and tooth ankylosis and increasing periodontal healing. In using the EBDM process, providers can be confident that they have the most current and relevant evidence available on which to base treatment decisions to provide the best treatment to improve the possibility of a successful outcome.

Using an EBDM approach requires understanding new concepts and developing new skills. In addition to evaluating patient care outcomes, another aspect of evaluation is in using the EBDM process. Questions that parallel each step in the EBDM process can be asked in evaluating self-performance. For example, "How well was the search conducted to find appropriate and relevant evidence to answer the question?" As with most learning, time and practice are essential to mastering new techniques.

Chapter Highlights

- Evidence-based decision making (EBDM) provides clinicians the skills to find, efficiently filter, interpret, and apply research findings so that what is known is reflected in the care provided.

- EBDM takes time and practice to learn to use.
- When mastered, EBDM is an efficient way for clinicians to stay current, and it maximizes the potential for successful patient care outcomes

Conclusion

An EBDM approach closes the gap between clinical research and the realities of practice by providing dental practitioners with the skills to find, efficiently filter, interpret, and apply research findings so that what is known is reflected in the care provided. This approach assists clinicians in keeping current with conditions that a patient may have by providing a mechanism for addressing gaps in knowledge to provide the best care possible.

As EBDM becomes standard practice, individuals must be knowledgeable about what constitutes the evidence and how it is reported. Understanding evidence-based methodology and distinctions among different types of articles allows the clinician to judge better the validity and relevance of reported findings. To assist practitioners with this endeavor, SRs and MAs are being conducted to answer specific clinical questions and to support the development of CPGs. Journals devoted to evidence-based practice are being published to alert readers about important advances in a concise and user-friendly manner. By integrating good science with clinical judgment and patient preferences, clinicians enhance their decision-making ability and maximize the potential for successful patient care outcomes.

CHAPTER 2

Critical Thinking

Assessing Evidence

Philippe P. Hujoel

CHAPTER OUTLINE

Twelve Tools for Assessing Evidence
Conclusion

Between 1950 and 2016, 2290 scientific articles were published that have the terms "periodontal diseases" and "antibacterial agents" as Medical Subject Headings. Which of these articles provide information that is clinically relevant? Are those articles that are clinically relevant selected and accurately summarized in educational courses, textbooks, or systematic reviews? Relying completely on authority to ensure that this happens can be dangerous.

Einstein purportedly said that "his own major scientific talent was his ability to look at an enormous number of experiments and journal articles, select the very few that were both correct and important, ignore the rest, and build a theory on the right ones."[6]

Most evidence-based clinicians aspire to the same goal when evaluating clinical evidence. In this search for good evidence, a "baloney detection kit"[71] can be helpful to separate salesmanship from science and suggestive hints from unequivocal evidence. This chapter introduces 12 tools that may be useful in assessing causality in clinical sciences.

Twelve Tools for Assessing Evidence

Be Skeptical

Of all machines ours is the most complicated and inexplicable.

—Thomas Jefferson

By 1990, it was concluded that "available data thus strongly support the hypothesis that dietary carotenoids reduce the risk of lung cancer."[85] Beta-carotene (β-carotene) was hypothesized to interfere passively with oxidative damage to deoxyribonucleic acid (DNA) and lipoproteins,[38] and these beliefs in part translated into $210 million sales of β-carotene in 1997 in the United States. Was this convincing evidence, or should it be evaluated skeptically? Two large randomized controlled trials (RCTs) were initiated, and both were stopped prematurely because β-carotene increased lung cancer risk, cardiovascular disease risk, and overall mortality risk.[60,79] In 2005, the primary investigator of one of the trials reported that "beta-carotene should be regulated as a human carcinogen."[59] In 2015, mechanistic studies started to demonstrate how antioxidants such as β-carotene accelerate the growth and invasiveness of tumors.[43,62] Similar dramatic turnarounds are in the process on the topic of the "heart-healthy" effects of vegetable oils,[66] dietary salt restriction,[2] or high-carbohydrate diets.[77]

Evidence on how to cure, manage, or prevent chronic diseases is notoriously contradictory, inconsistent, and unreliable. Mark Twain reminded people to be careful when reading health books because one may die of a misprint.[70] Powerful forces conspire to deliver a preponderance of misleading results:

1. Identifying a successful treatment for chronic diseases can be challenging. It has been estimated that less than 0.1% of all investigated treatments are effective. Because the odds of identifying successful interventions for chronic diseases are so small, most so-called effective treatments identified in small clinical trials turn out to be noneffective or harmful when they are evaluated in rigorously conducted pivotal trials.
2. Chronic diseases can be complex and include both environmental and genetic causes. The "obvious" causes of disease, such as tobacco and sugars for periodontitis, are often ignored.[47] As a result of such biased epidemiologic research, incomplete and mistaken understandings of chronic disease etiology can lead to a cascade of wrong turns in the exploration of possible diagnosis, prognosis, and treatment.
3. Poor scientific methodology is a common problem permeating most of the evidence that surrounds us. Popular press headlines tell it all: "Lies, Damned Lies And Medical Statistics,"[69] "Undermined by an Error of Significance: A Widespread Misconception Among Scientists Casts Doubt on the Reliability of a Huge Amount of Research,"[53] "Sloppy Stats Shame Science,"[72] or "How Science Goes Wrong."[27]
4. Finally, the possibility needs to be considered that no magic bullets exist against certain noxious aspects of civilized lifestyles. It was a popular idea in the 20th century that the harmful effects of smoking could be prevented by prescription (e.g., vitamin A), and not proscription (e.g., quit smoking). The experiences so far with finding prescriptions as protection against harmful lifestyles have been largely disastrous.

These factors may all be at play in periodontics, thus suggesting that skepticism is required in the evaluation of scientific evidence. First, the large number of "effective" periodontal treatments may be a telltale sign of a challenging chronic disease. Before 1917, hundreds of pneumonia treatments were available, none of which worked. Before the advent of antibiotics in the 1940s, the wealth of

available tuberculosis treatments was misleading in the sense that none really worked. The current "therapeutic wealth" for periodontal diseases may well mean poverty—an indication of the absence of truly effective treatments—and a suggestion that we are dealing with a challenging chronic disease. Second, many no longer regard periodontal diseases as the simple, plaque-related diseases they were thought to be in the mid-20th century, but rather as complex diseases. Complex diseases are challenging to diagnose, treat, and investigate. Third, the scientific quality of periodontal studies has been rated as low.[4] Major landmark trials were analyzed using wrong statistics,[34,46] most randomized studies were not properly randomized,[55] and the primary drivers of the periodontitis epidemic may have been misunderstood because of the definition of periodontal diseases as an infectious disease without properly controlled epidemiologic studies.[29,30,47] The chance that periodontal research somehow managed to escape the scientific challenges and hurdles that were present in research in medicine appears slim. The opposite appears more likely.

Do Not Trust Biologic Plausibility

Born but to die, and reasoning but to err.

—Alexander Pope

If an irregular heartbeat increases mortality risk and if encainide can turn an irregular heartbeat into a normal heartbeat, then encainide should improve survival.[64] If high serum lipid levels increase myocardial infarction risk and if clofibrate can successfully decrease lipid levels, clofibrate should improve survival.[67] If *Streptococcus mutans* causes dental decay and if chlorhexidine can eradicate *S. mutans,* then chlorhexidine can wipe out dental decay. Such "causal chain thinking" (A causes B, B causes C, therefore A causes C) is common and dangerous. These examples of treatment rationales, although seemingly reasonable and biologically plausible, turned out not to help but to harm patients. Causal chain thinking is sometimes referred to as "deductive inference," "deductive reasoning," or a "logical system."

In mathematics, “once the Greeks had developed the deductive method, they were correct in what they did, correct for all time.”[5] In medicine or dentistry, decisions based on deductive reasoning have not been “correct for all time” and are certainly not universal. Because of an incomplete understanding of biology, the use of deductive reasoning for clinical decisions may be dangerous. For thousands of years, deductive reasoning largely failed to lead to medical breakthroughs. In evidence-based medicine, evidence that is based on deductive inference is classified as level 5, which is the lowest level of evidence available.

Clinical Correlation

The Dietary Guidelines for Americans dropped their recommendation to floss because of the lack of scientific evidence. Dental floss has been recommended by oral hygiene companies and the dental profession based on the following biologic plausibility argument: dental plaque causes dental caries; floss removes dental plaque. Therefore, flossing will lower the risk of dental caries. Such reasoning is no longer accepted as evidence for effectiveness in the 21st century.

Unfortunately, much of our knowledge on how to prevent, manage, and treat chronic periodontitis depends largely on deductive reasoning. Small, short-term changes in pocket depth or attachment levels have been assumed to translate into tangible, long-term benefits to patients, but minimal evidence to support this deductive inference leap is available. In one small study without statistical hypothesis testing, dental plaque was related to the transition from an unnatural, inflammation-free condition referred to as “Aarhus superhealthy gingiva” to experimental gingivitis (which is different from clinical gingivitis).[48] Such studies do not offer proof that dental plaque bacteria cause destructive periodontal disease. It is even unclear whether experimental gingivitis and plaque are correlated at a site-specific level above and beyond what would be expected by chance alone. One subsequent study at the same university, using a similar population, and using a similar experimental design, failed to identify an association between

plaque and gingivitis.[48] Evidence that personal plaque control affects the most common forms of periodontal diseases is still weak and largely based on "biologic plausibility" arguments.[31] A move toward a higher level of evidence (higher than biologic plausibility) is needed to put periodontics on a firmer scientific footing.

Key Fact

Biologic plausibility will increasingly become an unacceptable rationale to recommend dental treatments.

What Level of Controlled Evidence Is Available?

Development of Western science is based on two great achievements: the invention of a formal logical system (in Euclidean geometry) by the Greek philosophers, and the discovery of the possibility to find out causal relationships by systematic experiment (during the Renaissance).

—*Albert Einstein*

Rational thought requires reliance on either deductive reasoning (biologic plausibility) or systematic experiments (sometimes referred to as inductive reasoning). Galileo is typically credited with the start of systematic experimentation in physics. Puzzlingly, it took until the latter half of the 20th century before systematic experiments became part of clinical research. Three systematic experiments are now routine in clinical research: the case-control study, the cohort study, and the RCT. In the following brief descriptions of these three systematic experimental designs, the term *exposure* refers to a suspected etiologic factor or an intervention, such as a treatment or a diagnostic test, and the term *endpoint* refers to the outcome of disease, quality-of-life measures, or any type of condition that may be of interest in clinical studies.

1. *RCT.* Individuals or clusters of individuals are randomly

assigned to different exposures and monitored longitudinally for the endpoint of interest. An association between the exposure and the endpoint is present when frequency of the endpoint occurrence differs among the exposure groups. The RCT is the "gold standard" design in clinical research. In evidence-based medicine, RCTs, when properly executed, are referred to as level 1 evidence and the highest (best) level of evidence available.

2. *Cohort study.* Exposed individuals are compared with nonexposed individuals and monitored longitudinally for the occurrence of the primary endpoint of interest. An association between the exposure and endpoint is present when the frequency of endpoint occurrences differs between exposed and nonexposed individuals. A cohort study is often considered the optimal study design in nonexperimental clinical research (i.e., for those study designs where randomization may not be feasible). In evidence-based medicine, cohort studies, when properly executed, are referred to as level 2 evidence.
3. *Case-control study.* Cases (individuals with the endpoint of interest) are compared with controls (individuals without the endpoint of interest) with respect to the prevalence of the exposure. If the prevalence of exposure differs between cases and controls, an association between the exposure and the endpoint is present. In a case-control study, it is challenging to select cases and controls in an unbiased manner and to obtain reliable information on possible causes of disease that occurred in the past. The case-control study is the most challenging study design to use for obtaining reliable evidence. As a result, in evidence-based medicine, case-control studies, when properly executed, are considered the lowest level of evidence.

All three study designs permit us to study the association between the exposure and the endpoint. This association can be represented schematically as follows:

Exposure → Endpoint

An important challenge in the assessment of controlled evidence is determining whether the association identified (→) is causal. Criteria used to assess causality include factors such as the assessment of temporality, the presence of a pretrial hypothesis, and the size or strength of the reported association. Unlike deductive reasoning, in which associations are either true or false, such absolute truths cannot be achieved with systematic experiments. Conclusions based on controlled study designs are always surrounded by a degree of uncertainty, a frustrating limitation to real-world clinicians who have to make yes/no decisions.

Did the Cause Precede the Effect?

You can't change the laws of physics, Captain.

—"Scotty" in Star Trek

In 2001, a study published in the *British Medical Journal* suggested that retroactive prayer shortened hospital stays in patients with bloodstream infection.[45] The only problem was that patients were already dismissed from the hospital when the nonspecified prayer to the nonspecified deity was made. To most scientists, findings in which the effect (shorter hospital stay) precedes the cause (the prayer) are impossible, and this provides an unequivocal example of a violation of correct temporality; the effect preceded the hypothesized cause. In chronic disease research, it is often challenging to disentangle temporality, and fundamental questions regarding temporality often remain disputed. For example, in Alzheimer disease research the amyloid in the senile plaques in the brain is often considered to be the cause of Alzheimer disease, but some researchers suggested that amyloid may be the result rather than the cause of Alzheimer disease and that the amyloid may be protective.[44] Or, it is widely believed that obesity is caused by overeating and insufficient physical activity. Yet, increasing evidence points to the opposite—that obesity is a disease induced by carbohydrates that leads to internal starvation and consequent

overeating and physical inactivity.[76] Vigorous investigation of temporality is a key aspect in scientific investigation.

Temporality is the only criterion that needs to be satisfied for claiming causality; the cause needs to precede the effect. In periodontal research, almost all studies relating plaque or specific infections to periodontal diseases suffer from unclear temporality.[47] Are observed microbial profiles the result or the cause of periodontitis? No cohort studies in adults have established that an infectious cause precedes the onset of chronic periodontitis.[47] Unequivocal establishment of temporality is an essential element of causality and can be surprisingly difficult to establish for chronic diseases, including periodontal diseases.

No Betting on the Horse After the Race Is Over

Predictions are difficult, especially about the future.

—Niels Bohr

One of the most pervasive cancers in clinical research is the inability of researchers to stick to a hypothesis. Science is about formulating a specific hypothesis, testing it in a clinical experiment, and accepting the findings for what they are. Not only does this rarely happen, but also powerful forces sometimes actively try to prevent regulations that would enforce such scientific behavior.

An acquired immunodeficiency syndrome (AIDS) researcher at an international AIDS conference was jeered when she claimed that AIDS therapy provided a significant benefit for a subgroup of trial participants.[58] A study published in the *New England Journal of Medicine*[49] was taken as a textbook example of poor science[19] when it claimed that coffee drinking was responsible for more than 50% of the pancreatic cancers in the United States. Results of a large collaborative study demonstrating that aspirin use after myocardial infarction increased mortality risk in patients born under Gemini or Libra provided a comical example of an important scientific principle: data-generated ideas are unreliable.

An essential characteristic of science is that hypotheses or ideas

predict observations, not that hypotheses or ideas can be fitted to observations. This essential characteristic of scientific enterprise—prediction—is often lost in medical and dental research when poorly defined prestudy hypotheses result in convoluted data-generated ideas or hypotheses that fit the observed data. It has been reported that even for well-organized studies with carefully written protocols, investigators often do not remember which hypotheses were defined in advance, which hypotheses were data derived, which hypotheses were "a priori" considered plausible, and which were unlikely.[87] A wealth of data-generated ideas can be created by exploring patient subgroups, exposures, and endpoints, as shown by the following:

1. Modifying study sample definition. A commonly observed posttrial modification of a hypothesis is to evaluate improper or proper subgroups of the original study sample. Improper subgroups are based on patients' characteristics that may have been influenced by the exposure. For example, one may evaluate tumor size only in those patients who survived or pocket depths only in those teeth that were not lost during maintenance. Results of improper subgroup analyses are almost always meaningless when establishing causality. Proper subgroups are based on patients' characteristics that cannot be influenced by the exposure, such as sex, race, or age. A review of trials in the area of cardiovascular disease suggested that even the results of proper subgroup analyses turn out to be misleading in a majority of cases.[87] In the human immunodeficiency virus (HIV) area, one proper subgroup analysis (based on racial characteristics) drew an investor lawsuit on the basis that company officials "deceived" investors with a "fraudulent scheme."[15]
2. Modifying exposure definition. After or during the conduct of a study, the exposure definition can be changed, or the number of exposures under study can be modified. In a controversial trial on the use of antibiotics for middle ear infections, the placebo treatment was replaced with a boutique antibiotic, thus causing a potentially misleading

perception of the antibiotics' effectiveness.[16,17,50] In another example of "betting on the horse after the race was over," a negative finding for cigarette smoking (the primary exposure) as a cause of pancreatic cancer reportedly led to the data-generated hypothesis that coffee drinking increased pancreatic cancer risk.[49] When this study was repeated in the same hospital, using the same protocol, but now with the pretrial hypothesis to evaluate coffee drinking, the results of the prior study could not be duplicated.

3. Modifying endpoint definition. Almost all pivotal trials specify one primary endpoint in the pretrial hypothesis. In periodontal research the absence of a specific pretrial defined endpoint is common and permits effortless changing of the endpoint definition. The typical periodontal trial has six endpoints and does not specify which endpoint is primary, and it is not always clear what is a good or a bad outcome.[19] Similarly, the definition of adverse pregnancy outcomes is flexible and susceptible to post hoc manipulations to squeeze out statistical significance. Statistical trickery to reach desired conclusions under such circumstances may be child's play. These problems have remained rampant in clinical research despite all efforts at preventing them. Two surveys of RCTs published in 2015 reported that 18% to 31% of the trials still changed primary endpoints, and 64% of the trials still changed secondary endpoints.[21,39]

Deviating from the pretrial hypothesis is often compared to data torturing.[54] Detecting the presence of data torturing in a published article is often challenging; just as the talented torturer leaves no scars on the victim's body, the talented data torturer leaves no marks on the published study. Long-term efforts at registering all trials (e.g., see www.alltrials.net) have still not solved this problem.[11] Opportunistic data torturing refers to exploring data without the goal of "proving" a particular point of view. Opportunistic data torturing is an essential aspect of scientific activity and hypothesis generation. Procrustean data torturing refers to exploring data with the goal of proving a particular point

of view. Just as the Greek mortal Procrustes fitted guests perfectly to his guest bed either through bodily stretching or through chopping of the legs to ensure correspondence between body height and bed length, so can data be fitted to the pretrial hypothesis by Procrustean means.

What Is a Clinically Relevant Pretrial Hypothesis?

Clinically relevant questions are designed to have an impact on improving patients' outcomes. Usually, clinically relevant questions share four important characteristics of the pretrial hypothesis: (1) a clinically relevant endpoint (referred to as the Outcome in the PICO question), (2) relevant exposure comparisons (referred to as the Intervention and the Control in the PICO question, (3) a study sample representative of real-world clinical patients (should be representative of the Patient defined in the PICO question), and (4) small error rates.

Clinically Relevant Endpoint

An endpoint is a measurement related to a disease process or a condition and is used to assess the exposure effect. Two different types of endpoints are recognized. True endpoints are tangible outcomes that directly measure how a patient feels, functions, or survives[78]; examples include tooth loss, death, and pain. Surrogate endpoints are intangible outcomes used as a substitute for true endpoints[22]; examples include blood pressure and probing depths of periodontal pockets. Treatment effects on surrogates do not necessarily translate into real clinical benefit (Table 2.1). Reliance on surrogate endpoints in clinical trials has led to widespread use of deadly medications, and such disasters have prompted minor changes in the drug approval process.[65] Most major causes of human disease (e.g., cigarette smoking) were identified through studies using true endpoints. A first requirement for a clinically relevant study is the pretrial specification of a true endpoint.

TABLE 2.1

Examples of Potentially Misleading Surrogates[a]

Disease or Condition	Experimental Treatment	Control Treatment	Effect on Surrogate Endpoint	Effect on True Endpoint	Misleading Conclusion	Referen
AIDS	Immediate zidovudine	Delayed zidovudine	Significant increase of 30–35 CD4 cells/mm^3	No change in incidence of AIDS, AIDS-related complex, or survival	False-positive	80
Osteoporosis	Fluoride	Placebo	Significant increase of 16% in bone mineral density of lumbar spine	Nonvertebral fracture rates increased by 85%	False-positive	
Lung cancer	ZD1839 (Iressa)	Placebo	Dramatic tumor shrinkage in 10% of patients	No effect	False-positive	82
Aphthous ulcers	Thalidomide	Placebo	Although thalidomide expected to decrease TNF-α production, significant increase of 4.4 pg/mL in TNF-α production occurred, suggesting harm	Pain diminished and ability to eat improved	False-negative	32
Edentulism dentures	Implant-supported	Conventional dentures	No impact on chewing cycles	Improved oral health–related quality of life	False-negative	5
Prostate cancer	Radical prostatectomy	Watchful waiting	Substantial elimination of tumor mass	No effect on overall mortality risk	False-positive	78
Advanced colorectal cancer	5-FU + LV	5-FU	23% of patients had 50% or greater reduction in tumor volume	No effect on overall survival	False-positive	40
Periodontitis	Surgery	Scaling	Mean pocket depth reduced by 0.5 mm	Effect on tooth loss or quality of life unknown	?	30a

[a]For some examples, the experimental treatment led to improvements in surrogate endpoints, whereas the true endpoint was either unaffected or worsened (a false-positive conclusion). For other examples, the experimental treatment had no impact or worsened the surrogate endpoint, whereas the true endpoint improved (a false-negative conclusion).

Common and Relevant Comparisons

The more prevalent a studied exposure is, the more relevant is the clinical question. A clinically relevant comparison implies the absence of comparator bias, which is defined as the presence of contrived or unethical control groups.[51] Providing the control subjects with less than the standard dose of the standard treatment and providing a control therapy that avoids the real clinical questions are examples of clinically irrelevant research. Similarly, the presence of a placebo treatment instead of "no" treatment in clinical trials can be critical given the large therapeutic effects that can be obtained by proper attention and care in medical settings. For instance, the absence of placebo controls in fluoride varnish trials for primary teeth raises serious doubts whether fluoride varnish has an effect above and beyond what would be observed with just a placebo. In case-control or cohort studies, the measurement and characterization of exposures (e.g., mercury, fluoride, chewing tobacco) can be difficult and imprecise, thus making answers to the questions almost unavoidably imprecise.

Representative Study Sample

The larger the discrepancy between the typical subjects enrolled in clinical studies and the patient you seek to treat, the more questionable the applicability of the study's conclusions becomes. When cholesterol-lowering drugs provided a small benefit in middle-aged men with abnormally high cholesterol levels, it was concluded that those benefits "could and should be extended" to other age groups and women with "more modest elevations" of cholesterol levels.[80] Findings on blood lipids and heart disease that were derived mostly from Polish immigrants in the Framingham Study were generalized to a much more diverse population. An

antidepressant that was approved for use in adults was widely prescribed for children, with unexpected, serious consequences.[1]

Ideally, clinical trials should use simple entry criteria in which the enrolled patients reflect the real-world clinical practice situation as closely as possible. Legislation has been enacted to reach this goal. In 1993, US policy ensured the recruitment of women and minority groups in clinical trials.[10] A US policy for the inclusion of children in clinical studies was then set into law in 1998. Experiments with long lists of inclusion and exclusion criteria can be expensive recipes for failure because they can lead to study subjects who are unrepresentative of most real-world clinical patients.

Small Type I and Type II Error Rates

The type I error rate is the likelihood of concluding that an effect exists when in truth no effect exists. The type I error rate is set by the investigator, and common values are 1% or 5%. The type II error rate is the likelihood of concluding that no effect exists when in truth an effect does exist. The type II error rate is typically set by the investigator at 10% or 20%. The complement of the type II error rate (i.e., 1 – type II error rate) is referred to as the power of the study. The likelihood of a false-positive or false-negative result depends, in addition to the type I and II error rates, on the likelihood that the treatment under investigation is truly effective. This last component is obviously not under the investigator's control, and yet it determines the likelihood of making correct conclusions. For chronic diseases, in which the likelihood of identifying effective treatments or true causes is low, the false-positive rate can be high even when the type I error rate is low. Clinically relevant studies require small type I and type II error rates to minimize false-positive and false-negative conclusions.[36]

Size Does Matter

Chronic hepatitis B infection increased the chances for liver cancer by more than 23,000%.[7] Proximity to electromagnetic radiation increased the chance for leukemia in children by 49%.[84] Periodontitis in populations with smokers increased the chance for

coronary heart disease by 12%.[32] No one doubts the causality of the association between chronic hepatitis B infection and liver cancer, but the role of periodontitis in coronary heart disease or electromagnetic radiation in childhood leukemia remain controversial. Why? To a large extent, the size of the association drives the interpretation of causality.

The larger an association, the less likely it is to be caused by bias, and the more likely it is causal. One simple way to calculate the size of the association is to calculate an odds ratio. The odds of an event represent the probability that an event happens divided by the probability that an event does not happen. An odds ratio is a ratio of odds. To calculate an odds ratio, a two-by-two (2 × 2) table is constructed in which the outcome is cross-tabulated with the exposure (Table 2.2). Odds ratios can be calculated for data from RCTs, cohort studies, and case-control studies.

TABLE 2.2

Two-by-Two Table Cross-Classifying Exposure and Endpoint[a]

		ENDPOINT	
		Failure	**Success**
Exposure	Experimental	A	B
	Control	C	D

[a]Note that the top left cell, by convention, tallies the number of failures for the experimental group.

The odds ratio is the ratio of the cross-products (ad/bc). The odds ratio associated with penciclovir use for oral lesion healing is (376 × 757) / (526 × 878) = 0.62 (Table 2.3). The odds ratio associated with chronic periodontitis for a fatal myocardial infarction is (2 × 1241) / (8 × 257) = 1.21 (Table 2.4). The 95% confidence interval can be approximated by exp[ln(odds ratio) ± 1.96 √ (1/a + 1/b + 1/c + 1/d)]. The 95% confidence intervals of the odds ratio for lesion healing and fatal myocardial infarction are, respectively, exp(−0.48 ± 1.96 √ 0.007), or 0.52 to 0.73, and exp(0.18 ± 1.96 √ 0.63), or 0.25 to 5.72.

TABLE 2.3

Two-by-Two Table on Association Between Penciclovir and Oral Lesion Healing

		ENDPOINT	
		No Lesion Healing by Day 6	**Lesion Healing by Day 6**
Exposure	1% Penciclovir	376	878
	Placebo	526	757

TABLE 2.4

Two-by-Two Table on Association Between Chronic Periodontitis and Fatal Myocardial Infarction

		ENDPOINT	
		Fatal MI	**No Fatal MI**
Exposure	CP	2	257
	No gingivitis or CP	8	1241

CP, Chronic periodontitis; *MI*, myocardial infarction.

The size of the odds ratio ranges between 0 and infinity. An odds ratio of 1 indicates the absence of an association, and if the two-by-two table is set up with the reference cell (poor outcome exposure of interest) in the left-hand side of the top data row, an odds ratio larger than 1 means a harmful effect (e.g., periodontitis increases the odds of a fatal myocardial infarction by 20%), and an odds ratio smaller than 1 means a protective effect (e.g., penciclovir decreases the odds of failed lesion healing by day 6 by 38%).

The confidence interval is the range of numbers between the upper confidence limit and the lower confidence limit. The confidence interval contains the true odds ratio with a certain predetermined probability (e.g., 95%). In a properly executed randomized trial, a conclusion of causality is typically made if the 95% confidence interval does not include the possibility of "no association" (e.g., odds ratio = 1). For example, because the 95% confidence interval for the odds ratio associated with penciclovir use is 0.52 to 0.73 and does not include 1, the effect can be referred to as "statistically significant." For the chronic periodontitis–myocardial infarction example, the 95% confidence interval ranges from 0.25 to 5.72, includes 1, and is therefore referred to as "statistically insignificant."

In epidemiology, where no randomization of individuals to exposures occurs, the interpretation of a confidence interval is challenging because no probabilistic basis (in the form of randomization) exists for making causal inference. A pessimist will

claim that because no randomization was present, no statistical interpretations are allowed.[24] The emphasis should be on visual display of the identified associations and on sensitivity analyses where the results are interpreted under "what if" assumptions. An optimist will argue that the absence of randomization does not preclude the making of statistical inferences, and that one always starts from the assumption that "assignments were random" (even when they were not).[88]

When individuals are randomly assigned to exposures, very small associations (i.e., associations very close to 1, such as 1.1) can reliably be identified. When individuals are not randomly assigned to exposures, as is the case in cohort studies and case-control studies, the size of the reported association (e.g., the odds ratio) becomes key in the interpretation of the findings. Because of the inherent biases in epidemiologic research, small odds ratios cannot be reliably identified. But what is small? Leading epidemiologists provide some guidelines on how to interpret the size of an association with respect to possible causality. Richard Doll, one of the founders of epidemiology, said, "No single epidemiological study is persuasive by itself unless the lower limit of its 95% confidence level falls above a threefold (200%) increased risk." Dimitrios Trichopoulos, past chairperson of the Department of Epidemiology at Harvard University, opted "for a fourfold (300%) increase at the lower limit (of the 95% confidence interval)." Marcia Angell, former editor of the *New England Journal of Medicine,* reported: "As a general rule of thumb we are looking for an odds ratio of 3 or more (≥200% increased odds) [before accepting a paper for publication]." Robert Temple, Director of the Food and Drug Administration, stated: "My basic rule is if the odds ratio isn't at least 3 or 4 (a 200% or 300% increased risk), forget it."[75] Textbooks on evidence-based medicine report an odds ratio of 3 for cohort studies and 4 for case-control studies as a reflection of a reliable result.[74] These opinions provide some guidelines on what size of odds ratio to look for when determining causality.

Clinical Correlation

Periodontitis during pregnancy was reported to increase the risk

for preterm low birth weight eightfold.[20]

Is a Better Alternative Explanation Available?

No amount of experimentation can ever prove me right; a single experiment can prove me wrong.

—Albert Einstein

When you have eliminated the impossible, whatever remains, however improbable, must be the truth.

—Sir Arthur Conan Doyle

Dozens of epidemiologic studies appeared to support the hypothesis that β-carotene intake lowered lung cancer risk. However, RCTs provided unequivocal evidence to the contrary. What went wrong? Different explanations that worked as well or better may have been inadequately explored. Possibly, smoking was not adequately considered as an alternative explanation and led to a misunderstanding of the health effects of β-carotene.[20,73] Similarly, a systematic review of epidemiologic studies appeared to support the hypothesis that chronic periodontitis caused low birth weight.[86] In contrast, however, a systematic review of RCTs suggested that the periodontitis–low birth weight theory may be dead.[83] Why was epidemiology misleading? Again, different explanations may have been inadequately explored. More efforts may have been expended toward proving associations by ignoring common causal factors rather than disproving associations. The highest goal of a scientist is the attempt to refute, disprove, and vigorously explore factors and alternative hypotheses that may "explain away" the observed association.[12] The efforts at refuting smoking and nutrition as potential confounders in periodontics have been minimal and may have led to a significant waste of clinical research resources.

« Flash Back

Epidemiologic studies are by nature unreliable. It has been estimated that 80% of the epidemiologic studies report false-positive findings. Two large pivotal trials on periodontal treatments and adverse pregnancy outcomes funded by the National Institutes of Health,[20,73] as well as subsequent epidemiologic studies,[86] failed to confirm the dramatic claims of previously published epidemiologic studies.

For a factor (i.e., a potential confounder) to explain away an observed association, two criteria need to be fulfilled. First, the factor must be related to the exposure, but not necessarily in causal way. Second, the factor must be causally related to the outcome and must not be in the causal pathway. If both criteria are satisfied, the factor is referred to as a confounder, and confounding is said to be present. For example, smoking satisfied the criteria for a confounder in the β-carotene–lung cancer association because (1) cigarette smokers consumed less β-carotene than nonsmokers and (2) smoking caused lung cancer. Confounding is often represented schematically (Fig. 2.1).

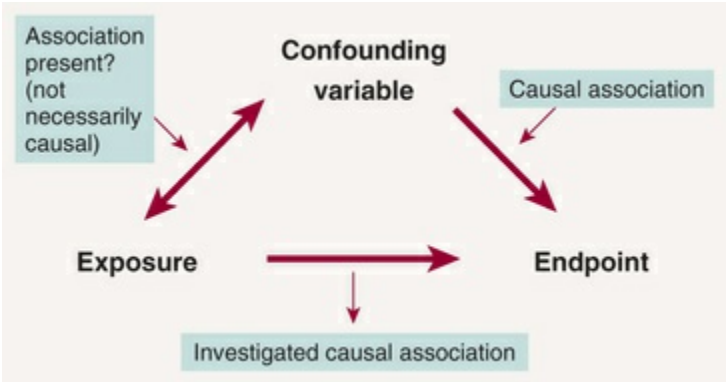

FIG. 2.1 Schematic representation of the two necessary criteria for a variable to induce spurious associations (i.e., to be a confounding variable). The confounding variable has to be associated with the exposure and causally linked to the outcome. When both criteria are satisfied, confounding is said to be present.

In randomized studies, confounding is typically not an issue because randomization balances known and unknown confounders across the compared groups with a high degree of certainty. In epidemiologic studies, in which no randomization is present, three questions related to confounding need to be considered in the

assessment of the causality, as addressed next.

First, were all important confounders identified? Complex diseases have multiple risk factors, which may act as confounders in the reported association. The multiple confounders need to be included in the statistical analyses. An association unadjusted for any potential confounders is sometimes referred to as the *crude association*. When this crude association is adjusted for potential confounders, it is referred to as an *adjusted association*. Typically, crude and adjusted odds ratios are both presented so readers can evaluate the direction of the bias.

Key Fact

Single epidemiologic studies reporting large odds ratios are unreliable.

Second, how accurately were confounders measured? Some potential confounders, such as age, sex, and race, can be measured relatively accurately. Other potential confounders, such as smoking or lifestyle factors such as nutrition, are notoriously more difficult to measure. A discrepancy between what is measured and what is the truth will result in the incomplete removal of bias and lead to spurious associations. The remaining bias is sometimes referred to as *residual confounding*. Residual confounding is common in epidemiology and is one of the reasons that case-control and cohort studies are less effective research tools than randomized trials in identifying small effects. For instance, an accurate summary of smoking history over a person's lifetime may be impossible.

Third, was the statistical modeling of the confounders appropriate? Any mis-specification of the functional relationships causes bias. For example, assuming a linear relationship between a confounder and an endpoint, whereas in truth the relationship is quadratic, causes bias.

Evaluating the impact of confounding can be a challenge. The goal of an epidemiologist is to come up with the best possible defense why an identified association is spurious. All possible efforts should be spent identifying known confounders, obtaining accurate measurements of the confounders, and exploring different

analytic approaches to refute the observed association. Smoking, a potential confounder in many studies, has been found to be such a strong confounder that several leading epidemiologists have suggested that restriction to never-smokers is required to eliminate the potential for residual confounding by smoking. Control for confounding is the major methodologic challenge in epidemiology, and randomization is the only tool available to eliminate confounding reliably.

Clinical Correlation

Epidemiologic evidence has suggested that periodontal patients who comply with periodontal maintenance procedures lose fewer teeth.[33]

Was the Study Properly Randomized?

It is often taken for granted that randomization is properly performed in RCTs. This is unfortunately not the case. Attempts by physicians to circumvent randomization are not isolated events; they used to be part of an endemic problem stemming from ignorance.[58]

Randomization can be a counterintuitive process because it (1) creates heterogeneity, (2) takes control over treatment assignment away from the physician, and (3) leads to apparently illogical situations in which patients randomly assigned to a treatment but refusing compliance still are analyzed as if they received the treatment. Although randomization was a radical innovation introduced for agriculture, some have suggested that it is doubtful whether it would have ever been widely introduced into medicine (and subsequently dentistry) if not for a confluence of factors surrounding the end of World War II in Great Britain. Because of the revolutionary nature of randomization, fundamental misunderstandings of this process remained prevalent until recently. In 1994, about one-third of the clinical trials published in elite medical journals apparently did not ensure that patients are assigned to different treatments by chance.[58] The majority of reported periodontal trials failed to convince reviewers that (1) the

studies were properly randomized, (2) randomization was concealed, or (3) randomized patients were accounted for.[55] Tampering with the delicate process of randomization can quickly, according to Ronald Fisher, a statistician and geneticist, turn an experiment into an experience.

Key Fact

Patients who comply with medical or dental recommendations are typically healthier. As a result, interventions that increase mortality risk in randomized trials will spuriously appear to decrease mortality in epidemiologic studies. The reason for this discrepancy is healthy user bias. A Canadian study[17a] demonstrated that patients compliant with taking statins are less likely to have accidents (e.g., burns), more likely to undergo medical screening (e.g., eye examination), less likely to have dental problems, and less likely to have other serious medical problems such as deep vein thrombosis. Such effects are typically interpreted as examples of healthy user bias. The effectiveness of periodontal treatments in providing tangible patient benefits cannot reliably be estimated in epidemiologic studies due to the healthy user bias.

Several studies have shown how an inadequate randomization process will bias study findings. In one review study, the ability to reject patients from the study after random treatment assignment tripled the likelihood of finding significant results and doubled the likelihood that confounders were unequally distributed among the compared groups.[13] Trials where clinicians can break the randomization code reported treatment effects that averaged 30% larger than effects in trials where the randomization could not be broken.[13] The common desire to eliminate noncompliant patients can similarly lead to biases, as shown by the following two examples. First, in one cardiovascular disease trial, patients compliant with a placebo pill had a 10% reduction in mortality risk compared with patients who were noncompliant with the placebo.[67] Second, in a caries trial, adolescents compliant with a placebo varnish had on average 2.2 fewer new caries lesions than adolescents noncompliant with a placebo varnish.[23] Such findings

suggest that factors related to compliance and unrelated to the treatments under investigation have a powerful influence on the outcome measured. Deleting such noncompliant patients may lead to biases.

Proper randomization ideally includes the following elements. First, subjects are enrolled into a study before randomization: important baseline disease characteristics are recorded and provided to an independent person or organization. This step ensures that baseline information is available for every patient who will be randomized. Without this step, randomized patients can be "lost," thus leading to biases. Subsequently, an independent person or organization randomly assigns subjects to treatments and informs the clinician regarding the treatment assignment. This randomization process needs to be auditable, a requirement that makes pseudorandom processes such as coin tosses unacceptable. The concealment of the randomization process ensures that clinicians cannot crack the code and that they will enroll only those patients they think are suited for the treatment that will be assigned. Finally, the outcome in the subject is evaluated regardless of follow-up time or compliance and according to the treatment assigned, not the treatment received. Imputation is used in sensitivity analyses to determine the extent that subjects with missing information can bias the conclusions. The whole process of randomization is complex and often deviated from, thereby leading to unreliable results.

When to Rely on Nonrandomized Evidence

Randomize the first patient.

—Thomas Chalmers

To tell the truth, all of the discussion today about the patient's informed consent still strikes me as absolute rubbish.

—Sir Austin Bradford Hill

Scores of epidemiologic studies reported evidence that hormone replacement therapy provided benefits to postmenopausal women.

Despite this “strong” evidence from “leading” researchers, and despite the opposition on ethical grounds to begin a placebo-controlled trial, the Women's Health Initiative trial was initiated. The “miracle” of hormone replacement therapy was shown to lead to increased breast cancer risk, dementia, myocardial infarction, and stroke. This example illustrates the need for randomized studies and for questioning well-established and widely accepted beliefs based on numerous epidemiologic studies. Nonetheless, the initiation of randomized trials can become difficult because of ethical considerations and expensively large sample sizes.

Ethical principles dictate that proposed interventions do more good than harm, that the populations in whom the study will be conducted will benefit from the findings, that informed consent is obtained from enrolled subjects, and that a genuine uncertainty exists with respect to treatment efficacy. The interpretation of these ethical principles is largely determined by culture and era. Ethical principles also play an important role in determining which clinical questions are sufficiently important to warrant the conduct of an RCT.

Sample size requirements represent another consideration that may prevent the conduct of RCTs. The smaller the rate at which endpoints occur in an RCT, the larger the required sample size will be. For rare events, such as bacterial endocarditis subsequent to a dental procedure or HIV conversion after exposure to an HIV-contaminated dental needle, RCTs may never be possible because the required sample sizes are in the 100,000s or millions of subjects.

In addition to both ethical and practical reasons, powerful political issues can surround the decision to initiate clinical trials. It has been pointed out that specialists are unlikely to support clinical trials that evaluate their main source of income.[63] This observation for medical specialties may also hold for periodontics. Although dental professional organizations commonly claim that periodontal disease is a major cause of tooth loss, evidence indicates that standard periodontal therapy is not effective at reducing tooth loss. Hopefully, well-designed and well-conducted studies in the future will allow us to compare different treatments effectively. Unequivocal evidence requires the conduct of rigorously designed and executed RCTs. The absence of RCT evidence for important

and answerable clinical questions can be frustrating to those who seek reliable, evidence-based practice guidelines.

Did the Investigators Take Into Account the Placebo or Nocebo Effects?

I never knew any advantage from electricity in (the treatment of) palsies that was permanent. And how far the apparent temporary advantage might arise from the exercise in the patient's journey, and coming daily to my house, or from the spirits given by the hope of success, enabling them to exert more strength in moving their limbs, I will not pretend to say.

—Benjamin Franklin[82]

Sham or mock surgical procedures have been used to evaluate whether implanting human fetal tissue in the brain decreases symptoms of Parkinson disease, whether surgical lavage and debridement decrease pain in arthritic knee joints,[56] whether mammary artery ligation improves heart disease outcomes,[14] and whether alveolar trephination relieves the pain of acute apical periodontitis.[26,57]

What motivates clinical investigators to subject patients to surgical risks and yet knowingly provide no hypothesized benefits to these patients? A partial answer to this question lies in a phenomenon known as placebo or nocebo effects: the beneficial or harmful effects patients may experience by participating in a study, by patient–physician interaction, by the patient's anticipation for improvement, or by the patient's desire to please the physician. One group of researchers suspects that the placebo or nocebo effect may be related to the balance of the parasympathetic and sympathetic nervous system, which could explain both placebo and nocebo effects.[41] Without mock surgical procedures it would be impossible to tell whether the improvements observed in clinical trials are caused by the placebo effects associated with the surgical procedures or by the hypothesized active ingredient of the surgery itself.

Two studies have quantified the placebo effect. In the first study, the magnitude of the placebo effect was estimated by evaluating patients' responses to ineffective treatments.[68] Five treatments were identified as ineffective (all these treatments had been abandoned by the medical profession and in at least one controlled study confirmed its ineffectiveness). With these ineffective treatments, good to excellent treatment responses were observed in 45% to 90% of the patients, a powerful placebo effect indeed. In the second study, placebo interventions (pharmacologic placebo, physical, or psychological interventions) were compared with true "no-treatment" interventions.[28] A significant placebo effect was observed for pain, the condition that was evaluated in the largest number of trials and that had the largest number of evaluated participants.

Placebo effects can reliably be estimated only when clinical trials randomly assign patients to a placebo treatment and no treatment. Such studies are rare. Some systematic reviews may provide a hint at the magnitude of placebo effects. One systematic review of 133 studies reported that the fluoride effect on caries was significantly larger when a no-treatment control group was used versus a placebo control group.[52] One possible interpretation for these differences is a placebo effect: the placebo lowered caries rates possible through re-equilibrating of parasympathetic and sympathetic nervous activity, which may influence factors such as improved saliva flow. Other explanations, such as the scientific quality of the studies, may, of course, also be responsible for such observed differences, especially for pain. Overall, sufficient evidence is available to suggest that placebo effects can be real and measurable, and that the magnitude of the placebo effect may depend on the treatment under study and the type of outcome evaluated.

Was Protection in Place Against Conflict of Interest?

In evidence-based medicine, the data from clinical research remain largely esoteric and of no real-world significance if the evidence fails to be translated into clinical practice. Spinal fusion,

vertebroplasty, and arthroscopic surgery for knee pain have all shown noneffectiveness in clinical trials, yet these trials had no impact on clinical practice. In some instance, the use of surgical procedures actually increased after a demonstration of noneffectiveness.[37,42] Such discrepancies between clinical practice and science have been in part attributed to "perverse financial incentives."[37]

Can one trust clinical recommendations regarding a novel, noninvasive cardiac bypass operation by a physician who has a $100 million stake in the procedure he or she is recommending? Is it possible that financial stakes are preventing physicians from disclosing a 10-fold increased mortality risk? Can one trust guidelines establishing sharply lowered lipid levels while knowing that eight of the nine panel experts have financial connections to the manufacturers of lipid-lowering drugs? Is it possible that panelists are picked for ideology?[8] Can one trust clinical guidelines published by professional dental organizations? The answers to these questions are not straightforward and in general are discussed under the heading of "conflicts of interest."

Conflict of interest has been defined as "a set of conditions in which professional judgment concerning a primary interest (such as patient's welfare or validity of research) tends to be unduly influenced by a secondary interest."[3] A common secondary interest is financial but can include others, such as religious or scientific beliefs, ideologic or political beliefs, or academic interests (e.g., promotion). Some examples of how conflicts of interests can bias evidence are now given:

1. Evidence can be suppressed by lawsuits. For example, a company initiated a multimillion-dollar legal action[15] against the investigator who reported that the company's HIV vaccine was ineffective.[40] Companies can attempt to suppress submitted scientific articles that they perceive as incorrect.
2. Negative evidence can disappear into a "black hole."[25] One can expect that 2 of 40 trials of an ineffective treatment will provide positive results by chance if the experiments are run with a type I error rate of 5%. If the 38 negative trial reports

go into a file drawer, and if the 2 positive reports lead to drug approval and are published in leading journals, a misleading perception of the drug's effectiveness will be given to the practicing community. Although a Food and Drug Administration official indicated that such situations have never happened,[18] reports on nondisclosed negative trials of an antidepressant drug suggests the contrary.[81] Although registries of clinical trials should succeed at eliminating the problem of disappearing trial results, and although many leading journals request a priori trial registration as a prerequisite for publishing, the problem of disappearing trial results remains with us today.

3. Conflicts of interest can lead to distortion of study designs and analyses to provide the desired results. Such distortions can range from data fabrication and data falsification to design and analysis "tweaks" such as contrived control groups, unplanned subgroup analyses, and only showing that time point in the analysis where the differences favor the investigated drug.
4. Conflicts of interests related to loss of patents or orphan drugs can shunt available research resources to the conduct of clinical trials that are not necessarily in the best interest of public health. The potential for conflict of interest appears to be ever increasing. The prevalence of industry-funded trials is increasing, and more and more universities hold stock in start-up companies that support clinical trials within those institutions. Such connections can be viewed with a skeptical eye. It has been confirmed over and over again that industry-sponsored studies are more likely to have proindustry conclusions than are non–industry-sponsored studies.[9]

Protection against potential conflict of interest is an important aspect of clinical research. Mandatory registration of clinical trials helps. The appointment of independent data and safety monitoring boards for trial monitoring provides protection against biases. Policy regulations established by journals, academic institutions, and governments can further decrease the impact of perceived

conflicts of interests. For instance, all the work that has been done toward establishing registries of RCTs helps in decreasing biases.

Conflict of interest issues may be just as prevalent in dental research as in other medical areas dealing with chronic disease. In 2002, an article published in a leading dental journal ended up on the cover of the *New York Times*.[61] In part, the reason was a perceived conflict of interest; the article did not disclose that funding for the study came from an advertising company. Disclosure of conflict of interest is often poorly enforced, and some dental journals do not have regulations in place to reveal potential conflicts of interest of authors. Such situations (1) make it challenging for clinicians to recognize the potential for conflicts of interest, (2) may reduce trust in dental journals, and (3) may affect the scientific integrity of dental research.

Conclusion

Lessons learned from other chronic disease areas do apply to the evaluation of evidence in the periodontal disease research arena. Randomization and confounding are as important in periodontal research as they are in cancer research. Work remains to be done to integrate evidence-based thinking into clinical practice. One challenging task is to lessen the excessive reliance on biologic plausibility in determining both research priorities and patient management and to transition to clinical thinking that is based on controlled clinical observations. Maybe, however, the most challenging task for the dental profession to eliminate this bias will be to comply with the Institute of Medicine guideline largely to exclude experts from writing clinical guidelines.[35] Although the 12 discussed tools for assessing evidence do not cover all necessary tools, or maybe even the most important tools, it is hoped that they provide a useful starting point for the further exploration of the issues and principles involved in the conduct of systematic experiments in periodontal disease research.

CHAPTER OUTLINE

Oral Mucosa
Gingiva
Periodontal Ligament
Cementum
Alveolar Process
Development of the Attachment Apparatus
External Forces and the Periodontium
Vascularization of the Supporting Structures

The normal periodontium provides the support necessary to maintain teeth in function. It consists of four principal components:

gingiva, periodontal ligament, cementum, and alveolar bone. Each of these periodontal components is distinct in its location, tissue architecture, biochemical composition, and chemical composition, but all of these components function together as a single unit. Research has revealed that the extracellular matrix components of one periodontal compartment can influence the cellular activities of adjacent structures. Therefore the pathologic changes that occur in one periodontal component may have significant ramifications for the maintenance, repair, or regeneration of other components of the periodontium.[18]

This chapter first discusses the structural components of the normal periodontium; it then describes their development, vascularization, innervation, and functions.

Oral Mucosa

The *oral mucosa* consists of the following three zones:

1. The gingiva and the covering of the hard palate, termed the *masticatory mucosa* (the *gingiva* is the part of the oral mucosa that covers the alveolar processes of the jaws and surrounds the necks of the teeth)
2. The dorsum of the tongue, covered by *specialized mucosa*
3. The oral mucous membrane lining the remainder of the oral cavity

Gingiva

Clinical Features

In an adult, normal gingiva covers the alveolar bone and tooth root to a level just coronal to the cementoenamel junction. The gingiva is divided anatomically into *marginal, attached,* and *interdental areas.* Although each type of gingiva exhibits considerable variation in differentiation, histology, and thickness according to its functional demands, all types are specifically structured to function appropriately against mechanical and microbial damage.[7] In other words, the specific structure of different types of gingiva reflects

each one's effectiveness as a barrier to the penetration by microbes and noxious agents into the deeper tissue.

Marginal Gingiva

The marginal or unattached gingiva is the terminal edge or border of the gingiva that surrounds the teeth in collar-like fashion (Figs. 3.1 and 3.2).[6] In about 50% of cases, it is demarcated from the adjacent attached gingiva by a shallow linear depression called the *free gingival groove*.[6] The marginal gingiva is usually about 1 mm wide, and it forms the soft-tissue wall of the gingival sulcus. It may be separated from the tooth surface with a periodontal probe. The most apical point of the marginal gingival scallop is called the *gingival zenith.* Its apicocoronal and mesiodistal dimensions vary between 0.06 and 0.96 mm.[171]

FIG. 3.1 Normal gingiva in a young adult. Note the demarcation (mucogingival line) *(arrows)* between the attached gingiva and the darker alveolar mucosa.

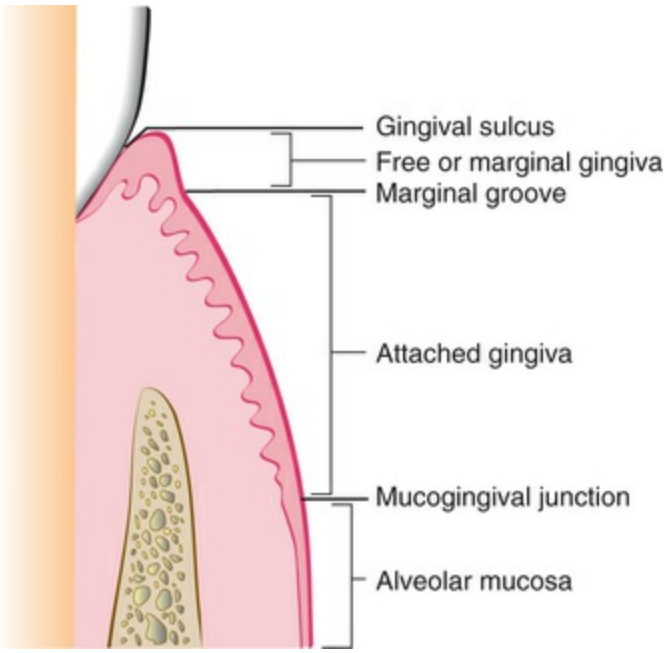

FIG. 3.2 Diagram showing the anatomic landmarks of the gingiva.

Gingival Sulcus

The gingival sulcus is the shallow crevice or space around the tooth bounded by the surface of the tooth on one side and the epithelium lining the free margin of the gingiva on the other side. It is V-shaped and barely permits the entrance of a periodontal probe. The clinical determination of the depth of the gingival sulcus is an important diagnostic parameter. Under absolutely normal or ideal conditions, the depth of the gingival sulcus is 0 mm or close to 0 mm.[105] These strict conditions of normalcy can be produced experimentally only in germ-free animals or after intense and prolonged plaque control.[13,49]

In clinically healthy human gingiva, a sulcus of some depth can be found. The depth of this sulcus, as determined in histologic sections, has been reported as 1.8 mm, with variations from 0 to 6 mm[195]; other studies have reported 1.5 mm[289] and 0.69 mm.[93] The clinical evaluation used to determine the depth of the sulcus involves the introduction of a metallic instrument (i.e., the periodontal probe) and the estimation of the distance it penetrates (i.e., the probing depth). The histologic depth of a sulcus does not need to be exactly equal to the depth of penetration of the probe. The penetration of the probe depends on several factors, such as

probe diameter, probing force, and level of inflammation.[91] Consequently, the probing depth is not necessarily exactly equal to the histologic depth of the sulcus. The so-called probing depth of a clinically normal gingival sulcus in humans is 2 to 3 mm (see Chapter 32).

Attached Gingiva

The attached gingiva is continuous with the marginal gingiva. It is firm, resilient, and tightly bound to the underlying periosteum of alveolar bone. The facial aspect of the attached gingiva extends to the relatively loose and movable alveolar mucosa; it is demarcated by the *mucogingival junction* (see Fig. 3.2).

The *width of the attached gingiva* is another important clinical parameter.[7] It is the distance between the mucogingival junction and the projection on the external surface of the bottom of the gingival sulcus or the periodontal pocket. It should not be confused with the *width of the keratinized gingiva,* although this also includes the marginal gingiva (see Fig. 3.2).

The width of the attached gingiva on the facial aspect differs in different areas of the mouth.[40] It is generally greatest in the incisor region (i.e., 3.5 to 4.5 mm in the maxilla, 3.3 to 3.9 mm in the mandible) and narrower in the posterior segments (i.e., 1.9 mm in the maxillary first premolars and 1.8 mm in the mandibular first premolars)[6] (Fig. 3.3).

FIG. 3.3 Mean width of the attached gingiva in the

human permanent dentition.

Because the mucogingival junction remains stationary throughout adult life,[4] changes in the width of the attached gingiva are caused by modifications in the position of its coronal portion. The width of the attached gingiva increases by the age of 4 years and in supraerupted teeth.[5] On the lingual aspect of the mandible, the attached gingiva terminates at the junction of the lingual alveolar mucosa, which is continuous with the mucous membrane that lines the floor of the mouth. The palatal surface of the attached gingiva in the maxilla blends imperceptibly with the equally firm and resilient palatal mucosa.

Interdental Gingiva

The interdental gingiva occupies the gingival embrasure, which is the interproximal space beneath the area of tooth contact. The interdental gingiva can be pyramidal, or it can have a "col" shape. In the former, the tip of one papilla is located immediately beneath the contact point; the latter presents a valley-like depression that connects a facial and lingual papilla and that conforms to the shape of the interproximal contact[62] (Figs. 3.4 and 3.5). The shape of the gingiva in a given interdental space depends on the presence or absence of a contact point between the adjacent teeth, the distance between the contact point and the osseous crest,[260] and the presence or absence of some degree of recession. Fig. 3.6 depicts the variations in normal interdental gingiva.

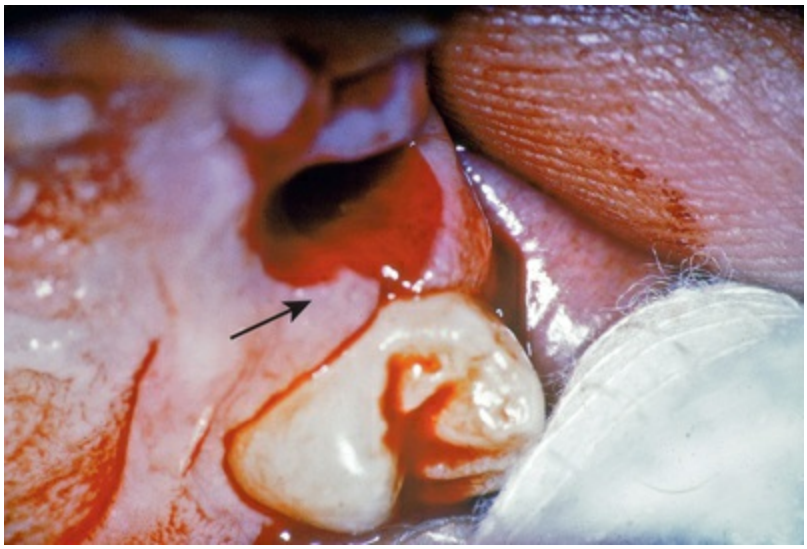

FIG. 3.4 Site of extraction showing the facial and palatal interdental papillae and the intervening col *(arrow).*

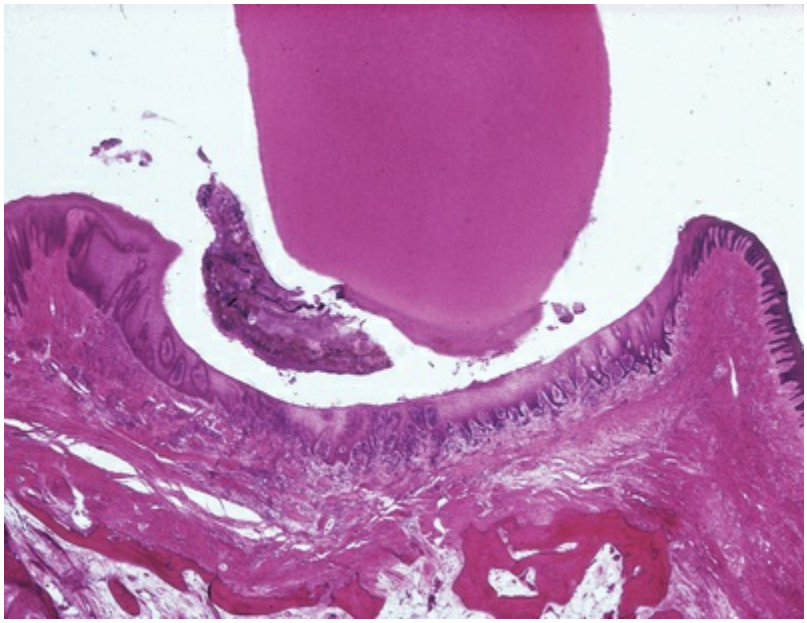

FIG. 3.5 Faciolingual section of a monkey showing the col between the facial and lingual interdental papillae. The col is covered with nonkeratinized stratified squamous epithelium.

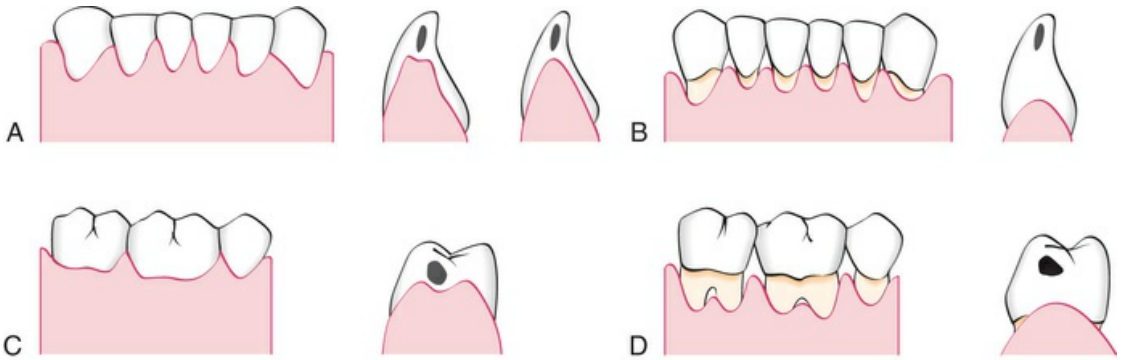

FIG. 3.6 A diagram that compares anatomic variations of the interdental col in the normal gingiva *(left side)* and after gingival recession *(right side)*. (A–B) Mandibular anterior segment, facial and buccolingual views, respectively. (C–D) Mandibular posterior region, facial and buccolingual views, respectively. Tooth contact points are shown with black marks in the lower individual teeth.

The facial and lingual surfaces are tapered toward the interproximal contact area, whereas the mesial and distal surfaces are slightly concave. The lateral borders and tips of the interdental papillae are formed by the marginal gingiva of the adjoining teeth. The intervening portion consists of attached gingiva (Fig. 3.7). If a diastema is present, the gingiva is firmly bound over the interdental bone to form a smooth, rounded surface without interdental papillae (Fig. 3.8).

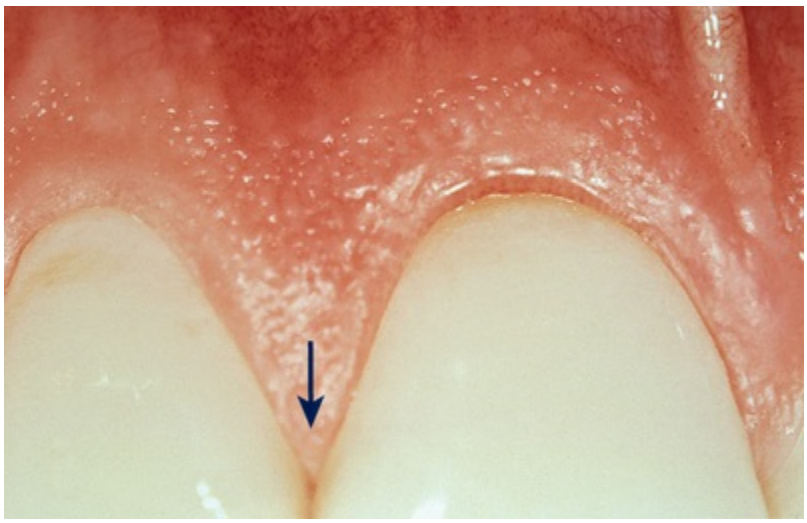

FIG. 3.7 Interdental papillae *(arrow)* with a central portion formed by the attached gingiva. The shape of

the papillae varies according to the dimension of the gingival embrasure. (Courtesy Dr. Osvaldo Costa.)

FIG. 3.8 An absence of interdental papillae and col where the proximal tooth contact is missing. (Courtesy Dr. Osvaldo Costa.)

Microscopic Features

Microscopic examination reveals that gingiva is composed of the overlying stratified squamous epithelium and the underlying central core of connective tissue. Although the epithelium is predominantly cellular in nature, the connective tissue is less cellular and composed primarily of collagen fibers and ground substance. These two tissues are considered separately. (A detailed description of gingival histology can be found in Schroeder HE: *The periodontium,* New York, 1986, Springer-Verlag; and in Biological structure of the normal and diseased periodontium, *Periodontol 2000* 13:1, 1997.)

Gingival Epithelium

General Aspects of Gingival Epithelium Biology

Historically, the epithelial compartment was thought to provide only a physical barrier to infection and the underlying gingival attachment. However, we now believe that epithelial cells play an active role in innate host defense by responding to bacteria in an

interactive manner,[67] which means that the epithelium participates actively in responding to infection, in signaling further host reactions, and in integrating innate and acquired immune responses. For example, epithelial cells may respond to bacteria by increased proliferation, the alteration of cell-signaling events, changes in differentiation and cell death, and, ultimately, the alteration of tissue homeostasis.[67] To understand this new perspective of the epithelial innate defense responses and the role of epithelium in gingival health and disease, it is important to understand its basic structure and function (Box 3.1).

Modified from Dale BA: Periodontal epithelium: a newly recognized role in health and disease. *Periodontol 2000* 30:71, 2002.

The gingival epithelium consists of a continuous lining of stratified squamous epithelium. There are three different areas that can be defined from the morphologic and functional points of view: the oral or outer epithelium, the sulcular epithelium, and the junctional epithelium.

The principal cell type of the gingival epithelium—as well as of other stratified squamous epithelia—is the *keratinocyte.* Other cells found in the epithelium are the clear cells or nonkeratinocytes, which include the Langerhans cells, the Merkel cells, and the melanocytes.

The main function of the gingival epithelium is to protect the deep structures while allowing for a selective interchange with the oral environment. This is achieved via the proliferation and differentiation of the keratinocytes. The *proliferation* of keratinocytes takes place by mitosis in the basal layer and less frequently in the suprabasal layers, in which a small proportion of cells remain as a proliferative compartment while a larger number begin to migrate to the surface.

Differentiation involves the process of keratinization, which

consists of progressions of biochemical and morphologic events that occur in the cell as they migrate from the basal layer (Fig. 3.9). The main morphologic changes include the following: (1) the progressive flattening of the cell with an increasing prevalence of tonofilaments; (2) the couple of intercellular junctions with the production of keratohyalin granules; and (3) the disappearance of the nucleus. (See Schroeder[230] for further details.)

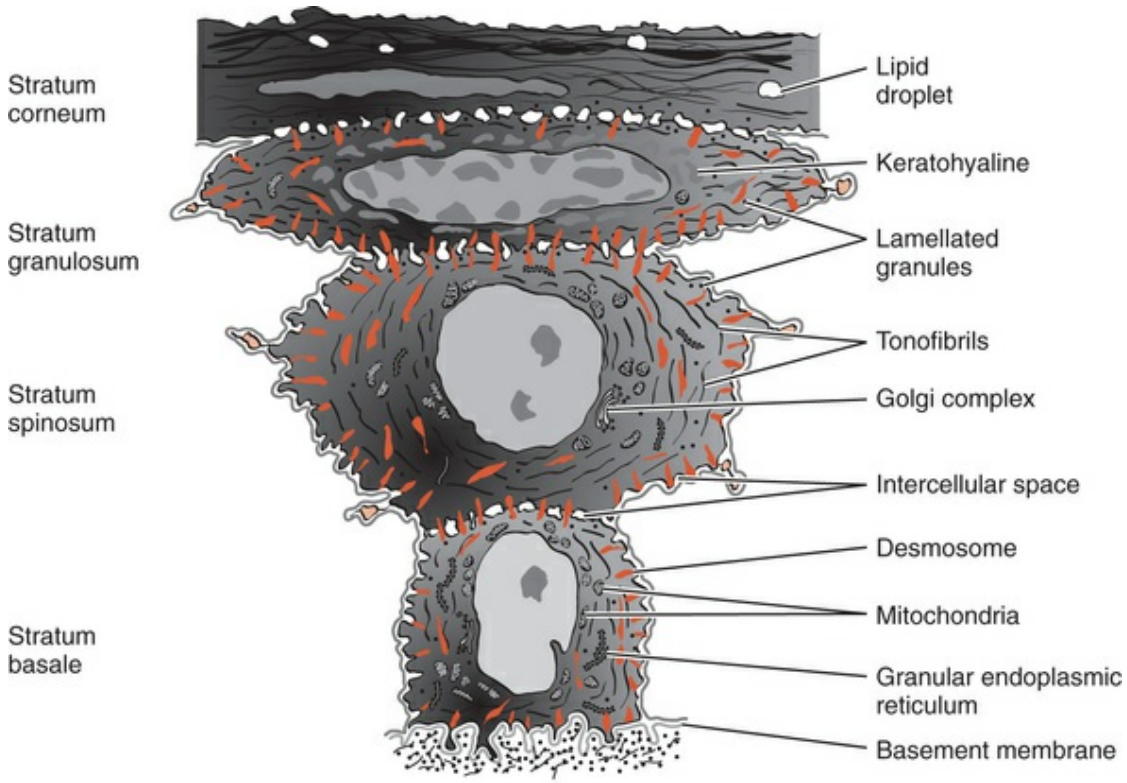

FIG. 3.9 Diagram showing representative cells from the various layers of stratified squamous epithelium as seen by electron microscopy. (Modified from Weinstock A: In Ham AW: *Histology,* ed 7, Philadelphia, 1974, Lippincott.)

A complete keratinization process leads to the production of an *orthokeratinized* superficial horny layer similar to that of the skin, with no nuclei in the stratum corneum and a well-defined stratum granulosum (Fig. 3.10). Only some areas of the outer gingival epithelium are orthokeratinized; the other gingival areas are covered by parakeratinized or nonkeratinized epithelium[45] and are considered to be at intermediate stages of keratinization. These areas can progress to maturity or dedifferentiate under different

physiologic or pathologic conditions.

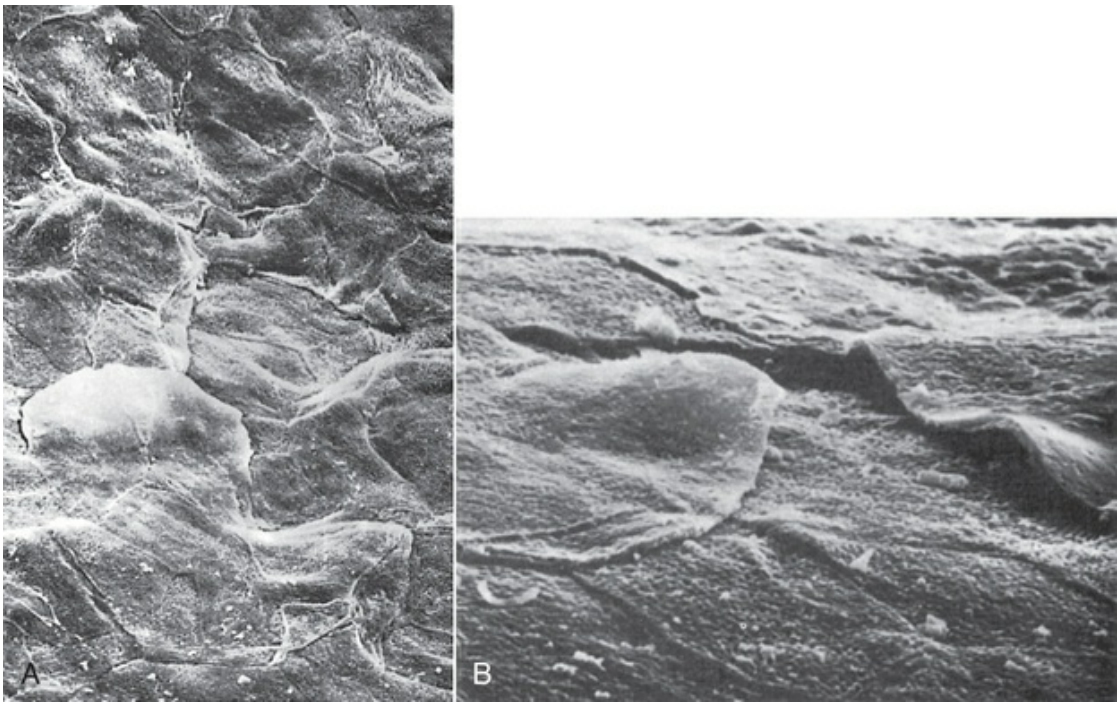

FIG. 3.10 (A) Scanning electron micrograph of keratinized gingiva showing the flattened keratinocytes and their boundaries on the surface of the gingiva (×1000). (B) Scanning electron micrograph of the gingival margin at the edge of the gingival sulcus showing several keratinocytes about to be exfoliated (×3000). (From Kaplan GB, Pameijer CH, Ruben MP: *J Periodontol* 48:446, 1977.)

In *parakeratinized epithelia,* the stratum corneum retains pyknotic nuclei, and the keratohyalin granules are dispersed rather than giving rise to a stratum granulosum. The *nonkeratinized epithelium* (although cytokeratins are the major component, as in all epithelia) has neither granulosum nor corneum strata, whereas superficial cells have viable nuclei.

Immunohistochemistry, gel electrophoresis, and immunoblot techniques have made the identification of the characteristic pattern of cytokeratins possible in each epithelial type. The keratin proteins are composed of different polypeptide subunits characterized by their isoelectric points and molecular weights. They are numbered in a sequence that is contrary to their molecular weight. In general,

basal cells begin synthesizing lower-molecular-weight keratins (e.g., K19 [40 kD]), and they express other higher-molecular-weight keratins as they migrate to the surface. K1 keratin polypeptide (68 kD) is the main component of the stratum corneum.[60]

Other proteins unrelated to keratins are synthesized during the maturation process. The most extensively studied are *keratolinin* and *involucrin,* which are precursors of a chemically resistant structure (the envelope) located below the cell membrane, and *filaggrin,* which has precursors that are packed into the keratohyalin granules. At the sudden transition to the horny layer, the keratohyalin granules disappear and give rise to filaggrin, which forms the matrix of the most differentiated epithelial cell, the *corneocyte.*

Thus in the fully differentiated state, the corneocytes are mainly formed by bundles of keratin tonofilaments embedded in an amorphous matrix of filaggrin and surrounded by a resistant envelope under the cell membrane. The immunohistochemical patterns of the different keratin types, envelope proteins, and filaggrin change under normal or pathologic stimuli, thereby modifying the keratinization process.[128-130]

Electron microscopy reveals that keratinocytes are interconnected by structures on the cell periphery called *desmosomes.*[154] These desmosomes have a typical structure that consists of two dense attachment plaques into which tonofibrils insert and an intermediate, electron-dense line in the extracellular compartment. Tonofilaments, which are the morphologic expression of the cytoskeleton of keratin proteins, radiate in brushlike fashion from the attachment plaques into the cytoplasm of the cells. The space between the cells shows cytoplasmic projections that resemble microvilli and that extend into the intercellular space and often interdigitate.

Less frequently observed forms of epithelial cell connections are tight junctions *(zonae occludens),* in which the membranes of the adjoining cells are thought to be fused.[268,287] Evidence suggests that these structures allow ions and small molecules to pass from one cell to another.

Cytoplasmic organelle concentration varies among different epithelial strata. Mitochondria are more numerous in deeper strata

and decrease toward the surface of the cell.

Accordingly, the histochemical demonstration of succinic dehydrogenase, nicotinamide-adenine dinucleotide, cytochrome oxidase, and other mitochondrial enzymes reveals a more active tricarboxylic cycle in basal and parabasal cells, in which the proximity of the blood supply facilitates energy production through aerobic glycolysis.

Conversely, enzymes of the pentose shunt (an alternative pathway of glycolysis), such as glucose-6-phosphatase, increase their activity toward the surface. This pathway produces a larger amount of intermediate products for the production of ribonucleic acid (RNA), which in turn can be used for the synthesis of keratinization proteins. This histochemical pattern is in accordance with the increased volume and the amount of tonofilaments observed in cells reaching the surface; the intensity of the activity is proportional to the degree of differentiation.[72,82,127,202]

The uppermost cells of the stratum spinosum contain numerous dense granules called *keratinosomes* or *Odland bodies,* which are modified lysosomes. They contain a large amount of acid phosphatase, an enzyme involved in the destruction of organelle membranes, which occurs suddenly between the granulosum and corneum strata and during the intercellular cementation of cornified cells. Thus acid phosphatase is another enzyme that is closely related to the degree of keratinization.[46,125,284] These contain tyrosinase, which hydroxylates tyrosine to dihydroxyphenylalanine (dopa), which in turn is progressively converted to melanin. Melanin granules are phagocytosed and contained within other cells of the epithelium and connective tissue called *melanophages* or *melanophores.*

Nonkeratinocyte cells are present in gingival epithelium as in other malpighian epithelia. *Melanocytes* are dendritic cells located in the basal and spinous layers of the gingival epithelium. They synthesize melanin in organelles called *premelanosomes* or *melanosomes*[61,228,252] (Fig. 3.11).

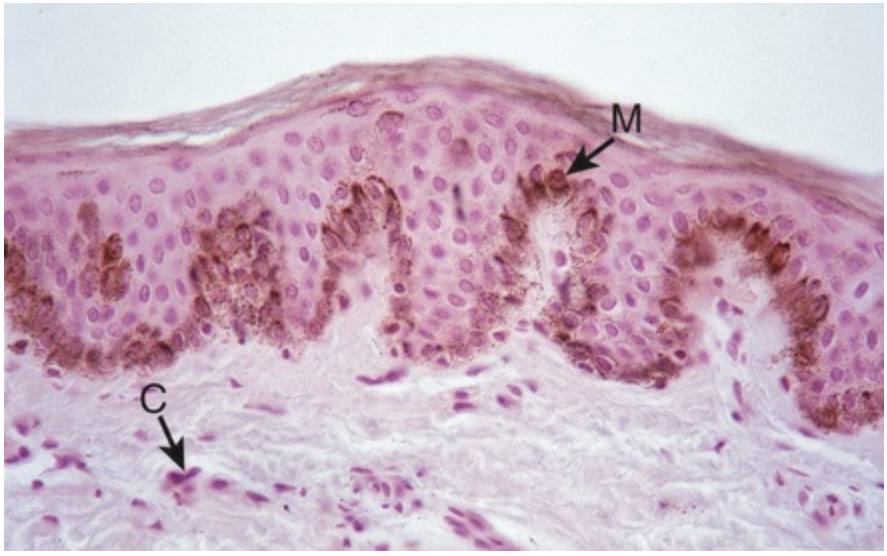

FIG. 3.11 Pigmented gingiva of dog showing melanocytes *(M)* in the basal epithelial layer and melanophores *(C)* in the connective tissue (Glucksman technique).

Langerhans cells are dendritic cells located among keratinocytes at all suprabasal levels (Fig. 3.12). They belong to the mononuclear phagocyte system (reticuloendothelial system) as modified monocytes derived from the bone marrow. They contain elongated granules, and they are considered macrophages with possible antigenic properties.[72] Langerhans cells have an important role in the immune reaction as antigen-presenting cells for lymphocytes. They contain g-specific granules (Birbeck granules), and they have marked adenosine triphosphatase activity. They are found in the oral epithelium of normal gingiva and in smaller amounts in the sulcular epithelium; they are probably absent from the junctional epithelium of normal gingiva.

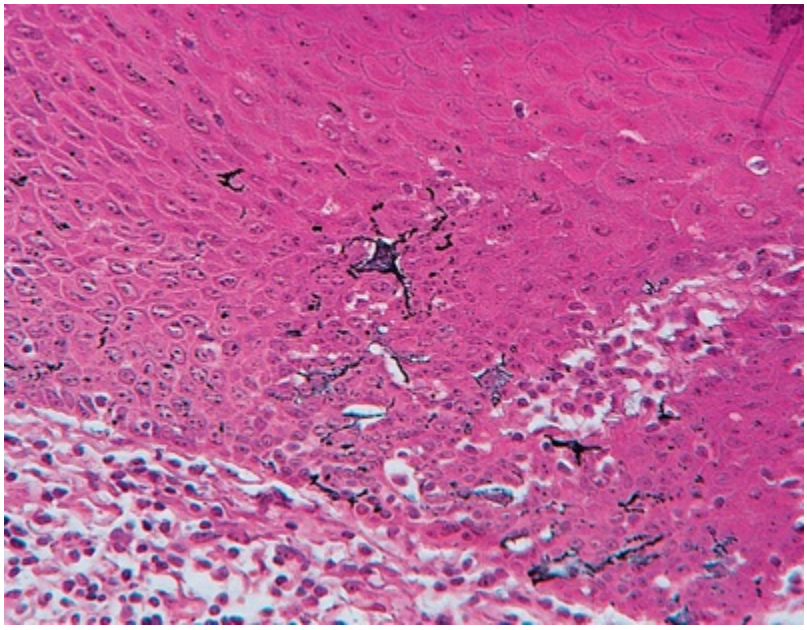

FIG. 3.12 Human gingival epithelium, oral aspect. Immunoperoxidase technique showing Langerhans cells.

Merkel cells are located in the deeper layers of the epithelium; they harbor nerve endings, and they are connected to adjacent cells by desmosomes. They have been identified as tactile perceptors.[188]

The epithelium is joined to the underlying connective tissue by a *basal lamina* 300 to 400 Å thick and lying approximately 400 Å beneath the epithelial basal layer.[147,235,254] The basal lamina consists of lamina lucida and lamina densa. Hemidesmosomes of the basal epithelial cells abut the lamina lucida, which is mainly composed of the glycoprotein laminin. The lamina densa is composed of type IV collagen.

The basal lamina, which is clearly distinguishable at the ultrastructural level, is connected to a reticular condensation of the underlying connective tissue fibrils (mainly collagen type IV) by the anchoring fibrils.[183,213,257] Anchoring fibrils have been measured at 750 nm in length from their epithelial end to their connective tissue end, where they appear to form loops around collagen fibers. The complex of basal lamina and fibrils is the periodic acid–Schiff–positive and argyrophilic line observed at the optical level [237,258] (Fig. 3.13). The basal lamina is permeable to fluids, but it acts as a barrier to particulate matter.

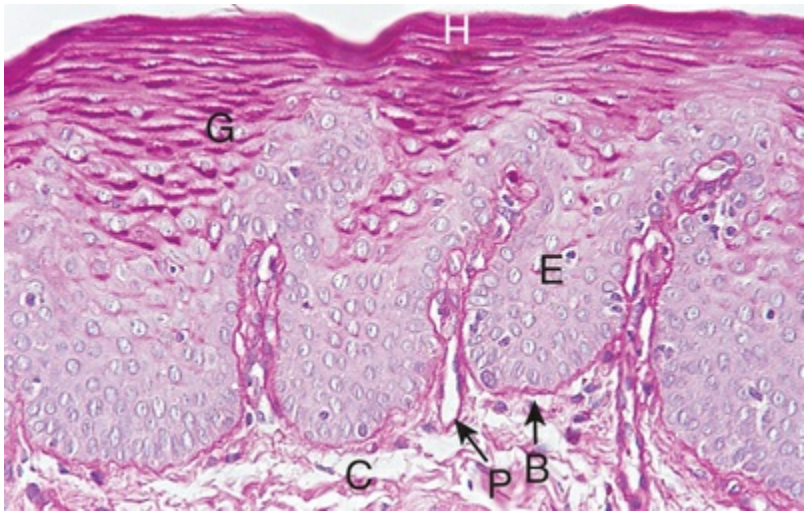

FIG. 3.13 Normal human gingiva stained with the periodic acid–Schiff histochemical method. The basement membrane *(B)* is seen between the epithelium *(E)* and the underlying connective tissue *(C)*. In the epithelium, glycoprotein material occurs in cells and cell membranes of the superficial hornified *(H)* and underlying granular layers *(G)*. The connective tissue presents a diffuse, amorphous ground substance and collagen fibers. The blood vessel walls stand out clearly in the papillary projections of the connective tissue *(P)*.

Structural and Metabolic Characteristics of Different Areas of Gingival Epithelium

The epithelial component of the gingiva shows regional morphologic variations that reflect tissue adaptation to the tooth and alveolar bone.[231] These variations include the oral epithelium, the sulcular epithelium, and the junctional epithelium. Whereas the oral epithelium and the sulcular epithelium are largely protective in function, the junctional epithelium serves many more roles and is of considerable importance in the regulation of tissue health.[18] It is now recognized that epithelial cells are not passive bystanders in the gingival tissues; rather, they are metabolically active and capable of reacting to external stimuli by synthesizing a number of cytokines, adhesion molecules, growth factors, and enzymes.[18]

The degree of gingival keratinization diminishes with age and the onset of menopause,[199] but it is not necessarily related to the different phases of the menstrual cycle.[131] Keratinization of the oral

mucosa varies in different areas in the following order: palate (most keratinized), gingiva, ventral aspect of the tongue, and cheek (least keratinized).[181]

Keratins K1, K2, and K10 through K12, which are specific to epidermal-type differentiation, are immunohistochemically expressed with high intensity in orthokeratinized areas and with less intensity in parakeratinized areas. K6 and K16, which are characteristic of highly proliferative epithelia, and K5 and K14, which are stratification-specific cytokeratins, also are present. Parakeratinized areas express K19, which is usually absent from orthokeratinized normal epithelia.[37,205]

In keeping with the complete or almost-complete maturation, histoenzyme reactions for acid phosphatase and pentose-shunt enzymes are very strong.[47,127]

Glycogen can accumulate intracellularly when it is not completely degraded by any of the glycolytic pathways. Thus its concentration in normal gingiva is inversely related to the degree of keratinization[236,285] and inflammation.[71,273,276]

Oral (Outer) Epithelium

The oral or outer epithelium covers the crest and outer surface of the marginal gingiva and the surface of the attached gingiva. On average, the oral epithelium is 0.2 to 0.3 mm in thickness. It is keratinized or parakeratinized, or it may present various combinations of these conditions (Fig. 3.14). The prevalent surface, however, is parakeratinized.[32,45,285] The oral epithelium is composed of four layers: stratum basale (basal layer), stratum spinosum (prickle cell layer), stratum granulosum (granular layer), and stratum corneum (cornified layer).

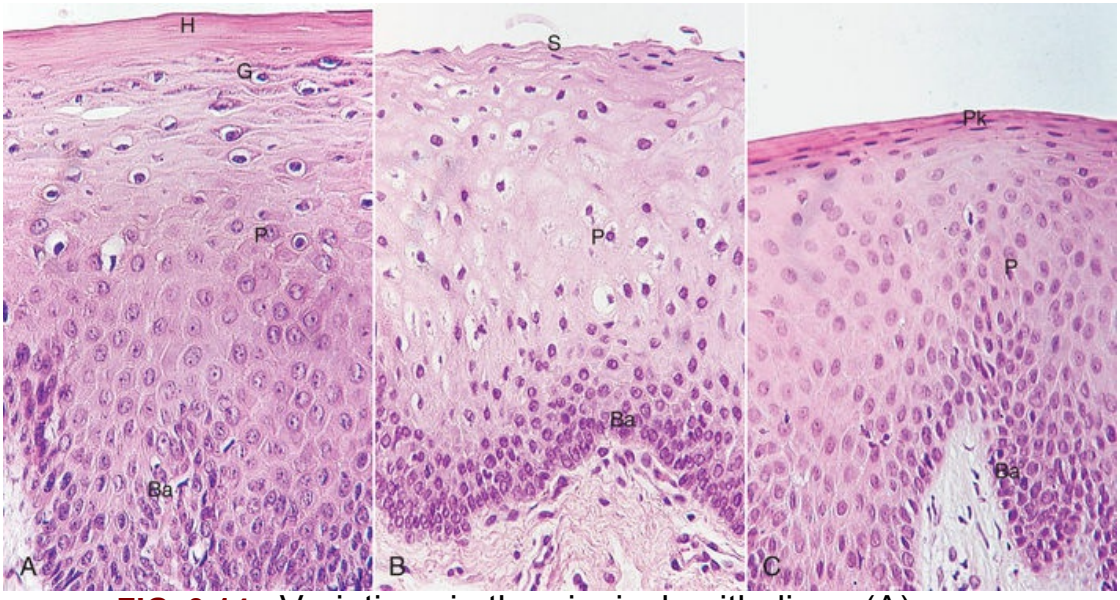

FIG. 3.14 Variations in the gingival epithelium. (A) Keratinized. (B) Nonkeratinized. (C) Parakeratinized. Horny layer *(H)*, granular layer *(G)*, prickle cell layer *(P)*, basal cell layer *(Ba)*, flattened surface cells *(S)*, and parakeratotic layer *(Pk)*.

Sulcular Epithelium

The sulcular epithelium lines the gingival sulcus (Fig. 3.15). It is a thin, nonkeratinized stratified squamous epithelium without rete pegs, and it extends from the coronal limit of the junctional epithelium to the crest of the gingival margin (Fig. 3.16). It usually shows many cells with hydropic degeneration.[32]

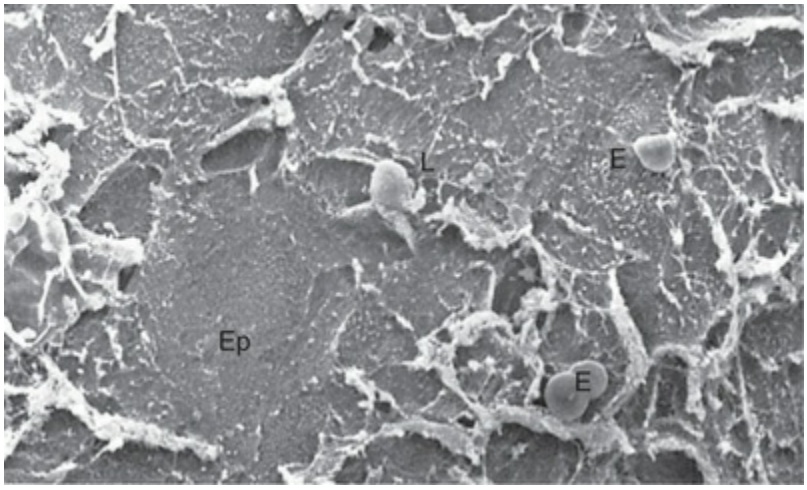

FIG. 3.15 Scanning electron microscopic view of the

epithelial surface facing the tooth in a normal human gingival sulcus. The epithelium *(Ep)* shows desquamating cells, some scattered erythrocytes *(E)*, and a few emerging leukocytes *(L)*. (×1000.)

FIG. 3.16 Epon-embedded human biopsy specimen showing a relatively normal gingival sulcus. The soft-tissue wall of the gingival sulcus is made up of the oral sulcular epithelium *(ose)* and its underlying connective tissue *(ct)*, whereas the base of the gingival sulcus is formed by the sloughing surface of the junctional epithelium *(je)*. The enamel space is delineated by a dense cuticular structure *(dc)*. A relatively sharp line of demarcation exists between the junctional epithelium and the oral sulcular epithelium *(arrow)*, and several polymorphonuclear leukocytes *(pmn)* can be seen traversing the junctional epithelium. The sulcus contains red blood cells that resulted from the hemorrhage that occurred at the time of biopsy. (×391; inset ×55.) (From Schluger S, Youdelis R, Page RC: *Periodontal disease,* ed 2, Philadelphia, 1990, Lea & Febiger.)

As with other nonkeratinized epithelia, the sulcular epithelium lacks granulosum and corneum strata and K1, K2, and K10 through K12 cytokeratins, but it contains K4 and K13, the so-called esophageal-type cytokeratins. It also expresses K19, and it normally does not contain Merkel cells.

Histochemical studies of enzymes have consistently revealed a lower degree of activity in the sulcular than in the outer epithelium, particularly in the case of enzymes related to keratinization. Glucose-6-phosphate dehydrogenase expresses a faint and homogeneous reaction in all strata, unlike the increasing gradient toward the surface observed in cornified epithelia.[127] Acid phosphatase staining is negative,[46] although lysosomes have been described in exfoliated cells.[148]

Despite these morphologic and chemical characteristics, the sulcular epithelium has the potential to keratinize if it is reflected and exposed to the oral cavity[44,48] or if the bacterial flora of the sulcus is totally eliminated.[50] Conversely, the outer epithelium loses its keratinization when it is placed in contact with the tooth.[50] These findings suggest that the local irritation of the sulcus prevents sulcular keratinization.

The sulcular epithelium is extremely important; it may act as a semipermeable membrane through which injurious bacterial products pass into the gingiva and through which tissue fluid from the gingiva seeps into the sulcus.[267] Unlike the junctional epithelium, however, the sulcular epithelium is not heavily infiltrated by polymorphonuclear neutrophil leukocytes, and it appears to be less permeable.[18]

Junctional Epithelium

The junctional epithelium consists of a collar-like band of stratified squamous nonkeratinizing epithelium. It is 3 to 4 layers thick in early life, but that number increases with age to 10 or even 20 layers. In addition, the junctional epithelium tapers from its coronal end, which may be 10 to 29 cells wide to 1 or 2 cells wide at its apical termination, which is located at the cementoenamel junction in healthy tissue. These cells can be grouped in two strata: the basal layer that faces the connective tissue and the suprabasal layer that extends to the tooth surface. The length of the junctional epithelium

ranges from 0.25 to 1.35 mm (Fig. 3.17).

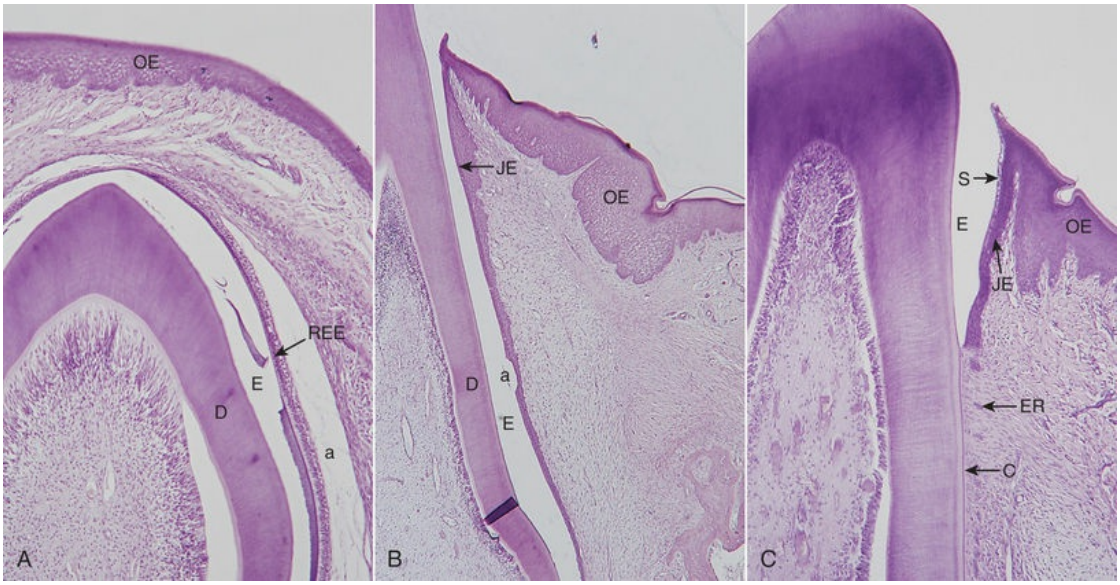

FIG. 3.17 Eruption process in cat's tooth. (A) Unerupted tooth. Dentin *(D)*, remnants of enamel matrix *(E)*, reduced enamel epithelium *(REE)*, oral epithelium *(OE)*, and artifact *(a)*. (B) Erupting tooth forming junctional epithelium *(JE)*. (C) Completely erupted tooth. Sulcus with epithelial debris *(S)*, cementum *(C)*, and epithelial rests *(ER)*.

The junctional epithelium is formed by the confluence of the oral epithelium and the reduced enamel epithelium during tooth eruption. However, the reduced enamel epithelium is not essential for its formation; in fact, the junctional epithelium is completely restored after pocket instrumentation or surgery, and it forms around an implant.[151]

Cell layers that are not juxtaposed to the tooth exhibit numerous free ribosomes, prominent membrane-bound structures (e.g., Golgi complexes), and cytoplasmic vacuoles that are presumably phagocytic. Lysosome-like bodies also are present, but the absence of keratinosomes (Odland bodies) and histochemically demonstrable acid phosphatase, which are correlated with the low degree of differentiation, may reflect a low-defense power against microbial plaque accumulation in the gingival sulcus. Similar morphologic findings have been described in the gingiva of germ-free rats. Polymorphonuclear neutrophil leukocytes are found

routinely in the junctional epithelium of both conventional rats and germ-free rats.[296] Research has shown that, although numerous migrating polymorphonuclear neutrophil leukocytes are evident and present around healthy junctional epithelium, a considerable increase in polymorphonuclear neutrophil leukocyte numbers can be expected with the accumulation of dental plaque and gingival inflammation.[18]

The different keratin polypeptides of the junctional epithelium have a particular histochemical pattern. Junctional epithelium expresses K19, which is absent from keratinized epithelia, and the stratification-specific cytokeratins K5 and K14.[224] Morgan and colleagues[182] reported that reactions to demonstrate K4 or K13 reveal a sudden change between sulcular and junctional epithelia; the junctional area is the only stratified nonkeratinized epithelium in the oral cavity that does not synthesize these specific polypeptides. Another particular behavior of junctional epithelium is the lack of expression of K6 and K16, which is usually linked to highly proliferative epithelia, although the turnover of the cells is very high.

Similar to sulcular epithelium, junctional epithelium exhibits lower glycolytic enzyme activity than outer epithelium, and it also lacks acid phosphatase activity.[46,127]

The junctional epithelium is attached to the tooth surface (epithelial attachment) by means of an internal basal lamina. It is attached to the gingival connective tissue by an external basal lamina that has the same structure as other epithelial–connective tissue attachments elsewhere in the body.[155,161]

The internal basal lamina consists of a lamina densa (adjacent to the enamel) and a lamina lucida to which hemidesmosomes are attached. Hemidesmosomes have a decisive role in the firm attachment of the cells to the internal basal lamina on the tooth surface.

Data suggest that the hemidesmosomes may also act as specific sites of signal transduction and thus may participate in the regulation of gene expression, cell proliferation, and cell differentiation.[134] Organic strands from the enamel appear to extend into the lamina densa.[256] The junctional epithelium attaches to afibrillar cementum that is present on the crown (usually restricted

to an area within 1 mm of the cementoenamel junction)[233] and root cementum in a similar manner.

Histochemical evidence for the presence of neutral polysaccharides in the zone of the epithelial attachment has been reported.[272] Data also have shown that the basal lamina of the junctional epithelium resembles that of endothelial and epithelial cells in its laminin content but differs in its internal basal lamina, which has no type IV collagen.[142,223] These findings indicate that the cells of the junctional epithelium are involved in the production of laminin and play a key role in the adhesion mechanism.

The attachment of the junctional epithelium to the tooth is reinforced by the gingival fibers, which brace the marginal gingiva against the tooth surface. For this reason, the junctional epithelium and the gingival fibers are considered together as a functional unit referred to as the *dentogingival unit*.[158]

In conclusion, it is usually accepted that the junctional epithelium exhibits several unique structural and functional features that contribute to preventing pathogenic bacterial flora from colonizing the subgingival tooth surface.[205] First, junctional epithelium is firmly attached to the tooth surface, thereby forming an epithelial barrier against plaque bacteria. Second, it allows access of gingival fluid, inflammatory cells, and components of the immunologic host defense to the gingival margin. Third, junctional epithelial cells exhibit rapid turnover, which contributes to the host–parasite equilibrium and the rapid repair of damaged tissue. Some investigators have also indicated that the cells of the junctional epithelium have an endocytic capacity equal to that of macrophages and neutrophils and that this activity may be protective in nature.[57]

Development of Gingival Sulcus

After enamel formation is complete, the enamel is covered with *reduced enamel epithelium* (REE), which is attached to the tooth by a basal lamina and hemidesmosomes.[156,255] When the tooth penetrates the oral mucosa, the REE unites with the oral epithelium and transforms into the junctional epithelium. As the tooth erupts, this united epithelium condenses along the crown, and the ameloblasts, which form the inner layer of the REE (see Fig. 3.17), gradually become squamous epithelial cells. The transformation of the REE

into a junctional epithelium proceeds in an apical direction without interrupting the attachment to the tooth. According to Schroeder and Listgarten,[233] this process takes between 1 and 2 years.

The junctional epithelium is a continually self-renewing structure, with mitotic activity occurring in all cell layers.[156,255] The regenerating epithelial cells move toward the tooth surface and along it in a coronal direction to the gingival sulcus, where they are shed[22] (Fig. 3.18). The migrating daughter cells provide a continuous attachment to the tooth surface. The strength of the epithelial attachment to the tooth has not been measured.

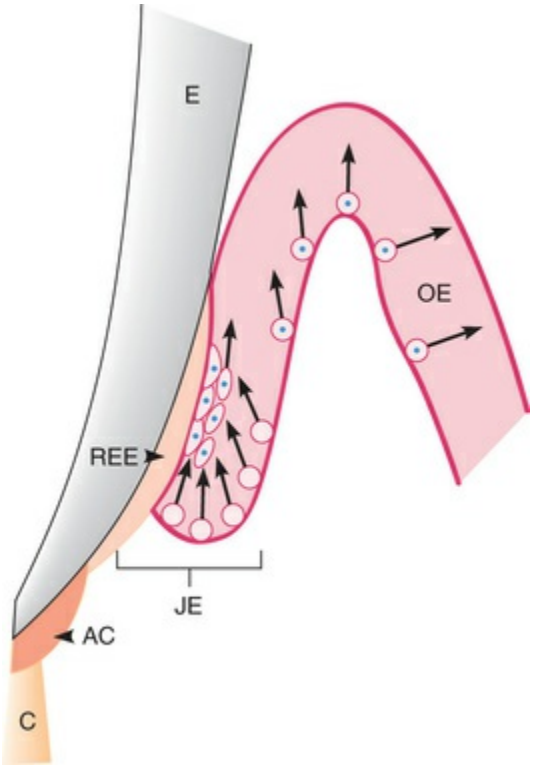

FIG. 3.18 Junctional epithelium on an erupting tooth. The junctional epithelium *(JE)* is formed by the joining of the oral epithelium *(OE)* and the reduced enamel epithelium *(REE)*. Afibrillar cementum *(AC)* is sometimes formed on enamel after the degeneration of the REE. The arrows indicate the coronal movement of the regenerating epithelial cells, which multiply more rapidly in the JE than in the OE. *E,* Enamel; *C,* root cementum. A similar cell turnover pattern exists in the fully erupted tooth. (Modified from Listgarten MA: *J Can Dent Assoc* 36:70, 1970.)

The gingival sulcus is formed when the tooth erupts into the oral cavity. At that time, the junctional epithelium and the REE form a broad band that is attached to the tooth surface from near the tip of the crown to the cementoenamel junction. The gingival sulcus is the shallow, V-shaped space or groove between the tooth and the gingiva that encircles the newly erupted tip of the crown. In the fully erupted tooth, only the junctional epithelium persists. *The sulcus consists of the shallow space that is coronal to the attachment of the junctional epithelium and bounded by the tooth on one side and the sulcular epithelium on the other. The coronal extent of the gingival sulcus is the gingival margin.*

Renewal of Gingival Epithelium

The oral epithelium undergoes continuous renewal. Its thickness is maintained by a balance between new cell formation in the basal and spinous layers and the shedding of old cells at the surface. The mitotic activity exhibits a 24-hour periodicity, with the highest and lowest rates occurring in the morning and evening, respectively.[256] The mitotic rate is higher in nonkeratinized areas and increased in gingivitis, without significant gender differences. Opinions differ with regard to whether the mitotic rate is increased[160,161,179] or decreased[15] with age.

The mitotic rate in experimental animals varies among different areas of the oral epithelium in descending order: buccal mucosa, hard palate, sulcular epithelium, junctional epithelium, outer surface of the marginal gingiva, and attached gingiva.[9,112,160,274] The following have been reported as turnover times for different areas of the oral epithelium in experimental animals: palate, tongue, and cheek, 5 to 6 days; gingiva, 10 to 12 days, with the same or more time required with age; and junctional epithelium, 1 to 6 days.[22,249]

With regard to junctional epithelium, it was previously thought that only epithelial cells facing the external basal lamina were rapidly dividing. However, evidence indicates that a significant number of the cells (e.g., the basal cells along the connective tissue) are capable of synthesizing deoxyribonucleic acid (DNA), thereby demonstrating their mitotic activity.[221,222] The rapid shedding of cells effectively removes bacteria that adhere to the epithelial cells and therefore is an important part of the antimicrobial defense

mechanisms at the dentogingival junction.[205]

Cuticular Structures on the Tooth

The term *cuticle* describes a thin acellular structure with a homogeneous matrix that is sometimes enclosed within clearly demarcated linear borders.

Listgarten[159] has classified cuticular structures into coatings of developmental origin and acquired coatings. *Acquired coatings* include those of exogenous origin such as saliva, bacteria, calculus, and surface stains (see Chapters 7 and 13). *Coatings of developmental origin* are those that are normally formed as part of tooth development. They include the REE, the coronal cementum, and the dental cuticle.

After enamel formation is completed, the ameloblastic epithelium is reduced to one or two layers of cells that remain attached to the enamel surface by hemidesmosomes and a basal lamina. This REE consists of postsecretory ameloblasts and cells from the stratum intermedium of the enamel organ. In some animal species, the REE disappears entirely and rapidly, thereby placing the enamel surface in contact with the connective tissue. Connective tissue cells then deposit a thin layer of cementum known as *coronal cementum* on the enamel. In humans, thin patches of afibrillar cementum sometimes may be seen in the cervical half of the crown.

Electron microscopy has demonstrated a dental cuticle that consists of a layer of homogeneous organic material of variable thickness (approximately 0.25 μm) overlying the enamel surface. It is nonmineralized, and it is not always present. In some cases, near the cementoenamel junction, it is deposited over a layer of afibrillar cementum, which in turn overlies enamel. The cuticle may be present between the junctional epithelium and the tooth. Ultrastructural histochemical studies have shown that the dental cuticle is proteinaceous,[143] and it may be an accumulation of tissue fluid components.[87,232]

Gingival Fluid (Sulcular Fluid)

The value of the gingival fluid is that it can be represented as either a transudate or an exudate. The gingival fluid contains a vast array of biochemical factors, thereby offering its potential use as a

diagnostic or prognostic biomarker of the biologic state of the periodontium in health and disease[81] (see Chapter 16). It also contains components of connective tissue, epithelium, inflammatory cells, serum, and microbial flora that inhabit the gingival margin or the sulcus (pocket).[79]

In the healthy sulcus, the amount of gingival fluid is very small. During inflammation, however, the gingival fluid flow increases, and its composition starts to resemble that of an inflammatory exudate.[59] The main route of the gingival fluid diffusion is through the basement membrane, through the relatively wide intercellular spaces of the junctional epithelium, and then into the sulcus.[205] The gingival fluid is believed to do the following: (1) cleanse material from the sulcus; (2) contain plasma proteins that may improve adhesion of the epithelium to the tooth; (3) possess antimicrobial properties; and (4) exert antibody activity to defend the gingiva.

Gingival Connective Tissue

The major components of the gingival connective tissue are collagen fibers (about 60% by volume), fibroblasts (5%), vessels, nerves, and matrix (about 35%). The connective tissue of the gingiva is known as the *lamina propria,* and it consists of two layers: (1) a *papillary layer* subjacent to the epithelium that consists of papillary projections between the epithelial rete pegs and (2) a *reticular layer* that is contiguous with the periosteum of the alveolar bone.

Connective tissue has a cellular compartment and an extracellular compartment composed of fibers and ground substance. Thus the gingival connective tissue is largely a fibrous connective tissue that has elements that originate directly from the oral mucosal connective tissue as well as some fibers (dentogingival) that originate from the developing dental follicle.[18]

The *ground substance* fills the space between fibers and cells; it is amorphous, and it has a high water content. It is composed of proteoglycans (mainly hyaluronic acid and chondroitin sulfate) and glycoproteins (mainly fibronectin). Glycoproteins account for the faint periodic acid–Schiff–positive reaction of the ground substance.[82] Fibronectin binds fibroblasts to the fibers and many other components of the intercellular matrix, thereby helping to

mediate cell adhesion and migration. Laminin, which is another glycoprotein found in the basal lamina, serves to attach it to epithelial cells.

The three types of connective tissue fibers are collagen, reticular, and elastic. Collagen type I forms the bulk of the lamina propria and provides the tensile strength to the gingival tissue. Type IV collagen (argyrophilic reticulum fiber) branches between the collagen type I bundles, and it is continuous with fibers of the basement membrane and the blood vessel walls.[161]

The elastic fiber system is composed of oxytalan, elaunin, and elastin fibers distributed among collagen fibers.[56] Therefore densely packed collagen bundles that are anchored into the acellular extrinsic fiber cementum just below the terminal point of the junctional epithelium form the connective tissue attachment. The stability of this attachment is a key factor in the limitation of the migration of junctional epithelium.[57]

Gingival Fibers

The connective tissue of the marginal gingiva is densely collagenous, and it contains a prominent system of collagen fiber bundles called the *gingival fibers.* These fibers consist of type I collagen.[213] The gingival fibers have the following functions:

1. To brace the marginal gingiva firmly against the tooth
2. To provide the rigidity necessary to withstand the forces of mastication without being deflected away from the tooth surface
3. To unite the free marginal gingiva with the cementum of the root and the adjacent attached gingiva

The gingival fibers are arranged in three groups: gingivodental, circular, and transseptal.[146]

The *gingivodental fibers* are those on the facial, lingual, and interproximal surfaces. They are embedded in the cementum just beneath the epithelium at the base of the gingival sulcus. On the facial and lingual surfaces, they project from the cementum in a fanlike conformation toward the crest and outer surface of the marginal gingiva, where they terminate short of the epithelium

(Figs. 3.19 and 3.20). They also extend externally to the periosteum of the facial and lingual alveolar bones, terminating in the attached gingiva or blending with the periosteum of the bone. Interproximally, the gingivodental fibers extend toward the crest of the interdental gingiva.

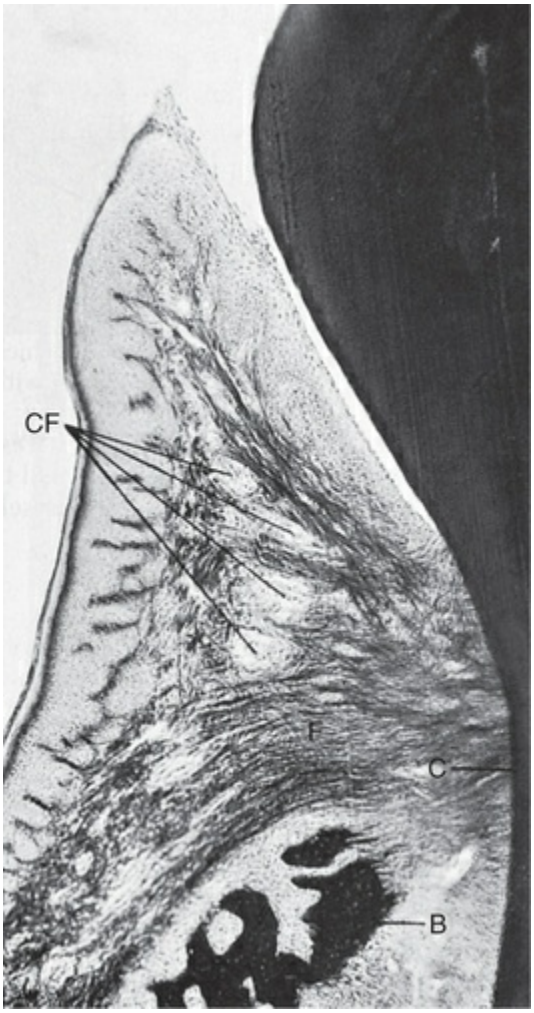

FIG. 3.19 Faciolingual section of marginal gingiva showing gingival fibers *(F)* that extend from the cementum *(C)* to the crest of the gingiva, to the outer gingival surface, and external to the periosteum of the bone *(B)*. Circular fibers *(CF)* are shown in cross-section between the other groups. (Courtesy Sol Bernick.)

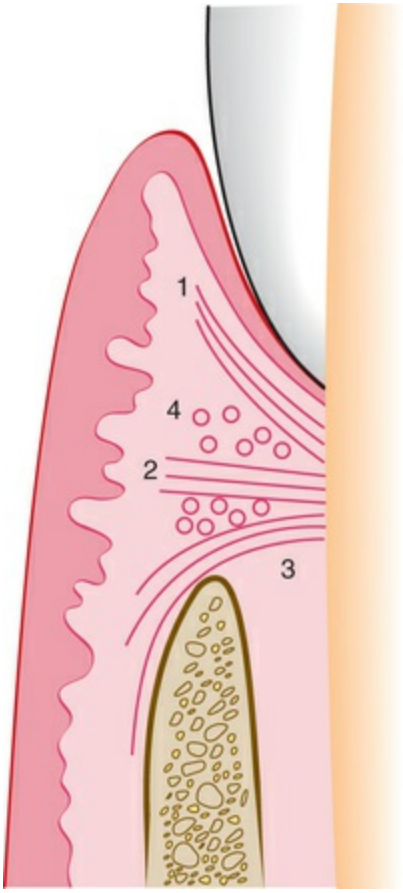

FIG. 3.20 Diagram of the gingivodental fibers that extend from the cementum *(1)* to the crest of the gingiva, *(2)* to the outer surface, and *(3)* external to the periosteum of the labial plate. Circular fibers *(4)* are shown in cross-section.

The *circular fibers* course through the connective tissue of the marginal and interdental gingivae and encircle the tooth in ringlike fashion.

The *transseptal fibers,* which are located interproximally, form horizontal bundles that extend between the cementum of the approximating teeth into which they are embedded. They lie in the area between the epithelium at the base of the gingival sulcus and the crest of the interdental bone, and they are sometimes classified with the principal fibers of the periodontal ligament.

Page and colleagues[198] described a group of *semicircular fibers* that attach at the proximal surface of a tooth immediately below the cementoenamel junction, go around the facial or lingual marginal gingiva of the tooth, and attach on the other proximal surface of the same tooth; they also discussed a group of *transgingival fibers* that

attach in the proximal surface of one tooth, traverse the interdental space diagonally, go around the facial or lingual surface of the adjacent tooth, again traverse the interdental space diagonally, and then attach in the proximal surface of the next tooth.

Tractional forces in the extracellular matrix produced by fibroblasts are believed to be responsible for generating tension in the collagen. This keeps the teeth tightly bound to each other and to the alveolar bone.

Cellular Elements

The preponderant cellular element in the gingival connective tissue is the *fibroblast.* Numerous fibroblasts are found between the fiber bundles. Fibroblasts are of mesenchymal origin and play a major role in the development, maintenance, and repair of gingival connective tissue. As with connective tissue elsewhere in the body, fibroblasts synthesize collagen and elastic fibers as well as the glycoproteins and glycosaminoglycans of the amorphous intercellular substance. Fibroblasts also regulate collagen degradation through phagocytosis and the secretion of collagenases.

Fibroblast heterogeneity is now a well-established feature of fibroblasts in the periodontium.[226] Although the biologic and clinical significance of such heterogeneity is not yet clear, it seems that this is necessary for the normal functioning of tissues in health, disease, and repair.[18]

Mast cells, which are distributed throughout the body, are numerous in the connective tissue of the oral mucosa and the gingiva.[52,244,245,288] *Fixed macrophages* and *histiocytes* are present in the gingival connective tissue as components of the mononuclear phagocyte system (reticuloendothelial system) and are derived from blood monocytes. *Adipose cells* and *eosinophils,* although scarce, are also present in the lamina propria.

In clinically normal gingiva, small foci of plasma cells and lymphocytes are found in the connective tissue near the base of the sulcus (Fig. 3.21). Neutrophils can be seen in relatively high numbers in both the gingival connective tissue and the sulcus. These inflammatory cells are usually present in small amounts in clinically normal gingiva.

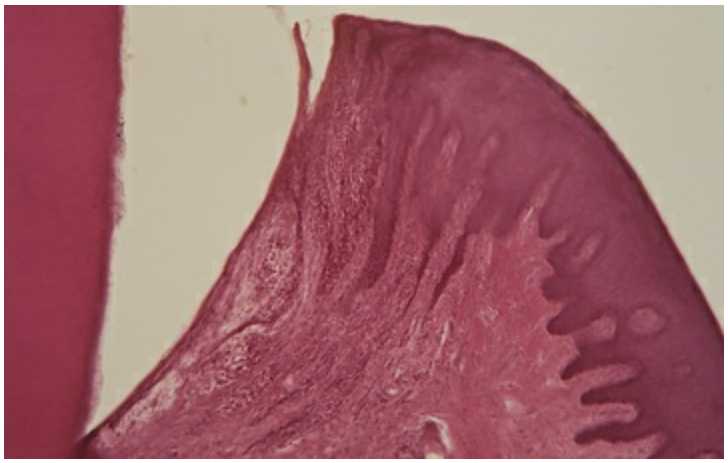

FIG. 3.21 Section of clinically normal gingiva showing some degree of inflammation, which is almost always present near the base of the sulcus.

Speculations about whether small amounts of leukocytes should be considered a normal component of the gingiva or an incipient inflammatory infiltrate without clinical expression are of theoretic rather than practical importance. Lymphocytes are absent when gingival normalcy is judged by strict clinical criteria or under special experimental conditions,[13,192] but they are practically constant in healthy, normal gingiva, even before complete tooth eruption.[150,167,229]

Immunohistochemical studies involving monoclonal antibodies have identified the different lymphocyte subpopulations. The infiltrate in the area below the junctional epithelium of healthy gingiva in newly erupted teeth in children is mainly composed of T lymphocytes (helper, cytotoxic, suppressor, and natural killer)[12,98,242] and thus could be interpreted as a normal lymphoid tissue involved in the early defense recognition system. As time elapses, B lymphocytes and plasma cells appear in greater proportions to elaborate specific antibodies against already-recognized antigens that are always present in the sulcus of clinically normal gingiva.[234]

Repair of Gingival Connective Tissue

Because of the high turnover rate, the connective tissue of the gingiva has remarkably good healing and regenerative capacity. Indeed, it may be one of the best healing tissues in the body, and it generally shows little evidence of scarring after surgical procedures. This is likely caused by the rapid reconstruction of the fibrous

architecture of the tissues.[178] However, the reparative capacity of gingival connective tissue is not as great as that of the periodontal ligament or the epithelial tissue.

Blood Supply, Lymphatics, and Nerves

Microcirculatory tracts, blood vessels, and lymphatic vessels play an important role in the drainage of tissue fluid and in the spread of inflammation. In individuals with gingivitis and periodontitis, the microcirculation and vascular formation change greatly in the vascular network directly under the gingival sulcular epithelium and the junctional epithelium.[170]

Blood vessels are easily evidenced in tissue sections by means of immunohistochemical reactions against proteins of endothelial cells (i.e., factor VIII and adhesion molecules). Before these techniques were developed, vascularization patterns of periodontal tissues had been described using histoenzymatic reactions for alkaline phosphatase and adenosine triphosphatase because of the great activity of these enzymes in endothelial cells.[54,297]

In experimental animals, perfusion with India ink also was used to study vascular distribution. The injection and subsequent demonstration of peroxidase allow for blood vessel identification and permeability studies.[239] The periodic acid–Schiff reaction also outlines vascular walls by revealing a positive line in the basal membrane.[237] Endothelial cells express 5-nucleotidase activity as well.[126] Scanning electron microscopy can be used after the injection of plastic into the vessels through the carotid artery, which is followed by the corrosion of the soft tissues.[84] In addition, laser Doppler flow measurement provides a noninvasive means for the observation of blood flow modifications related to disease.[8]

Three sources of blood supply to the gingiva are as follows (Figs. 3.22 and 3.23):

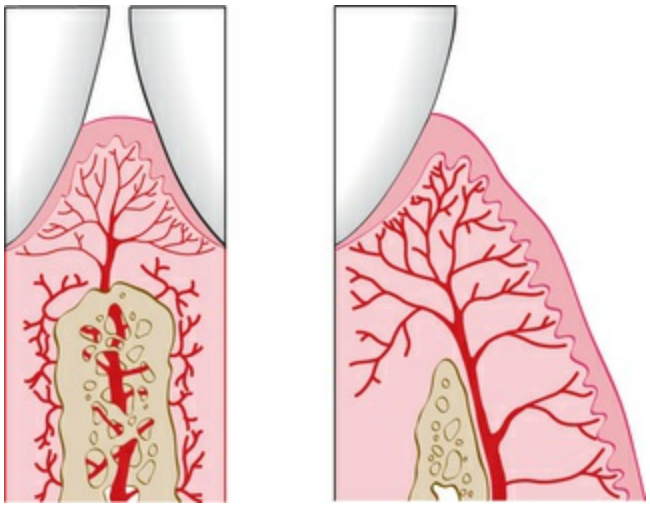

FIG. 3.22 Diagram of an arteriole penetrating the interdental alveolar bone to supply the interdental tissues *(left)* and a supraperiosteal arteriole overlying the facial alveolar bone, sending branches to the surrounding tissue *(right).*

FIG. 3.23 Blood supply and peripheral circulation of the gingiva. Tissues perfused with India ink. Note the

capillary plexus parallel to the sulcus *(S)* and the capillary loops in the outer papillary layer. Note also the supraperiosteal vessels external to the bone *(B)*, which supply the gingiva, and a periodontal ligament vessel anastomosing with the sulcus plexus. (Courtesy Sol Bernick.)

1. *Supraperiosteal arterioles* along the facial and lingual surfaces of the alveolar bone from which capillaries extend along the sulcular epithelium and between the rete pegs of the external gingival surface[8,76,113]: Occasional branches of the arterioles pass through the alveolar bone to the periodontal ligament or run over the crest of the alveolar bone.
2. *Vessels of the periodontal ligament,* which extend into the gingiva and anastomose with capillaries in the sulcus area.
3. *Arterioles,* which emerge from the crest of the interdental septa[84] and extend parallel to the crest of the bone to anastomose with vessels of the periodontal ligament, with capillaries in the gingival crevicular areas and vessels that run over the alveolar crest.

Beneath the epithelium on the outer gingival surface, capillaries extend into the papillary connective tissue between the epithelial rete pegs in the form of terminal hairpin loops with efferent and afferent branches, spirals, and varices[54,113] (Fig. 3.24; also see Fig. 3.23). The loops are sometimes linked by cross-communications,[86] and flattened capillaries serve as reserve vessels when the circulation is increased in response to irritation.[99]

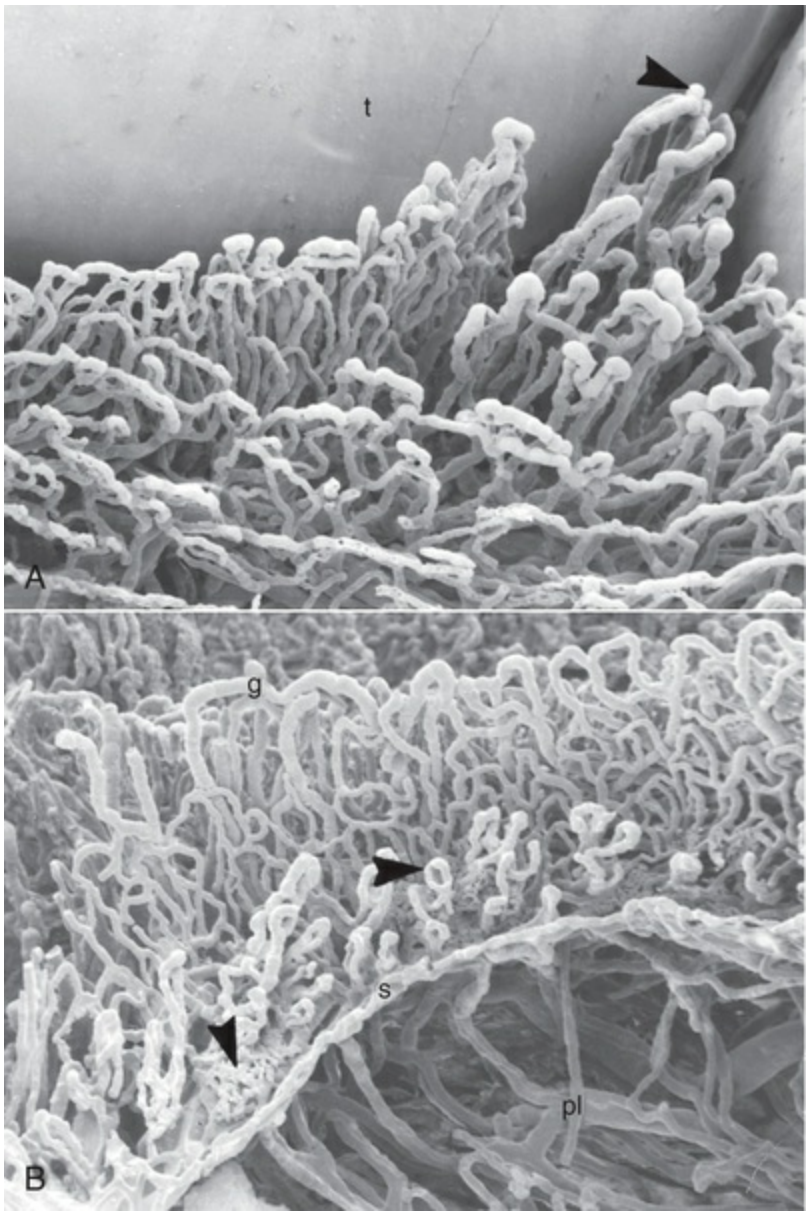

FIG. 3.24 Scanning electron microscopic view of the gingival tissues of rat molar palatal gingiva after the vascular perfusion of plastic and the corrosion of soft tissue. (A) Oral view of gingival capillaries: *t,* tooth; interdental papilla *(arrowhead)* (×180). (B) View from the tooth side. Note the vessels of the plexus next to the sulcular and junctional epithelium. The arrowheads point to vessels in the sulcus area with mild inflammatory changes. *g,* Crest of the marginal gingiva; *s,* bottom of the gingival sulcus; *pl,* periodontal ligament vessels. (×150.) (Courtesy NJ Selliseth and K Selvig, University of Bergen, Norway.)

Along the sulcular epithelium, capillaries are arranged in a flat,

anastomosing plexus that extends parallel to the enamel from the base of the sulcus to the gingival margin.[54] In the col area, a mixed pattern of anastomosing capillaries and loops occurs.

As mentioned previously, anatomic and histologic changes have been shown to occur in the gingival microcirculation of individuals with gingivitis. Prospective studies of the gingival vasculature in animals have demonstrated that, in the absence of inflammation, the vascular network is arranged in a regular, repetitive, and layered pattern.[54,216] By contrast, the inflamed gingival vasculature exhibits an irregular vascular plexus pattern, with the microvessels exhibiting a looped, dilated, and convoluted appearance.[216]

The role of the lymphatic system in removing excess fluids, cellular and protein debris, microorganisms, and other elements is important for controlling diffusion and the resolution of inflammatory processes.[168] The *lymphatic drainage of the gingiva* brings in the lymphatics of the connective tissue papillae.[238] It progresses into the collecting network external to the periosteum of the alveolar process and then moves to the regional lymph nodes, particularly the submaxillary group. In addition, lymphatics just beneath the junctional epithelium extend into the periodontal ligament and accompany the blood vessels.

Neural elements are extensively distributed throughout the gingival tissues. Within the gingival connective tissues, most nerve fibers are myelinated and closely associated with the blood vessels.[162] *Gingival innervation* is derived from fibers that arise from nerves in the periodontal ligament and from the labial, buccal, and palatal nerves.[30] The following nerve structures are present in the connective tissue: a meshwork of terminal argyrophilic fibers, some of which extend into the epithelium; Meissner-type tactile corpuscles; Krause-type end bulbs, which are temperature receptors; and encapsulated spindles.[14]

Correlation of Clinical and Microscopic Features

An understanding of the normal clinical features of the gingiva requires the ability to interpret them in terms of the microscopic structures that they represent.

Color

The color of the attached and marginal gingiva is generally described as "coral pink"; it is produced by the vascular supply, the thickness and degree of keratinization of the epithelium, and the presence of pigment-containing cells. The color varies among different persons and appears to be correlated with the cutaneous pigmentation. It is lighter in blond individuals with fair complexions than in swarthy, dark-haired individuals (Fig. 3.25).

FIG. 3.25 (A) Clinically normal gingiva in a young adult. (B) Heavily pigmented (melanotic) gingiva in a middle-aged adult. (From Glickman I, Smulow JB: *Periodontal disease: clinical, radiographic, and histopathologic features,* Philadelphia, 1974, Saunders.)

The attached gingiva is demarcated from the adjacent alveolar mucosa on the buccal aspect by a clearly defined mucogingival line. The alveolar mucosa is red, smooth, and shiny rather than pink and stippled. A comparison of the microscopic structure of the attached gingiva with that of the alveolar mucosa provides an explanation for the difference in appearance. The epithelium of the alveolar mucosa is thinner and nonkeratinized, and it contains no rete pegs (Fig. 3.26). The connective tissue of the alveolar mucosa is loosely

arranged, and the blood vessels are more numerous.

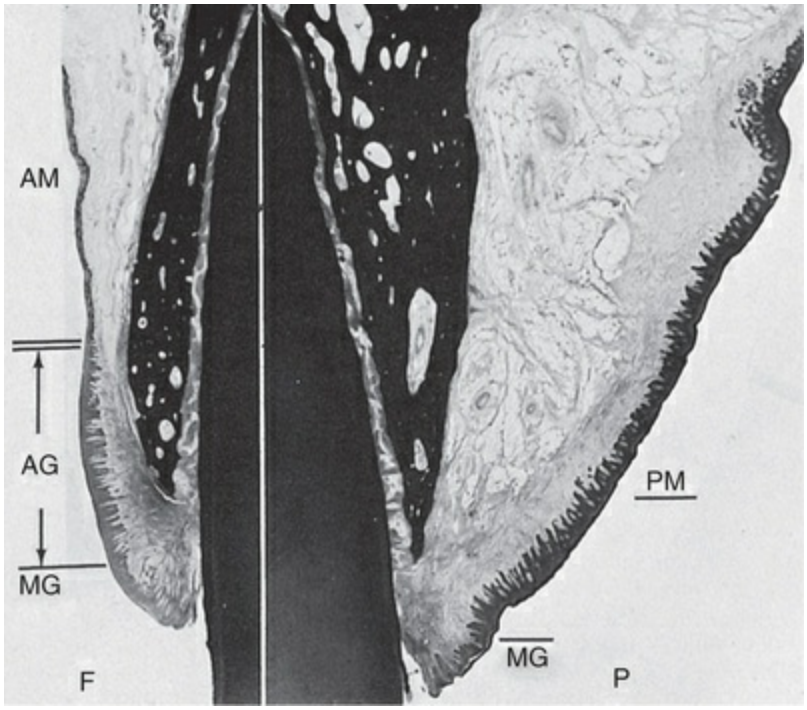

FIG. 3.26 Oral mucosa, facial and palatal surfaces. The facial surface *(F)* shows the marginal gingiva *(MG)*, the attached gingiva *(AG)*, and the alveolar mucosa *(AM)*. The double line marks the mucogingival junction. Note the differences in the epithelium and the connective tissue in the attached gingiva and the alveolar mucosa. The palatal surface *(P)* shows the marginal gingiva *(MG)* and the thick, keratinized palatal mucosa *(PM)*.

Physiologic Pigmentation (Melanin)

Melanin is a non–hemoglobin-derived brown pigment with the following characteristics:

- Melanin is responsible for the normal pigmentation of the skin, the gingiva, and the remainder of the oral mucous membrane.
- Melanin is present in all normal individuals (often not in sufficient quantities to be detected

clinically), but it is absent or severely diminished in albinos.
- Melanin pigmentation in the oral cavity is prominent in black individuals (see Fig. 3.25).
- Ascorbic acid directly down-regulates melanin pigmentation in gingival tissues.[246]

According to Dummett,[73] the distribution of oral pigmentation in black individuals is as follows: gingiva, 60%; hard palate, 61%; mucous membrane, 22%; and tongue, 15%. Gingival pigmentation occurs as a diffuse, deep-purplish discoloration or as irregularly shaped brown and light-brown patches. It may appear in the gingiva as early as 3 hours after birth, and it is often the only evidence of pigmentation.[73]

Oral repigmentation refers to the clinical reappearance of melanin pigment after a period of clinical depigmentation of the oral mucosa as a result of chemical, thermal, surgical, pharmacologic, or idiopathic factors.[74] Information about the repigmentation of oral tissues after surgical procedures is extremely limited, and no definitive treatment is offered at this time.

Size

The size of the gingiva corresponds with the sum total of the bulk of cellular and intercellular elements and their vascular supply. Alteration in size is a common feature of gingival disease.

Contour

The contour or shape of the gingiva varies considerably and depends on the shape of the teeth and their alignment in the arch, the location and size of the area of proximal contact, and the dimensions of the facial and lingual gingival embrasures.

The marginal gingiva envelops the teeth in collar-like fashion and follows a scalloped outline on the facial and lingual surfaces. It forms a straight line along teeth with relatively flat surfaces. On teeth with pronounced mesiodistal convexity (e.g., maxillary canines) or teeth in labial version, the normal arcuate contour is

accentuated, and the gingiva is located farther apically. On teeth in lingual version, the gingiva is horizontal and thickened (Fig. 3.27). In addition, the gingival tissue biotype varies significantly. A thin and clear gingiva is found in one-third of the population and primarily in females with slender teeth with a narrow zone of keratinized tissue, whereas a clear, thick gingiva with a broad zone of keratinized tissue is present in two-thirds of the population and primarily in males.[70]

FIG. 3.27 A thickened, shelflike contour of gingiva on a tooth in lingual version aggravated by local irritation caused by plaque accumulation.

Shape

The shape of the interdental gingiva is governed by the contour of the proximal tooth surfaces and the location and shape of the gingival embrasures.

When the proximal surfaces of the crowns are relatively flat faciolingually, the roots are close together, the interdental bone is thin mesiodistally, and the gingival embrasures and interdental gingiva are narrow mesiodistally. Conversely, with proximal surfaces that flare away from the area of contact, the mesiodistal diameter of the interdental gingiva is broad (Fig. 3.28). The height of the interdental gingiva varies with the location of the proximal contact. Thus in the anterior region of the dentition, the interdental

papilla is pyramidal in form, whereas the papilla is more flattened in a buccolingual direction in the molar region.

FIG. 3.28 Shape of the interdental gingival papillae correlated with the shape of the teeth and the embrasures. (A) Broad interdental papillae. (B) Narrow interdental papillae.

Consistency

The gingiva is firm and resilient and, with the exception of the movable free margin, tightly bound to the underlying bone. The collagenous nature of the lamina propria and its contiguity with the mucoperiosteum of the alveolar bone determine the firmness of the attached gingiva. The gingival fibers contribute to the firmness of the gingival margin.

Surface Texture

The gingiva presents a textured surface similar to that of an orange peel and is referred to as *stippled* (see Fig. 3.25). Stippling is best viewed by drying the gingiva. *The attached gingiva is stippled; the marginal gingiva is not.* The central portion of the interdental papillae is usually stippled, but the marginal borders are smooth. The pattern and extent of stippling vary among individuals and among different areas of the same mouth.[108,216] Stippling is less prominent on lingual than facial surfaces and may be absent in some persons.

Stippling varies with age. It is absent during infancy, it appears in some children at about 5 years of age, it increases until adulthood, and it frequently begins to disappear during old age.

Microscopically, stippling is produced by alternate rounded

protuberances and depressions in the gingival surface. The papillary layer of the connective tissue projects into the elevations, and the elevated and depressed areas are covered by stratified squamous epithelium (Fig. 3.29). The degree of keratinization and the prominence of stippling appear to be related.

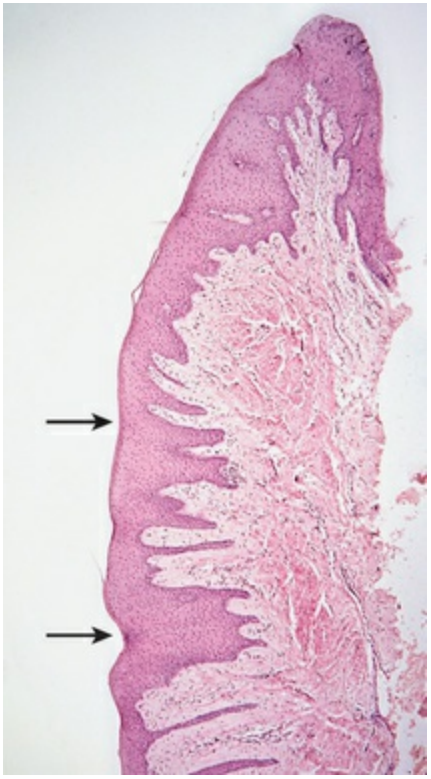

FIG. 3.29 Gingival biopsy of the patient shown in Fig. 3.7 demonstrating alternate elevations and depressions *(arrows)* in the attached gingiva that are responsible for the stippled appearance.

Scanning electron microscopy has shown considerable variation in shape but a relatively constant depth of stippling. At low magnification, a rippled surface is seen, and this is interrupted by irregular depressions that are 50 μm in diameter. At higher magnification, cell micropits are seen.[61]

Stippling is a form of adaptive specialization or reinforcement for function. It is a feature of healthy gingiva, and the reduction or loss of stippling is a common sign of gingival disease. When the gingiva is restored to health after treatment, the stippled appearance returns.

The surface texture of the gingiva is also related to the presence and degree of epithelial keratinization. Keratinization is considered a protective adaptation to function. It increases when the gingiva is stimulated by toothbrushing. However, research on free gingival grafts (see Chapter 65) has shown that when connective tissue is transplanted from a keratinized area to a nonkeratinized area, it becomes covered by a keratinized epithelium.[140] This finding suggests a connective-tissue–based genetic determination of the type of epithelial surface.

Position

The *position* of the gingiva is the level at which the gingival margin is attached to the tooth. When the tooth erupts into the oral cavity, the margin and sulcus are at the tip of the crown; as eruption progresses, they are seen closer to the root. During this eruption process, as described previously, the junctional epithelium, the oral epithelium, and the reduced enamel epithelium undergo extensive alterations and remodeling while maintaining the shallow physiologic depth of the sulcus. Without this remodeling of the epithelia, an abnormal anatomic relationship between the gingiva and the tooth would result.

Continuous Tooth Eruption

According to the concept of continuous eruption,[105] eruption does not cease when the teeth meet their functional antagonists; rather, it continues throughout life. Eruption consists of an active phase and a passive phase. *Active eruption* is the movement of the teeth in the direction of the occlusal plane, whereas *passive eruption* is the exposure of the teeth via apical migration of the gingiva.

This concept distinguishes between the anatomic crown (i.e., the portion of the tooth covered by enamel) and the anatomic root (i.e., the portion of the tooth covered by cementum) and between the clinical crown (i.e., the part of the tooth that has been denuded of its gingiva and projects into the oral cavity) and the clinical root (i.e., the portion of the tooth covered by periodontal tissues). When the teeth reach their functional antagonists, the gingival sulcus and the junctional epithelium are still on the enamel, and the clinical crown is approximately two-thirds of the anatomic crown.

Gottlieb and Orban[105] believed that active and passive eruption proceed together. Active eruption is coordinated with attrition; the teeth erupt to compensate for tooth substance that has been worn away by attrition. Attrition reduces the clinical crown and prevents it from becoming disproportionately long in relation to the clinical root, thus avoiding excessive leverage on the periodontal tissues. Ideally, the rate of active eruption keeps pace with tooth wear, thereby preserving the vertical dimension of the dentition.

As teeth erupt, cementum is deposited at the apices and furcations of the roots, and bone is formed along the fundus of the alveolus and at the crest of the alveolar bone. In this way, part of the tooth substance lost by attrition is replaced by the lengthening of the root, and the socket depth is maintained to support the root.

Although originally thought to be a normal physiologic process, passive eruption is now considered a pathologic process. Passive eruption is divided into the following four stages (Fig. 3.30):

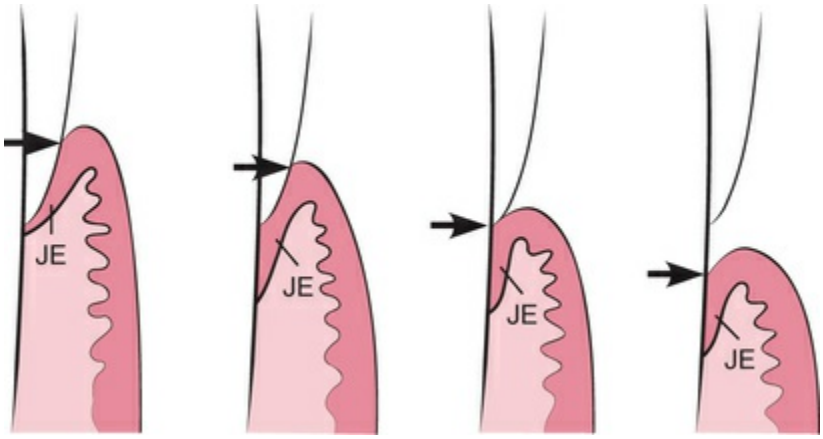

FIG. 3.30 Diagrammatic representation of the four steps of passive eruption according to Gottlieb and Orban.[105] **1,** The base of the gingival sulcus *(arrow)* and the junctional epithelium *(JE)* are on the enamel. **2,** The base of the gingival sulcus *(arrow)* is on the enamel, and part of the junctional epithelium is on the root. **3,** The base of the gingival sulcus *(arrow)* is at the cementoenamel line, and the entire junctional epithelium is on the root. **4,** The base of the gingival sulcus *(arrow)* and the junctional epithelium are on the root.

Stage 1: The teeth reach the line of occlusion. The junctional epithelium and the base of the gingival sulcus are on the enamel.
Stage 2: The junctional epithelium proliferates so that part is on the cementum and part is on the enamel. The base of the sulcus is still on the enamel.
Stage 3: The entire junctional epithelium is on the cementum, and the base of the sulcus is at the cementoenamel junction. As the junctional epithelium proliferates from the crown onto the root, it does not remain at the cementoenamel junction any longer than at any other area of the tooth.
Stage 4: The junctional epithelium has proliferated farther on the cementum. The base of the sulcus is on the cementum, a portion of which is exposed. Proliferation of the junctional epithelium onto the root is accompanied by degeneration of the gingival and periodontal ligament fibers and their detachment from the tooth. The cause of this degeneration is not understood. At present, it is believed to be the result of chronic inflammation and therefore a pathologic process.

As noted, apposition of bone accompanies active eruption. The distance between the apical end of the junctional epithelium and the crest of the alveolus remains constant throughout continuous tooth eruption (i.e., 1.07 mm).[93]

Exposure of the tooth via the apical migration of the gingiva is called *gingival recession* or *atrophy.* According to the concept of continuous eruption, the gingival sulcus may be located on the crown, the cementoenamel junction, or the root, depending on the age of the patient and the stage of eruption. Therefore some root exposure with age would be considered normal and referred to as *physiologic recession.* Again, this concept is not accepted at present. Excessive exposure is termed *pathologic recession* (see Chapter 23).

Periodontal Ligament

The periodontal ligament is composed of a complex vascular and highly cellular connective tissue that surrounds the tooth root and connects it to the inner wall of the alveolar bone.[175] It is continuous

with the connective tissue of the gingiva, and it communicates with the marrow spaces through vascular channels in the bone. Although the average width of the periodontal ligament space is documented to be about 0.2 mm, considerable variation exists. The periodontal space is diminished around teeth that are not in function and in unerupted teeth, but it is increased in teeth that have been subjected to hyperfunction.

Periodontal Fibers

The most important elements of the periodontal ligament are the *principal fibers,* which are collagenous and arranged in bundles and which follow a wavy course when viewed in longitudinal section (Fig. 3.31). The terminal portions of the principal fibers that are inserted into cementum and bone are termed *Sharpey fibers* (Fig. 3.32). The principal fiber bundles consist of individual fibers that form a continuous anastomosing network between tooth and bone.[25,58] Once embedded in the wall of the alveolus or in the tooth, Sharpey fibers calcify to a significant degree. They are associated with abundant noncollagenous proteins that are typically found in bone, and they have also been identified in tooth cementum.[33,132,175] Notable among these proteins are osteopontin and bone sialoprotein. These proteins are thought to contribute to the regulation of mineralization and to tissue cohesion at sites of increased biomechanical strain.[175]

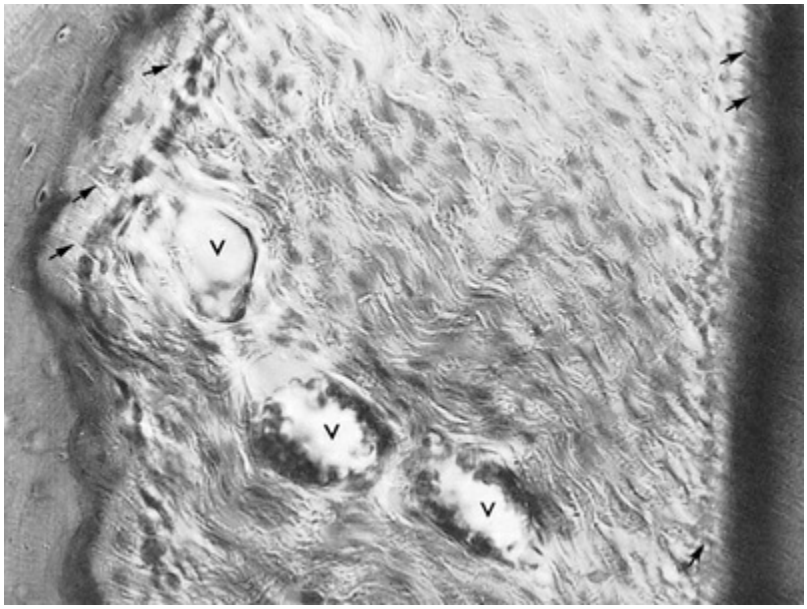

FIG. 3.31 Principal fibers of the periodontal ligament follow a wavy course when sectioned longitudinally. The formative function of the periodontal ligament is illustrated by the newly formed osteoid and osteoblasts along a previously resorbed bone surface *(left)* and the cementoid and cementoblasts *(right).* Note the fibers embedded in the forming calcified tissues *(arrows). V,* Vascular channels.

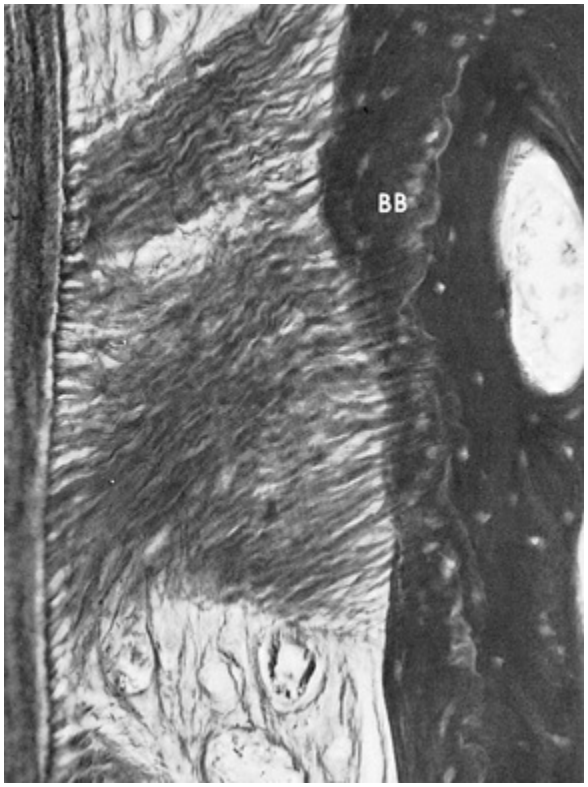

FIG. 3.32 Collagen fibers embedded in the cementum *(left)* and the bone *(right)* (silver stain). Note the Sharpey fibers within the bundle bone *(BB)* overlying the lamellar bone.

Collagen is a protein that is composed of different amino acids, the most important of which are glycine, proline, hydroxylysine, and hydroxyproline.[51] The amount of collagen in a tissue can be determined by its hydroxyproline content. Collagen is responsible for the maintenance of the framework and the tone of tissue, and it exhibits a wide range of diversity.[80] There are at least 19 recognized collagen species encoded by at least 25 separate genes dispersed among 12 chromosomes.[80]

Collagen biosynthesis occurs inside the fibroblasts to form tropocollagen molecules. These aggregate into microfibrils that are packed together to form fibrils. Collagen fibrils have a transverse striation with a characteristic periodicity of 64 μm; this striation is caused by the overlapping arrangement of the tropocollagen molecules. In collagen types I and III, these fibrils associate to form fibers; in collagen type I, the fibers associate to form bundles (Fig. 3.33).

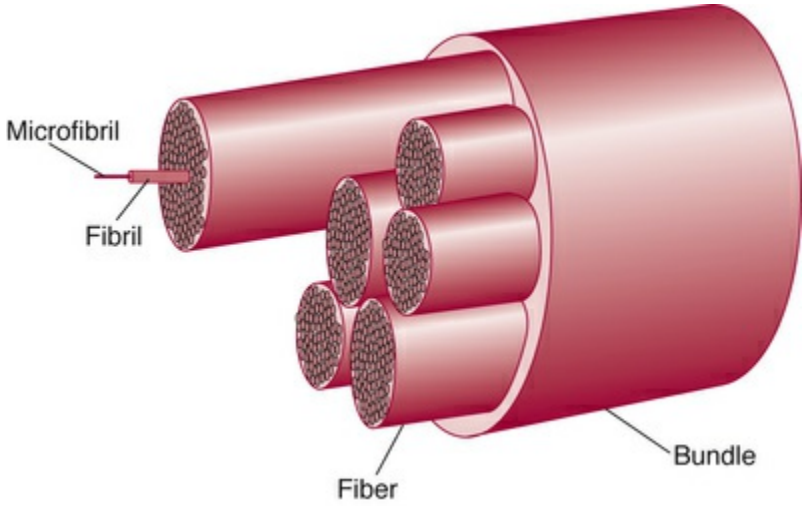

FIG. 3.33 Collagen microfibrils, fibrils, fibers, and bundles.

Collagen is synthesized by fibroblasts, chondroblasts, osteoblasts, odontoblasts, and other cells. The several types of collagen are all distinguishable by their chemical composition, distribution, function, and morphology.[138] The principal fibers are composed mainly of collagen type I,[211] whereas reticular fibers are composed of collagen type III. Collagen type IV is found in the basal lamina.[212,214] The expression of type XII collagen during tooth development is timed with the alignment and organization of periodontal fibers and is limited in tooth development to cells within the periodontal ligament.[164] Type VI collagen has also been immunolocalized in the periodontal ligament and the gingiva.[83]

The molecular configuration of collagen fibers provides them with a tensile strength that is greater than that of steel. Consequently, collagen imparts a unique combination of flexibility and strength to the tissues.[138]

The principal fibers of the periodontal ligament are arranged in six groups that develop sequentially in the developing root: the transseptal, alveolar crest, horizontal, oblique, apical, and interradicular fibers (Fig. 3.34).

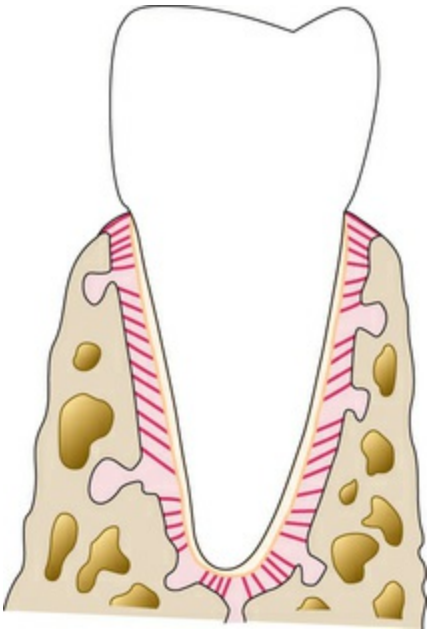

FIG. 3.34 Diagram of the principal fiber groups.

Transseptal fibers extend interproximally over the alveolar bone crest and are embedded in the cementum of adjacent teeth (Fig. 3.35). They are reconstructed even after destruction of the alveolar bone that results from periodontal disease. These fibers may be considered as belonging to the gingiva, because they do not have osseous attachment.

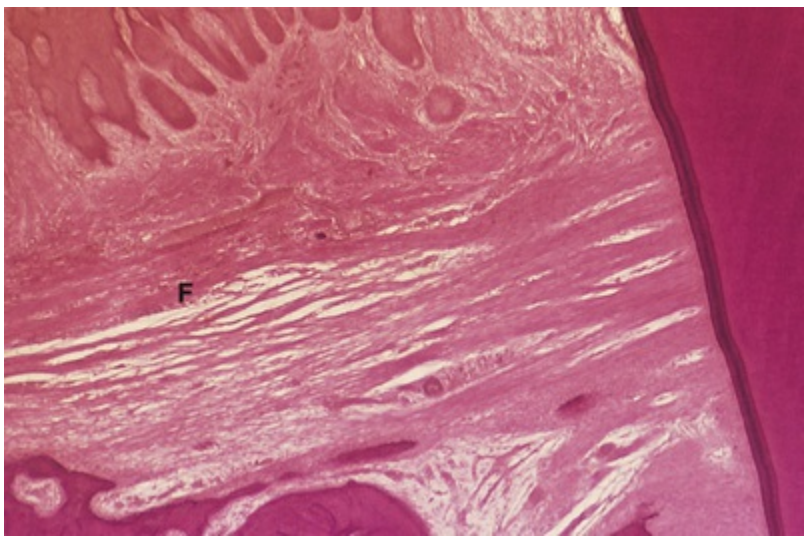

FIG. 3.35 Transseptal fibers *(F)* at the crest of the interdental bone.

Alveolar crest fibers extend obliquely from the cementum just

beneath the junctional epithelium to the alveolar crest (Fig. 3.36). Fibers also run from the cementum over the alveolar crest and to the fibrous layer of the periosteum that covers the alveolar bone. The alveolar crest fibers prevent the extrusion of the tooth[53] and resist lateral tooth movements. The incision of these fibers during periodontal surgery does not increase tooth mobility unless significant attachment loss has occurred.[97]

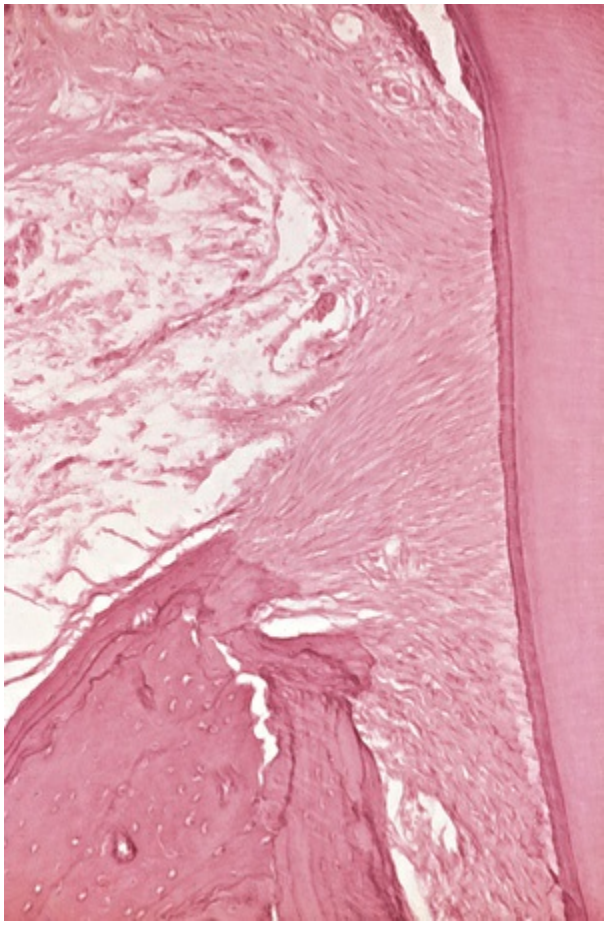

FIG. 3.36 Rat molar section showing alveolar crest fibers radiating coronally.

Horizontal fibers extend at right angles to the long axis of the tooth from the cementum to the alveolar bone.

Oblique fibers, which constitute the largest group in the periodontal ligament, extend from the cementum in a coronal direction obliquely to the bone (see Fig. 3.34). They bear the brunt of vertical masticatory stresses and transform such stresses into tension on the alveolar bone.

The *apical fibers* radiate in a rather irregular manner from the cementum to the bone at the apical region of the socket. They do not occur on incompletely formed roots.

The *interradicular fibers* fan out from the cementum to the tooth in the furcation areas of multirooted teeth.

Other well-formed fiber bundles interdigitate at right angles or splay around and between regularly arranged fiber bundles. Less regularly arranged collagen fibers are found in the interstitial connective tissue between the principal fiber groups; this tissue contains the blood vessels, lymphatics, and nerves.

Although the periodontal ligament does not contain mature elastin, two immature forms are found: oxytalan and elaunin. The so-called oxytalan fibers[89,103] run parallel to the root surface in a vertical direction and bend to attach to the cementum[89] in the cervical third of the root. They are thought to regulate vascular flow.[88] An elastic meshwork has been described in the periodontal ligament[133] as being composed of many elastin lamellae with peripheral oxytalan fibers and elaunin fibers. Oxytalan fibers have been shown to develop de novo in the regenerated periodontal ligament.[219]

The principal fibers are remodeled by the periodontal ligament cells to adapt to physiologic needs[265,295] and in response to different stimuli.[277] In addition to these fiber types, small collagen fibers associated with the larger principal collagen fibers have been described. These fibers run in all directions and form a plexus called the *indifferent fiber plexus*.[243]

Cellular Elements

Four types of cells have been identified in the periodontal ligament: connective tissue cells, epithelial rest cells, immune system cells, and cells associated with neurovascular elements.[26,27]

Connective tissue cells include fibroblasts, cementoblasts, and osteoblasts. Fibroblasts are the most common cells in the periodontal ligament; they appear as ovoid or elongated cells oriented along the principal fibers, and they exhibit pseudopodia-like processes.[210] These cells synthesize collagen and possess the capacity to phagocytose "old" collagen fibers and degrade them[265]

via enzyme hydrolysis. Thus collagen turnover appears to be regulated by fibroblasts in a process of intracellular degradation of collagen that does not involve the action of collagenase.[24]

Phenotypically distinct and functionally different subpopulations of fibroblasts exist in the adult periodontal ligament. They appear to be identical at both the light and electron microscopic levels,[115] but they may have different functions, such as the secretion of different collagen types and the production of collagenase.

Osteoblasts, cementoblasts, osteoclasts, and odontoclasts are also seen in the cemental and osseous surfaces of the periodontal ligament.

The *epithelial rests of Malassez* form a latticework in the periodontal ligament and appear as either isolated clusters of cells or interlacing strands (Fig. 3.37), depending on the plane in which the microscopic section is cut. Continuity with the junctional epithelium has been suggested in experimental animals.[106] The epithelial rests are considered remnants of the Hertwig root sheath, which disintegrates during root development (Fig. 3.37A).

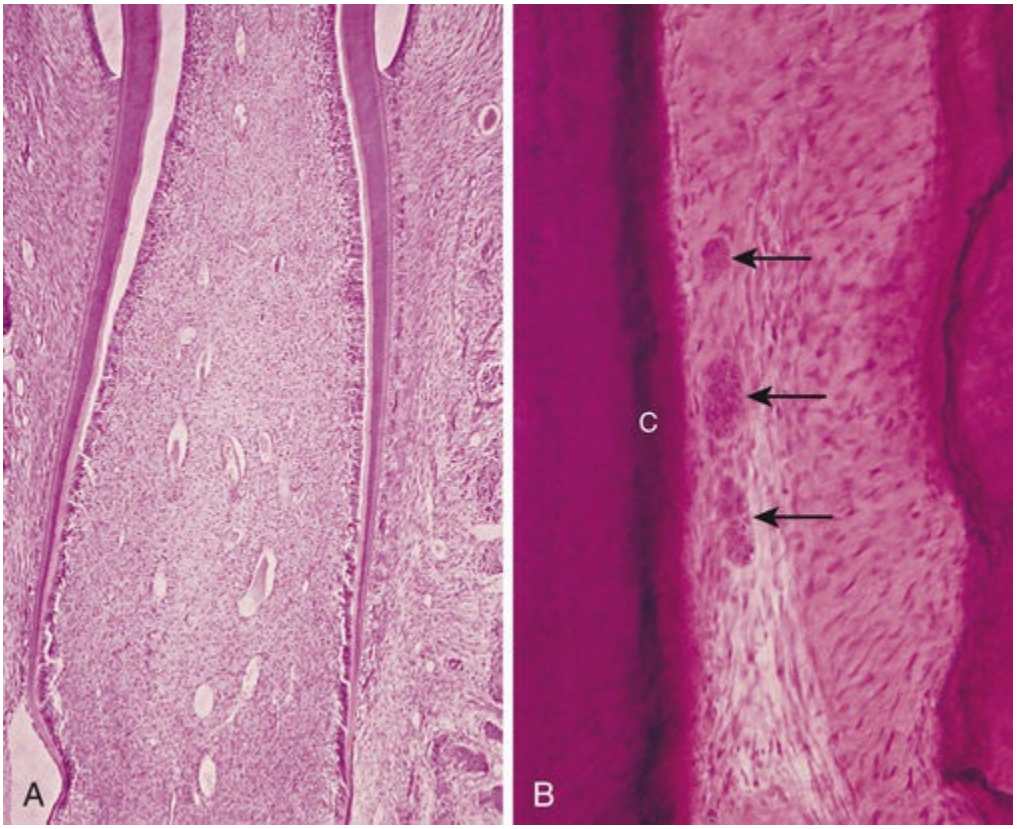

FIG. 3.37 Epithelial rests of Malassez. (A) Erupting

tooth in a cat. Note the fragmentation of the Hertwig epithelial root sheath giving rise to epithelial rests located along and close to the root surface. (B) Human periodontal ligament with rosette-shaped epithelial rests *(arrows)* lying close to the cementum *(C)*.

Epithelial rests are distributed close to the cementum throughout the periodontal ligament of most teeth; they are most numerous in the apical area[207] and the cervical area.[279,280] They diminish in number with age[248] by degenerating and disappearing or by undergoing calcification to become cementicles. The cells are surrounded by a distinct basal lamina, they are interconnected by hemidesmosomes, and they contain tonofilaments.[24]

Although their functional properties are still considered to be unclear,[259] the epithelial rests are reported to contain keratinocyte growth factors, and they have been shown to be positive for tyrosine kinase A neurotrophin receptor.[92,281,291] In addition, epithelial rests proliferate when stimulated,[261,266,275] and they participate in the formation of periapical cysts and lateral root cysts.

The *defense cells* in the periodontal ligament include neutrophils, lymphocytes, macrophages, mast cells, and eosinophils. These cells, as well as those associated with neurovascular elements, are similar to the cells found in other connective tissues.

Ground Substance

The periodontal ligament also contains a large proportion of ground substance that fills the spaces between fibers and cells. This substance consists of two main components: *glycosaminoglycans,* such as hyaluronic acid and proteoglycans, and *glycoproteins,* such as fibronectin and laminin. It also has a high water content (i.e., 70%).

The cell surface proteoglycans participate in several biologic functions, including cell adhesion, cell–cell and cell–matrix interactions, binding to various growth factors as coreceptors, and cell repair.[292] For example, fibromodulin (a small proteoglycan rich in keratan sulfate and leucine) has been identified in bovine periodontal ligament.[283] The most comprehensive study of the proteoglycans in periodontal ligament was performed with the use

of fibroblast cultures of human ligament.[149]

The periodontal ligament may also contain calcified masses called *cementicles,* which are adherent to or detached from the root surfaces (Fig. 3.38).

FIG. 3.38 Cementicles in the periodontal ligament. One is lying free and the other is adherent to the tooth surface.

Cementicles may develop from calcified epithelial rests; around small spicules of cementum or alveolar bone traumatically displaced into the periodontal ligament; from calcified Sharpey fibers; and from calcified, thrombosed vessels within the periodontal ligament.[180]

Functions of Periodontal Ligament

The functions of the periodontal ligament are categorized as physical, formative and remodeling, nutritional, and sensory.

Physical Functions

The physical functions of the periodontal ligament entail the following:

1. Provision of a soft-tissue "casing" to protect the vessels and nerves from injury by mechanical forces
2. Transmission of occlusal forces to the bone
3. Attachment of the teeth to the bone
4. Maintenance of the gingival tissues in their proper relationship to the teeth
5. Resistance to the impact of occlusal forces (i.e., shock absorption)

Resistance to Impact of Occlusal Forces (Shock Absorption)

Two theories pertaining to the mechanism of tooth support have been considered: the tensional theory and the viscoelastic system theory.

The tensional theory of tooth support states that the principal fibers of the periodontal ligament are the major factor in supporting the tooth and transmitting forces to the bone. When a force is applied to the crown, the principal fibers first unfold and straighten, and they then transmit forces to the alveolar bone, thereby causing an elastic deformation of the bony socket. Finally, when the alveolar bone has reached its limit, the load is transmitted to the basal bone. Many investigators find this theory insufficient to explain available experimental evidence.

The viscoelastic system theory states that the displacement of the tooth is largely controlled by fluid movements, with fibers having only a secondary role.[31,43] When forces are transmitted to the tooth, the extracellular fluid passes from the periodontal ligament into the marrow spaces of the bone through the foramina in the cribriform plate. These perforations of the cribriform plate link the periodontal ligament with the cancellous portion of the alveolar bone; they are more abundant in the cervical third than in the middle and apical thirds (Fig. 3.39).

FIG. 3.39 Foramina perforating the lamina dura of a dog jaw.

After the depletion of tissue fluids, the fiber bundles absorb the slack and tighten. This leads to a blood vessel stenosis. Arterial back pressure causes ballooning of the vessels and passage of the blood ultrafiltrates into the tissues, thereby replenishing the tissue fluids.[31]

Transmission of Occlusal Forces to Bone

The arrangement of the principal fibers is similar to that of a suspension bridge or a hammock. When an axial force is applied to a tooth, a tendency toward displacement of the root into the alveolus occurs. The oblique fibers alter their wavy, untensed pattern, assume their full length, and sustain the major part of the axial force. When a horizontal or tipping force is applied, two phases of tooth movement occur. The first is within the confines of the periodontal ligament, and the second produces a displacement of the facial and lingual bony plates.[69] The tooth rotates about an axis that may change as the force is increased.

The apical portion of the root moves in a direction that is opposite to the coronal portion. In areas of tension, the principal fiber bundles are taut rather than wavy. In areas of pressure, the fibers are compressed, the tooth is displaced, and a corresponding distortion of bone exists in the direction of root movement.[203]

In single-rooted teeth, the axis of rotation is located in the area between the apical third and the middle third of the root (Fig. 3.40). The root apex[184] and the coronal half of the clinical root have been

suggested as other locations of the axis of rotation. The periodontal ligament, which has an hourglass shape, is narrowest in the region of the axis of rotation[65,145] (Table 3.1). In multirooted teeth, the axis of rotation is located in the bone between the roots (Fig. 3.41). In compliance with the physiologic mesial migration of the teeth, the periodontal ligament is thinner on the mesial root surface than on the distal surface.

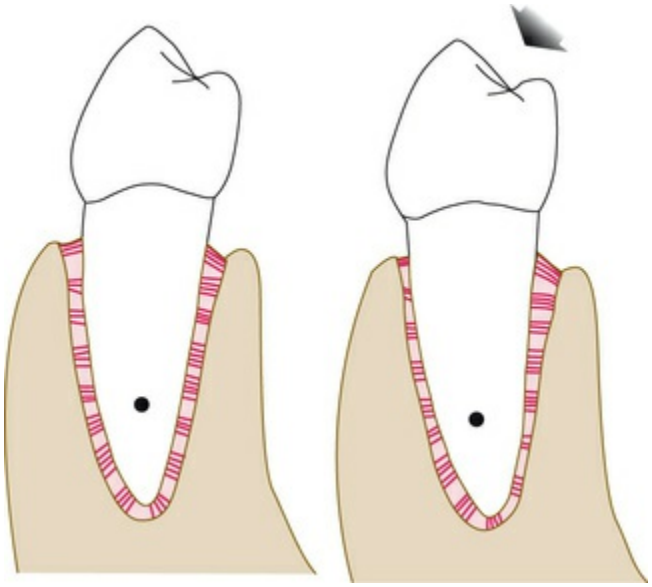

FIG. 3.40 *Left,* Diagram of a mandibular premolar in a resting state. *Right,* When a force is exerted on the tooth—in this case, in faciolingual direction *(arrow)*—the tooth rotates around the fulcrum or axis of rotation *(black circle on root)*. The periodontal ligament is compressed in areas of pressure and distended in areas of tension.

TABLE 3.1

Thickness of the Periodontal Ligaments of 172 Teeth From 15 Human Subjects

	Average of Alveolar Crest (mm)	Average of Midroot (mm)	Average of Apex (mm)	Average of Tooth (mm)
Ages 11 through 16 years	0.23	0.17	0.24	0.21
83 teeth from 4 jaws				

Ages 32 through 50 years	0.20	0.14	0.19	0.18
36 teeth from 5 jaws				
Ages 51 through 67 years	0.17	0.12	0.16	0.15
35 teeth from 5 jaws				
Age 24 years (1 case)	0.16	0.09	0.15	0.13
18 teeth from 1 jaw				

Modified from Coolidge ED: The thickness of the human periodontal membrane. *J Am Dent Assoc* 24:1260, 1937.

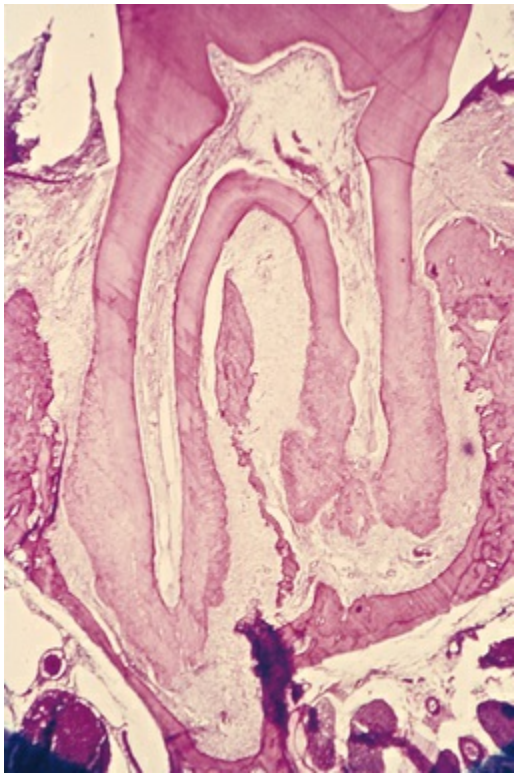

FIG. 3.41 Microscopic view of a rat molar subjected to occlusohorizontal forces. Note the alternating widened and narrowed areas of the periodontal ligament as the tooth rotates around its axis of rotation. The axis of rotation is in the interradicular space.

Formative and Remodeling Function

Periodontal ligament and alveolar bone cells are exposed to physical forces in response to mastication, parafunction, speech, and orthodontic tooth movement.[173] Cells of the periodontal ligament participate in the formation and resorption of cementum and bone, which occur during physiologic tooth movement, during the accommodation of the periodontium to occlusal forces, and during the repair of injuries.

Variations in cellular enzyme activity are correlated with the remodeling process.[94-96] Although applied loads may induce vascular and inflammatory reactive changes in periodontal ligament cells, current evidence suggests that these cells have a mechanism to respond directly to mechanical forces via the activation of various mechanosensory signaling systems, including adenylate cyclase, stretch-activated ion channels, and via changes in cytoskeletal organization.[173]

Cartilage formation in the periodontal ligament, although unusual, may represent a metaplastic phenomenon in the repair of this ligament after injury.[20]

The periodontal ligament is constantly undergoing remodeling. Old cells and fibers are broken down and replaced by new ones, and mitotic activity can be observed in the fibroblasts and the endothelial cells.[185] Fibroblasts form the collagen fibers, and the residual mesenchymal cells develop into osteoblasts and cementoblasts. Therefore the rate of formation and the differentiation of osteoblasts, cementoblasts, and fibroblasts affect the rate of formation of collagen, cementum, and bone.

Radioautographic studies with radioactive thymidine, proline, and glycine indicate a high turnover rate of collagen in the periodontal ligament. The rate of collagen synthesis is twice as fast as that in the gingiva and four times as fast as that in the skin, as established in the rat molar.[250] A rapid turnover of sulfated glycosaminoglycans in the cells and amorphous ground substance of the periodontal ligament also occurs.[21] It should be noted that most of these studies have been performed in rodents and that information about primates and humans is scarce.[232]

Nutritional and Sensory Functions

The periodontal ligament supplies nutrients to the cementum, bone,

and gingiva by way of the blood vessels, and it also provides lymphatic drainage as discussed later in this chapter. In relation to other ligaments and tendons, the periodontal ligament is highly vascularized tissue; almost 10% of its volume in the rodent molar is blood vessels.[35,174] This relatively high blood vessel content may provide hydrodynamic damping to applied forces as well as high perfusion rates to the periodontal ligament.[173]

The periodontal ligament is abundantly supplied with sensory nerve fibers that are capable of transmitting tactile, pressure, and pain sensations via the trigeminal pathways.[14,30] Nerve bundles pass into the periodontal ligament from the periapical area and through channels from the alveolar bone that follow the course of the blood vessels. The bundles divide into single myelinated fibers, which ultimately lose their myelin sheaths and end in one of four types of neural termination: (1) free endings, which have a treelike configuration and carry pain sensation; (2) Ruffini-like mechanoreceptors, which are located primarily in the apical area; (3) coiled Meissner corpuscles and mechanoreceptors, which are found mainly in the midroot region; and (4) spindle-like pressure and vibration endings, which are surrounded by a fibrous capsule and located mainly in the apex.[88,166]

Regulation of Periodontal Ligament Width

Some of the most interesting features of the periodontal ligament in animals are its adaptability to rapidly changing applied force and its capacity to maintain its width at constant dimensions throughout its lifetime.[174] These are important measures of periodontal ligament homeostasis that provide insight into the function of the biologic mechanisms that tightly regulate the metabolism and spatial locations of the cell populations involved in the formation of bone, cementum, and periodontal ligament fibers. In addition, the ability of periodontal ligament cells to synthesize and secrete a wide range of regulatory molecules is an essential component of tissue remodeling and periodontal ligament homeostasis.[173]

Cementum

Cementum is the calcified, avascular mesenchymal tissue that forms the outer covering of the anatomic root. The two main types of cementum are acellular *(primary)* and cellular *(secondary)* cementum.[104] Both consist of a calcified interfibrillar matrix and collagen fibrils.

The two main sources of collagen fibers in cementum are Sharpey fibers *(extrinsic)*, which are the embedded portion of the principal fibers of the periodontal ligament[214] and which are formed by the fibroblasts, and fibers that belong to the cementum matrix *(intrinsic)*, which are produced by the cementoblasts.[240] Cementoblasts also form the noncollagenous components of the interfibrillar ground substance, such as proteoglycans, glycoproteins, and phosphoproteins. Proteoglycans are most likely to play a role in regulating cell–cell and cell–matrix interactions, both during normal development and during the regeneration of the cementum.[17] In addition, immunohistochemical studies have shown that the distribution of proteoglycans is closely associated with the cementoblasts and the cementocytes.[1,2]

The major proportion of the organic matrix of cementum is composed of type I (90%) and type III (about 5%) collagens. Sharpey fibers, which constitute a considerable proportion of the bulk of cementum, are composed of mainly type I collagen.[206] Type III collagen appears to coat the type I collagen of the Sharpey fibers.[16]

Acellular cementum is the first cementum formed; it covers approximately the cervical third or half of the root, and it does not contain cells (Fig. 3.42). This cementum is formed before the tooth reaches the occlusal plane, and its thickness ranges from 30 to 230 μm.[248] Sharpey fibers make up most of the structure of acellular cementum, which has a principal role in supporting the tooth. Most fibers are inserted at approximately right angles into the root surface and penetrate deep into the cementum, but others enter from several different directions. Their size, number, and distribution increase with function.[123] Sharpey fibers are completely calcified, with the mineral crystals oriented parallel to the fibrils as in dentin and bone, except in a 10- to 50-μm–wide zone near the cementodentinal junction, where they are only partially calcified. The peripheral portions of Sharpey fibers in actively mineralizing

cementum tend to be more calcified than the interior regions, according to evidence obtained by scanning electron microscopy.[137] Acellular cementum also contains intrinsic collagen fibrils that are calcified and irregularly arranged or parallel to the surface.[232]

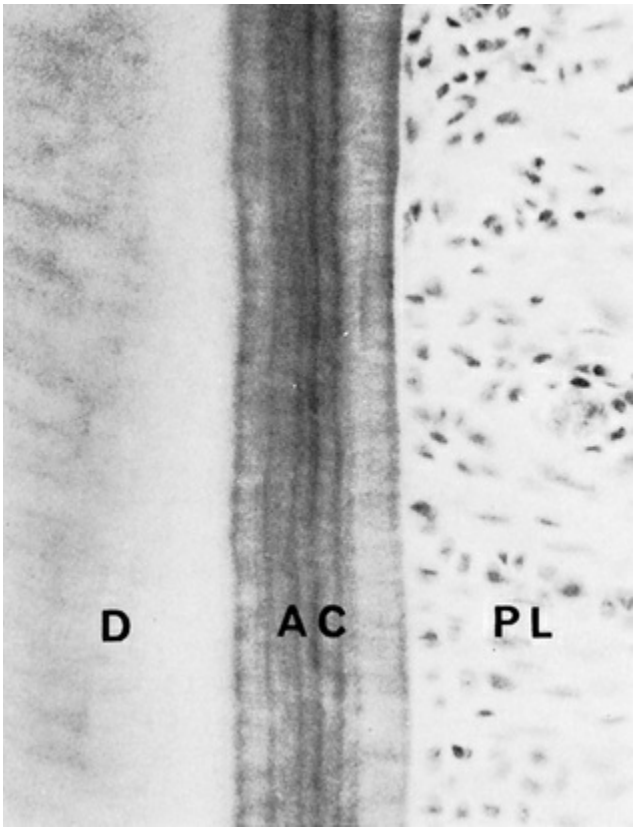

FIG. 3.42 Acellular cementum *(AC)* showing incremental lines running parallel to the long axis of the tooth. These lines represent the appositional growth of cementum. Note the thin, light lines running into the cementum perpendicular to the surface; these represent the Sharpey fibers of the periodontal ligament *(PL)*. *D*, Dentin. (×300.)

Cellular cementum, which is formed after the tooth reaches the occlusal plane, is more irregular and contains cells (cementocytes) in individual spaces (lacunae) that communicate with each other through a system of anastomosing canaliculi (Fig. 3.43). Cellular cementum is less calcified than the acellular type.[124] Sharpey fibers occupy a smaller portion of cellular cementum and are separated by other fibers that are arranged either parallel to the root surface or at random. Sharpey fibers may be completely or partially calcified, or

they may have a central, uncalcified core surrounded by a calcified border.[135,240]

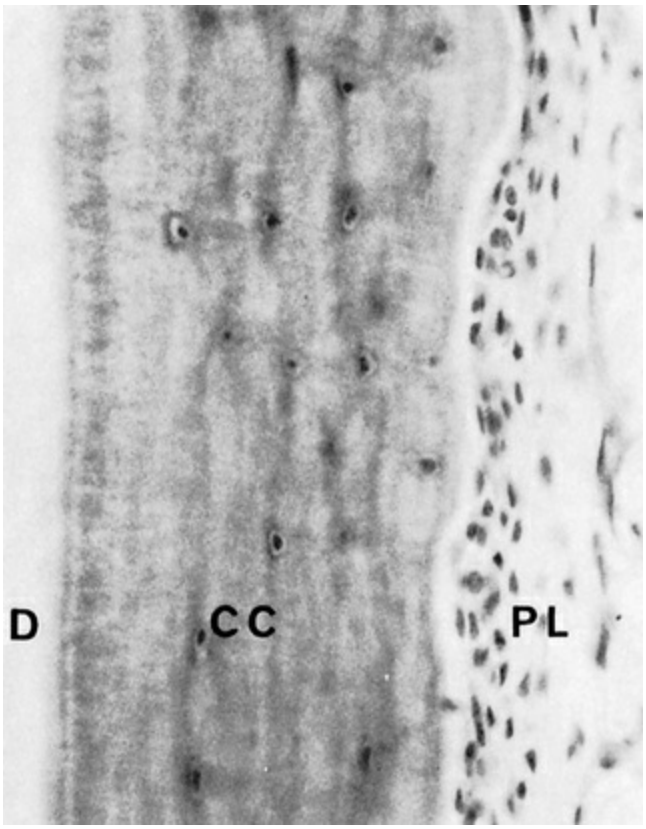

FIG. 3.43 Cellular cementum *(CC)* showing cementocytes lying within the lacunae. Cellular cementum is thicker than acellular cementum. The evidence of incremental lines also exists, but they are less distinct than in the acellular cementum. The cells adjacent to the surface of the cementum in the periodontal ligament *(PL)* space are cementoblasts. *D*, Dentin. (×300.)

Both acellular cementum and cellular cementum are arranged in lamellae separated by incremental lines parallel to the long axis of the root (see Figs. 3.42 and 3.43). These lines represent "rest periods" in cementum formation, and they are more mineralized than the adjacent cementum.[215] In addition, the loss of the cervical part of the reduced enamel epithelium at the time of tooth eruption may place portions of mature enamel in contact with the connective tissue, which then will deposit an acellular and afibrillar type of cementum over the enamel.[157]

On the basis of these findings, Schroeder[133,134] has classified cementum as follows:

- Acellular afibrillar cementum contains neither cells nor extrinsic or intrinsic collagen fibers, except for a mineralized ground substance. Acellular afibrillar cementum is a product of cementoblasts and found as coronal cementum in humans, with a thickness of 1 to 15 μm.
- Acellular extrinsic fiber cementum is composed almost entirely of densely packed bundles of Sharpey fibers and lacks cells. Acellular extrinsic fiber cementum is a product of fibroblasts and cementoblasts. It is found in the cervical third of roots in humans, but it may extend farther apically. Its thickness is between 30 and 230 μm.
- Cellular mixed stratified cementum is composed of extrinsic (Sharpey) and intrinsic fibers, and it may contain cells. Cellular mixed stratified cementum is a co-product of fibroblasts and cementoblasts. In humans, it appears primarily in the apical third of the roots and apices and in furcation areas. Its thickness ranges from 100 to 1000 μm.
- Cellular intrinsic fiber cementum contains cells but no extrinsic collagen fibers. Cellular intrinsic fiber cementum is formed by cementoblasts, and, in humans, it fills the resorption lacunae.

Intermediate cementum is a poorly defined zone near the cementodentinal junction of certain teeth that appears to contain cellular remnants of the Hertwig sheath embedded in a calcified

ground substance.[77,153]

Inorganic content of cementum (hydroxyapatite; Ca10[Po4]6[OH]2) is 45% to 50%, which is less than that of bone (65%), enamel (97%), or dentin (70%).[299] Opinions differ with regard to whether the microhardness increases[189] or decreases with age,[282] and no relationship has been established between aging and the mineral content of cementum.

It is well known that the protein extracts of mature cementum promote cell attachment and cell migration and stimulate the protein synthesis of gingival fibroblasts and periodontal ligament cells.[225] Studies of cementum have identified adhesion proteins with arginyl–glycyl–aspartic acid sequences: bone sialoprotein, osteopontin, and osteonectin.[39,175] Bone sialoprotein and osteopontin are expressed during early tooth root development by cells along the root surface, and they are thought to play a major role in the differentiation of the cementoblast progenitor cells to the cementoblasts.[109,225]

Some of the molecules unique to the cementum have been described. Researchers have investigated the role of *cementum attachment protein,* which is a collagenous cementum-derived protein. Cementum attachment protein has been shown to promote the adhesion and spreading of mesenchymal cell types, with osteoblasts and periodontal ligament fibroblasts showing better adhesion than gingival fibroblasts and keratinocytes.[220] In addition, Ikezawa and colleagues[122] described the characterization of *cementum-derived growth factor,* which is an insulin-like, growth factor-I–like molecule. Cementum-derived growth factor has been shown to enhance the proliferation of gingival fibroblasts and periodontal ligament cells.

Permeability of Cementum

In very young animals, acellular cementum and cellular cementum are very permeable and permit the diffusion of dyes from the pulp and the external root surface. In cellular cementum, the canaliculi in some areas are contiguous with the dentinal tubuli. The permeability of cementum diminishes with age.[36]

Cementoenamel Junction

The cementum at and immediately subjacent to the *cementoenamel junction* is of particular clinical importance in root-scaling procedures. Three types of relationships involving the cementum may exist at the cementoenamel junction.[190] In about 60% to 65% of cases, cementum overlaps the enamel (Fig. 3.44); in about 30%, an edge-to-edge butt joint exists; and in 5% to 10%, the cementum and enamel fail to meet. In the last case, gingival recession may result in accentuated sensitivity as a result of exposed dentin.

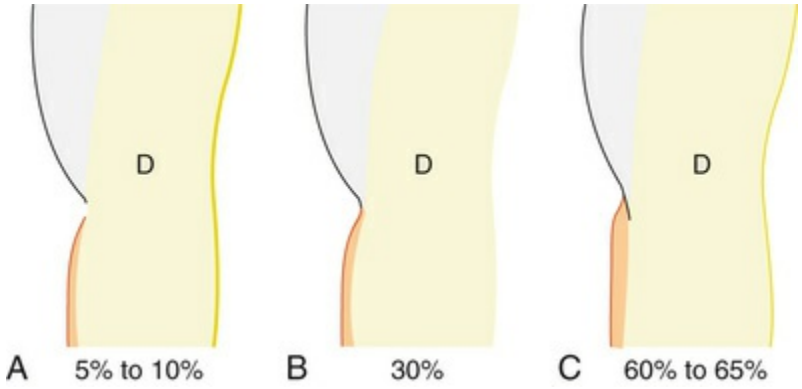

FIG. 3.44 Normal variations in tooth morphology at the cementoenamel junction. (A) Space between the enamel and the cementum with the dentin *(D)* exposed. (B) End-to-end relationship of enamel and cementum. (C) Cementum overlapping the enamel.

Cementodentinal Junction

The terminal apical area of the cementum where it joins the internal root canal dentin is known as the *cementodentinal junction.* When root canal treatment is performed, the obturating material should be at the cementodentinal junction. There appears to be no increase or decrease in the width of the cementodentinal junction with age; its width appears to remain relatively stable.[253] Scanning electron microscopy of the human teeth reveals that the cementodentinal junction is 2 to 3 μm wide. The fibril-poor layer contains a significant amount of proteoglycans, and fibrils intermingle between the cementum and the dentin.[293,294]

Thickness of Cementum

Cementum deposition is a continuous process that proceeds at varying rates throughout life. Cementum formation is most rapid in the apical regions, where it compensates for tooth eruption, which itself compensates for attrition.

The thickness of cementum on the coronal half of the root varies from 16 to 60 μm, which is about the thickness of a hair. It attains its greatest thickness (≤150 to 200 μm) in the apical third and in the furcation areas. It is thicker in distal surfaces than in mesial surfaces, probably because of functional stimulation from mesial drift over time.[68] Between the ages of 11 and 70 years, the average thickness of the cementum increases threefold, with the greatest increase seen in the apical region. Average thicknesses of 95 μm at the age of 20 years and of 215 μm at the age of 60 years have been reported.[298]

Abnormalities in the thickness of cementum may range from an absence or paucity of cellular cementum (i.e., cemental aplasia or hypoplasia) to an excessive deposition of cementum (i.e., cemental hyperplasia or hypercementosis).[152]

The term *hypercementosis* refers to a prominent thickening of the cementum. It is largely an age-related phenomenon, and it may be localized to one tooth or affect the entire dentition. As a result of considerable physiologic variation in the thickness of cementum among different teeth in the same person and also among different persons, distinguishing between hypercementosis and the physiologic thickening of cementum is sometimes difficult. Nevertheless, the excessive proliferation of cementum may occur with a broad spectrum of neoplastic and nonneoplastic conditions, including benign cementoblastoma, cementifying fibroma, periapical cemental dysplasia, florid cemento-osseous dysplasia, and other benign fibro-osseous lesions.[152]

Hypercementosis occurs as a generalized thickening of the cementum, with nodular enlargement of the apical third of the root. It also appears in the form of spikelike excrescences (i.e., cemental spikes) created by either the coalescence of cementicles that adhere to the root or the calcification of periodontal fibers at the sites of insertion into the cementum.[153]

Radiographically, the radiolucent shadow of the periodontal

ligament and the radiopaque lamina dura are always seen on the outer border of an area of hypercementosis, enveloping it as it would in normal cementum.[152] On the other hand, from a diagnostic standpoint, periapical cemental dysplasia, condensing osteitis, and focal periapical osteopetrosis may be differentiated from hypercementosis, because all of these entities are located outside of the shadow of the periodontal ligament and the lamina dura.[290]

The cause of hypercementosis varies and is not completely understood. The spikelike type of hypercementosis generally results from excessive tension caused by orthodontic appliances or occlusal forces. The generalized type occurs in a variety of circumstances. In teeth without antagonists, hypercementosis is interpreted as an effort to keep pace with excessive tooth eruption. In teeth that are subject to low-grade periapical irritation that arises from pulp disease, it is considered compensation for the destroyed fibrous attachment to the tooth. The cementum is deposited adjacent to the inflamed periapical tissue. Hypercementosis of the entire dentition may occur in patients with Paget disease.[218] Other systemic disturbances that may lead to or may be associated with hypercementosis include acromegaly, arthritis, calcinosis, rheumatic fever, and thyroid goiter.[152]

Hypercementosis itself does not require treatment. It could pose a problem if an affected tooth requires extraction. In a multirooted tooth, sectioning of the tooth may be required before extraction.[19]

Cementum Resorption and Repair

Permanent teeth do not undergo physiologic resorption as primary teeth do. However, the cementum of erupted (as well as unerupted) teeth is subject to resorptive changes that may be of microscopic proportion or sufficiently extensive to present a radiographically detectable alteration in the root contour.

Microscopic cementum resorption is extremely common; in one study, it occurred in 236 of 261 teeth (90.5%).[118] The average number of resorption areas per tooth was 3.5. Of the 922 areas of resorption, 708 (76.8%) were located in the apical third of the root, 177 (19.2%) in the middle third, and 37 (4.0%) in the gingival third.

Approximately 70% of all resorption areas were confined to the cementum without involving the dentin.

Cementum resorption may be caused by local or systemic factors, or it may occur without apparent etiology (i.e., idiopathic). Local conditions that cause cementum resorption include trauma from occlusion[194] (Fig. 3.45); orthodontic movement[117,193,217]; pressure from malaligned erupting teeth, cysts, and tumors[144]; teeth without functional antagonists; embedded teeth; replanted and transplanted teeth[3,135]; periapical disease; and periodontal disease. Systemic conditions that are cited as predisposing an individual to or inducing cemental resorption include calcium deficiency,[136] hypothyroidism,[23] hereditary fibrous osteodystrophy,[269] and Paget disease.[218]

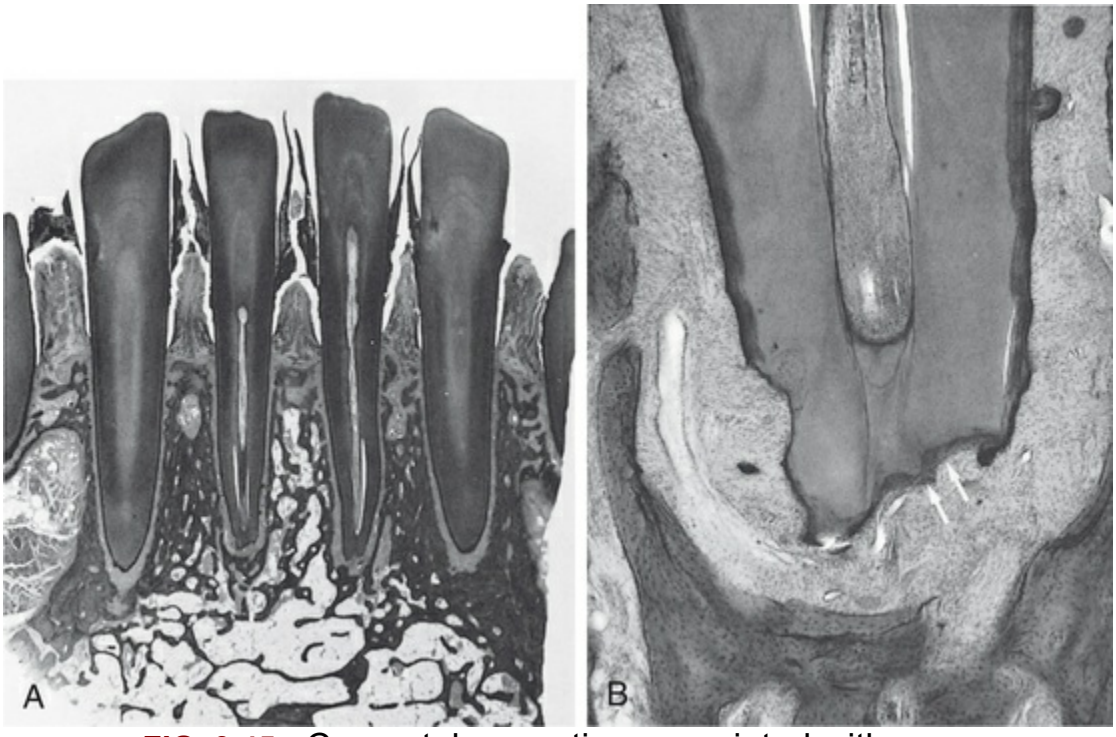

FIG. 3.45 Cemental resorption associated with excessive occlusal forces. (A) Low-power histologic section of the mandibular anterior teeth. (B) High-power micrograph of the apex of the left central incisor shortened by the resorption of cementum and dentin. Note the partial repair of the eroded areas *(arrows)* and the cementicle at the upper right.

Cementum resorption appears microscopically as baylike

concavities in the root surface. (Fig. 3.46) Multinucleated giant cells and large mononuclear macrophages are generally found adjacent to cementum that is undergoing active resorption (Fig. 3.47). Several sites of resorption may coalesce to form a large area of destruction. The resorptive process may extend into the underlying dentin and even into the pulp, but it is usually painless. Cementum resorption is not necessarily continuous and may alternate with periods of repair and the deposition of new cementum. The newly formed cementum is demarcated from the root by a deeply staining irregular line termed a *reversal line,* which delineates the border of the previous resorption. One study showed that the reversal lines of human teeth contain a few collagen fibrils and highly accumulated proteoglycans with mucopolysaccharides (glycosaminoglycans) and that fibril intermingling occurs only in some places between reparative cementum and resorbed dentin or cementum.[293,294] Embedded fibers of the periodontal ligament reestablish a functional relationship in the new cementum.

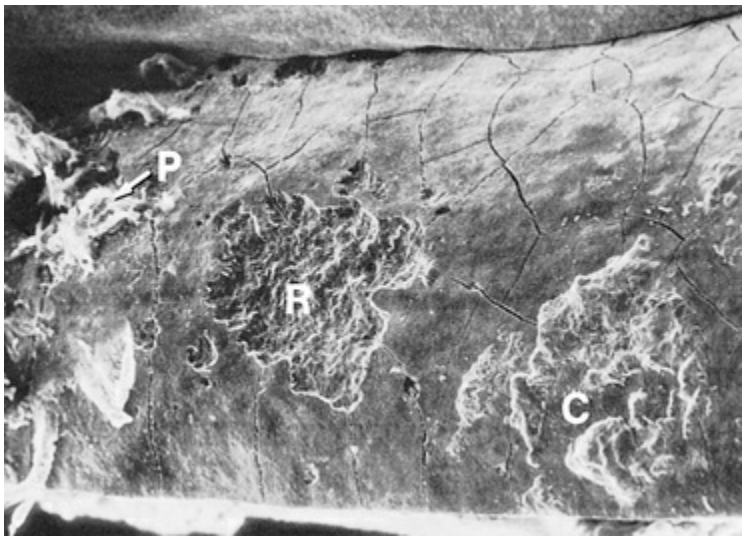

FIG. 3.46 Scanning electron micrograph of a root exposed by periodontal disease showing a large resorption bay *(R)*. Remnants of the periodontal ligament *(P)* and calculus *(C)* are visible. Cracking of the tooth surface occurs as a result of the preparation technique. (×160.) (Courtesy Dr. John Sottosanti, La Jolla, California.)

Cementum repair requires the presence of viable connective tissue. If epithelium proliferates into an area of resorption, repair will not take place. Cementum repair can occur in devitalized as well as vital teeth.

Histologic evidence demonstrates that cementum formation is critical for the appropriate maturation of the periodontium, both during development and during the regeneration of lost periodontal tissues.[225] In other words, a variety of macromolecules present in the extracellular matrix of the periodontium are likely to play a regulatory role in cementogenesis.[169]

The regeneration of cementum requires cementoblasts, but the origin of the cementoblasts and the molecular factors that regulate their recruitment and differentiation are not fully understood. However, research provides a better understanding; for example, the epithelial cell rests of Malassez are the only odontogenic epithelial cells that remain in the periodontium after the eruption of teeth, and they may have some function in cementum repair and

regeneration under specific conditions.[114] The rests of Malassez may be related to cementum repair by activating their potential to secrete matrix proteins that have been expressed in tooth development, such as amelogenins, enamelins, and sheath proteins. Several growth factors have been shown to be effective in cementum regeneration, including members of the transforming growth factor superfamily (i.e., bone morphogenetic proteins), platelet-derived growth factor, insulin-like growth factor, and enamel matrix derivatives[139,225] (Fig. 3.48).

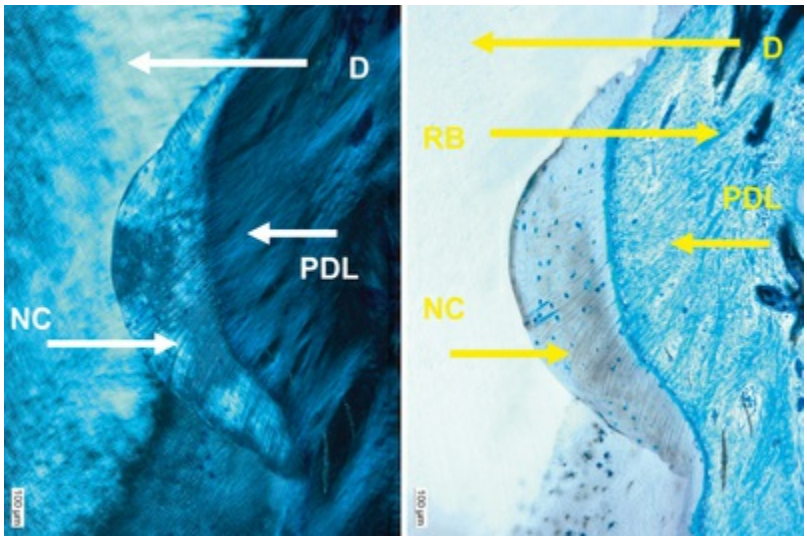

FIG. 3.48 A clinical human histology shows that new cementum and new periodontal ligament fiber formed at a previous periodontal defect treated with recombinant human platelet-derived growth factor-BB with β-tricalcium phosphate. (Courtesy Dr. Daniel WK Kao, Philadelphia, Pennsylvania.)

Ankylosis

Fusion of the cementum and the alveolar bone with obliteration of the periodontal ligament is termed *ankylosis.* Ankylosis occurs in teeth with cemental resorption, which suggests that it may represent a form of abnormal repair. Ankylosis may also develop after chronic periapical inflammation, tooth replantation, and occlusal trauma and around embedded teeth. This condition is relatively uncommon, and it occurs most frequently in the primary

dentition.[176]

Ankylosis results in the resorption of the root and its gradual replacement by bone tissue. For this reason, reimplanted teeth that ankylose will lose their roots after 4 to 5 years and will be exfoliated. Clinically, ankylosed teeth lack the physiologic mobility of normal teeth, which is one diagnostic sign for ankylotic resorption. In addition, these teeth usually have a special metallic percussion sound; if the ankylotic process continues, they will be in infraocclusion.[90] However, the clinical diagnosis of ankylosis by mobility and percussion tests alone is only reliable when at least 20% of the root surface is affected.[10]

As the periodontal ligament is replaced with bone during ankylosis, proprioception is lost, because pressure receptors in the periodontal ligament are deleted or do not function correctly. Furthermore, the physiologic drifting and eruption of teeth can no longer occur, and thus the ability of the teeth and periodontium to adapt to altered force levels or directions of force is greatly reduced.[173] Radiographically, resorption lacunae are filled with bone, and the periodontal ligament space is missing.

Because no definitive causes can be found in ankylotic root resorption, no predictable treatment can be suggested. Treatment modalities range from a conservative approach, such as restorative intervention, to surgical, such as the extraction of the affected tooth.[186]

When titanium implants are placed in the jaw, healing results in bone that is formed in direct apposition to the implant without intervening connective tissue. This may be interpreted as a form of ankylosis. Because resorption of the metallic implant cannot occur, the implant remains indefinitely "ankylosed" to the bone. In addition, a true periodontal pocket will not form; the apical proliferation of the epithelium along the root, which is a key element of pocket formation, is not possible because of the ankylosis.

Exposure of Cementum to the Oral Environment

Cementum becomes exposed to the oral environment in cases of

gingival recession and as a result of the loss of attachment in pocket formation. The cementum is sufficiently permeable to be penetrated in these cases by organic substances, inorganic ions, and bacteria. Bacterial invasion of the cementum occurs frequently in individuals with periodontal disease, and cementum caries can develop (see Chapter 23).

Alveolar Process

The alveolar process is the portion of the maxilla and mandible that forms and supports the tooth sockets (alveoli). It forms when the tooth erupts to provide the osseous attachment to the forming periodontal ligament; it disappears gradually after the tooth is lost.

Because the alveolar processes develop and undergo remodeling with tooth formation and eruption, they are tooth-dependent bony structures.[227] Therefore the size, shape, location, and function of the teeth determine their morphology. Interestingly, although the growth and development of the bones of the jaw determine the position of the teeth, a certain degree of repositioning of the teeth can be accomplished through occlusal forces and in response to orthodontic procedures that rely on the adaptability of the alveolar bone and the associated periodontal tissues.[251]

The alveolar process consists of the following:

1. An external plate of cortical bone is formed by haversian bone and compacted bone lamellae.
2. The inner socket wall of thin, compact bone called the *alveolar bone proper* is seen as the lamina dura in radiographs. Histologically, it contains a series of openings (i.e., the *cribriform plate*) through which neurovascular bundles link the periodontal ligament with the central component of the alveolar bone: the cancellous bone.
3. Cancellous trabeculae between these two compact layers act as supporting alveolar bone. The *interdental septum* consists of cancellous supporting bone enclosed within a compact border (Fig. 3.49).

FIG. 3.49 Mesiodistal section through the mandibular molars of a 17-year-old girl obtained at autopsy. Note the interdental bony septa between the first and second molars. The dense cortical bony plates represent the alveolar bone proper (i.e., the cribriform plates) and are supported by cancellous bony trabeculae. The third molar is still in the early stages of root formation and eruption.

In addition, the bones of the jaw include the basal bone, which is the portion of the jaw located apically but unrelated to the teeth (Fig. 3.50).

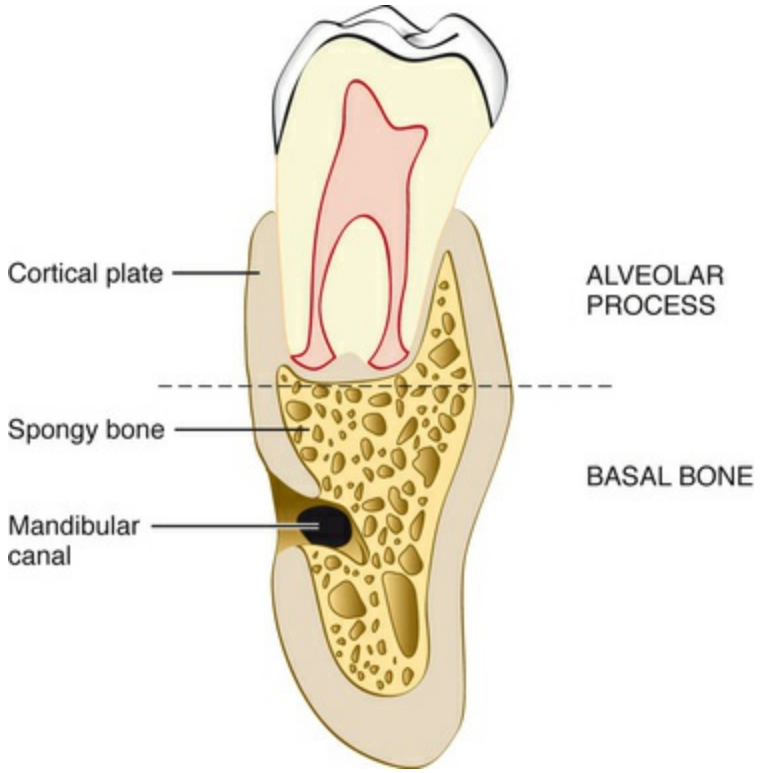

FIG. 3.50 Section through a human jaw with a tooth in situ. The dotted line indicates the separation between the basal bone and the alveolar bone. (Redrawn from Ten Cate AR: *Oral histology: development, structure, and function,* ed 4, St Louis, 1994, Mosby.)

The alveolar process is divisible into separate areas on an anatomic basis, but it functions as a unit, with all parts interrelated in the support of the teeth. Figs. 3.51 and 3.52 show the relative proportions of cancellous bone and compact bone that form the alveolar process. Most of the facial and lingual portions of the sockets are formed by compact bone alone; cancellous bone surrounds the lamina dura in apical, apicolingual, and interradicular areas.

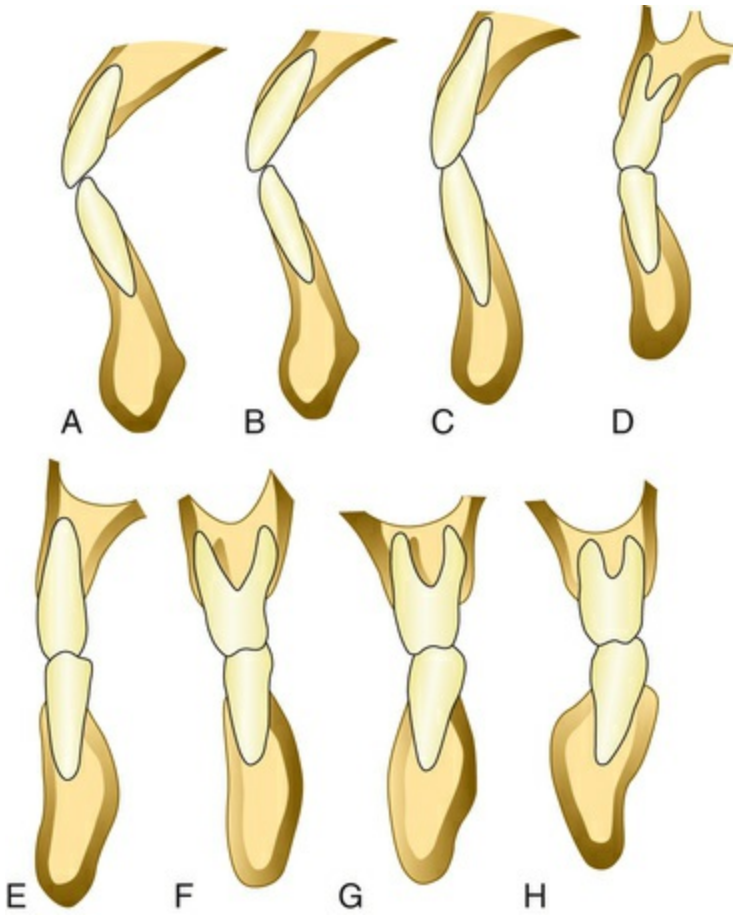

FIG. 3.51 Relative proportions of cancellous bone and compact bone in a longitudinal faciolingual section of (A) mandibular molars, (B) lateral incisors, (C) canines, (D) first premolars, (E) second premolars, (F) first molars, (G) second molars, and (H) third molars.

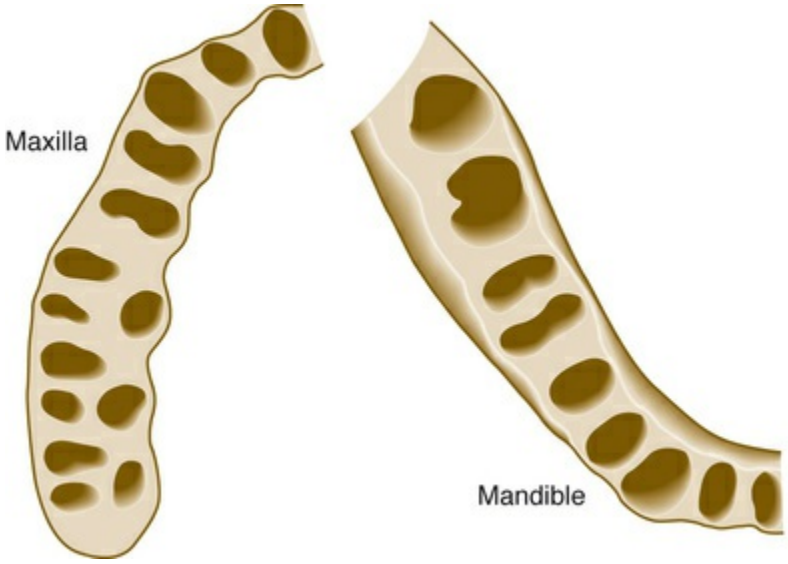

FIG. 3.52 The shape of the roots and the surrounding bone distribution in a transverse section of maxilla and mandible at the midroot level.

Bone consists of two-thirds inorganic matter and one-third organic matrix. The inorganic matter is composed principally of the minerals calcium and phosphate, along with hydroxyl, carbonate, citrate, and trace amounts of other ions[101,102] such as sodium, magnesium, and fluorine. The mineral salts are in the form of hydroxyapatite crystals of ultramicroscopic size and constitute approximately two-thirds of the bone structure.

The organic matrix[75] consists mainly of collagen type I (90%),[185] with small amounts of noncollagenous proteins such as osteocalcin, osteonectin, bone morphogenetic protein, phosphoproteins, and proteoglycans.[209] Osteopontin and bone sialoprotein are cell-adhesion proteins that appear to be important for the adhesion of both osteoclasts and osteoblasts.[163] In addition, paracrine factors, including cytokines, chemokines, and growth factors, have been implicated in the local control of mesenchymal condensations that occur at the onset of organogenesis. These factors probably play a prominent role in the development of the alveolar processes.[251]

Although the alveolar bone tissue is constantly changing its internal organization, it retains approximately the same form from childhood through adult life. Bone deposition by osteoblasts is balanced by resorption by osteoclasts during tissue remodeling and renewal. It is well known that the number of osteoblasts decreases with aging; however, no remarkable change in the number of osteoclasts has ever been reported.[191]

Remodeling is the major pathway of bony changes in shape, resistance to forces, repair of wounds, and calcium and phosphate homeostasis in the body. Indeed, the coupling of bone resorption with bone formation constitutes one of the fundamental principles by which bone is necessarily remodeled throughout its life. Bone remodeling involves the coordination of activities of cells from two distinct lineages, the osteoblasts and the osteoclasts, which form and resorb the mineralized connective tissues of bone.[251]

The regulation of bone remodeling is a complex process that involves hormones and local factors acting in an autocrine and a paracrine manner on the generation and activity of differentiated

bone cells.[251] Bone contains 99% of the body's calcium ions and therefore is the major source for calcium release when the calcium blood levels decrease; this is monitored by the parathyroid gland. A decrease in blood calcium is mediated by receptors on the chief cells of the parathyroid glands, which then release parathyroid hormone. Parathyroid hormone stimulates osteoblasts to release interleukin-1 and interleukin-6, which stimulate monocytes to migrate into the bone area. Leukemia-inhibiting factor, which is secreted by osteoblasts, coalesces monocytes into multinucleated osteoclasts, which then resorb bone, thereby releasing calcium ions from hydroxyapatite into the blood. This release normalizes the blood level of calcium. A feedback mechanism of normal blood levels of calcium turns off the secretion of parathyroid hormone. Meanwhile, osteoclasts have resorbed organic matrix along with hydroxyapatite. The breakdown of collagen from the organic matrix releases various osteogenic substrates, which are covalently bound to collagen. This in turn stimulates the differentiation of osteoblasts, which ultimately deposit bone. This interdependency of osteoblasts and osteoclasts in remodeling is called *coupling.*

The bone matrix that is laid down by osteoblasts is nonmineralized osteoid. While new osteoid is being deposited, the older osteoid located below the surface becomes mineralized as the mineralization front advances.

Bone resorption is a complex process that is morphologically related to the appearance of eroded bone surfaces (i.e., Howship lacunae) and large, multinucleated cells (osteoclasts) (Fig. 3.53). Osteoclasts originate from hematopoietic tissue[55,110,197] and are formed by the fusion of mononuclear cells of asynchronous populations.[141,201,264] When osteoclasts are active rather than resting, they possess an elaborately developed ruffled border from which hydrolytic enzymes are thought to be secreted.[278] These enzymes digest the organic portion of bone. The activity of osteoclasts and the morphology of the ruffled border can be modified and regulated by hormones such as parathyroid hormone (indirectly) and calcitonin, which has receptors on the osteoclast membrane.

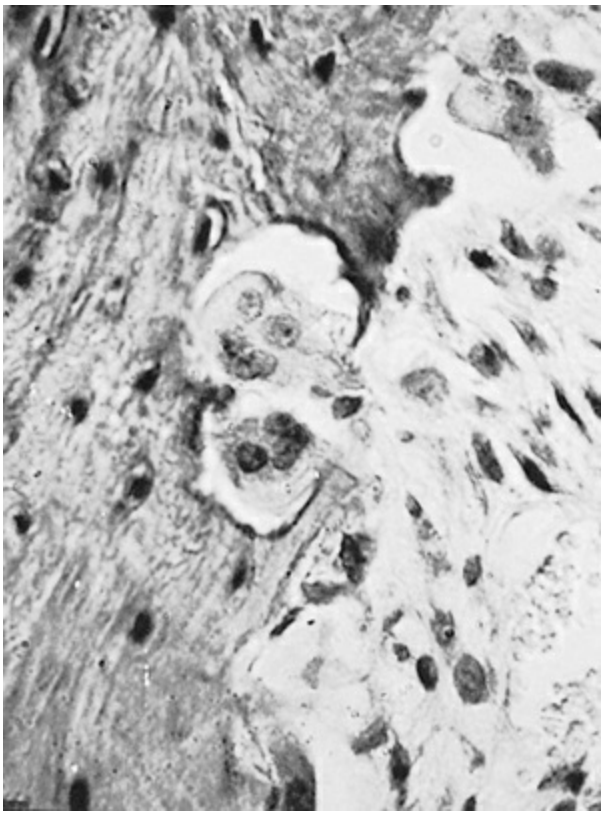

FIG. 3.53 Rat alveolar bone. This histologic view show two multinucleated osteoclasts in the Howship lacuna.

Another mechanism of bone resorption involves the creation of an acidic environment on the bone surface, thereby leading to the dissolution of the mineral component of bone. This event can be produced by different conditions, including a proton pump through the cell membrane of the osteoclast,[34] bone tumors, and local pressure[197] translated through the secretory activity of the osteoclast.

Ten Cate[264] described the sequence of events in the resorptive process as follows:

1. Attachment of osteoclasts to the mineralized surface of bone
2. Creation of a sealed acidic environment through the action of the proton pump, which demineralizes bone and exposes the organic matrix
3. Degradation of the exposed organic matrix to its constituent amino acids via the action of released enzymes (e.g., acid phosphatase, cathepsin)
4. Sequestering of mineral ions and amino acids within the osteoclast

Notably, the cellular and molecular events involved in bone remodeling have a strong similarity to many aspects of inflammation and repair. The relationships among matrix molecules (e.g., osteopontin, bone sialoprotein, SPARC [secreted protein, acidic, rich in cysteine], osteocalcin), blood clotting, and wound healing are clearly evident.[251]

Cells and Intercellular Matrix

Osteoblasts, which are the cells that produce the organic matrix of bone, are differentiated from pluripotent follicle cells. Alveolar bone is formed during fetal growth by intramembranous ossification, and it consists of a calcified matrix with osteocytes enclosed within spaces called *lacunae.* The osteocytes extend processes into *canaliculi* that radiate from the lacunae. The canaliculi form an anastomosing system through the intercellular matrix of the bone, which brings oxygen and nutrients to the osteocytes through the blood and removes metabolic waste products. Blood vessels branch extensively and travel through the periosteum. The endosteum lies adjacent to the marrow vasculature. Bone growth occurs via the apposition of an organic matrix that is deposited by osteoblasts. Haversian systems (i.e., *osteons*) are the internal mechanisms that bring a vascular supply to bones that are too thick to be supplied only by surface vessels. These are found primarily in the outer cortical plates and the alveolar bone proper.

Socket Wall

The socket wall consists of dense, lamellated bone, some of which is arranged in haversian systems and bundle bone. *Bundle bone* is the term given to bone adjacent to the periodontal ligament that contains a great number of Sharpey fibers[286] (Fig. 3.54). It is characterized by thin lamellae arranged in layers parallel to the root, with intervening appositional lines (Fig. 3.55). Bundle bone is localized within the alveolar bone proper. Some Sharpey fibers are completely calcified, but most contain an uncalcified central core within a calcified outer layer.[240] Bundle bone is not unique to the jaws; it occurs throughout the skeletal system wherever ligaments and muscles are attached.

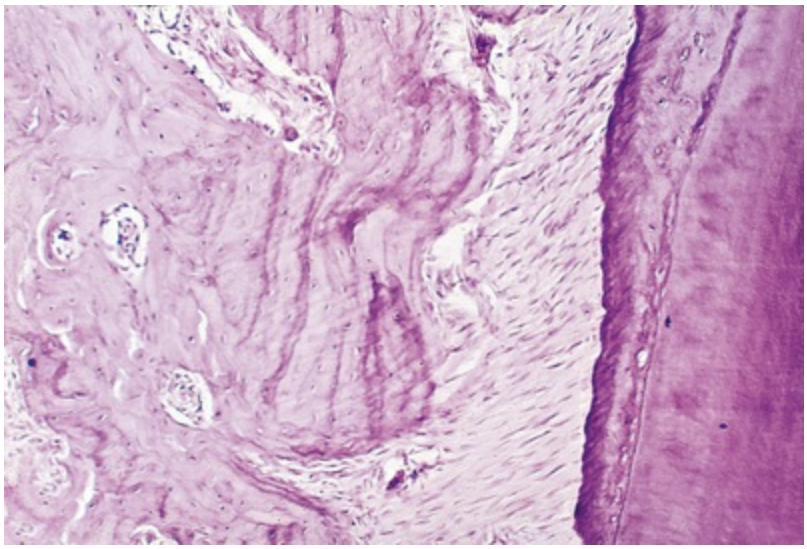

FIG. 3.54 Deep penetration of Sharpey fibers into bundle bone of a rat molar.

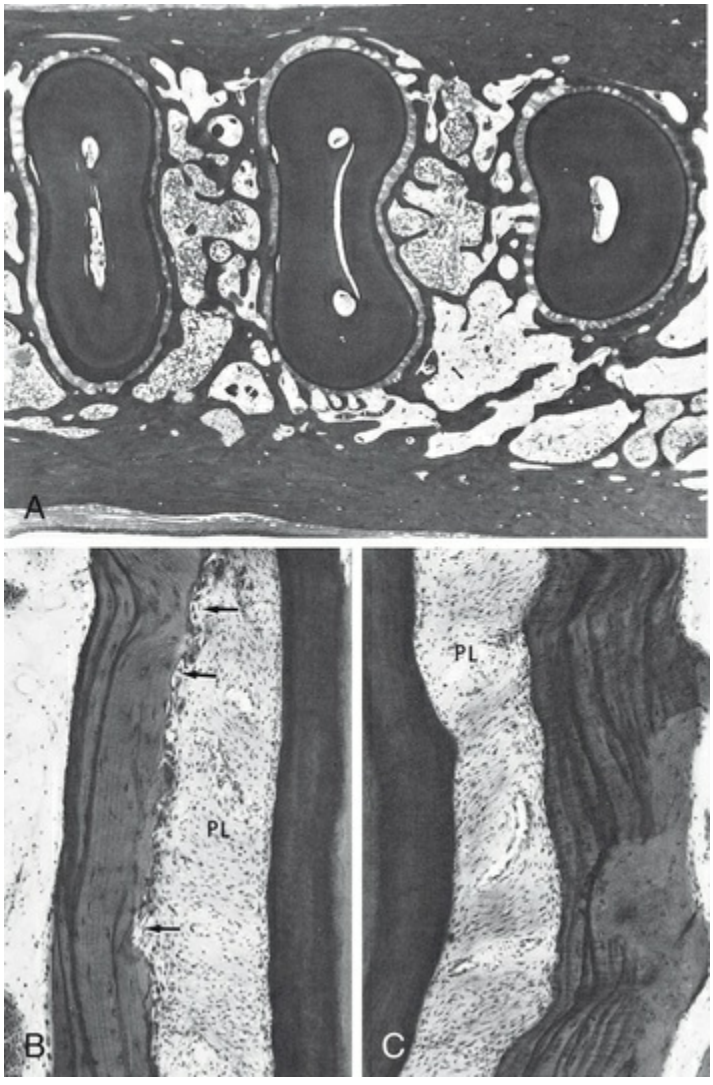

FIG. 3.55 Bundle bone associated with the physiologic mesial migration of the teeth. (A) Horizontal section through the molar roots during the process of mesial migration (*left*, mesial; *right*, distal). (B) Mesial root surface showing osteoclasis of bone *(arrows).* (C) Distal root surface showing bundle bone that has been partially replaced with dense bone on the marrow side. *PL*, Periodontal ligament.

The cancellous portion of the alveolar bone consists of trabeculae that enclose irregularly shaped marrow spaces lined with a layer of thin, flattened endosteal cells. Wide variation occurs in the trabecular pattern of cancellous bone,[200] which is affected by occlusal forces. The matrix of the cancellous trabeculae consists of irregularly arranged lamellae separated by deeply staining incremental and resorption lines indicative of previous bone activity, with an occasional haversian system.

Cancellous bone is found predominantly in the interradicular and interdental spaces and in limited amounts facially or lingually, except in the palate. In the adult human, more cancellous bone exists in the maxilla than in the mandible.

Bone Marrow

In the embryo and the newborn, the cavities of all bones are occupied by red hematopoietic marrow. The red marrow gradually undergoes a physiologic change to the fatty or yellow inactive type of marrow. In the adult, the marrow of the jaw is normally of the latter type, and red marrow is found only in the ribs, sternum, vertebrae, skull, and humerus. However, foci of the red bone marrow are occasionally seen in the jaws, often accompanied by the resorption of bony trabeculae.[41] Common locations are the maxillary tuberosity, the maxillary and mandibular molar and premolar areas, and the mandibular symphysis and ramus angle, which may be visible radiographically as zones of radiolucency.

Periosteum and Endosteum

Layers of differentiated osteogenic connective tissue cover all of the bone surfaces. The tissue that covers the outer surface of bone is

termed *periosteum,* whereas the tissue that lines the internal bone cavities is called *endosteum.*

The periosteum consists of an *inner layer* composed of osteoblasts surrounded by osteoprogenitor cells, which have the potential to differentiate into osteoblasts, and an *outer layer* rich in blood vessels and nerves and composed of collagen fibers and fibroblasts. Bundles of periosteal collagen fibers penetrate the bone, thereby binding the periosteum to the bone. The endosteum is composed of a single layer of osteoblasts and sometimes a small amount of connective tissue. The inner layer is the osteogenic layer, and the outer layer is the fibrous layer.

Cellular events at the periosteum modulate bone size throughout an individual's life span, and a change in bone size is probably the result of the balance between periosteal osteoblastic and osteoclastic activities. Little is currently known about the control of periosteal osteoblastic activity or the clinical importance of variations in periosteal bone formation.[196] Moreover, the nature and impact of periosteal bone resorption are virtually unexplored.

Interdental Septum

The interdental septum consists of cancellous bone that is bordered by the socket wall cribriform plates (i.e., lamina dura or alveolar bone proper) of approximating teeth and the facial and lingual cortical plates (Fig. 3.56). If the interdental space is narrow, the septum may consist of only the cribriform plate. In one study, for example, the space between the mandibular second premolars and first molars consisted of cribriform plate and cancellous bone in 85% of the cases and of only cribriform plate in the remaining 15%.[116] If the roots are too close together, an irregular “window” can appear in the bone between adjacent roots (Fig. 3.57). Between maxillary molars, the septum consisted of cribriform plate and cancellous bone in 66.6% of cases; it was composed of only cribriform plate in 20.8%, and it had a fenestration in 12.5%.[116]

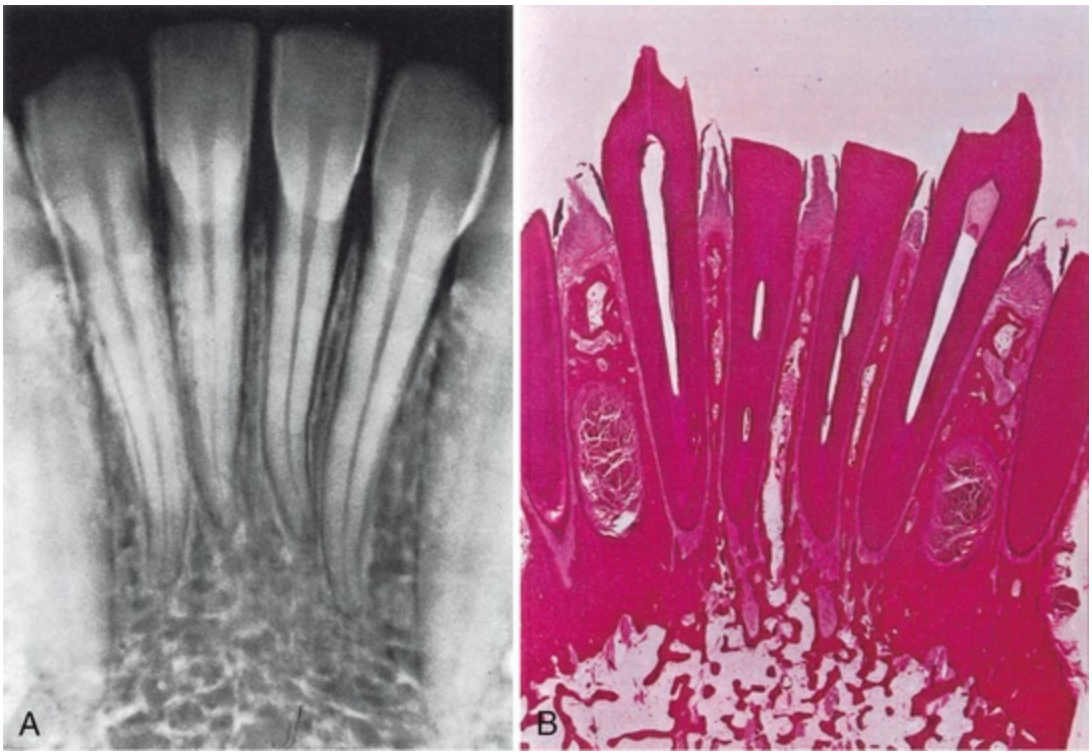

FIG. 3.56 Interdental septa. (A) Radiograph of the mandibular incisor area. Note the prominent lamina dura. (B) Interdental septa between the mandibular anterior teeth shown in A. There is a slight reduction in bone height with widening of the periodontal ligament in the coronal areas. The central cancellous portion is bordered by the dense bony cribriform plates of the socket, which form the lamina dura around the teeth in the radiograph. Attachments for the mentalis muscle are seen between the canine and lateral incisors. (From Glickman I, Smulow J: *Periodontal disease: clinical, radiographic, and histopathologic features,* Philadelphia, 1974, Saunders.)

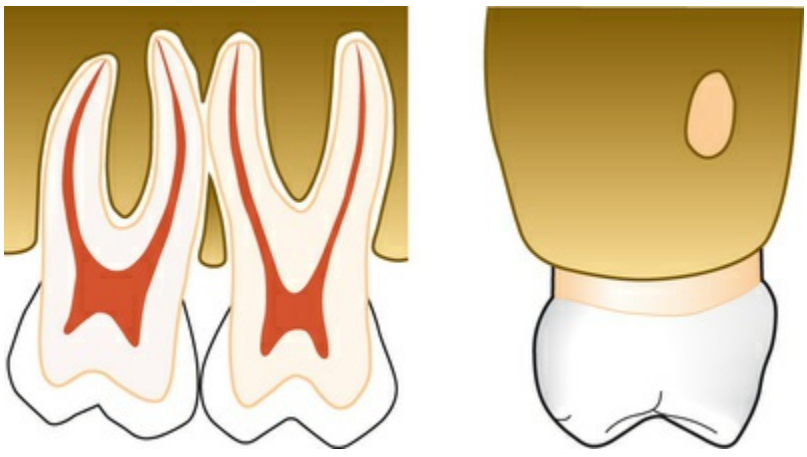

FIG. 3.57 Boneless “window” between adjoining close roots of molars.

Determining root proximity radiographically is important (see Chapters 33 and 35). The mesiodistal angulation of the crest of the interdental septum usually parallels a line drawn between the cementoenamel junctions of the approximating teeth.[209] The distance between the crest of the alveolar bone and the cementoenamel junction in young adults varies between 0.75 and 1.49 mm (average, 1.08 mm). This distance increases with age to an average of 2.81 mm.[93] However, this phenomenon may not be as much a function of age as of periodontal disease.

The mesiodistal and faciolingual dimensions and shape of the interdental septum are governed by the size and convexity of the crowns of the two approximating teeth as well as by the position of the teeth in the jaw and their degree of eruption.[209]

Osseous Topography

The bone contour normally conforms to the prominence of the roots, with intervening vertical depressions that taper toward the margin (Fig. 3.58). Alveolar bone anatomy varies among patients and has important clinical implications. The height and thickness of the facial and lingual bony plates are affected by the alignment of the teeth, the angulation of the root to the bone, and occlusal forces.

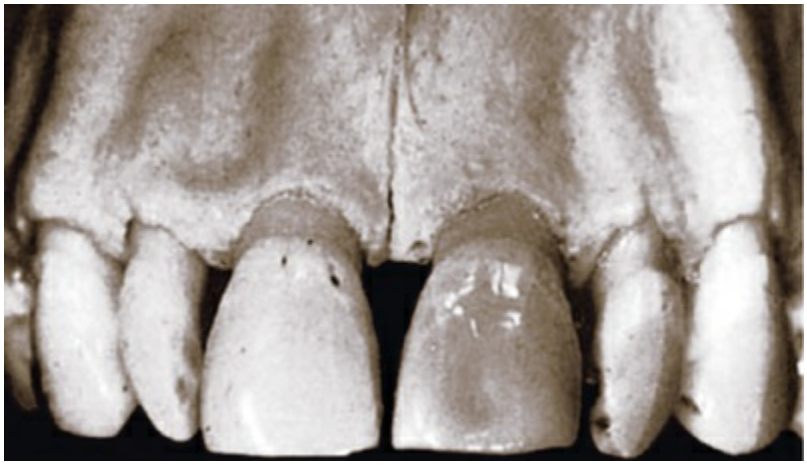

FIG. 3.58 Normal that the bone contour conforms to the prominence of the roots.

On teeth in labial version, the margin of the labial bone is located farther apically than it is on teeth that are in proper alignment. The bone margin is thinned to a knife edge, and it presents an accentuated arc in the direction of the apex. On teeth in lingual version, the facial bony plate is thicker than normal. The margin is blunt, rounded, and horizontal rather than arcuate. The effect of the root-to-bone angulation on the height of alveolar bone is most noticeable on the palatal roots of the maxillary molars. The bone margin is located farther apically on the roots, and it forms relatively acute angles with the palatal bone.[120] The cervical portion of the alveolar plate is sometimes considerably thickened on the facial surface, apparently as reinforcement against occlusal forces (Fig. 3.59).

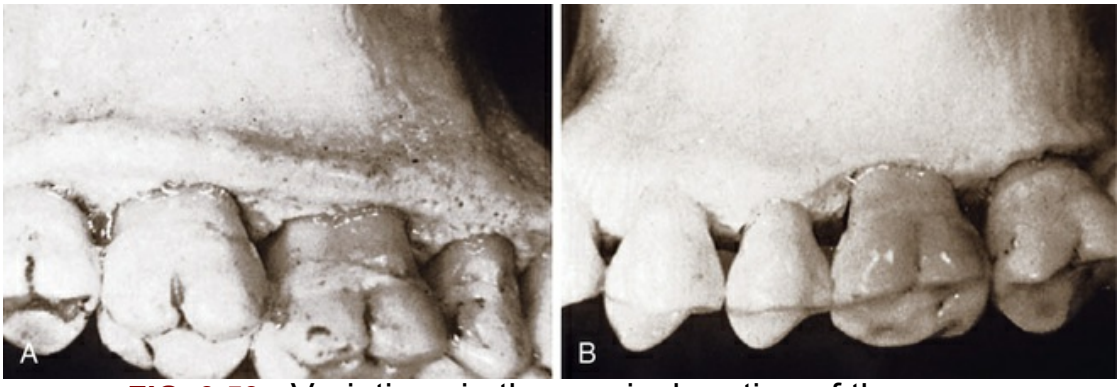

FIG. 3.59 Variations in the cervical portion of the buccal alveolar plate. (A) Shelflike conformation. (B) Comparatively thin buccal plate.

Fenestration and Dehiscence

Isolated areas in which the root is denuded of bone and the root surface is covered only by periosteum and overlying gingiva are termed *fenestrations.* In these areas, the marginal bone is intact. When the denuded areas extend through the marginal bone, the defect is called a *dehiscence* (Fig. 3.60).

FIG. 3.60 Dehiscence on the canine and fenestration of the first premolar.

Such defects occur on approximately 20% of the teeth; they occur more often on the facial bone than on the lingual bone, they are more common on anterior teeth than on posterior teeth, and they are frequently bilateral. Microscopic evidence of lacunar resorption may be present at the margins. The cause of these defects is not clear. Prominent root contours, malposition, and labial protrusion of the root in combination with a thin bony plate are predisposing factors.[78] Fenestration and dehiscence are important because they may complicate the outcome of periodontal surgery.

Remodeling of Alveolar Bone

In contrast with its apparent rigidity, alveolar bone is the least stable of the periodontal tissues, because its structure is in a constant state of flux. A considerable amount of internal remodeling takes place by means of resorption and formation, and this is regulated by local and systemic influences. Local influences include functional requirements on the tooth and age-related changes in bone cells. Systemic influences are probably hormonal (e.g., parathyroid hormone, calcitonin, vitamin D_3).

The remodeling of the alveolar bone affects its height, contour, and density and is manifested in the following three areas: adjacent

to the periodontal ligament, in relation to the periosteum of the facial and lingual plates, and along the endosteal surface of the marrow spaces.

Development of the Attachment Apparatus

After the crown has formed, the stratum intermedium and the stellate reticulum of the enamel organ disappear. The outer and inner epithelia of the enamel organ remain and form REE. The apical portion of this constitutes the Hertwig epithelial root sheath, which will continue to grow apically and which determines the shape of the root. Before the beginning of root formation, the root sheath bends horizontally at the future cementoenamel junction, thereby narrowing the cervical opening and forming the epithelial diaphragm. The epithelial diaphragm separates the dental follicle from the dental papilla.

After root dentin formation begins, the Hertwig root sheath breaks up and partially disappears; the remaining cells form the epithelial clusters or strands known as the *epithelial rests of Malassez* (see Fig. 3.37A). In multirooted teeth, the epithelial diaphragm grows in such a way that tonguelike extensions develop horizontally, thereby leaving spaces for each of the future roots to form.

The role of the Hertwig epithelial root sheath in root development, especially as it relates to the initiation of cementogenesis, has become a focus of research.[271] On the basis of various studies, it is now generally accepted that there is a transient period of the secretion of proteins (e.g., bone sialoprotein, osteopontin, amelin) by the cells of the Hertwig epithelial root sheath.[38,85] In addition, research shows that growth and differentiation factors may play roles in the development of the attachment apparatus of periodontal tissues. Pluripotent dental follicle cells have been shown to differentiate into osteoblasts, cementoblasts, and periodontal fibroblasts.[241]

Cementum

The rupture of the Hertwig root sheath allows the mesenchymal cells of the dental follicle to contact the dentin, where they start forming a continuous layer of cementoblasts. On the basis of immunochemical and ultrastructural studies, Thomas[270] and others[35,165] have speculated that cementoblasts can be of epithelial origin (i.e., the Hertwig root sheath), having undergone an epithelial mesenchymal transformation.

Cementum formation begins with the deposition of a meshwork of irregularly arranged collagen fibrils sparsely distributed in a ground substance or matrix called *precementum* or *cementoid.* This is followed by a phase of matrix maturation, which subsequently mineralizes to form cementum. Cementoblasts, which are initially separated from the cementum by uncalcified cementoid, sometimes become enclosed within the matrix and are trapped. After they are enclosed, they are referred to as *cementocytes,* and they will remain viable in a manner similar to that of osteocytes.

A layer of connective tissue known as the *dental sac* surrounds the enamel organ and includes the epithelial root sheath as it develops. The zone that is immediately in contact with the dental organ and continuous with the ectomesenchyme of the dental papilla is called the *dental follicle,*[262,263,266] and it consists of undifferentiated fibroblasts.

Periodontal Ligament

As the crown approaches the oral mucosa during tooth eruption, these fibroblasts become active and start producing collagen fibrils. They initially lack orientation, but they soon acquire an orientation that is oblique to the tooth. The first collagen bundles then appear in the region immediately apical to the cementoenamel junction and give rise to the gingivodental fiber groups. As tooth eruption progresses, additional oblique fibers appear and become attached to the newly formed cementum and bone. The transseptal and alveolar crest fibers develop when the tooth merges into the oral cavity. Alveolar bone deposition occurs simultaneously with periodontal ligament organization.[250]

Studies of the squirrel monkey have shown that, during eruption, cemental Sharpey fibers appear first, followed by Sharpey fibers

emerging from the bone.[107] Sharpey fibers are fewer in number and more widely spaced than those that emerge from the cementum. At a later stage, alveolar fibers extend into the middle zone to join the lengthening cemental fibers and to attain their classic orientation, thickness, and strength when occlusal function is established.

Early investigators suggested that the individual fibers, rather than being continuous, consisted of two separate parts spliced together midway between the cementum and the bone in a zone called the *intermediate plexus.* The plexus has been reported in the periodontal ligament of continuously growing incisors but not in the posterior teeth of rodents[119,177,300] or in actively erupting human and monkey teeth[107] and not after teeth reach occlusal contact. The rearrangement of the fiber ends in the plexus is supposed to accommodate tooth eruption without necessitating the embedding of new fibers into the tooth and the bone.[177] The existence of such a plexus, however, has not been confirmed by radioautographic data and other studies, and it is considered a microscopic artifact.[232]

The developing periodontal ligament and the mature periodontal ligament contain undifferentiated stem cells that retain the potential to differentiate into osteoblasts, cementoblasts, and fibroblasts.[172]

Alveolar Bone

Just before mineralization, osteoblasts start producing matrix vesicles. These vesicles contain enzymes (e.g., alkaline phosphatase) that help to jump-start the nucleation of hydroxyapatite crystals. As these crystals grow and develop, they form coalescing bone nodules, which, with fast-growing nonoriented collagen fibers, are the substructure of woven bone and the first bone formed in the alveolus. Later, through bone deposition, remodeling, and the secretion of oriented collagen fibers in sheets, mature lamellar bone is formed.[28,29]

The hydroxyapatite crystals are generally aligned with their long axes parallel to the collagen fibers, and they appear to be deposited on and within the collagen fibers in mature lamellar bone. In this way, bone matrix is able to withstand the heavy mechanical stresses applied to it during function.

The alveolar bone develops around each tooth follicle during

odontogenesis. When a deciduous tooth is shed, its alveolar bone is resorbed. The succedaneous permanent tooth moves into place and develops its own alveolar bone from its own dental follicle. As the tooth root forms and the surrounding tissues develop and mature, alveolar bone merges with the separately developing basal bone, and the two become one continuous structure. Although alveolar bone and basal bone have different intermediate origins, both are ultimately derived from neural crest ectomesenchyme.

Mandibular basal bone begins mineralization at the exit of the mental nerve from the mental foramen, whereas the maxillary basal bone begins at the exit of the infraorbital nerve from the infraorbital foramen.

Physiologic Migration of the Teeth

Tooth movement does not end when active eruption is completed and the tooth is in functional occlusion. With time and wear, the proximal contact areas of the teeth are flattened, and the teeth tend to move mesially. This is referred to as *physiologic mesial migration.* By the age of 40 years, this process results in a reduction of about 0.5 cm in the length of the dental arch from the midline to the third molars. Alveolar bone is reconstructed in compliance with the physiologic mesial migration of the teeth. Bone resorption is increased in areas of pressure along the mesial surfaces of the teeth, and new layers of bundle bone are formed in areas of tension on the distal surfaces (see Fig. 3.55).

External Forces and the Periodontium

The periodontium exists for the purpose of supporting teeth during function, and it depends on the stimulation that it receives from function for the preservation of its structure. Therefore a constant and sensitive balance is present between external forces and the periodontal structures.

Alveolar bone undergoes constant physiologic remodeling in response to external forces, particularly occlusal forces. Bone is removed from areas where it is no longer needed and added to areas where it is presently needed.

The socket wall reflects the responsiveness of alveolar bone to external forces. Osteoblasts and newly formed osteoid line the socket in areas of tension; osteoclasts and bone resorption occur in areas of pressure. Forces exerted on the tooth also influence the number, density, and alignment of cancellous trabeculae. The bony trabeculae are aligned in the path of the tensile and compressive stresses to provide maximal resistance to the occlusal force with a minimum of bone substance[100,247] (Fig. 3.61). When forces are increased, the cancellous bony trabeculae increase in number and thickness, and bone may be added to the external surface of the labial and lingual plates.

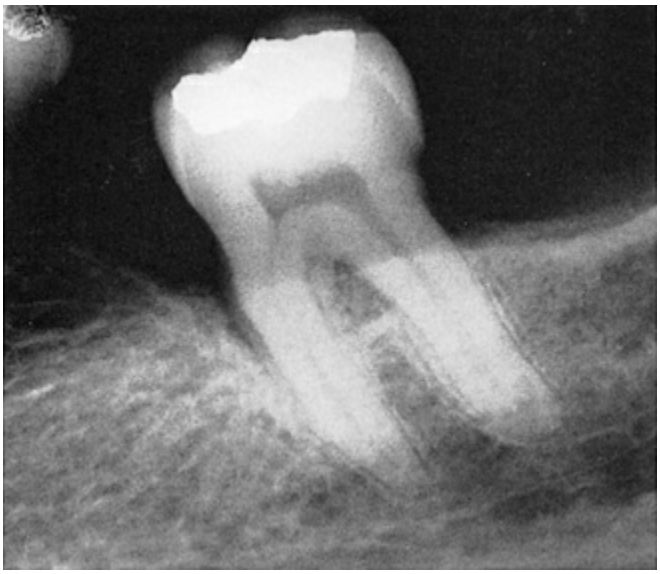

FIG. 3.61 Bony trabeculae realigned perpendicular to the mesial root of a tilted molar.

A study has shown that the presence of antagonists of occlusal force and the severity of periodontal disease increase the extension of periodontal tissue resorption.[66]

The periodontal ligament also depends on the stimulation provided by function to preserve its structure. Within physiologic limits, the periodontal ligament can accommodate increased function with an increase in width (Table 3.2), a thickening of its fiber bundles, and an increase in the diameter and number of Sharpey fibers. Forces that exceed the adaptive capacity of the periodontium produce injury called *trauma from occlusion.* Because

trauma from occlusion can only be confirmed histologically, the clinician is challenged to use clinical and radiographic surrogate indicators in an attempt to facilitate and assist with its diagnosis[111] (see Chapter 26).

TABLE 3.2

Comparison of Periodontal Width of Functioning and Functionless Teeth in a 38-Year-Old Man

	AVERAGE WIDTH OF PERIODONTAL SPACE		
	Entrance of Alveolus (mm)	**Middle of Alveolus (mm)**	**Fundus of Alveolus (mm)**
Heavy Function	0.35	0.28	0.30
Left upper second bicuspid			
Light Function	0.14	0.10	0.12
Left lower first bicuspid			
Functionless	0.10	0.06	0.06
Left upper third molar			

Modified from Kronfeld R: Histologic study of the influence of function on the human periodontal membrane. *J Am Dent Assoc* 18:1242, 1931.

When occlusal forces are reduced, the number and thickness of the trabeculae are reduced.[64] The periodontal ligament also atrophies and appears thinned; the fibers are reduced in number and density, disoriented,[11,208] and ultimately arranged parallel to the root surface (Fig. 3.62). This phenomenon is termed *disuse atrophy* or *afunctional atrophy*. With this condition, the cementum is either unaffected[64] or thickened, and the distance from the cementoenamel junction to the alveolar crest is increased.[204]

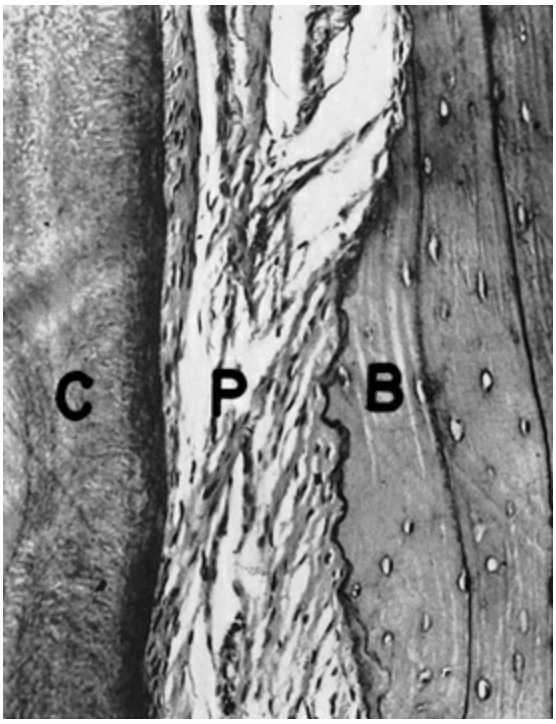

FIG. 3.62 Atrophic periodontal ligament *(P)* of a tooth devoid of function. Note the scalloped edge of the alveolar bone *(B)*, which indicates that resorption has occurred. *C,* Cementum.

Decreased occlusal function causes changes in the periodontal microvasculature, such as the occlusion of blood vessels and a decrease in the number of blood vessels.[121] For example, Murrell and colleagues[187] reported that the application and removal of orthodontic force produced significant changes in blood vessel number and density; however, no evidence-based explanation exists for why the force stimulated such changes in the number of blood vessels.

Orthodontic tooth movement is thought to result from site-specific bone remodeling in the absence of inflammation. It is well recognized that tensional forces will stimulate the formation and activity of osteoblastic cells, whereas compressive forces promote osteoclastic activity.[251]

Vascularization of the Supporting Structures

The blood supply to the supporting structures of the tooth is

derived from the inferior and superior alveolar arteries to the mandible and maxilla, and it reaches the periodontal ligament from three sources: apical vessels, penetrating vessels from the alveolar bone, and anastomosing vessels from the gingiva.[63]

The branches of the apical vessels supply the apical region of the periodontal ligament before the vessels enter the dental pulp. The transalveolar vessels are branches of the intraseptal vessels that perforate the lamina dura and enter the ligament. The intraseptal vessels continue to vascularize the gingiva; these gingival vessels in turn anastomose with the periodontal ligament vessels of the cervical region.[84]

The vessels within the periodontal ligament are contained in the interstitial spaces of loose connective tissue between the principal fibers, and they are connected in a netlike plexus that runs longitudinally and closer to the bone than the cementum[54] (Figs. 3.63 and 3.64). The blood supply increases from the incisors to the molars; it is greatest in the gingival third of single-rooted teeth, less in the apical third, and least in the middle; it is equal in the apical and middle thirds of multirooted teeth; it is slightly greater on the mesial and distal surfaces than on the facial and lingual surfaces; and it is greater on the mesial surfaces of the mandibular molars than on the distal surfaces.[33]

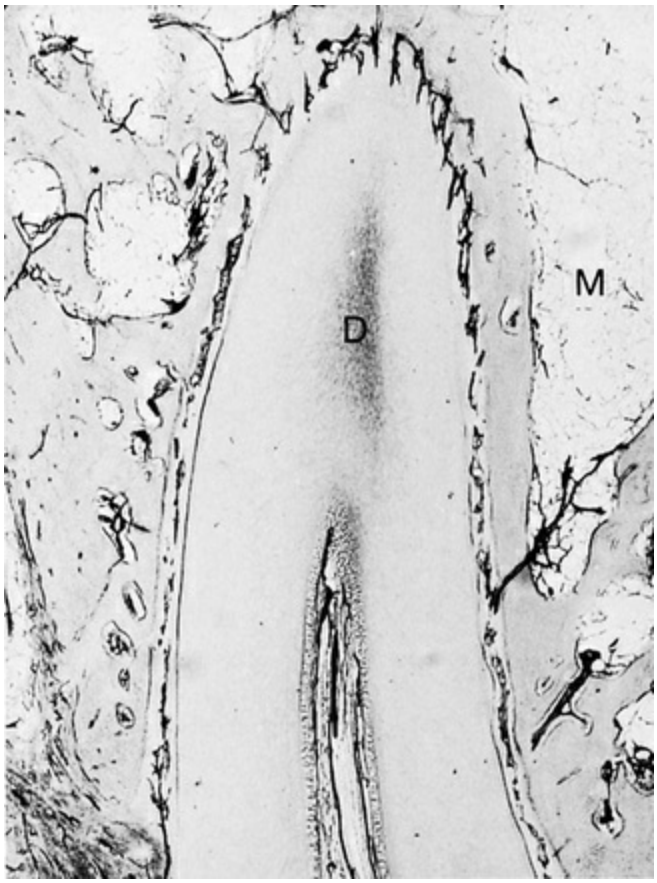

FIG. 3.63 Vascular supply of a monkey periodontium perfused with India ink. Note the longitudinal vessels in the periodontal ligament and the alveolar arteries passing through channels between the bone marrow *(M)* and the periodontal ligament. *D,* Dentin. (Courtesy Dr. Sol Bernick, Los Angeles, California.)

FIG. 3.64 Vascular supply to the periodontal ligament in a rat molar as viewed by scanning electron microscopy after perfusion with plastic and tissue corrosion. Middle and apical areas of the periodontal ligament are shown with longitudinal blood vessels from the apex *(below)* to the gingiva *(above)*, perforating vessels entering the bone *(b)*, and many transverse connections *(arrowheads)*. Apical vessels *(a)* form a cap that connects with the pulpal vessels.
(Courtesy NJ Selliseth and K Selvig, University of Bergen, Norway.)

The vascular supply to the bone enters the interdental septa through nutrient canals together with veins, nerves, and lymphatics. Dental arterioles, which also branch off the alveolar arteries, send tributaries through the periodontal ligament, and some small branches enter the marrow spaces of the bone through the perforations in the cribriform plate. Small vessels that emanate from the facial and lingual compact bone also enter the marrow and spongy bone.

The *venous drainage* of the periodontal ligament accompanies the arterial supply. Venules receive the blood through the abundant capillary network. In addition, arteriovenous anastomoses bypass the capillaries and are seen more frequently in apical and interradicular regions; their significance is unknown.

Lymphatics supplement the venous drainage system. Lymphatic channels that drain the region just beneath the junctional epithelium pass into the periodontal ligament and accompany the blood vessels into the periapical region.[42] From there, they pass through the alveolar bone to the inferior dental canal in the mandible or the infraorbital canal in the maxilla and then go on to the submaxillary lymph nodes.

CHAPTER 4

Aging and the Periodontium

Ian Needleman

CHAPTER OUTLINE

Effects of Aging on the Periodontium
Effects of Aging on the Progression of Periodontal Diseases
Aging and the Response to Treatment of the Periodontium

Increased health awareness and improvements in preventive dentistry have led to decreasing tooth loss for all age groups. The effects of this shift in tooth retention need to be considered carefully. In particular, increased life expectancy and greater health expectations may lead to changes in demand from older individuals for periodontal treatment and potentially a substantial increase in supportive periodontal therapy. Therefore, an understanding of the impact of aging on the periodontium is critical. This chapter first reviews the literature concerning the fundamental aspects of aging

on the periodontal tissues; broader aspects of aging are then examined and their possible effects on treatment outcomes discussed. The chapter has been updated following a detailed search of new research published since 2012.

The evidence base is not without problems, many of which make it difficult to draw conclusions about the effects of aging. Some of these problems include inconsistency with regard to the definition of a true "older" group, the inadequate exclusion of adults with systemic diseases that can modify study findings, and attempts to extrapolate results from animal research. For the purposes of this chapter, the effects of aging are limited to a narrow review of possible biologic and microbiologic changes. (For further information on the effects of aging on the dental and periodontal patient, the reader should consult Holm-Pedersen P, Walls AW, Ship JA: *Textbook of geriatric dentistry,* ed 3, Oxford, UK, 2015, Wiley-Blackwell.[23]) The reader should be fully aware that this narrower scope excludes many important age-associated phenomena, including reductions in an individual's cognitive or motor function skills, which may have a direct impact on periodontal management. These issues are discussed more fully in Chapter 42. Several studies have reported associations between periodontitis and cognitive impairment and aging,[16,51] although whether these findings reflect causation or simply association remains unclear. These links are difficult to entangle because *"chronic inflammation is a prominent feature of aging and of age-related diseases."*[48]

Clinical Correlation

For a full understanding of aging and managing periodontal health, in addition to this chapter on biology readers should understand aging more broadly, including cognitive and motor function effects that could affect oral hygiene, for instance.

Since first writing this chapter in 1999, the volume of new research into aging and the periodontium has not increased substantially. Highly sensitive molecular and genomic techniques have been employed in related laboratory research, and these are starting to provide insight into age-associated effects. These

approaches will likely prove fruitful in the future. Despite the limited data directly related to the periodontium, much effort and many resources have been used to research questions at least partially related to this topic. These include the effect of periodontal infection on general health (see Chapter 15) and the impact of osteoporosis on periodontal status (see Chapter 14).

Effects of Aging on the Periodontium

Gingival Epithelium

Thinning and decreased keratinization of the gingival epithelium have been reported with age.[52] The significance of these findings could mean an increase in epithelial permeability to bacterial antigens, a decreased resistance to functional trauma, or both. If so, such changes may influence long-term periodontal outcomes. However, other studies have found no age-related differences in the gingival epithelium of humans or dogs.[8,25] Other reported changes with aging include the flattening of rete pegs and altered cell density. Conflicting data regarding the surgical regeneration times for gingival epithelium have been ascribed to problems with research methodology.[57]

The effect of aging on the location of the junctional epithelium has been the subject of much speculation. Some reports show migration of the junctional epithelium from its position in healthy individuals (i.e., on the enamel) to a more apical position on the root surface, with accompanying gingival recession.[8] However, in other animal studies, no apical migration has been noted.[27] With continuing gingival recession, the width of the attached gingiva would be expected to decrease with age, but the opposite appears to be true.[2,3] Alternatively, the migration of the junctional epithelium to the root surface could be caused by the tooth erupting through the gingiva in an attempt to maintain occlusal contact with its opposing tooth (i.e., passive eruption) as a result of tooth surface loss from attrition (Fig. 4.1). The consensus is that gingival recession is not an inevitable physiologic process of aging, but rather that it can be explained by the cumulative effects of inflammation or trauma on the periodontium[6,8] (Fig. 4.2); this is discussed in more

detail later in this chapter. Changes in the apoptotic gene expression of gingival tissue with age have been reported in nonhuman primates.[19] This finding requires further research to understand its potential impact on gingival homeostasis and the pathogenesis of periodontal diseases.

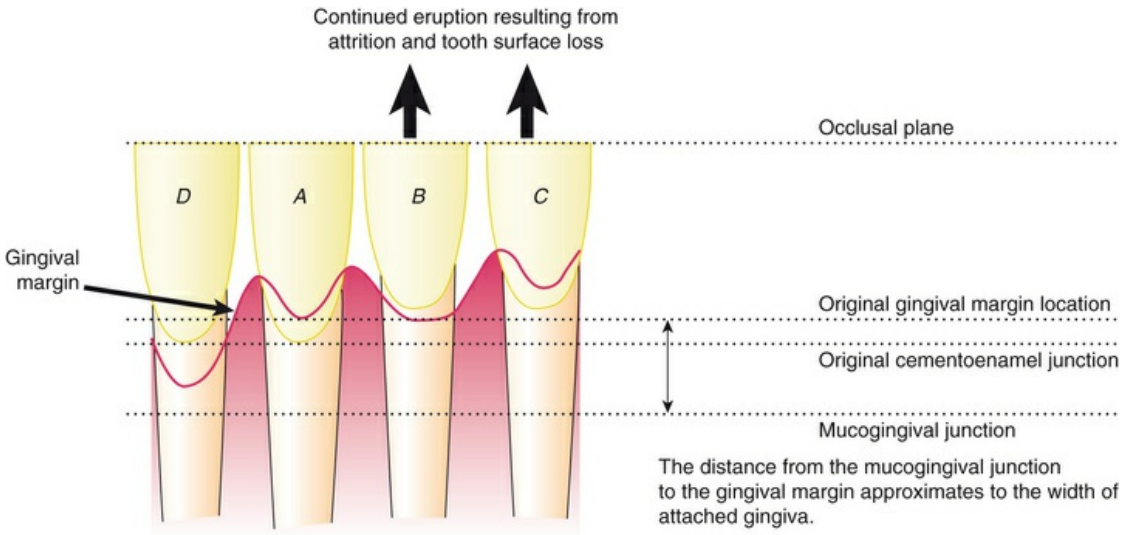

FIG. 4.1 Diagram showing the relationship of the gingival margin with the crown and root surface. *A,* Normal relationship with the gingival margin 1 to 2 mm above the cementoenamel junction. *B,* Wear of the incisal edge and continued tooth eruption. The gingival margin remains in the same position as shown in *A.* Therefore, the root surface is exposed, and clinical recession is evident. The width of the attached gingiva has not changed. *C,* Wear of the incisal edge and continued tooth eruption. The gingival margin has moved with the tooth; therefore, the entire dentogingival complex has moved coronally, with a resulting increase in the width of the attached gingiva. *D,* No wear of incisal edge is evident. The gingiva has moved apically, and clinical recession is evident. The width of attached gingiva is reduced.

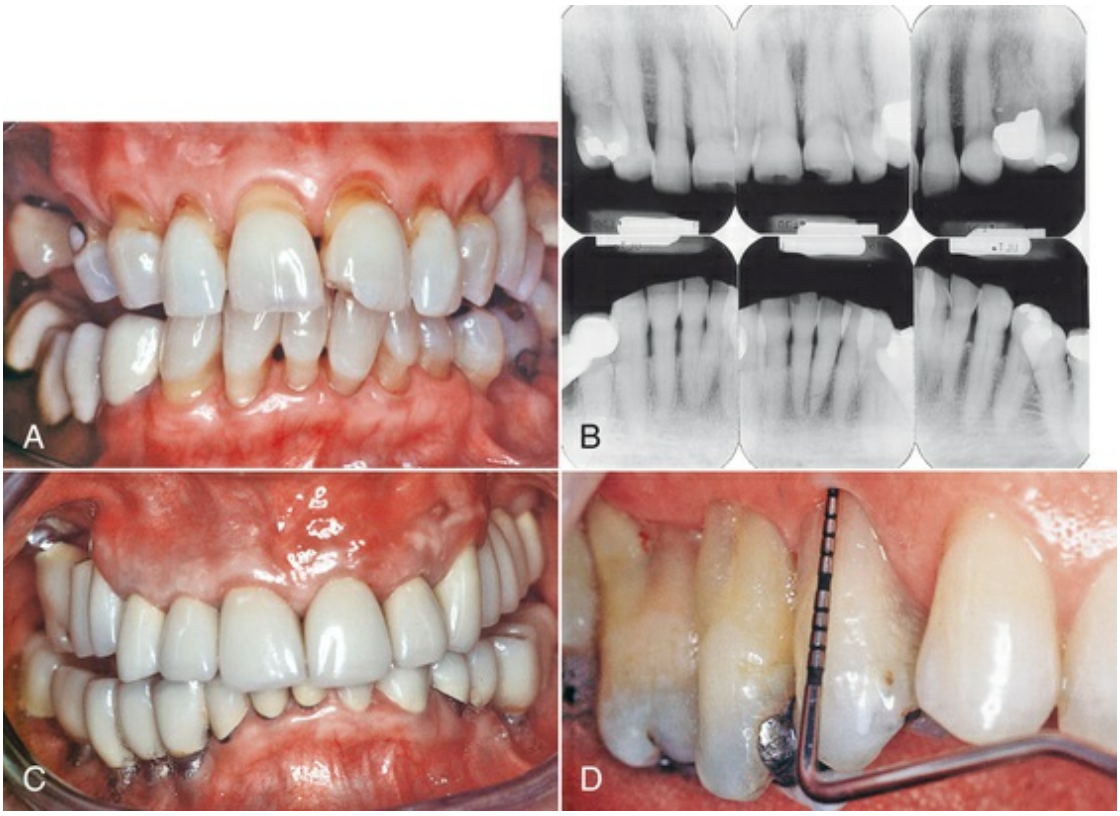

FIG. 4.2 Three scenarios illustrating the variation of the position of the gingival margin with age. (A) Overeruption with recession in an older individual (i.e., a 68-year-old woman) with generalized recession and a history of previously treated periodontitis. Note some overeruption of the lower anterior teeth and wear of teeth related to oral hygiene measures. (B) Radiographs of the patient shown in A. (C) Overeruption without recession in an older individual (i.e., a 72-year-old woman) with no periodontitis but marked lower incisor tooth wear and overeruption. Note how the gingival margin has migrated coronally with the erupting teeth. (D) Extensive recession in a younger individual (i.e., a 32-year-old man) with marked recession and no history of periodontitis. The recession has resulted from a combination of anatomically thin tissues and toothbrush-related trauma.

Key Fact

Gingival recession is not an inevitable consequence of aging but is

the cumulative result of trauma or periodontitis.

Gingival Connective Tissue

Increasing age results in coarser and denser gingival connective tissues.[59] Qualitative and quantitative changes in collagen have been reported. These changes include an increased rate of conversion of soluble to insoluble collagen, increased mechanical strength, and increased denaturing temperature. These results indicate increased collagen stabilization caused by changes in the macromolecular conformation.[49] Not surprisingly, an increased collagen content has been found in the gingivae of older animals, despite a lower rate of collagen synthesis decreasing with age.[8,57]

Periodontal Ligament

Changes in the periodontal ligament that have been reported with aging include decreased numbers of fibroblasts and a more irregular structure, thus paralleling the changes seen in the gingival connective tissues.[8,49,57] Other findings include decreased organic matrix production, decreased epithelial cell rests, and increased amounts of elastic fiber.[57] Conflicting results have been reported for changes in the width of the periodontal ligament in human and animal models. Although true variation may exist, this finding probably reflects the functional status of the teeth in the studies: the width of the space will decrease if the tooth is unopposed (i.e., hypofunction) or increase with excessive occlusal loading.[57] Both scenarios can be anticipated as a result of tooth loss in this population. These effects may also explain the variability in studies that have reported qualitative changes within the periodontal ligament.

Recognition that the periodontal ligament has an important role in alveolar bone metabolism has led to an increased interest in investigating this role in relation to the maintenance of periodontal health and the pathogenesis of periodontitis. One approach to investigating this role is to examine mediators of bone homeostasis, such as receptor activator of nuclear factor-κB ligand (RANKL) and osteoprotegerin (OPG). RANKL is widely recognized for its role in activating osteoclasts, whereas OPG antagonizes RANKL binding,

thus helping to maintain balance. The interplay of cytokines—and, in particular, the interleukin family—has also been extensively researched in periodontal pathogenesis. Some of the interleukins are potent mediators of inflammation (e.g., IL-1), whereas others have been shown to down-regulate this process (e.g., IL-4, IL-10). Therefore, evaluating the balance between these homeostatic processes would seem to be of great merit when assessing possible negative changes in the periodontium. Such a strategy appears to be predictive of hard tissue destruction among individuals with rheumatoid arthritis.[15] Findings comparing periodontal ligament cells in older individuals (i.e., >60 years old) with those of younger individuals (i.e., 15 to 20 years old) have suggested greater gene expression for proinflammatory cytokines.[7] This finding has been reported more widely as an age-associated change, although it is unclear whether it is a cause or an effect.[41] However, in addition to increased IL-1 and IL-6 expression, OPG was also increased, which suggests that increased OPG may be a homeostatic response to the up-regulation of inflammation.[7] If this homeostatic mechanism was effective, it may explain why an increase in inflammation did not result in greater tissue damage with age. Periodontal ligament cell proliferation was decreased with age, thereby suggesting an impairment of repair potential, although such an impact does not appear to be manifested clinically.[58] Further research investigating periodontal ligament cells from individuals diagnosed with periodontitis will be important to understand the potentially important relationship between aging and periodontal ligament cells.

Cementum

Some consensus regarding the effect of aging on cementum exists. An increase in cemental width is a common finding; this increase may be 5 to 10 times wider than in those of younger age.[8] This finding is not surprising because deposition continues after tooth eruption. The increase in width is greater apically and lingually.[57] Although cementum has limited capacity for remodeling, an accumulation of resorption bays explains the finding of increasing surface irregularity.[20]

Alveolar Bone

Reports of morphologic changes in alveolar bone mirror age-related changes in other bony sites. Specific to the periodontium are findings of a more irregular periodontal surface of bone and the less-regular insertion of collagen fibers.[57] Although age is a risk factor for the bone mass reductions in individuals with osteoporosis, it is not causative and therefore should be distinguished from physiologic aging processes.[24] Overriding the diverse observations of bony changes with age is the important finding that the healing rate of bone in extraction sockets appears to be unaffected by increasing age.[4] Indeed, the success of osseointegrated dental implants, which relies on intact bone healing responses, does not appear to be age related.[9] However, balancing this view is the observation that bone graft preparations (i.e., decalcified freeze-dried bone) from donors who were more than 50 years old possessed significantly less osteogenic potential than graft material from younger donors.[50] The possible significance of this phenomenon for normal healing responses needs to be investigated.

Bacterial Plaque

Dentogingival plaque accumulation has been suggested to increase with age.[22] This may be explained by the increase in hard tissue surface area as a result of gingival recession and the surface characteristics of the exposed root surface as a substrate for plaque formation as compared with enamel. Other studies have shown no difference in plaque quantity with age. This contradiction may reflect the different age ranges of experimental groups as variable degrees of gingival recession and root surface exposure. For supragingival plaque, no real qualitative differences have been shown for plaque composition.[22] With regard to subgingival plaque, one study showed subgingival flora to be similar to normal flora, whereas another study reported increased numbers of enteric rods and pseudomonads in older adults.[37,55] Mombelli[35] suggested caution when interpreting this finding because of the increased oral carriage of these species among older adults. It has been speculated that a shift occurs in the importance of certain periodontal

pathogens with age, specifically including an increased role for *Porphyromonas gingivalis* and a decreased role for *Aggregatibacter actinomycetemcomitans.* However, differentiating true age-related effects from the changes in ecologic determinants for periodontal bacteria will be difficult.

Another approach to investigating microbiology consists of conducting intervention studies and examining the impact on the microflora. Among individuals who were 60 to 75 years old, the prevalence of *P. gingivalis, Treponema forsythia, Treponema denticola, A. actinomycetemcomitans,* and *Prevotella intermedia* was high and was not clearly related to probing depth.[45] The finding of high levels of the organisms could have been related to the sample of individuals: the participants were mostly those with low incomes and with no recent dental care. Long-term use (i.e., 5 years) of a 0.12% chlorhexidine mouthrinse did not promote reductions in the proportions of the organisms in individuals experiencing alveolar bone loss as compared with the placebo mouthrinse, possibly because the mouthrinse routine may have been less frequent than daily.[45]

Immune and Inflammatory Responses

Advances in the study of the effects of aging on the immune response (i.e., immunosenescence) have altered the understanding of this phenomenon. In particular, more recent studies have set tighter controls on excluding individuals with systemic conditions known to affect the immune response. As a result, age has been recognized as having much less effect on the alteration of the host response than previously thought.[31] Differences between younger and older individuals can be demonstrated for T and B cells, cytokines, and natural killer cells, with increased inflammatory-type (M1) macrophage subset gene expression (in a nonhuman primate model),[18] but not for polymorphonuclear cells. McArthur[31] concluded the following: "Measurement of indicators of immune and inflammatory competency suggested that, within the parameters tested, there was no evidence for age-related changes in host defenses correlating with periodontitis in an elderly (65 to 75 years) group of individuals, with and without disease." Laboratory

studies have shown age-related changes in the expression of proinflammatory mediators,[11] innate immunity[21] and major histocompatibility complex II (MHC II) pathway gene expression,[17] with the potential to alter the pathology of periodontal diseases or antimicrobial function. However, the relevance of these findings to the clinical situation has not been demonstrated. Age-related differences in the inflammatory response among individuals with gingivitis have been clearly demonstrated and are discussed later in this textbook.

In relation to systematic inflammatory responses, C-reactive protein (CRP) is an acute phase protein that is widely regarded as a marker of inflammatory burden and response to bacterial infection.[53] In an investigation of serum CRP levels among individuals who were 60 to 75 years old and comparing individuals with progressive periodontitis with those with stable disease, CRP levels were increased in people with progressive periodontitis and no other systemic conditions.[56] This finding may indicate that inflammatory burden can be investigated with the use of CRP, although growing evidence indicates that CRP alone may not be as reliable a marker in older people.[46]

A further modulator of the immune and inflammatory responses is nutrition. Interest in this field is increasing rapidly as part of both medicine and periodontology.[10] Nutrition has been studied extensively in geriatric medicine as a result of the nutritional intake changes that occur with age. The impact of nutrition as a potential risk factor for periodontal diseases and their progression is therefore of interest. Emerging data suggest a negative association of serum folate with periodontitis. After controlling for major known confounders, lower serum folate levels in dentate adults who are more than 60 years old are associated with greater levels of periodontitis.[61] These cross-sectional data cannot demonstrate causality alone, but the recognized relationship between folate protection and chronic inflammatory diseases (e.g., cardiovascular disease[33]) offers biologic plausibility to a potential relationship that merits further investigation with prospective studies.

Although many contradictions exist, a survey of the literature demonstrates that some age-related changes are evident in the periodontium and the host response. Whether these changes are

significant in the alteration of the progression of periodontal diseases or the response of an older adult to periodontal treatment will be examined next.

Effects of Aging on the Progression of Periodontal Diseases

In a classic experimental gingivitis study, subjects were rendered free of plaque and inflammation through frequent professional cleaning. After this was achieved, the subjects abstained from oral hygiene measures for periods of 3 weeks to allow gingivitis to develop.[30] In this experimental model, a comparison of developing gingivitis between younger and older individuals demonstrated a greater inflammatory response in older subjects, both in humans and in dogs.[8,12,13,22] In the older age group (i.e., 65 to 80 years), the findings included a greater amount of infiltrated connective tissue, increased gingival crevicular fluid flow, and an increased gingival index.[12,13] Other studies have not demonstrated differences between subjects; this finding may be related to smaller differences between the ages of the younger and older experimental groups.[60] Intriguingly, even at the baseline level of excellent gingival health before the commencement of plaque accumulation, differences may exist between groups, with older individuals demonstrating more inflammation.[12,13]

The phrase "getting long in the tooth" expresses a widespread belief that age is inevitably associated with an increased loss of connective tissue attachment. However, this observation may equally reflect cumulative exposure to a number of potentially destructive processes. These exposures may include plaque-associated periodontitis, long-term mechanical trauma from toothbrushing, and iatrogenic damage from unfavorable restorative dentistry or repeated scaling and root planing. The effects of these exposures act in one direction only (i.e., an increased loss of attachment).

In an attempt to differentiate the effects of age from these other processes, several studies have been designed to eliminate confounding issues and to address more clearly the question of age

as a risk factor for periodontitis. A *risk factor* is defined as "any characteristic, behavior, or exposure with an association to a particular disease. The relationship is not necessarily causal in nature. … Some risk factors, if causal, can be modified to reduce one's risk of initiation or progression of disease, such as smoking or improved oral hygiene … while other factors cannot be modified, such as genetic factors."[14] The conclusions from these studies are strikingly consistent and show that the effect of age is either nonexistent or provides a small and clinically insignificant increased risk of loss of periodontal support.[29,34,38,42,43] Indeed, in comparison with the odds ratio of 20.52 for poor oral hygiene status and periodontitis, the odds ratio for age was only 1.24,[1] and smoking was much more influential than age.[38] Therefore, age has been suggested to be not a true risk factor but rather a background or associated factor for periodontitis.[42] In addition, the clarification of a genetic basis for susceptibility to severe forms of periodontitis underlines the overriding importance of plaque, smoking, and susceptibility in explaining most of the variations in periodontal disease severity among individuals.[26] Nevertheless, a longitudinal study of essentially untreated periodontitis in an older adult (≥70 years old) Japanese population indicated that 296 of 394 individuals (75%) had a least 1 site with 3 mm or more loss of attachment over a 2-year period.[39] Smoking and a baseline attachment level of 6 mm or more were significantly associated with disease progression. A more recent study modeling the transition of periodontal health states over a 2-year period estimated that the risk of transitioning from health to gingivitis was overall reduced by 3% with age.[32] Each year of age increase was associated with a 2% decreased risk of such a transition. Furthermore, increased age was not statistically associated with an increased risk of transitioning from health or gingivitis to periodontitis.

Aging and the Response to Treatment of the Periodontium

The successful treatment of periodontitis requires both meticulous home plaque control by the patient and meticulous supragingival

and subgingival debridement by the therapist.[36] Unfortunately, only a few studies have directly compared such an approach among patients of different age groups. The few studies that have done so clearly demonstrate that, despite the histologic changes in the periodontium with aging, no differences in response to nonsurgical or surgical treatment have been shown for periodontitis.[5,28,58] However, if plaque control is not ideal, the continued loss of attachment is inevitable. Furthermore, without effective periodontal therapy, the progression of disease may be faster with increasing age.[44] Attempts to increase plaque control by chemical means have also been reported.[54]

A purely biologic or physiologic review indicates that aging has some impact on the structure and function of the periodontium, as well as on the immune response and the nature of either supragingival or subgingival plaque. However, these changes have a negligible impact on an individual's responsiveness to treatment. Aging may affect other aspects of the management of periodontal health (e.g., the risk of root caries[47]; see Chapter 42), and the resulting difficulties should not be underestimated. One study identified greater compliance with supportive maintenance among older individuals as compared with younger patients.[40]

Key Fact

The biologic effects of aging have either no impact or a minimal impact on an individual's response to periodontal treatment. However, other factors may have a profound impact, including cognitive and motor skills as well as medical history.

Case Scenario 4.1

Patient:
72-year-old male

Chief Complaint:
"My gums are receding."

Background Information

Patient is a past smoker (quit smoking 20 years ago), he did not report any systemic conditions, and he is not on any medications except iron supplements. He drinks three cups of coffee a day. His last dental cleaning was done 3 years ago, and patient denies flossing but reports brushing once a day. He reports consuming orange juice every day.

Current Findings:

Probing depths were in the range of 2 to 7 mm; bleeding on probing % was 47 with poor oral hygiene.

Case-Based Questions	Solution and Explanation
1. Based on the history presented by this patient, the following are likely sources of the black staining noted on his teeth EXECPT: A. Orange juice intake B. Coffee consumption C. Intake of iron supplements D. Tobacco use	**Answer: A** **Explanation:** Except orange juice, the rest, if ingested for a prolonged period of time, causes brown to black staining of teeth.
2. Does aging influence the microbiology of dental plaque? A. Yes B. No	**Answer: B** **Explanation:** Scientific evidence indicates that aging has minimal influence on the microbiology of dental plaque.
3. Is aging a risk factor for periodontal disease? A. Yes B. No	**Answer: B** **Explanation:** Aging does not appear to be a true risk factor for developing periodontitis.

CHAPTER OUTLINE

Gingival Diseases
Periodontitis
Medication-Related Osteonecrosis of the Jaw
Necrotizing Periodontal Diseases
Abscesses of the Periodontium
Periodontitis Associated With Endodontic Lesions
Developmental or Acquired Deformities and Conditions

Our understanding of the causes and pathogenesis of oral diseases

and conditions changes continually with increased scientific knowledge. In light of this fact, a classification can be most consistently defined by the differences in the clinical manifestations of diseases and conditions: they are clinically consistent and require little (if any) clarification by laboratory testing. The current classification of periodontal diseases is based on their extent (generalized versus localized), severity (slight, moderate, or severe), rate of progression (aggressive versus chronic), and localization (i.e., contained within the gingiva, as in gingivitis, or further involving periodontal bone loss, as in periodontitis). The existing definitions encompass the best available way to universally define a spectrum of diseases affecting the periodontal tissues and to guide therapeutic approaches. Nonetheless, the disease state is dynamic, and the appropriate diagnosis for an individual can change over time. For instance, a patient diagnosed with existing periodontitis who undergoes successful periodontal therapy may be classified as having a healthy but reduced periodontium (with slight, moderate, or severe attachment loss) at the reevaluation. Subsequently, if the same individual presents with gingival inflammation without signs of further attachment loss at a future appointment, the appropriate diagnosis would be "gingivitis on a reduced periodontium." Depending on their future compliance with home care and maintenance visits, patients may progress to periodontitis or maintain a healthy but reduced periodontium. The case example highlights the importance of conceptualizing the dynamic nature of inflammatory diseases that affect the periodontium, while appreciating the importance of commonly accepted definitions for periodontal diseases. If a case of gingivitis on a reduced periodontium relapses into periodontitis, the prognosis of the affected teeth will depend on the preexisting attachment loss.

The classification presented in this chapter is based on the most recent internationally accepted consensus on the diseases and conditions that affect the tissues of the periodontium. Box 5.1 presents the overall classification system that was proposed at the 1999 International Workshop for a Classification of Periodontal Diseases and Conditions. More recent views on the Classification of Periodontal Diseases and Conditions are also discussed. Each disease or condition is explored where clarification is needed. In

each case, the reader is referred to pertinent reviews on the subject and specific chapters within this book that discuss the topics in more detail.

Box 5.1

Classification of Periodontal Diseases and Conditions

Gingival Diseases

Plaque-induced gingival diseases[a]
Non–plaque-induced gingival lesions

Chronic Periodontitis[b]

Localized
Generalized

Aggressive Periodontitis

Localized
Generalized

Periodontitis as a Manifestation of Systemic Diseases

Necrotizing Periodontal Diseases

Necrotizing ulcerative gingivitis (NUG)
Necrotizing ulcerative periodontitis (NUP)

Abscesses of the Periodontium

Gingival abscess
Periodontal abscess
Pericoronal abscess

Periodontitis Associated With Endodontic Lesions

Endodontic–periodontal lesion
Periodontal–endodontic lesion
Combined lesion

Developmental or Acquired Deformities and Conditions

Localized tooth-related factors that predispose to plaque-induced gingival diseases or periodontitis
Mucogingival deformities and conditions around teeth
Mucogingival deformities and conditions on edentulous ridges
Occlusal trauma

[a]These diseases may occur on a periodontium with no attachment loss or on a periodontium with attachment loss that is stable and not progressing.

[b]Chronic periodontitis can be further classified based on extent and severity. As a general guide, extent can be characterized as localized (<30% of teeth involved) or generalized (>30% of teeth involved). Severity can be characterized based on the amount of clinical attachment loss (CAL) as follows: *slight* = 1 or 2 mm CAL, *moderate* = 3 or 4 mm CAL, and *severe* ≥5 mm CAL.

Data from Armitage GC: Development of a classification system for periodontal diseases and conditions. *Ann Periodontol* 4:1, 1999.

An updated classification system, which is currently being developed jointly by the American Academy of Periodontology (AAP) and the European Federation of Periodontology (EFP), is scheduled to publish around the time of the release of this book. The goal of this effort is to address some of the shortcomings that exist with the current classification system (discussed in this chapter), including diagnostic inaccuracy and significant overlap of disease entities. Several working groups were created to focus on specific disease entities using the currently available scientific evidence, resulting in the most substantial update to the classification system since 1999.

the companion website www.expertconsult.com.

Gingival Diseases

Dental Plaque–Induced Gingival Diseases

Gingivitis that is associated with retained dental plaque is the most common form of gingival disease (Fig. 5.1). Box 5.2 outlines the classifications of gingival diseases. These diseases may occur on a periodontium with no attachment loss or on a periodontium with attachment loss that is stable and not progressing (i.e., reduced periodontium). The epidemiology of periodontal diseases is reviewed in Chapter 6, and its causes are detailed in Chapters 7 through 15 in this textbook.[15,23,26,39,40] What separates gingivitis from periodontitis is the containment of the inflammatory lesion within the gingiva in the former. As such, gingivitis is not associated with progressive attachment loss. This is not to say that gingivitis is solely associated with teeth showing no attachment loss (Fig. 5.2). Gingivitis can also be diagnosed in the gingiva of periodontitis-affected teeth that have previously lost attachment but that have been successfully treated with periodontal therapy to prevent any further attachment loss. In these treated cases, where gingival inflammation recurs around teeth with existing attachment loss due to a history of treated periodontitis, the appropriate diagnosis would be gingivitis on a reduced periodontium. This implies that gingivitis may be the diagnosis for inflamed gingival tissues associated with a tooth with no previous attachment loss or with a tooth that has previously undergone attachment and bone loss (i.e., with reduced periodontal support) and is not currently losing attachment or bone, even though gingival inflammation is present. Clinical attachment levels and radiographic records are needed to establish this diagnosis.

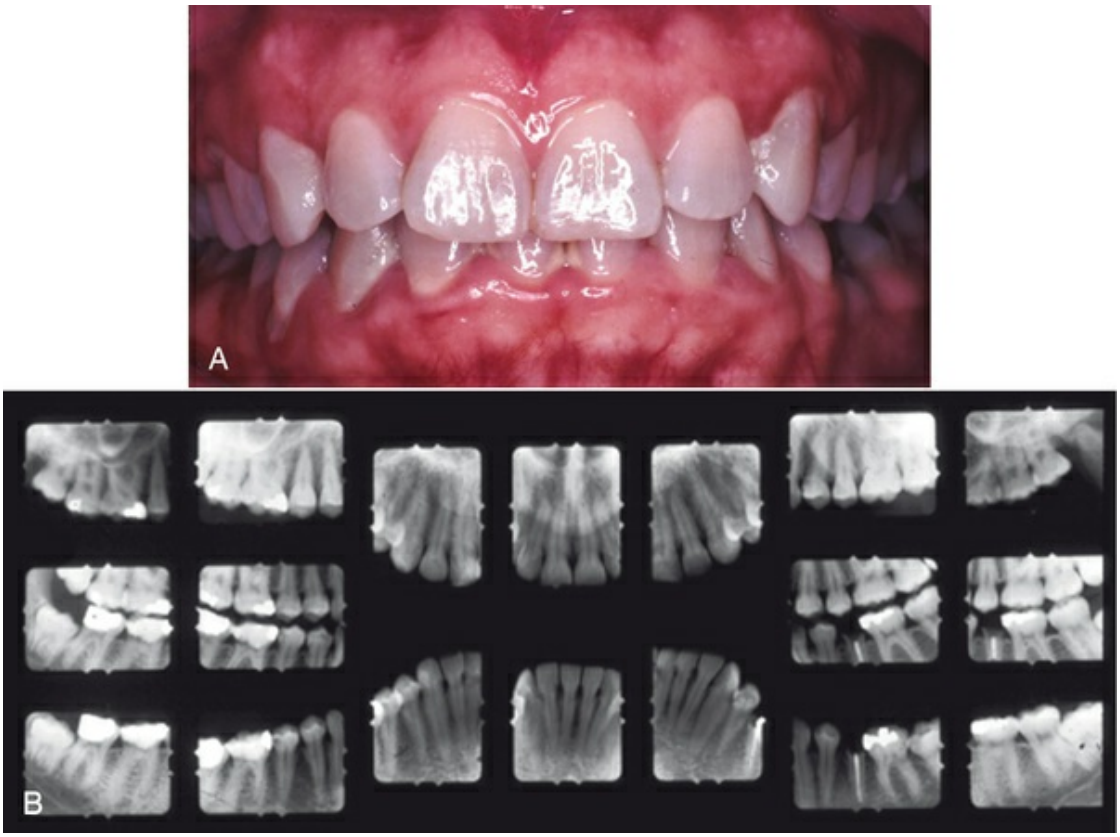

FIG. 5.1 (A) Plaque-related gingivitis depicts marginal and papillary inflammation, with 1- to 4-mm probing depths and generalized zero clinical attachment loss, except recession in tooth #28. (B) Radiographic images of the patient.

Box 5.2

Gingival Diseases

Dental Plaque–Induced Gingival Diseases

These diseases may occur on a periodontium with no attachment loss or with attachment loss that is stable and not progressing.

I. Gingivitis associated with dental plaque only
   A. Without local contributing factors
   B. With local contributing factors (see Box 5.4)

II. Gingival diseases modified by systemic factors
   A. Associated with endocrine system

1. Puberty-associated gingivitis
2. Menstrual cycle–associated gingivitis
3. Pregnancy associated
    a. Gingivitis
    b. Pyogenic granuloma
4. Diabetes mellitus–associated gingivitis

B. Associated with blood dyscrasias
1. Leukemia-associated gingivitis
2. Other

III. Gingival diseases modified by medications
A. Drug-influenced gingival diseases
1. Drug-influenced gingival enlargements
2. Drug-influenced gingivitis
    a. Oral contraceptive–associated gingivitis
    b. Other

IV. Gingival diseases modified by malnutrition
A. Ascorbic acid deficiency gingivitis
B. Other

Non–Plaque-Induced Gingival Lesions

I. Gingival diseases of specific bacterial origin
A. *Neisseria gonorrhoeae*
B. *Treponema pallidum*
C. *Streptococcus* species
D. Other

II. Gingival diseases of viral origin
A. Herpesvirus infections
1. Primary herpetic gingivostomatitis
2. Recurrent oral herpes
3. Varicella zoster

B. Other

III. Gingival diseases of fungal origin
A. *Candida* species infections: generalized gingival candidiasis
B. Linear gingival erythema

- C. Histoplasmosis
- D. Other

IV. Gingival lesions of genetic origin
- A. Hereditary gingival fibromatosis
- B. Other

V. Gingival manifestations of systemic conditions
- A. Mucocutaneous lesions
  1. Lichen planus
  2. Pemphigoid
  3. Pemphigus vulgaris
  4. Erythema multiforme
  5. Lupus erythematosus
  6. Drug induced
  7. Other
- B. Allergic reactions
  1. Dental restorative materials
     a. Mercury
     b. Nickel
     c. Acrylic
     d. Other
  2. Reactions attributable to the following:
     a. Toothpastes or dentifrices
     b. Mouth rinses or mouthwashes
     c. Chewing gum additives
     d. Foods and additives
  3. Other

VI. Traumatic lesions (factitious, iatrogenic, or accidental)
- A. Chemical injury
- B. Physical injury
- C. Thermal injury

VII. Foreign body reactions

VIII. Not otherwise specified

Data from Holmstrup P: Non–plaque-induced gingival lesions. *Ann Periodontol* 4:20, 1999; and Mariotti A: Dental plaque-induced gingival diseases. *Ann Periodontol* 4:7, 1999.

FIG. 5.2 Maxillary second molar exhibits mild inflammation at mesial-palatal surface. However, the clinical attachment loss has been stable for 15 years after apical positioned flap and periodontal maintenance, which is consistent with remission. The appropriate diagnosis is gingivitis on a reduced periodontium.

Key Fact

Gingivitis may be the diagnosis for inflamed gingival tissues associated with a tooth without previous attachment loss or with a tooth that has previously undergone attachment and bone loss (i.e., with reduced periodontal support) but is not currently losing attachment, even though gingival inflammation is present. In the latter case the appropriate definition would be "gingivitis on a reduced periodontium."

Gingivitis Associated With Dental Plaque Only

Plaque-induced gingival disease is the result of an interaction between the microorganisms found in the dental plaque biofilm and the inflammatory host response. A cause-and-effect relationship between microbial plaque and gingivitis has been elegantly demonstrated by a classic experiment demonstrating that the cessation of oral hygiene consistently leads to the manifestation of gingivitis within 2 to 3 weeks in healthy adults.[25] Clinical

gingivitis is histologically characterized by a dense infiltrate of lymphocytes and other mononuclear cells, fibroblast alterations, increased vascular permeability, and continuing loss of collagen in response to the microbial challenge. However, the alveolar bone is not affected. Microbial plaque is thus considered to be the primary etiologic factor for gingivitis. The severity and duration of the inflammatory response interaction can be altered by the modifying local (see Chapter 13) or systemic modifying factors (see Chapters 14 and 15). Gingivitis is fully reversible in otherwise healthy persons within weeks following the removal of local factors and reduction of the microbial load around the teeth. As noted earlier, gingivitis is rapidly established in cases of generalized or localized inefficient plaque removal. Therefore it is crucial that patients are instructed in oral hygiene to maintain long-term gingival health.

Gingival Diseases Modified by Systemic Factors

Systemic factors that contribute to gingivitis—such as the endocrine changes associated with puberty (Fig. 5.3), the menstrual cycle, pregnancy (Fig. 5.4A), and diabetes—may exacerbate the gingival inflammatory response to plaque.[23,39] This altered response appears to result from the effects of systemic conditions on the host's cellular and immunologic functions, but the primary etiologic factor is still considered to be microbial plaque. One example of altered host response due to systemic factors is apparent during pregnancy when the incidence and severity of gingival inflammation may increase even in the presence of low levels of plaque.

FIG. 5.3 A 13-year-old female with hormone-exaggerated marginal and papillary inflammation, with 1- to 4-mm probing depths yet minimal clinical attachment loss. (A) Facial view. (B) Lingual view.

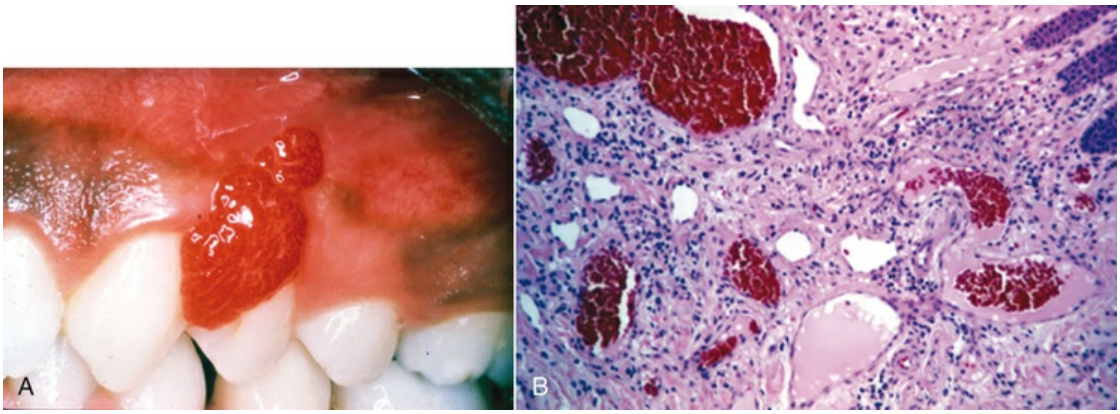

FIG. 5.4 (A) Clinical image of pyogenic granuloma in a 27-year-old pregnant female. (B) Histologic image depicts dense inflammatory infiltrate and prominent vessels.

Clinical Correlation

Increased estrogen and progesterone levels in pregnant women during their third trimester have been associated with increased severity of gingivitis via substituting nutrient needs for certain oral bacteria and stimulating their proliferation. One species that has been specifically associated with gingivitis during pregnancy is *Prevotella intermedia.*

In blood dyscrasias (e.g., leukemia), the reduced number of immunocompetent lymphocytes in the periodontal tissues is associated with increased edema, erythema, and bleeding of the gingiva as well as gingival enlargement that may be associated with the swollen, spongy gingival tissues caused by the excessive infiltration of malignant blood cells (Fig. 5.5).

FIG. 5.5 A 12-year-old female with a primary medical diagnosis of leukemia that exhibits swollen/spongy gingiva.

Gingival Diseases Modified by Medications

Gingival diseases that are modified by medications include gingival overgrowth due to anticonvulsant drugs such as phenytoin, immunosuppressive drugs such as cyclosporine (Fig. 5.6), and

calcium channel blockers such as nifedipine (Fig. 5.7), verapamil, diltiazem, and sodium valproate.[15,26,39] The development and severity of gingival enlargement in response to medications is patient specific and may be influenced by uncontrolled plaque accumulation as well as by elevated hormonal levels. The increased use of oral contraceptives by premenopausal women has also been previously associated with a higher incidence of gingival inflammation and gingival enlargement. Although this fact stood true for earlier contraceptive formulations, existing contraceptives that include more modest doses of active ingredients are not commonly associated with gingival inflammation.

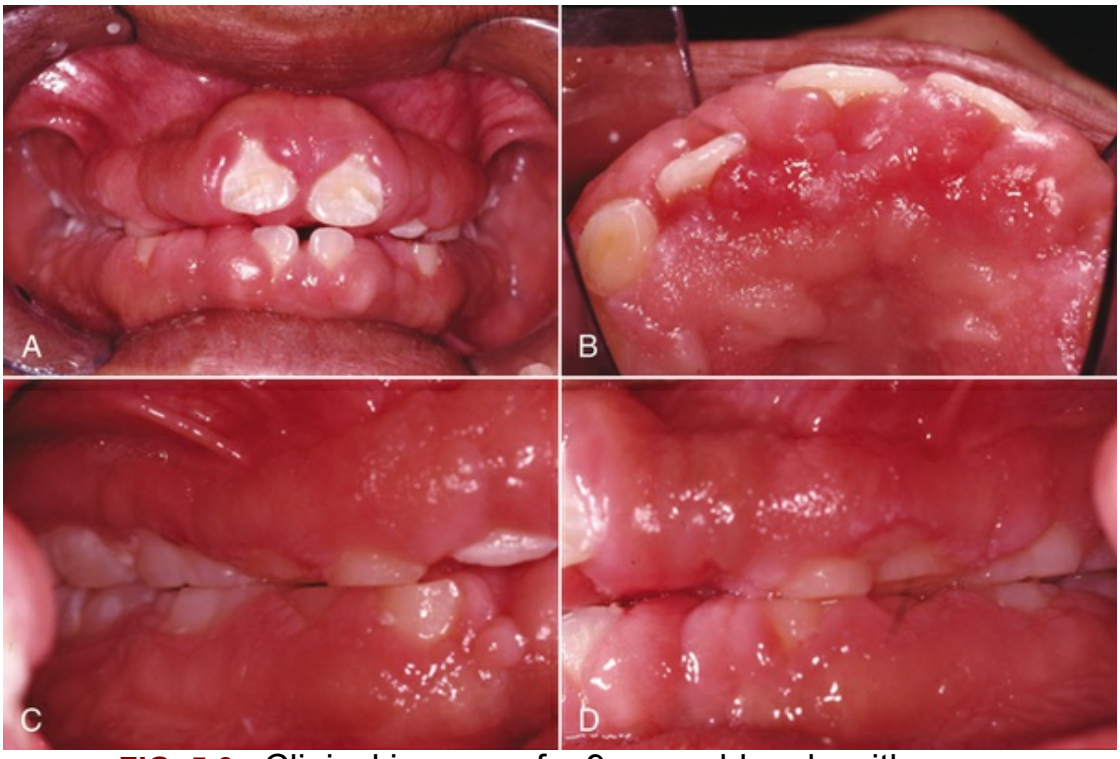

FIG. 5.6 Clinical images of a 9-year-old male with severe gingival overgrowth secondary to heart transplant and cyclosporine therapy.

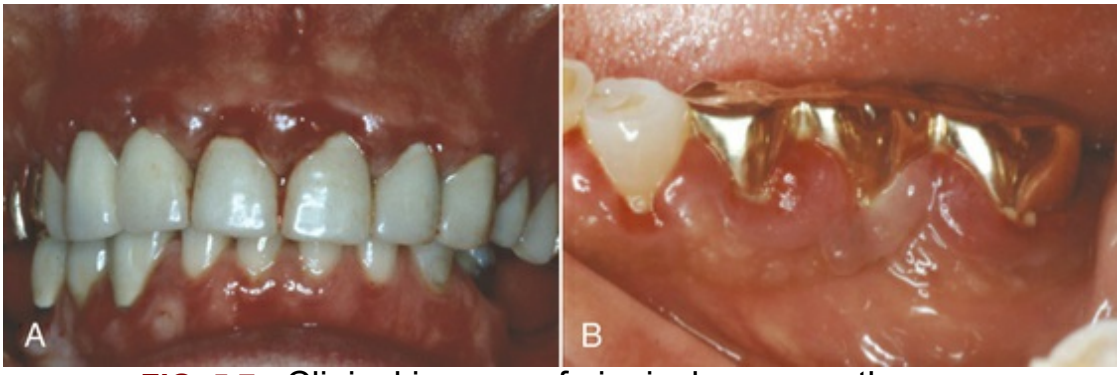

FIG. 5.7 Clinical images of gingival overgrowth following use a of calcium channel blocker to control hypertension.

Gingival Diseases Modified by Malnutrition

Gingival diseases modified by malnutrition have received attention because of clinical descriptions of bright red, swollen, and bleeding gingiva associated with severe ascorbic acid (vitamin C) deficiency or scurvy.[26] Various nutrients, such as long chain omega-3 fatty acids, have been found to have immunomodulatory properties, whereas others act to ameliorate the destructive effects of reactive oxygen species (ROS) functioning as ROS scavengers. Nonetheless, the available evidence to support a clinically impactful role for mild nutritional deficiencies in the development or severity of gingival inflammation in humans is limited. Data have shed light on the implication of increased dietary carbohydrate intake on gingivitis, in addition to its known causal role on the occurrence of dental caries.[19]

Non–Plaque-Induced Gingival Lesions

Oral manifestations of systemic conditions that produce lesions in the tissues of the periodontium are less common than plaque-induced gingivitis. This category mainly encompasses lesions of autoimmune or idiopathic etiology that can manifest in the gingiva. Benign mucous membrane pemphigoid is an example of a non–plaque-induced lesion associated with sloughing gingival tissues, which leave painful ulcerations of the gingiva (Fig. 5.8). In pemphigoid, autoimmune antibodies are targeted at the basement membrane, and histologically the destruction resembles a

subepithelial blister (Fig. 5.8C–D). Case Scenario 5.2 depicts gingival recession accompanied by a mucosal lesion located on the gingiva manifesting with a white lacy pattern with characteristic striations.

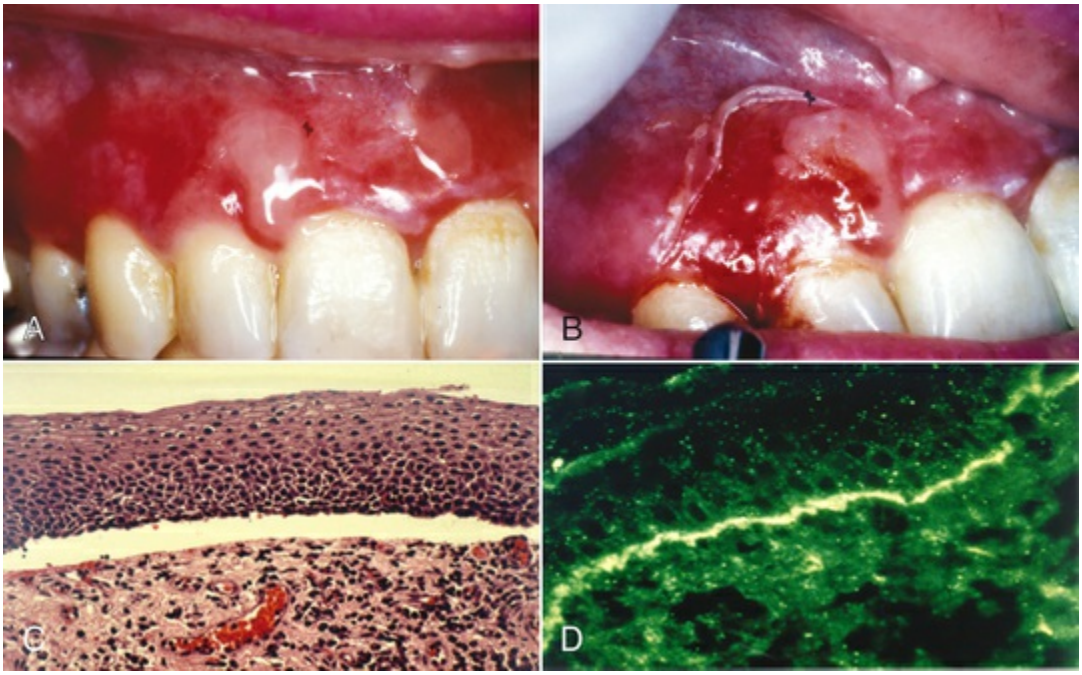

FIG. 5.8 A 62-year-old female with benign mucous membrane pemphigoid. (A–B) Clinical image with sloughing epithelial surface. (C) Hematoxylin and eosin (H&E) stain depicting separation of epithelium from connective tissue. (D) Immunofluorescent-labeled antibodies to basement membrane.

Gingival Diseases of Specific Bacterial Origin

Gingival diseases of this category are attributed to specific bacteria that cause characteristic lesions in the gingiva. *Neisseria gonorrhoeae* and *Treponema pallidum* that can be transferred as a result of sexually transmitted diseases such as gonorrhea and syphilis, respectively, cause characteristic lesions in the gingiva.[41,46] Refer to the online references for further description. Streptococcal gingivitis or gingivostomatitis is a rare entity that may present as an acute condition with fever, malaise, and pain associated with acutely inflamed, diffuse, red, and swollen gingiva with increased bleeding and occasional gingival abscess formation. The gingival infections

are usually preceded by tonsillitis.

Gingival Diseases of Viral Origin

Gingival diseases of viral origin may be caused by a variety of deoxyribonucleic acid and ribonucleic acid viruses, with the most common being the herpesviruses. A case example of herpetic stomatitis is demonstrated in Fig. 5.9A–B. Herpetic lesions are not uncommon and develop as intraoral blisters, usually grouped together, that quickly burst, leaving minuscule ulcerations. Lesions are frequently related to the reactivation of latent viruses, especially as a result of reduced immune function. The oral manifestations of viral infection have been comprehensively reviewed.[20,45] Viral gingival diseases are treated with topical or systemic antiviral drugs (Fig. 5.9C–D).

FIG. 5.9 (A–B) A 29-year-old male with primary herpetic infection and severe gingival inflammation. (C–D) Six weeks post systemic acyclovir.

Clinical Correlation

Unlike other herpetic recurrences, varicella zoster virus (VZV) usually manifests with a prodrome of tingling, itching, burning, or a unilateral numbness at the affected dermatome. These symptoms are followed by moderate to severe pain shortly after initiation and are very important for differential diagnosis.

Gingival Diseases of Fungal Origin

Gingival diseases of fungal origin are relatively uncommon in immunocompetent individuals, but they occur more frequently in immunocompromised individuals and in those with disturbed microbiota by the long-term use of broad-spectrum antibiotics.[20,46,47] The most common oral fungal infection is candidiasis (*Candida albicans* is often implicated). Candidiasis can also be seen under prosthetic devices, in individuals using topical steroids, and in individuals with decreased salivary flow, increased salivary glucose, or decreased salivary pH. A generalized candidal infection may manifest as white patches on the gingiva, tongue, or oral mucous membrane that can potentially be removed with gauze and leave a red, bleeding surface. In human immunodeficiency virus (HIV) seropositive persons, candidal infection may present as continuous erythematous stripe of the attached gingiva; this has been referred to as *linear gingival erythema* or *HIV-associated gingivitis* (see Chapter 30). The diagnosis of candidal infection can be made by culture, smear, or biopsy. Less common fungal infections have also been described.[46,47]

Gingival Diseases of Genetic Origin

Gingival diseases of genetic origin may involve the tissues of the periodontium and have been described in detail.[2] One of the most clinically evident conditions is *hereditary gingival fibromatosis,* which exhibits autosomal-dominant or (rarely) autosomal-recessive modes of inheritance. The gingival enlargement may completely cover the teeth, delay eruption, and present as an isolated finding; alternatively, it may be associated with several more generalized syndromes.

Gingival Manifestations of Systemic Conditions

Gingival manifestations of systemic conditions may appear as desquamative lesions, ulcerations of the gingiva, or both.[20,38,46] Allergic reactions that manifest with gingival changes are uncommon but have been observed in association with several restorative materials (Fig. 5.10A), toothpastes, mouthwashes, chewing gums (Fig. 5.11), and foods (see Box 5.2). The diagnosis of these conditions may prove difficult and may require an extensive history and the selective elimination of potential causes. Conjoint assessment with an allergologist is indicated, and percutaneous tests are often recommended. Histologic traits of biopsies from gingival allergic reactions include a dense infiltrate of eosinophilic cells (Fig. 5.10B–C).

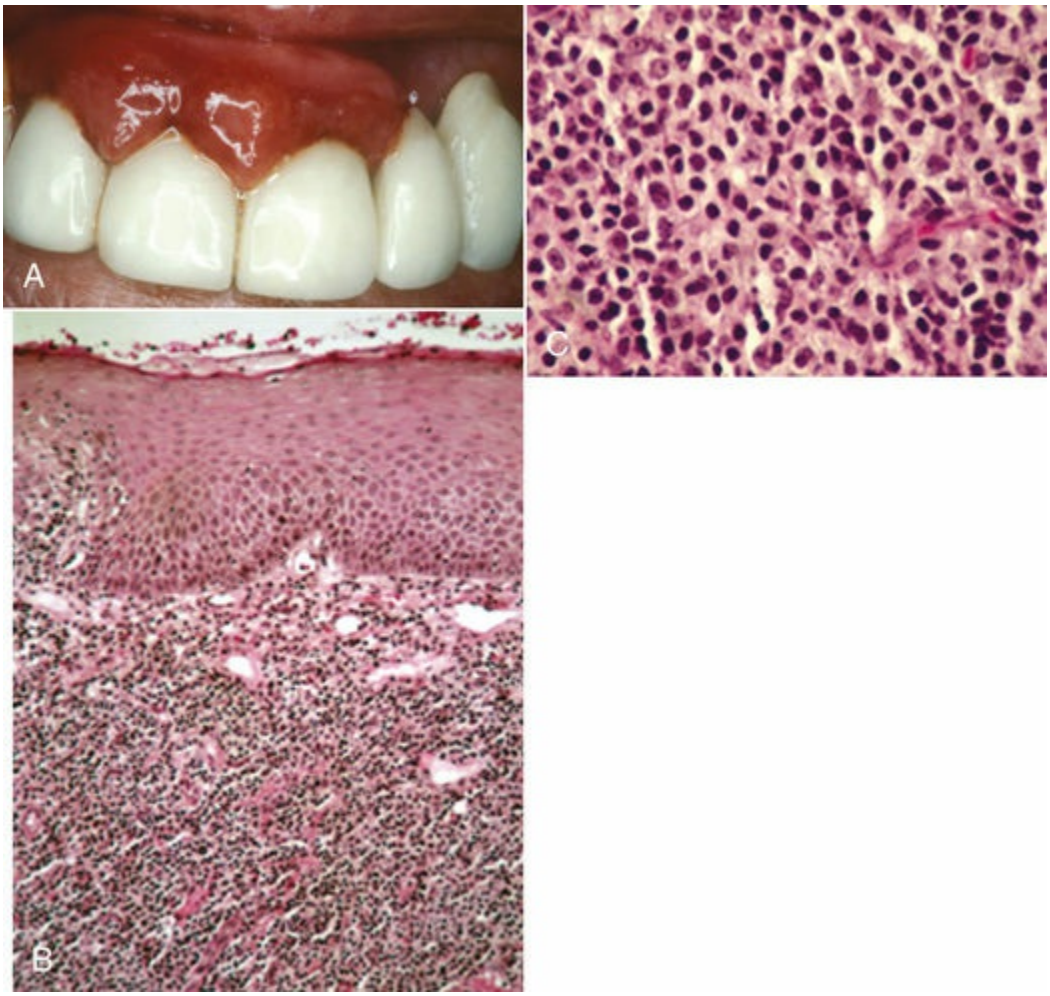

FIG. 5.10 (A) Localized pronounced gingival inflammation secondary to nickel allergy. (B–C) Biopsy

depicts dense infiltrate of plasma cells.

FIG. 5.11 Generalized severe allergic response of gingiva as a result of additive in chewing gum.

Traumatic Lesions

Traumatic lesions may be self-inflicted and *factitious* in origin, which means that they are intentionally or unintentionally produced by artificial means (Fig. 5.12). Other examples of traumatic lesions include toothbrush trauma that results in gingival ulceration, recession, or both.

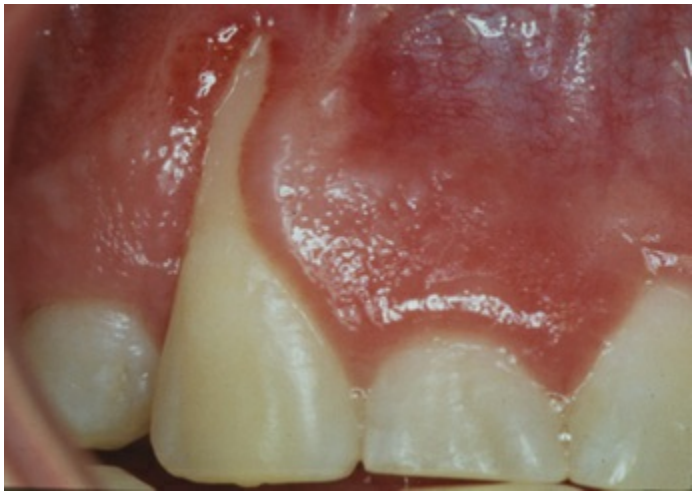

FIG. 5.12 Self-inflicted gingival dehiscence induced via

patient's fingernail.

Clinical Correlation

Individuals who perform aggressive horizontal brushing are often found to have gingival recession or cervical abrasion on the teeth quadrants contralateral to their dominant hand.

Iatrogenic trauma (i.e., induced by the dentist or health professional) to the gingiva may also lead to a gingival lesion. Such trauma may be caused directly (i.e., via use of dental instruments) or by the induction of cement or preventive or restorative materials (Fig. 5.13A). Peripheral ossifying fibroma may develop in response to the embedment of a foreign body (Fig. 5.13B–C). Self-inflicted *accidental damage* to the gingiva may also occur as a result of minor burns from hot foods and drinks.[20]

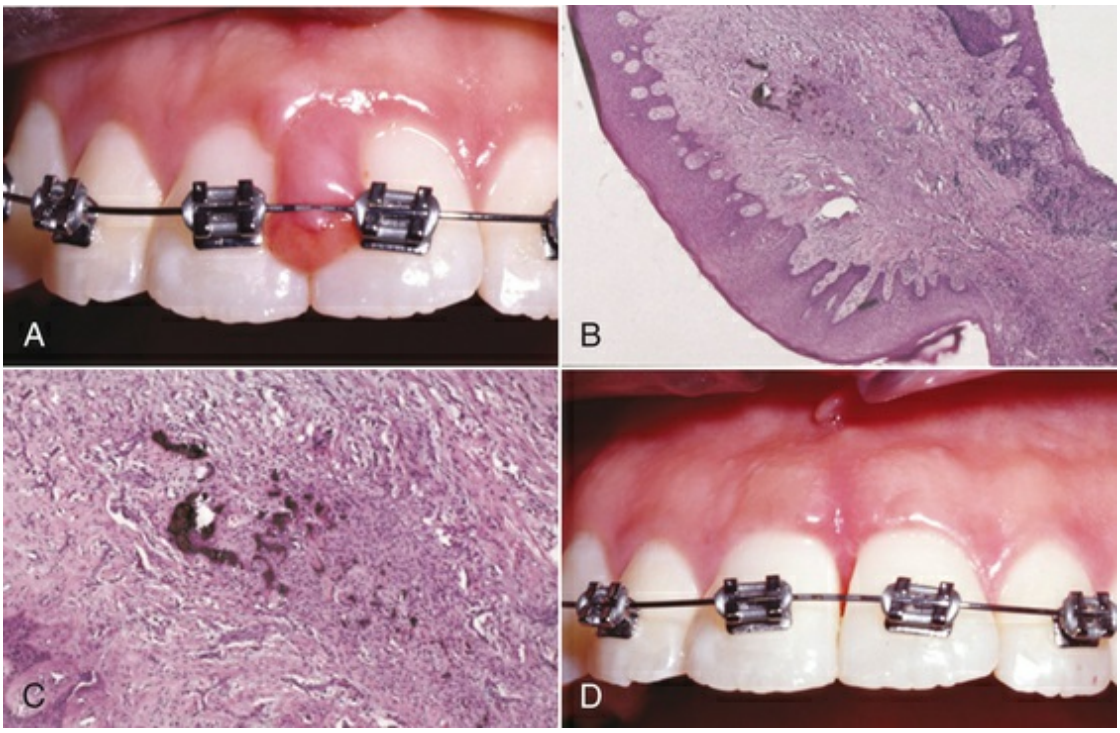

FIG. 5.13 (A) Proliferative gingival overgrowth secondary to impaction of foreign body. (B) Histology of peripheral ossifying fibroma. (C) Higher magnification of image in part B. (D) Four weeks post

excisional biopsy.

Foreign-Body Reactions

Foreign-body reactions lead to localized inflammatory conditions of the gingiva and are caused by the introduction of foreign material into the gingival connective tissues through breaks in the epithelium.[20] Common examples are the introduction of amalgam into the gingiva during the placement of a restoration, the extraction of a tooth, or an endodontic apicoectomy with retrofill leaving an amalgam tattoo (Fig. 5.14A), with resultant metal fragments observed during biopsies (Fig. 5.14B); abrasives may also be introduced during polishing procedures.

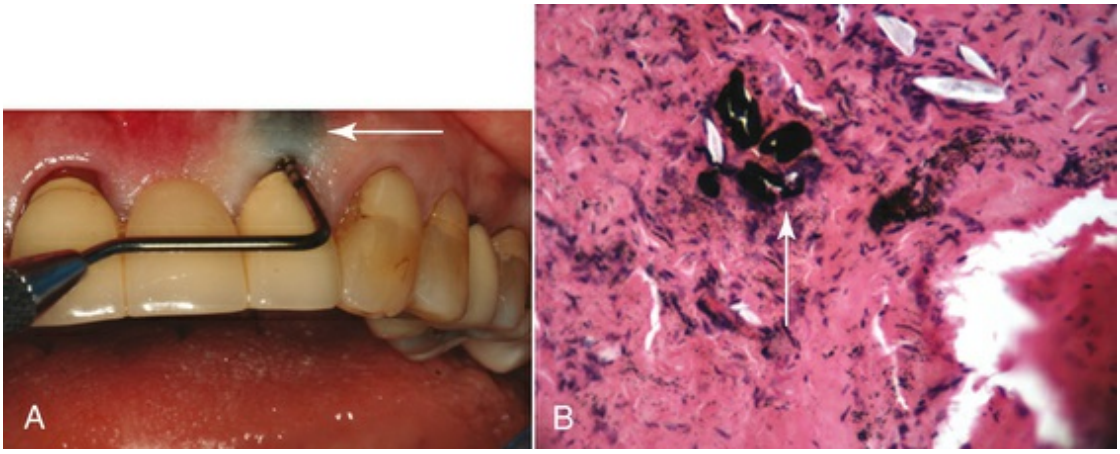

FIG. 5.14 (A) Gingival pigmentation associated with previous apicoectomy and amalgam retro-fill. (B) Biopsy depicts metal fragments.

Periodontitis

Periodontitis is defined as "an inflammatory disease of the supporting tissues of the teeth caused by specific microorganisms or groups of specific microorganisms, resulting in progressive destruction of the periodontal ligament and alveolar bone with increased probing depth formation, recession, or both."[51] The clinical feature that distinguishes periodontitis from gingivitis is the presence of clinically detectable attachment loss as a result of

inflammatory destruction of the periodontal ligament and alveolar bone. This loss is often accompanied by periodontal pocket formation and changes in the density and height of the subjacent alveolar bone. In some cases, recession of the marginal gingiva may accompany attachment loss, thereby masking ongoing disease progression if only probing depth measurements are taken without measurements of clinical attachment levels.

Key Fact

Probing depth measurement alone is inadequate for an assessment of periodontitis. Clinical attachment loss is usually assessed by adding the extent of gingival recession to the probing depth measurement to estimate the total extent of tissue loss from the cementoenamel junction (CEJ) of the tooth. However, when recession is not visible, it is essential that height of the marginal gingiva coronal to the CEJ be determined and that measurement subtracted from the probing depth to establish the extent of clinical attachment loss. The measurement of clinical attachment around a tooth provides insights on the history and extent of periodontal destruction around the tooth. One common pitfall of clinical periodontal examination is the direct translation of probing depths as clinical attachment levels when the gingival margin lies above the cementoenamel junction, leading to an overestimation of attachment levels.

Clinical signs of inflammation—such as changes in color, contour, and consistency as well as bleeding with probing—may not always be positive indicators of ongoing attachment loss. However, the presence of continued bleeding with probing during sequential visits has proved to be a reliable indicator of the presence of inflammation and an increased risk for subsequent attachment loss at the bleeding site. The attachment loss associated with periodontitis may occur in a cyclic fashion, with attachment loss progressing either continuously or in episodic bursts of disease activity. However, the available clinical instruments for detecting disease are not sensitive enough to capture the cycles of attachment loss and repair that occur during disease activity and remission,

respectively (i.e., the periodontal probe is graded in 1-mm increments).

Key Fact

In the AAP/EFP 2018 classification of periodontal diseases, a multidimensional staging and grading system will be introduced to subclassify periodontitis disease entities. The severity of periodontal disease at the time of presentation and the complexity of disease management will dictate the staging, while grading offers additional information, including the rate of past progression of the disease and the risk for future progression.

Although many classifications of the different clinical manifestations of periodontitis have been presented since the late 1990s, consensus workshops in North America in 1989[8] and in Europe in 1993[6] identified that periodontitis may present in early-onset, adult-onset, and necrotizing forms (Table 5.1). In addition, the AAP consensus concluded that periodontitis may be associated with systemic conditions (e.g., diabetes, HIV) and that some forms of periodontitis may be refractory to conventional therapy. Early-onset disease was distinguished from adult-onset disease by the age of onset (< 35 years of age was set as an arbitrary separation of diseases), the rate of disease progression, and the presence of alterations in host defenses. The early-onset diseases were more aggressive, occurred in individuals younger than 35 years old, and were associated with defects in host defenses. Adult forms of disease were slowly progressive, became clinically more evident during the fourth decade of life, and were not associated with defects in host defenses. In addition, early-onset periodontitis was subclassified into prepubertal, juvenile, and rapidly progressive forms with localized or generalized disease distributions.

TABLE 5.1

Classification of the Various Forms of Periodontitis

Classification	Forms of Periodontitis	Disease Characteristics
AAP World Workshop in	Adult periodontitis	Age of onset >35 years

Clinical Periodontics, 1989[5]		Slow rate of disease progression No defects in host defenses
	Early-onset periodontitis (may be prepubertal, juvenile, or rapidly progressive)	Age of onset <35 years Rapid rate of disease progression Defects in host defenses Associated with specific microflora
	Periodontitis associated with systemic disease	Systemic diseases that predispose to rapid rates of periodontitis
		Diseases: diabetes, Down syndrome, HIV infection, Papillon–Lefèvre syndrome
	Necrotizing ulcerative periodontitis	Similar to acute necrotizing ulcerative gingivitis but with associated clinical attachment loss
	Refractory periodontitis	Recurrent periodontitis that does not respond to treatment
European Workshop in Periodontology, 1993[3]	Adult periodontitis	Age of onset: fourth decade of life
		Slow rate of disease progression
		No defects in host response
	Early-onset periodontitis	Age of onset: before fourth decade of life
		Rapid rate of disease progression
		Defects in host defense
	Necrotizing periodontitis	Tissue necrosis with attachment and bone loss
AAP International Workshop for Classification of Periodontal Diseases, 1999[2]	Chronic periodontitis Aggressive periodontitis Periodontitis as a manifestation of systemic diseases	See Box 5.3

AAP, American Academy of Periodontology; *HIV*, human immunodeficiency virus.

Extensive clinical and basic scientific research involving these disease entities has been performed in many countries, and emerging information has provided support for the unification of many of the preexisting disease categories.[13,23,49] In particular, supporting evidence was lacking for the distinct classifications of adult periodontitis, refractory periodontitis, and the various different forms of early-onset periodontitis as outlined by the AAP Workshop for the International Classification of Periodontal Diseases in 1999[5] (see Table 5.1). It has been observed that chronic periodontal destruction caused by the accumulation of local factors (e.g., plaque, calculus) can occur before the age of 35 years and that the aggressive disease seen in young patients may be independent of age and instead have a familial (genetic) association. With

respect to refractory periodontitis, little evidence supports the theory that this condition is indeed a distinct clinical entity. The causes of continued loss of clinical attachment and alveolar bone after periodontal therapy are currently poorly defined and apply to many disease entities. In addition, clinical data from the medical community emerged to support the belief that forms of periodontitis that were collectively referred to as prepubertal periodontitis were in fact representing periodontitis as a manifestation of distinct systemic diseases, such as in leukocyte adhesion deficiency syndromes. As a result, the AAP held an International Workshop for the Classification of Periodontal Diseases in 1999 to further refine the classification system with the use of current clinical and scientific data.[5] The resulting classification of the different forms of periodontitis was simplified to describe three general disease forms: chronic periodontitis, aggressive periodontitis, and periodontitis as a manifestation of systemic disease (Table 5.1 and Box 5.3).

Box 5.3

Periodontitis

The disease periodontitis can be subclassified into the following three major types based on clinical, radiographic, historical, and laboratory characteristics.

Chronic Periodontitis

The following characteristics are common to patients with chronic periodontitis:

- Prevalent in adults but can occur in children
- Amount of destruction consistent with local factors
- Associated with a variable microbial pattern
- Subgingival calculus frequently found
- Slow-to-moderate rate of progression with possible periods of rapid progression
- Possibly modified by or associated with the following:

- Systemic diseases such as diabetes mellitus and human immunodeficiency virus (HIV) infection
- Local factors predisposing to periodontitis
- Environmental factors such as cigarette smoking and emotional stress

Chronic periodontitis may be further subclassified into localized and generalized forms and characterized as mild, moderate, or severe based on the common features described previously and the following specific features:

- Localized form: <30% of teeth involved
- Generalized form: >30% of teeth involved
- Mild: 1 to 2 mm clinical attachment loss (CAL)
- Moderate: 3 to 4 mm CAL
- Severe: ≥5 mm CAL

Aggressive Periodontitis

The following characteristics are common to patients with aggressive periodontitis:

- Otherwise clinically healthy patient (note the distinction with periodontitis as a manifestation of systemic disease)
- Rapid attachment loss and bone destruction
- Familial aggregation of diseased individuals

The following characteristics are common but not universal:

- Amount of microbial deposits inconsistent with disease severity
- Increased levels of *Actinobacillus actinomycetemcomitans*
- Abnormalities in phagocyte function
- Hyper-responsive macrophages, producing increased prostaglandin E_2 (PGE_2) and interleukin-1β (IL-1β)
- In some cases, self-arresting disease progression

Aggressive periodontitis may be further classified into localized and generalized forms based on the common features described here and the following specific features.

Localized Form

- Circumpubertal onset of disease
- Localized first molar or incisor disease with proximal attachment loss on at least two permanent teeth, one of which is a first molar
- Robust serum antibody response to infecting agents

Generalized Form

- Usually affecting persons under 30 years of age (however, may be older)
- Generalized proximal attachment loss affecting at least three teeth other than first molars and incisors
- Pronounced episodic nature of periodontal destruction
- Poor serum antibody response to infecting agents

Periodontitis as a Manifestation of Systemic Diseases

Periodontitis may be observed as a manifestation of the following systemic diseases:

1. Hematologic disorders
    a. Acquired neutropenia
    b. Leukemias
    c. Other
2. Genetic disorders
    a. Familial and cyclic neutropenia
    b. Down syndrome
    c. Leukocyte adhesion deficiency syndromes
    d. Papillon–Lefèvre syndrome
    e. Chédiak–Higashi syndrome
    f. Histiocytosis syndromes
    g. Glycogen storage disease

h. Infantile genetic agranulocytosis
i. Cohen syndrome
j. Ehlers-Danlos syndrome (types IV and VIII autosomal dominant [AD])
k. Hypophosphatasia
l. Other

3. Not otherwise specified

Data from Flemmig TF: Periodontitis. *Ann Periodontol* 4:32, 1999; Kinane DF: Periodontitis modified by systemic factors. *Ann Periodontol* 4:54, 1999; and Tonetti MS, Mombelli A: Early-onset periodontitis. *Ann Periodontol* 4:39, 1999.

Since the establishment of the currently accepted 1999 classification, a taskforce commissioned by the AAP proposed an update to the existing classification scheme in 2015.[3] The update focused on suggestions to address the challenges in clinical documentation of attachment level changes and the distinction between chronic and aggressive periodontitis. In particular, the AAP task force recommended the consideration of probing depth levels, in addition to attachment levels, in determining the severity of periodontitis to avoid overestimation. The classification of diseases and conditions of the periodontium discussed in this chapter will focus on the currently accepted 1999 classification with references to the AAP update when appropriate.

Chronic Periodontitis

Chronic periodontitis is the most common form of periodontitis[13]; Box 5.3 includes the characteristics of this form of periodontitis. Chronic periodontitis is most prevalent in adults, but it can also be observed in children. Different classification schemes have confirmed or discarded the age range of more than 35 years to separate chronic versus aggressive periodontitis. According to the existing definition, persons younger than 35 years may exhibit a rate of progression of disease consistent with the definition of chronic periodontitis. Nonetheless, epidemiologic evidence supports the suggestion that persons younger than 25 years at disease onset are likely to exhibit aggressive periodontitis. Intraoral radiographs along with periodontal charting records are of

paramount importance to the documentation of disease onset and rate of progression.

Chronic periodontitis is associated with the accumulation of plaque and calculus. It generally has a slow to moderate rate of disease progression, but periods of more rapid destruction may also be observed. Increases in the rate of disease progression may be caused by the impact of local, systemic, or environmental factors that may influence the normal host–bacteria interaction. Local factors may influence plaque accumulation (Box 5.4), whereas systemic diseases (e.g., diabetes mellitus, HIV) may influence the host's defenses, and environmental factors (e.g., cigarette smoking, stress) may influence the response of the host to plaque accumulation. Chronic periodontitis may occur as a localized disease in which less than 30% of evaluated teeth demonstrate attachment and bone loss, or it may occur as generalized when more than 30% of teeth are affected.

Box 5.4

Developmental or Acquired Deformities and Conditions

Localized Tooth-Related Factors That Modify or Predispose to Plaque-Induced Gingival Diseases or Periodontitis

1. Tooth anatomic factors
2. Dental restorations or appliances
3. Root fractures
4. Cervical root resorption and cemental tears

Mucogingival Deformities and Conditions Around Teeth

1. Gingival or soft tissue recession
    a. Facial or lingual surfaces
    b. Interproximal (papillary)
2. Lack of keratinized gingiva

3. Decreased vestibular depth
4. Aberrant frenum or muscle position
5. Gingival excess
    a. Pseudopocket
    b. Inconsistent gingival margin
    c. Excessive gingival display
    d. Gingival enlargement (see Box 5.2)
    e. Abnormal color

Mucogingival Deformities and Conditions on Edentulous Edges

1. Vertical and/or horizontal ridge deficiency
2. Lack of gingiva or keratinized tissue
3. Gingival or soft tissue enlargements
4. Aberrant frenum or muscle position
5. Decreased vestibular depth
6. Abnormal color

Occlusal Trauma

1. Primary occlusal trauma
2. Secondary occlusal trauma

Data from Blieden TM: Tooth-related issues. *Ann Periodontol* 4:91, 1999; Halmon WW: Occlusal trauma: effect and impact on the periodontium. *Ann Periodontol* 4:102, 1999; and Pini Prato GP: Mucogingival deformities. *Ann Periodontol* 4:98, 1999.

Key Fact

Chronic periodontitis is classified by extent and severity of disease, such as generalized (extent), moderate (severity) chronic periodontitis.

Chronic periodontitis can be further classified on the basis of its extent and severity. The severity of disease has been traditionally determined as either slight/mild (1 to 2 mm of loss; Fig. 5.15), moderate (3 to 4 mm of loss; Fig. 5.16), or severe (≥5 mm of loss; Fig.

5.17) on the basis of the amount of clinical attachment loss (see Box 5.3). Clinical attachment levels provide important benefits over probing depth alone to monitor disease progression using the CEJ as a fixed reference point. In fact, probing depth levels only have poor to moderate sensitivity for predicting attachment level changes overtime. Nonetheless, clinical experience has revealed that oftentimes measurement of clinical attachment levels in practice may prove to be erroneous. The most common error occurs in the case of sites without gingival recession, whereby the location of the gingival margin is coronal to the CEJ. If the clinician in such a case only records the probing depth without charting the location of the CEJ (often charted as "positive recession" in electronic periodontal charts), the resulting attachment levels will be erroneously recorded as being equal to the probing depth. To prevent such an overestimate of disease, it has been suggested that clinicians consider that mild periodontitis be associated with probing depths of <4 mm, moderate periodontitis with probing depths of 5 to 6 mm, and severe periodontitis with probing depths of ≥7 mm. However, probing depths alone should not be used to classify periodontitis without simultaneous consideration of clinical attachment levels and radiographic bone loss.

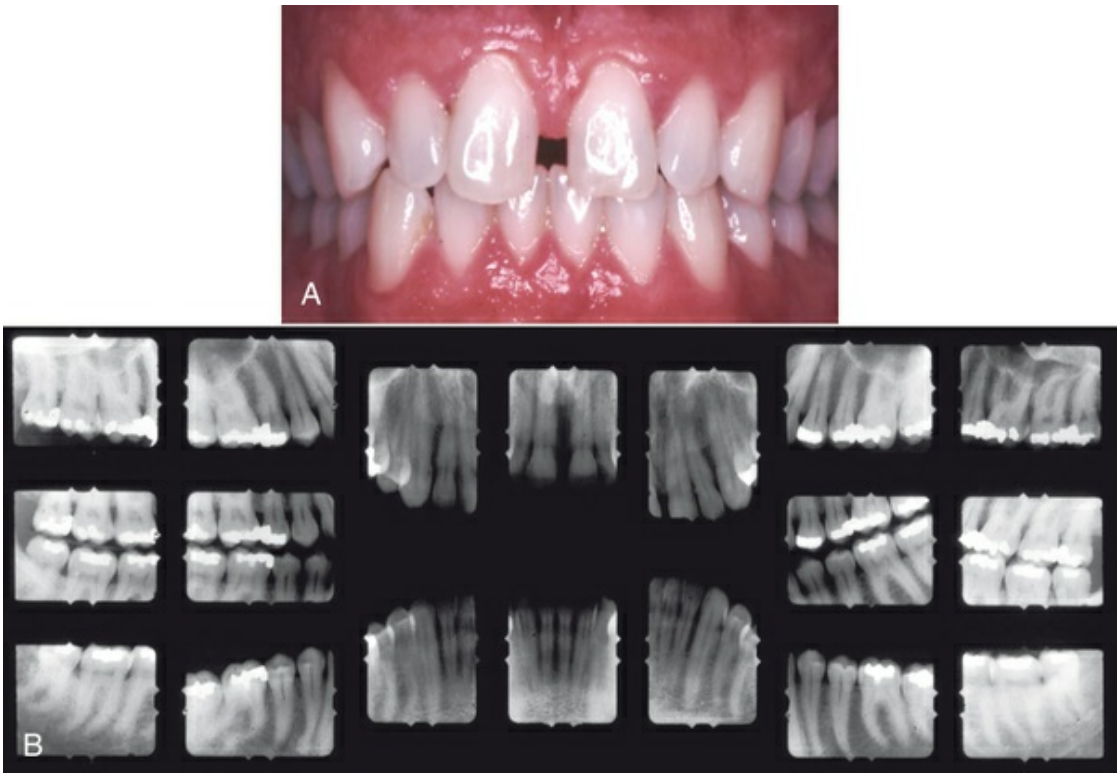

FIG. 5.15 (A) Clinical image of plaque-related slight/early chronic periodontitis with 1- to 2-mm clinical attachment loss in 40-year-old female. (B) Radiographic images of the patient.

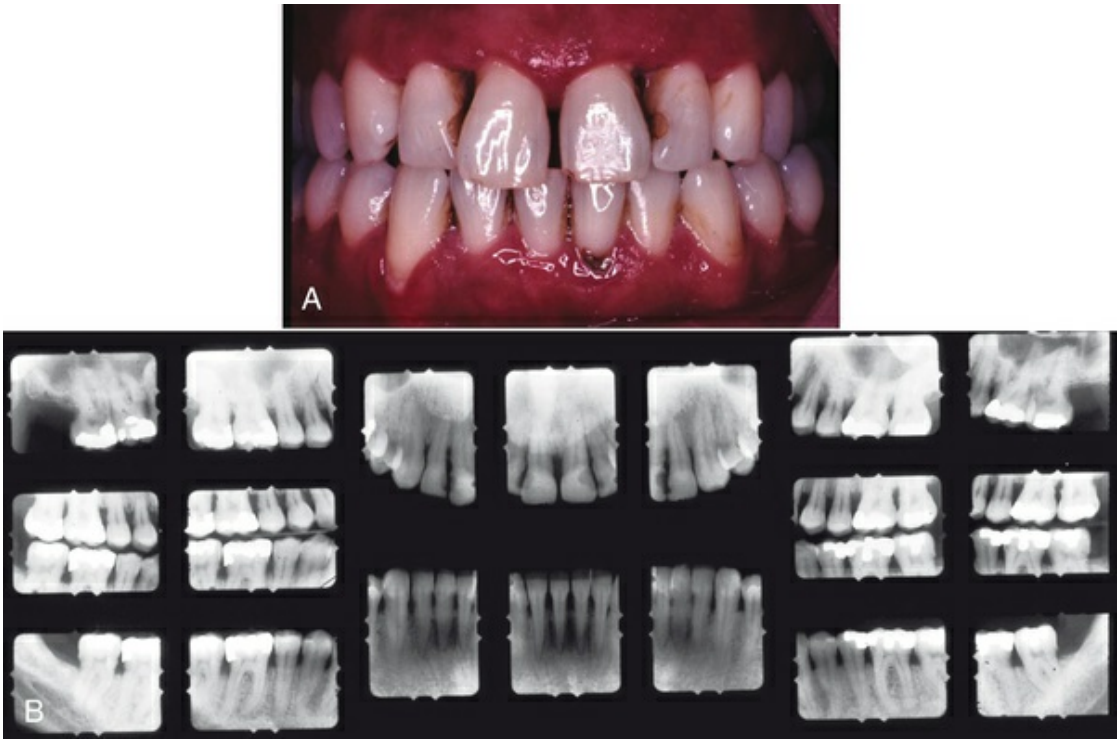

FIG. 5.16 (A) Clinical image of plaque-related moderate chronic periodontitis with 3- to 4-mm clinical attachment loss in a 53-year-old male smoker. (B) Radiographic images of the patient.

FIG. 5.17 (A) Clinical image of plaque-related severe/advanced chronic periodontitis with >5 mm clinical attachment loss in a 47-year-old female. (B) Radiographic images of the patient.

Key Fact

In the AAP/EFP 2018 classification of periodontal diseases, one of the major changes that will be implemented is avoidance of a separate category of "aggressive periodontitis." Both chronic and aggressive periodontitis disease entities will be grouped together and will be simply called *periodontitis*.

Aggressive Periodontitis

Aggressive periodontitis differs from the chronic form primarily by the rapid rate of disease progression seen in an otherwise healthy individual (Figs. 5.18 and 5.19). The absence of large accumulations of plaque and calculus, with a positive family history of aggressive disease, is suggestive of a genetic trait[34,49] (see Box 5.3). This form of periodontitis was previously classified as early-onset periodontitis (see Table 5.1) and therefore still includes many of the characteristics previously identified with the localized and generalized forms of early-onset periodontitis. Although the clinical presentation of aggressive disease appears to be universal, the causative factors involved are not always consistent. Box 5.3 outlines additional clinical, microbiologic, and immunologic characteristics of aggressive disease that may be present. As was previously described for early-onset disease, aggressive forms of periodontitis usually affect young individuals during or shortly after puberty and may be observed during the second and third decades of life (i.e., 10 to 30 years of age). The disease may be localized, as previously described for localized juvenile periodontitis, or generalized, as previously described for generalized juvenile periodontitis and rapidly progressive periodontitis (see Table 5.1). Box 5.3 describes the common features of the localized and generalized forms of aggressive periodontitis.

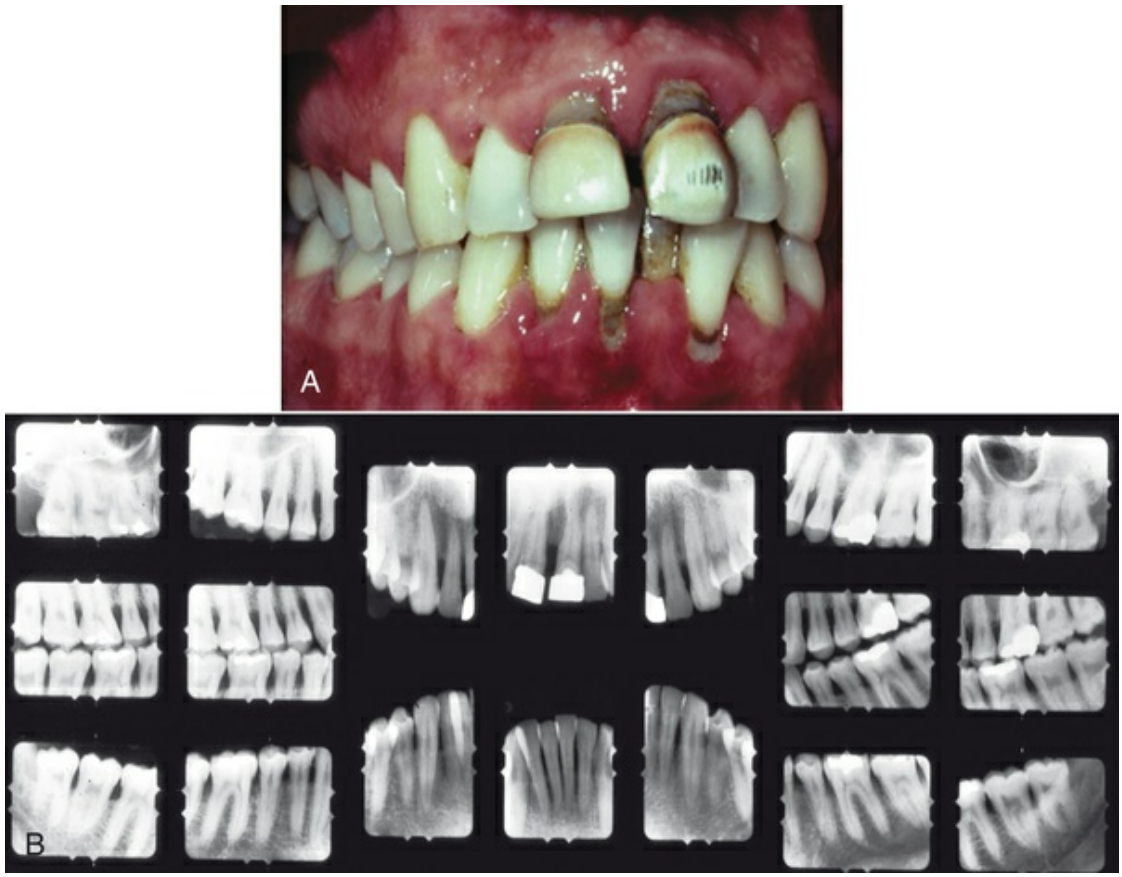

FIG. 5.18 (A) Clinical image of plaque-related aggressive moderate periodontitis with 1- to 7-mm PD and 3- to 4-mm clinical attachment loss in a 31-year-old male. (B) Radiographic images of the patient.

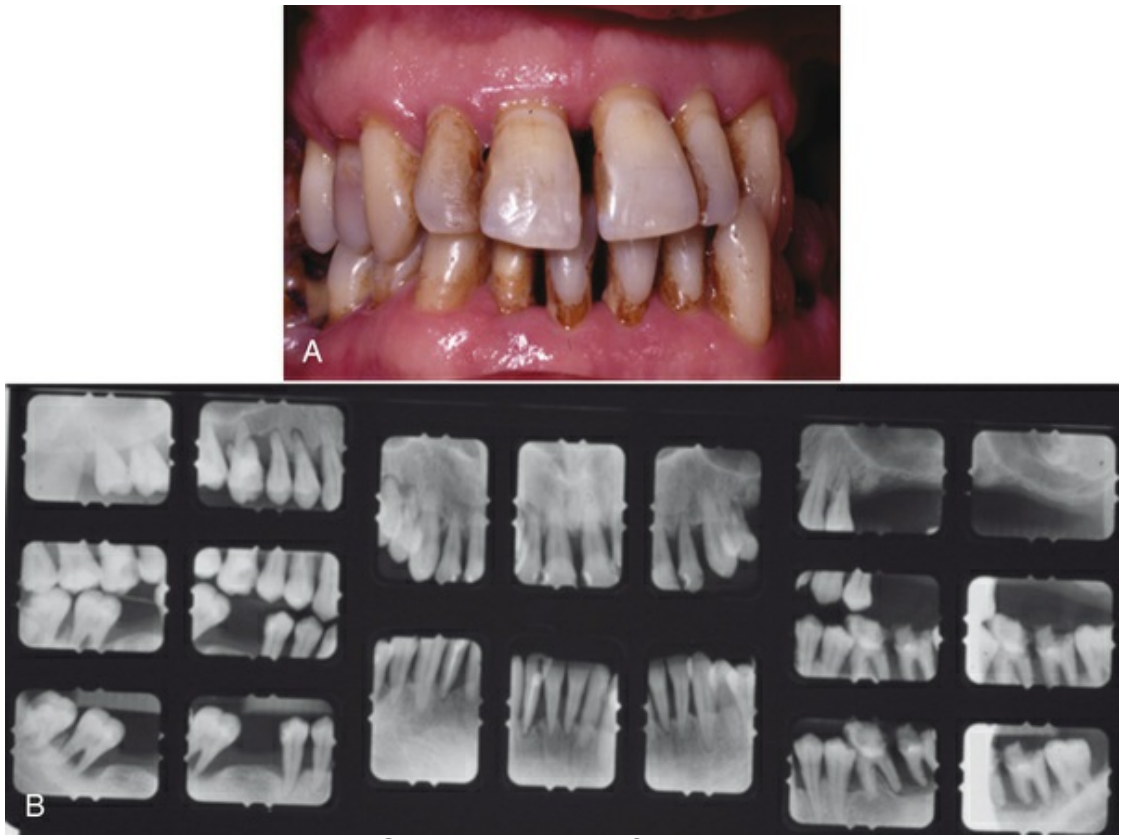

FIG. 5.19 (A) Clinical image of plaque-related aggressive severe periodontitis with 3- to 13-mm PD and 7- to 15-mm clinical attachment loss in a 32-year-old male. (B) Radiographic images of the patient.

« Flash Back

Recall that chronic periodontitis is also categorized by the extent of *localized* or *generalized* disease according to the percentage of teeth involved with 30% of teeth being the cutoff between the two categories. Importantly, there is a distinct difference in the use of these definitions in the context of aggressive periodontitis. For aggressive periodontitis, the localized form is recognized to have a specific clinical phenotype, which is typically limited to incisor and first molar teeth.

Periodontitis as a Manifestation of Systemic Disease

Several hematologic and genetic disorders have been associated

with the development of periodontitis in affected individuals[22,23] (see Box 5.3). The majority of existing publications are case reports, whereas only a few research studies have been performed to investigate the exact nature of the effect of the specific condition on the tissues of the periodontium primarily because of the rare occurrence of many of these diseases. It is speculated that the major effect of these disorders is through alterations in immune response, such as in the case of interleukin-17 overexpression in leukocyte adhesion deficiency[30] or due to tissue metabolic disorders such as in some forms of Ehlers–Danlos syndrome.[2] The clinical manifestation of many of these disorders appears at an early age and may be confused with aggressive forms of periodontitis depicting rapid attachment loss and the potential for early tooth loss. This was one of the drivers for the transition from the term *early-onset periodontitis,* which characterized a heterogeneous group of diseases, to the definitions of aggressive periodontitis and periodontitis as a manifestation of systemic diseases. With the introduction of this form of periodontitis (see Table 5.1), the potential exists for overlap and confusion between periodontitis as a manifestation of systemic disease in both the aggressive and the chronic forms of disease when a systemic component is suspected. At present, *periodontitis as a manifestation of systemic disease* is the diagnosis to be used when the systemic condition is the major predisposing factor and when local factors (e.g., large quantities of plaque and calculus) are not clearly evident or their presence alone does not justify the severity or progression of disease. This definition is reserved for a specific group of diseases and syndromes that have been documented to have a profound destructive effect on the periodontium. The removal of local factors as part of conventional periodontal therapy in such cases is often inadequate to arrest the periodontal destruction due to the systemic effect. When periodontal destruction is clearly the result of local factors but has been exacerbated by the onset of conditions such as diabetes mellitus (Figs. 5.20 and 5.21) or HIV infection, the diagnosis should be *chronic periodontitis modified by the systemic condition.*

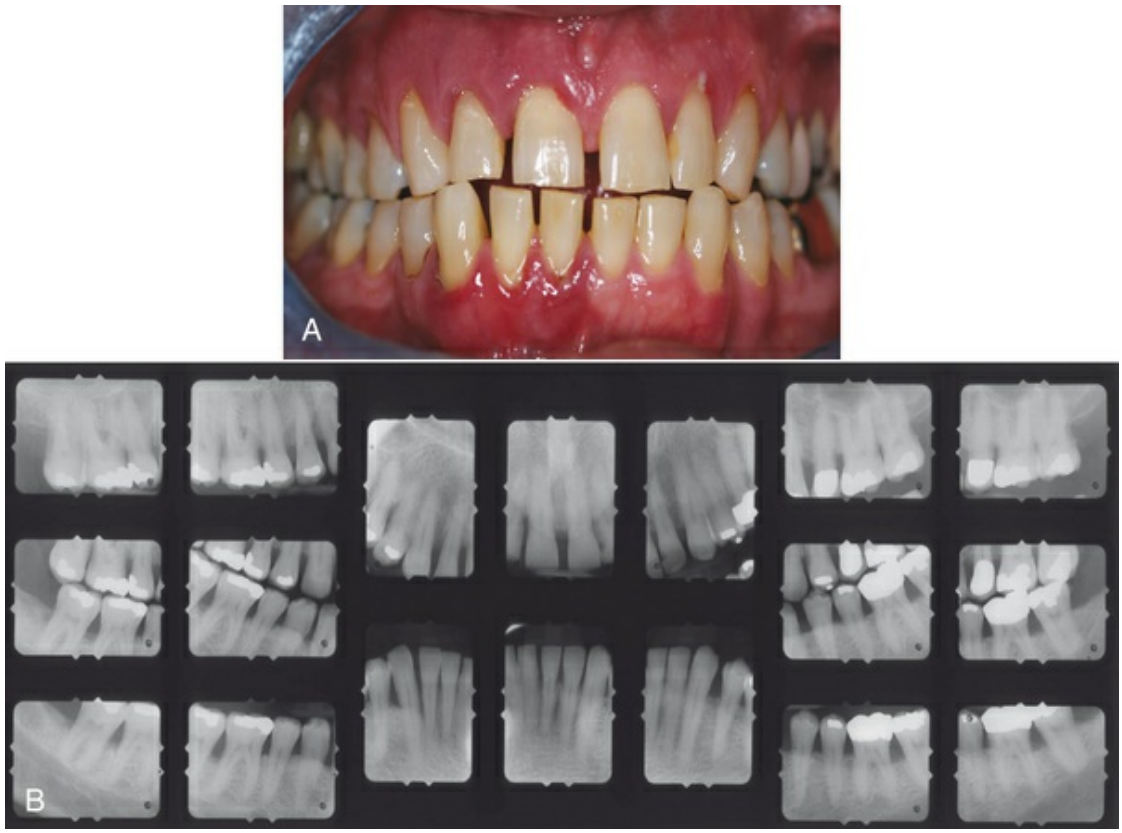

FIG. 5.20 (A) Clinical image of plaque-related severe aggressive periodontitis in a 53-year-old male, smoker with diabetes and hemoglobin A_{1c} (HbA_{1c}) = 10.7. (B) Radiographic images of the patient.

FIG. 5.21 Selective probing depths of the same 53-year-old diabetic patient shown in Fig. 5.20 with severe aggressive periodontitis.

Papillon–Lefèvre syndrome (PLS) is one example of a condition that causes severe periodontitis as one of its manifestations. PLS is an autosomal-recessive disorder caused by mutations in the cathepsin C gene located on chromosome 11q14.[17] The clinical manifestations of the syndrome include severe aggressive periodontitis and diffuse keratoderma on the palms, the soles, the knees, or all three[16] (Figs. 5.22 and 5.23). The consanguinity of the parents is a common finding in approximately one-third of the cases.[31]

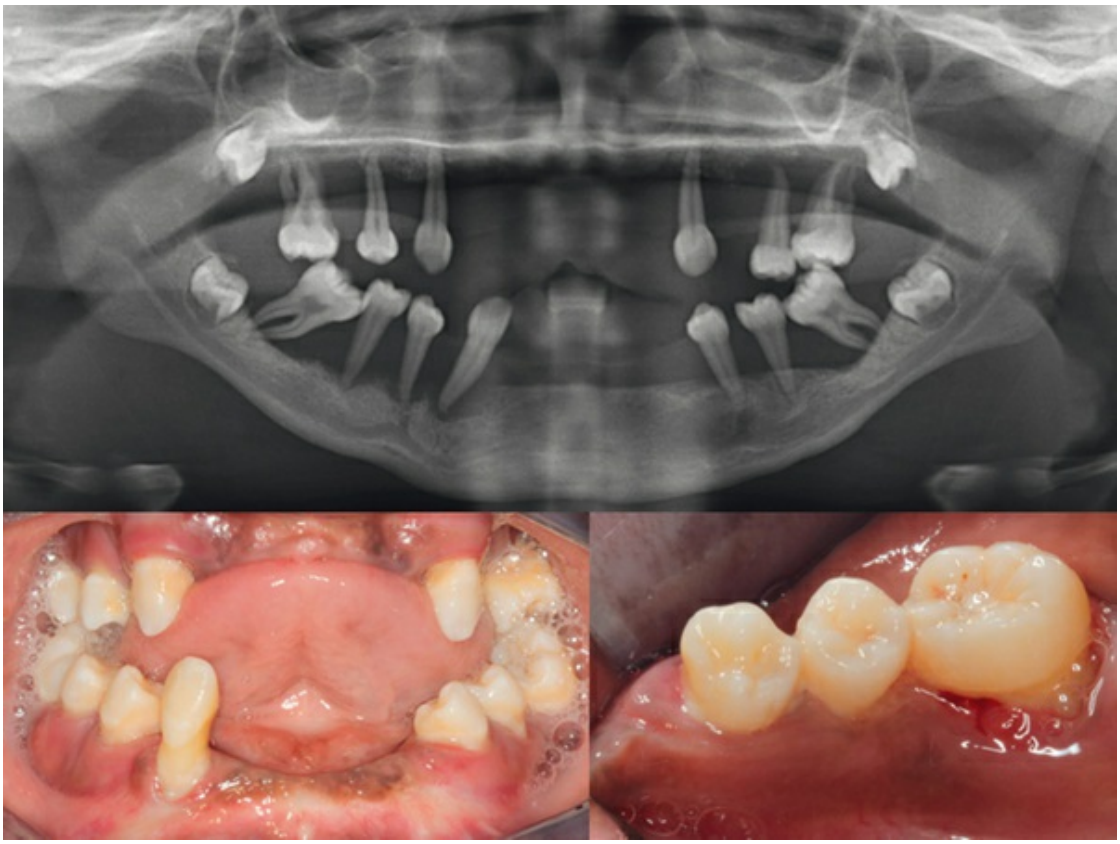

FIG. 5.22 Panoramic radiograph and clinical photos of a 13-year-old female with Papillon–Lefèvre syndrome (PLS). PLS is an autosomal recessive disorder caused by mutations in the cathepsin C gene located on chromosome 11q14. The clinical manifestations of the syndrome are severe aggressive periodontitis as well as diffuse keratoderma on the palms, soles, or knees.

In PLS patients by the age of 4 to 5 years, the primary teeth have typically exfoliated or been extracted due to severe periodontal destruction. Subsequently, an edentulous phase occurs during which a reduction in the oral microbial load is noted and gingival health is restored. Following eruption of the permanent dentition, a similar cycle of severe periodontal inflammation is repeated that generally does not respond to conventional periodontal therapy. An increase in tooth mobility and periodontal abscesses is frequently observed shortly after the eruption of permanent teeth. (Courtesy Dr. Georgios Kotsakis, Seattle, Washington.)

FIG. 5.23 Patient with Papillon-Lefèvre (PLS) syndrome exhibiting hyperkeratosis on palms of the hand and soles of the feet. PLS clinically affects both the primary and permanent dentition. Signs of palmoplantar keratoderma usually appear simultaneously with the eruption of the first primary teeth (5–6 months), but may appear as early as 1 month of age. (Courtesy Dr. Georgios Kotsakis, Seattle, Washington.)

Clinical Correlation

When monogenic diseases are encountered, consanguinity can be a common finding particularly in certain ethnic cultures where it is socially acceptable. Appropriate genetic counseling is advisable. In addition, when the diagnosis for the proband (the first offspring for whom disease is noted) is established, it is crucial that the siblings are carefully examined for prompt diagnosis of additional cases.

Impaired neutrophil function is considered to be the primary cause of PLS and to eventually result in the deregulation of the polymorphonuclear leukocyte response to microbial infection.[11] Although the subgingival microbiota associated with PLS is diverse, opportunistic periodontal pathogens such as *Aggregatibacter actinomycetemcomitans* (Aa), *Porphyromonas gingivalis, Tannerella forsythia, Fusobacterium nucleatum,* and *Prevotella intermedia* are frequently identified among plaque samples from PLS patients.[1,50] Serum immunoglobulin G titers against Aa are typically elevated in individuals with PLS, thereby implicating Aa as a significant causative factor.[50] Individuals with PLS are often initially screened by a dermatologist or a pediatrician, and the phenotype of the syndrome may be mistaken for atopic dermatitis (eczema) or palmoplantar keratoderma.[35] The case presented in Figs. 5.22 and 5.23 was treated for several years by a dermatologist as atopic dermatitis with occasional cauterization of misdiagnosed "plantar warts." The diagnosis of PLS was established in a periodontal office. A multidisciplinary treatment approach for these patients including referral to a periodontist cannot be overemphasized. After a diagnosis of PLS has been established, it is important to collect a complete family history and to construct a pedigree to help identify undiagnosed or misdiagnosed siblings (Fig. 5.24). In 1979 Haneke proposed palmoplantar hyperkeratosis, the loss of primary and permanent teeth, and an autosomal-recessive pattern of inheritance as being essential criteria to verify a diagnosis of PLS.[16] Secondary manifestations of PLS may include ectopic intracranial calcifications and increased susceptibility to infections, including pyogenic liver abscesses that can be fatal.[9]

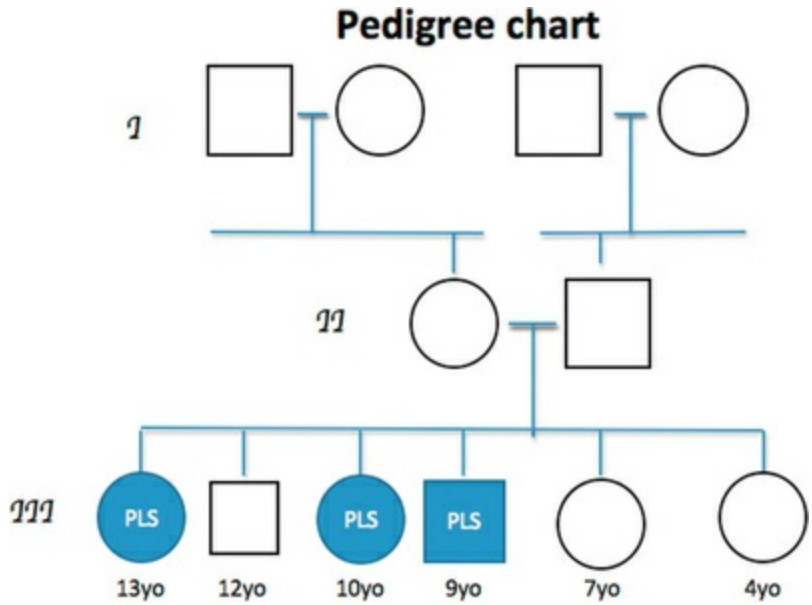

FIG. 5.24 No history of consanguinity was reported in this case. However, approximately one-third of the diagnosed Papillon-Lefèvre (PLS) cases descend from same ancestor. Offsprings III1, III3, and III4 display a PLS phenotype. All siblings should be thoroughly examined by a periodontist once a case of PLS has been diagnosed.

PLS clinically affects both the primary and permanent dentition. Signs of palmoplantar keratoderma usually appear simultaneously with the eruption of the first primary teeth (i.e., 5 to 6 months of age), but they may appear as early as the age of 1 month. By the age of 4 to 5 years, the primary teeth have typically exfoliated or been extracted as a result of severe periodontal destruction. Subsequently, an edentulous phase occurs during which a reduction in the oral microbial load is noted and gingival health is restored. After the eruption of the permanent dentition, a similar cycle of severe periodontal inflammation is repeated that generally does not respond to conventional periodontal therapy.[11] An increase in tooth mobility and periodontal abscesses is frequently observed shortly after the eruption of the permanent teeth.

The periodontal prognosis for patients with PLS has significantly improved in response to an increase in the prompt and accurate diagnosis of the syndrome, the better understanding of its pathogenesis, and more efficient professional supervision. There appears to be a consensus among clinicians that the successful treatment of periodontitis among individuals with PLS requires the

eradication of Aa.[10,12,43] Treatment of the primary dentition includes frequent prophylaxis appointments to ensure that the patient maintains adequate masticatory function and nutrition during early childhood. To create a healthy environment for the permanent teeth to erupt into, it has been advocated that a course of antibiotics effective against Aa be systemically administered along with the extraction of all primary teeth 6 to 12 months before the eruption of the first permanent tooth. However, culture and sensitivity testing of the subgingival plaque may enhance the selection of the most effective antibiotic regimen. De Vree and colleagues described two patients with PLS.[10] Aa was eradicated from one individual, who was able to retain most of his teeth over a 15-year period; the second individual's Aa was found to be resistant to the antibiotics combination, and he lost all of his teeth despite intensive treatment. The combination of trimethoprim and sulfamethoxazole (i.e., cotrimoxazole) has also been shown to be effective against Aa and to lead to a significant improvement in neutrophilic function against Aa.[24] A stringent periodontal maintenance schedule is of utmost importance to efficaciously monitor the patient's oral hygiene and to be able to intercede promptly if signs of inflammation reoccur.[32] Retinoids, which are synthetic analogues of vitamin A, a treatment modality against PLS skin manifestations, have also been considered as immunomodulatory adjuncts for the treatment of PLS-associated periodontitis.[12,24]

Sarcoidosis is a chronic disease that is expressed as a cell-mediated, delayed-type hypersensitivity that primarily affects the lungs, lymph nodes, skin, eyes, liver, spleen, and small bones of the hands and feet.[36] Sarcoidosis rarely affects the oral cavity, with incidence of occurrence in descending order noted in the lymph nodes, lips, soft palate, buccal mucosa, gingiva, tongue, and bone.[36] Fig. 5.25 depicts the pretreatment pattern of bone loss and recession associated with sarcoidosis, with pulmonary parenchymal fibrous infiltrate noted in the lungs as depicted by a white lacy pattern on a chest radiograph (Fig. 5.25C). Histologic features of sarcoidosis include the presence of an intense chronic inflammatory infiltrate with focal areas of noncaseating granulomas and a positive Kveim test (Fig. 5.26C). The remineralization of alveolar bone is noted on radiographs obtained 1 year after the systemic administration of

steroids (e.g., prednisone) (Fig. 5.26A).

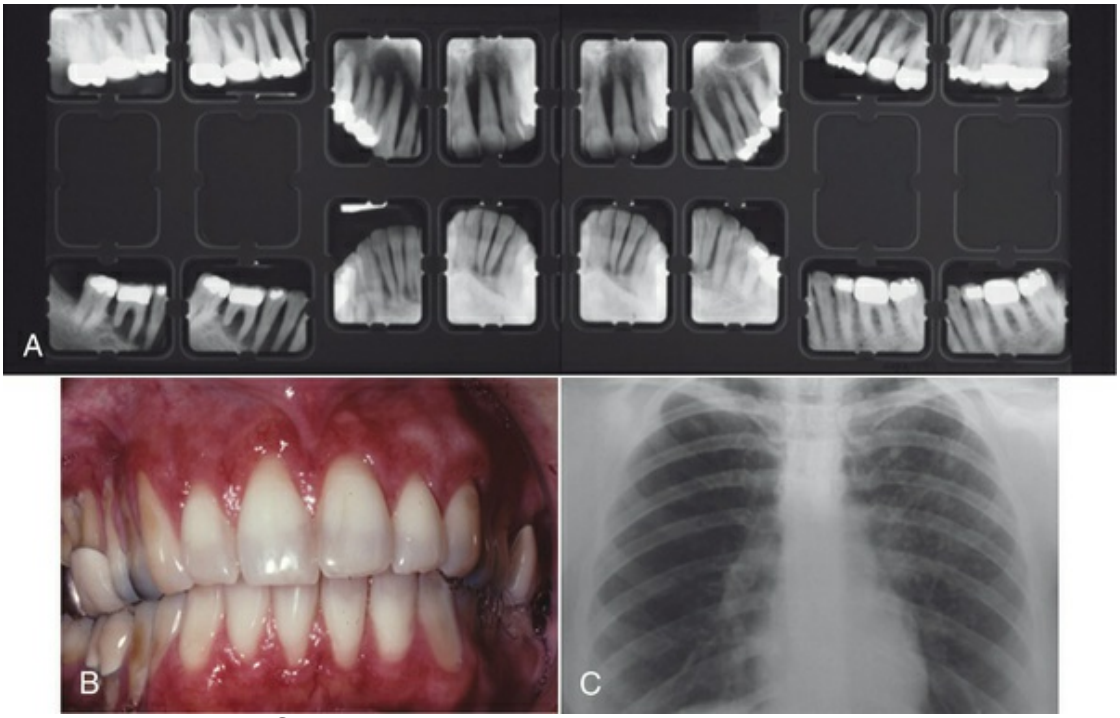

FIG. 5.25 Sarcoidosis pretreatment. (A) Intraoral x-rays depict more extensive bone loss for anterior teeth than clinical attachment loss. (B) Extensive recession plus clinical attachment loss. (C) Pulmonary parenchymal fibrous infiltrate.

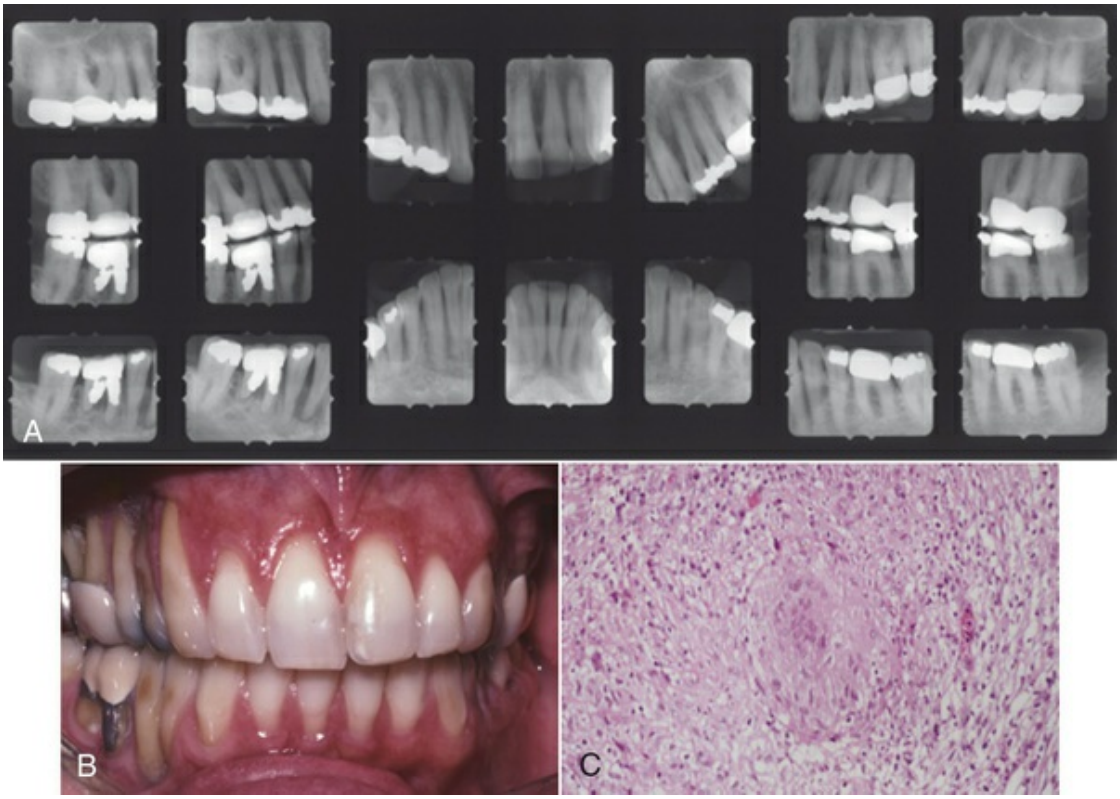

FIG. 5.26 Sarcoidosis after treatment with prednisone. (A) Intraoral x-rays depict remineralization of bone. (B) Reduction in gingival inflammation while extensive recession and clinical attachment loss persist. (C) Pretreatment biopsy.

Medication-Related Osteonecrosis of the Jaw

Medication-related osteonecrosis of the jaw (MRONJ) is an updated term that has replaced the phrase bisphosphonate-related osteonecrosis of the jaw (BRONJ). Bisphosphonates (BPs) are pyrophosphate analogues with a high affinity for hydroxyapatite crystals. They inhibit osteoclast-mediated bone resorption and play a key role in the management of osteolytic bone disorders, including osteoporosis, Paget disease, bone metastasis, and multiple myeloma.[44] However, their prolonged use is associated with MRONJ.[18]

The American Association of Oral and Maxillofacial Surgeons defined MRONJ as "exposed bone in the maxillofacial area

occurring in the absence of head and neck irradiation and showing no evidence of healing for at least 8 weeks after identification in patients treated with BP therapy"[4] (Figs. 5.27 and 5.28). To date, the true incidence of, causes of, and risk factors for the development of MRONJ are largely unknown. An overwhelming proportion (i.e., 97%) of the reported cases are related to the high-dose intravenous BP given to patients with cancer. However, a small fraction (i.e., 3%) has been reported in patients with osteoporosis and patients with Paget disease who are receiving oral BP.[18] The estimated incidence of MRONJ in patients with osteoporosis who are receiving oral BP is around 0.7 per 100,000 persons/years of exposure.[4] The incidence of MRONJ among patients with cancer who are receiving intravenous BP ranges from 0.72% to 7.4%.[18]

FIG. 5.27 Exposed bone on buccal lower premolar and molar in medication-related osteonecrosis of the jaw (MRONJ) patient following extraction of the first molar.
(Courtesy Dr. Vivek Thumbigere Math, Minneapolis.)

FIG. 5.28 Medication-related osteonecrosis of the jaw (MRONJ) patient with exposed bone on lingual aspect of lower premolar and molar following root canal treatment. (Courtesy Dr. Vivek Thumbigere Math, Minneapolis.)

MRONJ lesions may be asymptomatic, or they may present with pain, purulent discharge, swelling, tooth mobility, and paresthesia, culminating in a reduced ability to eat and speak. MRONJ occurs most frequently in the mandible (65%), followed by the maxilla (26%) and both jaws (95%).[52] The frequency of MRONJ is higher in the posterior region of the jaw. Among patients who develop MRONJ, approximately 60% of cases occur after an invasive dental procedure (e.g., tooth extraction), whereas 40% develop spontaneously.[48] Radiographic evaluation is usually inconclusive for early lesions. In advanced cases, a poorly defined moth-eaten radiolucency is noted with radiopaque sequestra.

Currently, there is no effective treatment for MRONJ. The discontinuance of BP is not helpful because BPs tend to reside in the bone for very long periods of time. Radical surgical intervention often exacerbates the condition, and the merit of hyperbaric oxygen treatment for the management of MRONJ is not conclusive. Patients are typically treated via minimally invasive conservative debridement, antibiotics, and chlorhexidine mouth rinses to limit the extent of the damage and to facilitate wound healing.[48] The American Dental Association suggests that an oral health program that consists of sound hygiene practices and regular dental care is a valuable approach to lowering the risk of developing MRONJ.[18]

Practitioners are encouraged to use atraumatic surgical techniques and to minimize the extent of dentoalveolar manipulation. Communication with the patient's physician and proper risk assessment are fundamental to the successful management of patients who are receiving BP therapy.

The use of the term *MRONJ* was introduced to capture the rising number of osteonecrosis cases of the jaw that are associated with new types of medication, such as other antiresorptive (denosumab) and antiangiogenic therapies, by the American Association of Oral and Maxillofacial Surgeons (AAOMS) in their 2014 update. Readers are referred to the position paper by the AAOMS for additional information on MRONJ.[4]

Necrotizing Periodontal Diseases

The clinical characteristics of necrotizing periodontal diseases may include (but are not limited to) ulcerated and necrotic papillary and marginal gingiva that is covered by a yellowish white or grayish slough or pseudomembrane, blunting and cratering of the papillae, bleeding on provocation or spontaneous bleeding, pain, and fetid breath. These diseases may be accompanied by fever, malaise, and lymphadenopathy, although these characteristics are not consistent. Two forms of necrotizing periodontal disease have been described: *necrotizing ulcerative gingivitis (NUG)* (Fig. 5.29) and *necrotizing ulcerative periodontitis (NUP)* (Fig. 5.30). NUG was previously classified as "gingival disease" or "gingivitis," because clinical attachment loss is not a consistent feature. NUP has been classified as a form of "periodontitis," because attachment loss is present. Nonetheless, NUP cases are almost exclusively reported in immunocompromised persons. Both NUG and NUP have been determined to constitute a separate group of diseases that have *tissue necrosis* as a primary clinical feature (see Box 5.1).

FIG. 5.29 (A) Ulcerative gingivitis illustrating sloughing of marginal gingiva. (B) Phase-contrast microscopy reveals spirochetes in subgingival plaque sample.

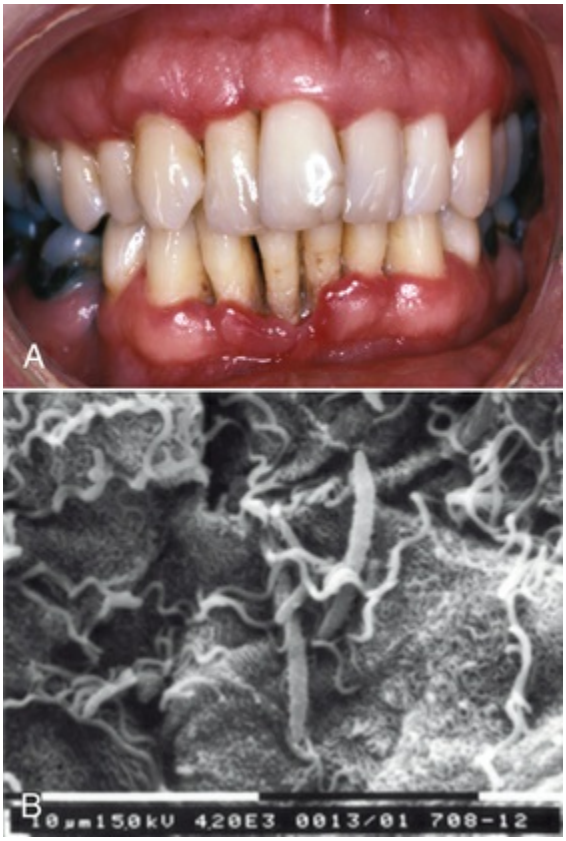

FIG. 5.30 (A) Necrotizing ulcerative periodontitis with severe clinical attachment loss in a 28-year-old male infected with human immunodeficiency virus (HIV). (B) Spirochetes noted on surface of sloughed epithelial cells.

Necrotizing Ulcerative Gingivitis

The clinical and causative characteristics of NUG[42] are described in detail in Chapter 20. The defining characteristics of NUG are its bacterial cause, necrotic lesion, and predisposing factors, such as psychologic stress, smoking, and immunosuppression. In addition, malnutrition may be a contributing factor in developing countries. NUG is usually seen as an acute lesion that responds well to antimicrobial therapy in combination with professional plaque and calculus removal as well as improved oral hygiene.

Necrotizing Ulcerative Periodontitis

NUP differs from NUG in that the loss of clinical attachment and alveolar bone is a consistent feature originating from the proximal region.[33] The characteristics of NUP are described in detail in Chapter 29. NUP may be observed among HIV seropositive individuals with low CD4 counts. Clinical manifestations include local ulceration and the necrosis of gingival tissue with the exposure and rapid destruction of underlying bone as well as spontaneous bleeding and severe pain. HIV+ persons with NUP are 20.8 times more likely to have CD4+ cell counts of less than 200 cells/mm^3 of peripheral blood as compared with those without NUP, which suggests that immunosuppression is a major contributing factor. NUP has also been associated with severe malnutrition in developing countries. More aggressive cases of necrotizing stomatitis exhibit tissue necrosis beyond the confines of the periodontium to include other oral tissues, such as the hard palate.

Key Fact

Necrotizing stomatitis is a serious inflammatory condition that develops in systemically compromised individuals and is characterized by soft tissue necrosis that extends beyond the gingiva, with potential bony sequestrum formation. This disease entity is now included in the AAP/EFP 2018 classification of periodontal disease.

Abscesses of the Periodontium

A periodontal abscess is a localized purulent infection of periodontal tissues, and it is classified by its tissue of origin as gingival, periodontal, or pericoronal abscesses.[28] The clinical, microbiologic, immunologic, and predisposing characteristics are discussed in Chapters 8, 9, and 13.

Periodontitis Associated With Endodontic Lesions

The classification of lesions that affect the periodontium and the pulp is based on the sequence of the disease process.

Endodontic–Periodontal Lesions

Pulpal necrosis precedes periodontal changes in endodontic–periodontal lesions. A periapical lesion that originates with pulpal infection and necrosis may drain to the oral cavity through the periodontal ligament, resulting in the destruction of the periodontal ligament and the adjacent alveolar bone. This may present clinically as a localized, deep, periodontal probing depth that extends to the apex of the tooth (Fig. 5.31A). If the endodontic infection is left untreated in such cases, an extensive alveolar ridge defect may occur (Fig. 5.31B–C), thereby necessitating reconstructive surgery (Fig. 5.31D) before the placement of implants and prostheses (Fig. 5.32) to reestablish a functional and aesthetic outcome. Pulpal infection may also drain through accessory canals, especially in the area of the furcation, which may lead to furcal involvement through the loss of clinical attachment and alveolar bone.

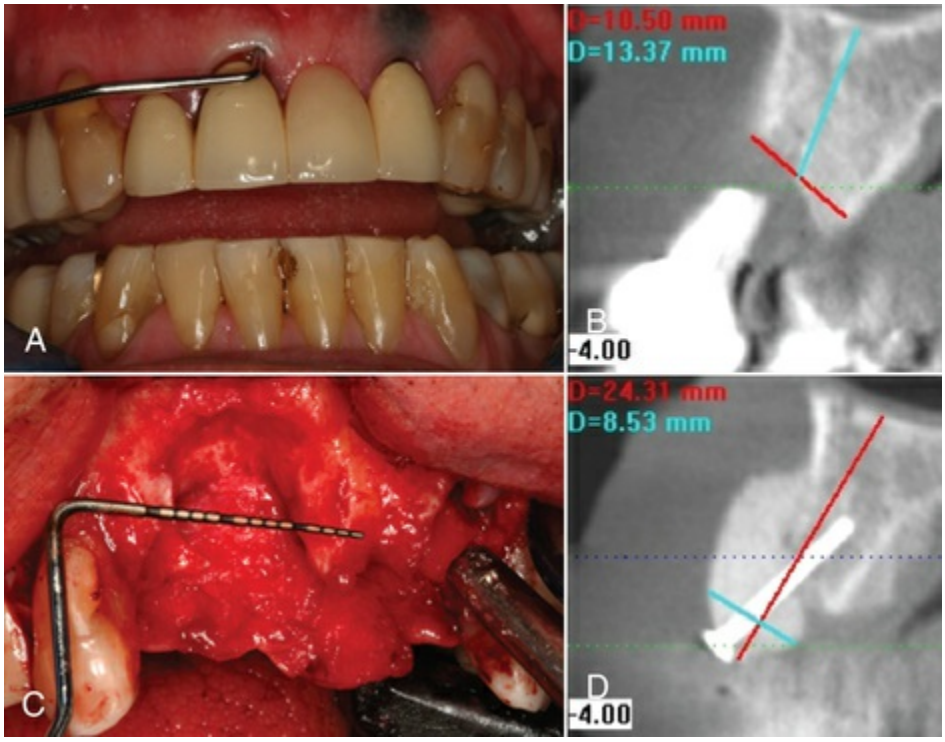

FIG. 5.31 (A and C) Clinical images of extensive loss of alveolar ridge secondary to periapical endodontic lesion. (B) CT scan depicts alveolar bone loss. (D) CT image of regenerated ridge via allogenic bone graft, tenting screw, and membrane.

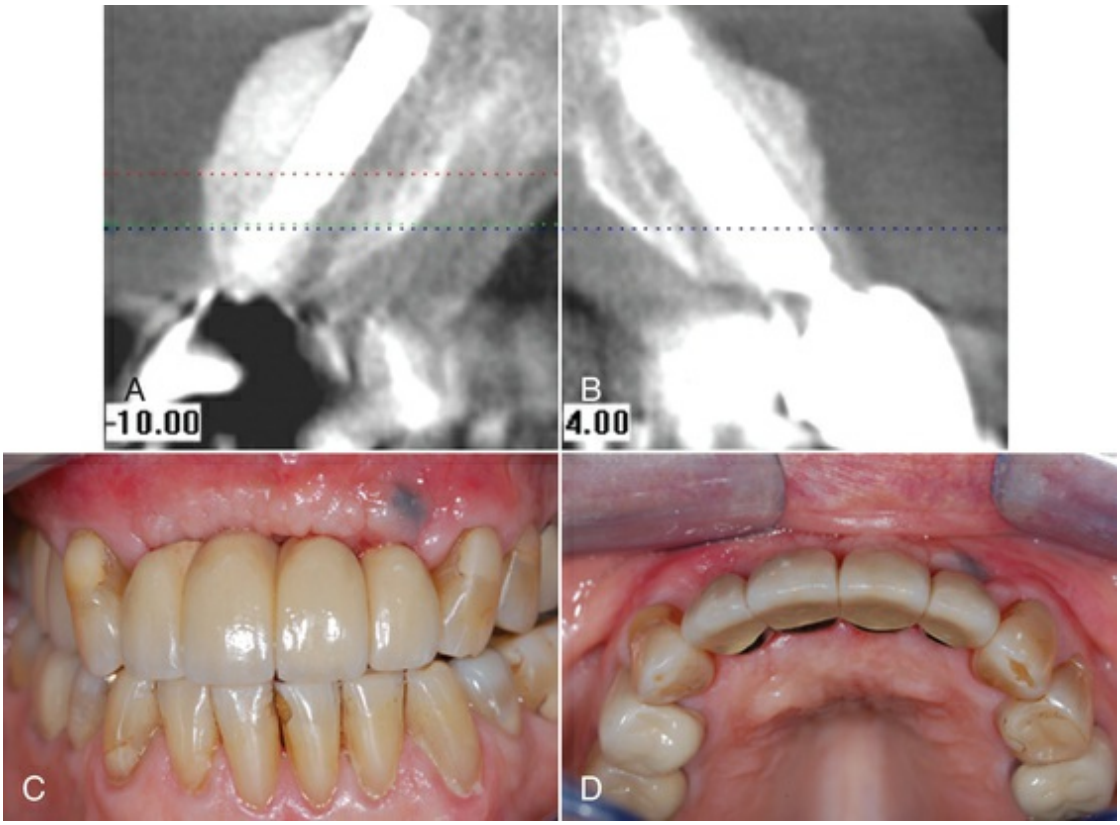

FIG. 5.32 Same patient depicted in Fig. 5.31. (A–B) CT scans of regenerated ridge with implants placed in areas 7, 9, and 10. (C–D) Clinical images of implant-supported bridge.

Clinical Correlation

In early stages of primary endodontic lesions, root canal therapy may be the only treatment necessary to restore the periodontal apparatus.

Periodontal–Endodontic Lesions

It is more uncommon for periodontal disease to lead to endodontic disease than vice versa. In a periodontal–endodontic lesion, the bacterial infection from a periodontal pocket leads to loss of attachment, and root exposure then spreads to the pulp, resulting in pulpal necrosis. In the case of advanced periodontal disease, the infection may reach the pulp through the apical foramen. Nonetheless, existing studies have shown that although scaling and

root planing remove cementum and underlying dentin, they may lead to dentine hypersensitivity but not to irreversible pulpitis.

Combined Lesions

Combined lesions occur when pulpal necrosis and a periapical lesion occur on a tooth that is also periodontally involved. An intrabony defect that communicates with a periapical lesion of pulpal origin results in a combined periodontal–endodontic lesion.

In all cases of periodontitis associated with endodontic lesions, the endodontic infection should be controlled before the definitive management of the periodontal lesion begins, especially when regenerative or bone-grafting techniques are planned.[29] Tooth prognosis in combined lesions highly depends on the outcome of the periodontal treatment.

Developmental or Acquired Deformities and Conditions

Localized Tooth-Related Factors That Modify or Predispose Individuals to Plaque-Induced Gingival Diseases or Periodontitis

In general, localized tooth-related factors contribute to the initiation and progression of periodontal disease through the enhancement of plaque accumulation or the prevention of effective plaque removal via normal oral hygiene measures.[7] These factors fall into the four subgroups outlined in Box 5.4.

Tooth Anatomic Factors

Tooth anatomic factors are associated with malformations of tooth development or tooth location. Anatomic factors (e.g., cervical enamel projections, palatal grooves, enamel pearls) have been associated with clinical attachment loss, especially in furcation areas. Cervical enamel projections are found on 15% to 24% of

mandibular molars and on 9% to 25% of maxillary molars, and strong associations have been observed with furcation involvement.[27] Palatogingival grooves, which are found primarily on maxillary incisors, are observed in 8.5% of the population and are associated with increased plaque accumulation and clinical attachment as well as bone loss. Proximal root grooves on incisors and maxillary premolars also predispose individuals to plaque accumulation, inflammation, and the loss of clinical attachment and bone.

Tooth location is considered important for the initiation and development of disease. Misaligned teeth predispose individuals to plaque accumulation with resultant inflammation in children, and they may predispose adults to clinical attachment loss, especially when they are associated with poor oral hygiene habits. Open interproximal contacts that contribute to food impaction have been associated with an increased loss of attachment.[21]

Dental Restorations and Appliances

Dental restorations or appliances are frequently associated with the development of gingival inflammation. Restorations placed deep in the sulcus or within the junctional epithelium may impinge on the biologic width resulting in inflammation and the loss of clinical attachment and bone. Contour of a complete crown restoration can affect plaque retention with flat surfaces being more hygienic as compared to convex restorations exhibiting increased bulk of material at the cervical region.

Root Fractures

Root fractures may be associated with endodontic or restorative procedures as well as traumatic forces (Fig. 5.33A–C) and may lead to periodontal involvement through the apical migration of plaque along the fracture line (Fig. 5.33D).

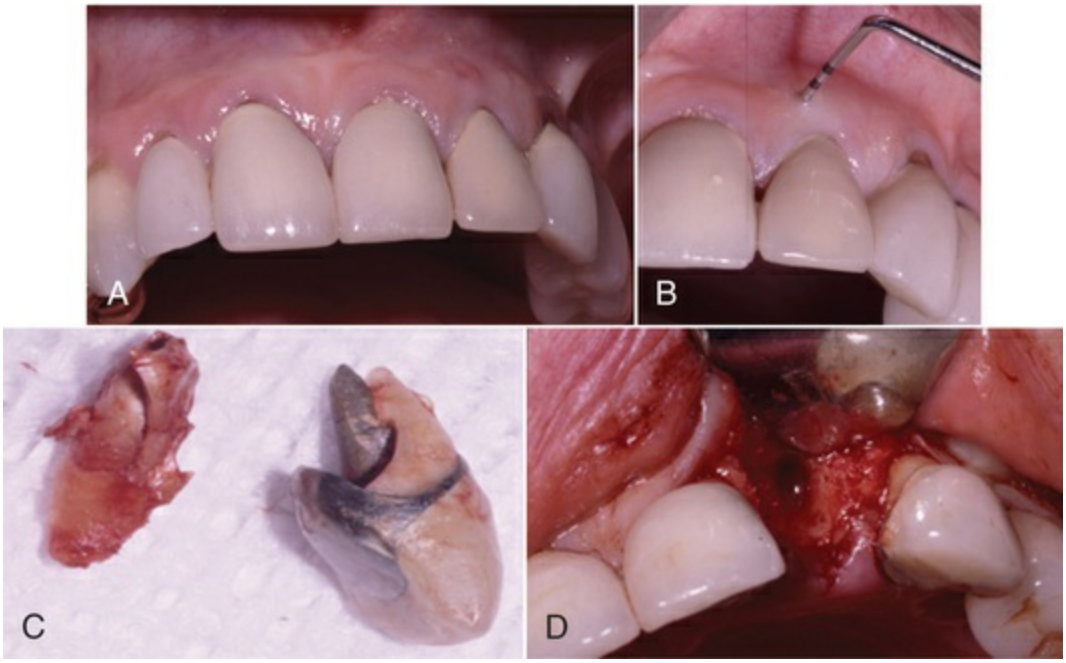

FIG. 5.33 (A–B) Clinical images of fistula tract. (C) Root fracture. (D) Resultant alveolar ridge defect.

« Flash Back

Vertical root fractures involving both the pulp and PDL are true combined endodontic–periodontal lesions.

Cervical Root Resorption and Cemental Tears

Invasive cervical root resorption (ICR) (as noted on the cone beam computed tomography scans shown in Fig. 5.34A–B) and cemental tears may lead to periodontal destruction when the lesion communicates with the oral cavity and allows bacteria to migrate subgingivally. The atraumatic removal of teeth with progressed cervical resorption lesions and the reconstruction of resultant ridge defects with bone grafts, dental implants, and prostheses are viable solutions for such defects (Fig. 5.35). Avulsed teeth that are reimplanted frequently develop ankylosis and cervical root resorption many years after reimplantation. If the patient is still in the phase of skeletal growth, decoronation may be the treatment of choice for ridge preservation. In adults with completed skeletal growth, atraumatic removal of such ankylosed teeth, followed by ridge reconstruction and placement of implants and prosthesis, is a

viable treatment option in adults (see Fig. 5.35).

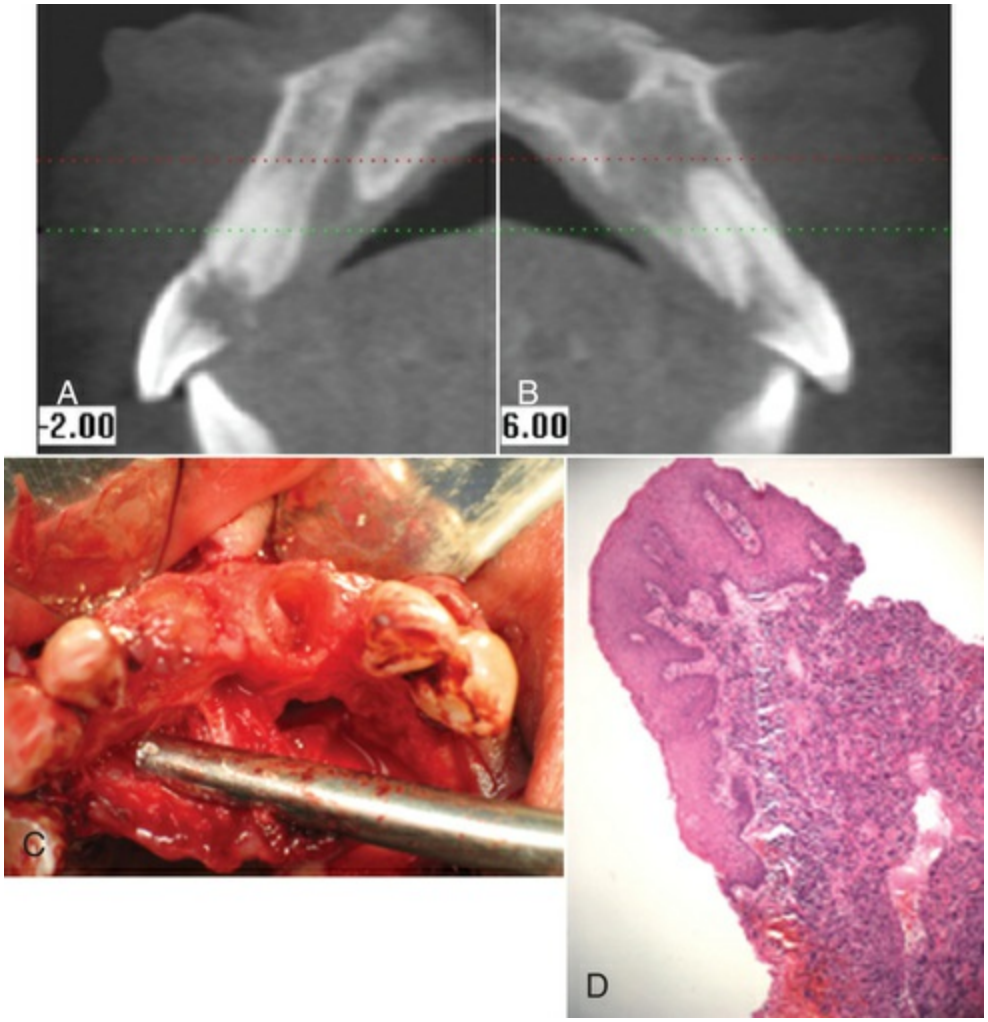

FIG. 5.34 (A–B) CT scans reveal severe cervical root resorption of maxillary central incisors and periapical abscess. (C) Crowns fractured because of resorption. (D) Biopsy of soft tissue from resorption.

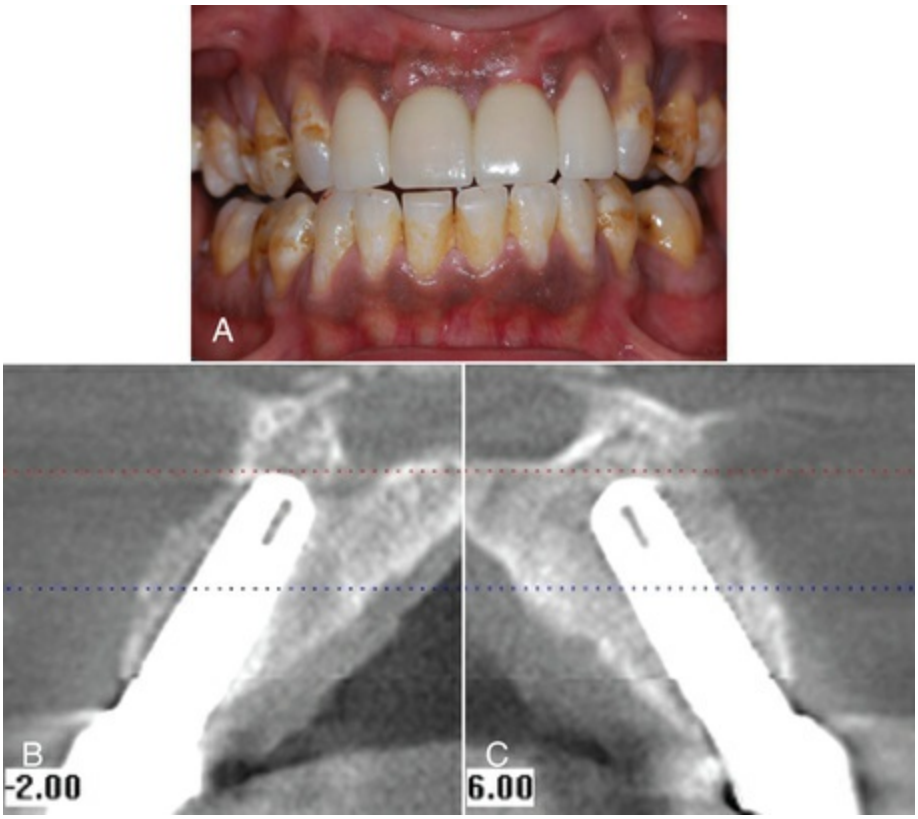

FIG. 5.35 (A) Posttreatment clinical image of same patient depicted in Fig. 5.34 with implant-supported crowns and veneers on laterals. (B–C) CT scans of bone grafts and implants replacing central incisors lost as the result of severe cervical root resorption.

Mucogingival Deformities and Conditions Around the Teeth

Mucogingival deformity is a generic term used to describe the mucogingival junction and its relationship to the gingiva (Fig. 5.36), the alveolar mucosa, and frenula muscle attachments. A mucogingival deformity is a significant departure from the normal shape of the gingiva and the alveolar mucosa, and it may involve the underlying alveolar bone. Mucogingival surgery and periodontal plastic and aesthetic surgery correct defects in the morphology, position, or amount of gingiva. This subject is described in detail in Chapter 65. The surgical correction of mucogingival deformities may be performed for aesthetic reasons, to enhance function, or to facilitate oral hygiene.[37]

FIG. 5.36 (A) Mucogingival defect depicted by recession. (B) Defects extend into alveolar mucosa and lack keratinized gingiva.

Mucogingival Deformities and Conditions of the Edentulous Ridges

Mucogingival deformities, such as a lack of stable keratinized gingiva between the vestibular fornices and the floor of the mouth (Fig. 5.37A), may require soft-tissue grafting and vestibular deepening before prosthodontic reconstruction (Fig. 5.37B–D). Alveolar bone defects in edentulous ridges (Fig. 5.38A–B) usually require corrective surgery (Fig. 5.38C–D) to restore form and function before the placement of implants and prostheses to replace missing teeth (Fig. 5.39).[37]

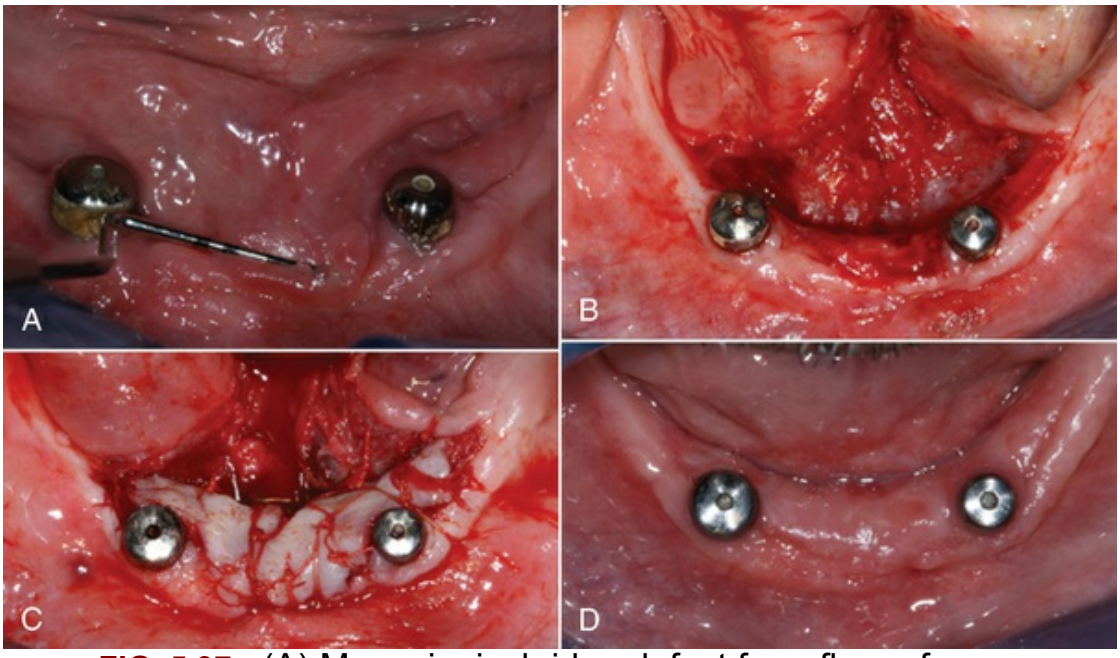

FIG. 5.37 (A) Mucogingival ridge defect from floor of mouth to vestibular fornix. (B) Partial thickness flap with vestibular deepening. (C) Placement of free gingival graft. (D) Reestablishment of vestibular depth and keratinized attached gingiva.

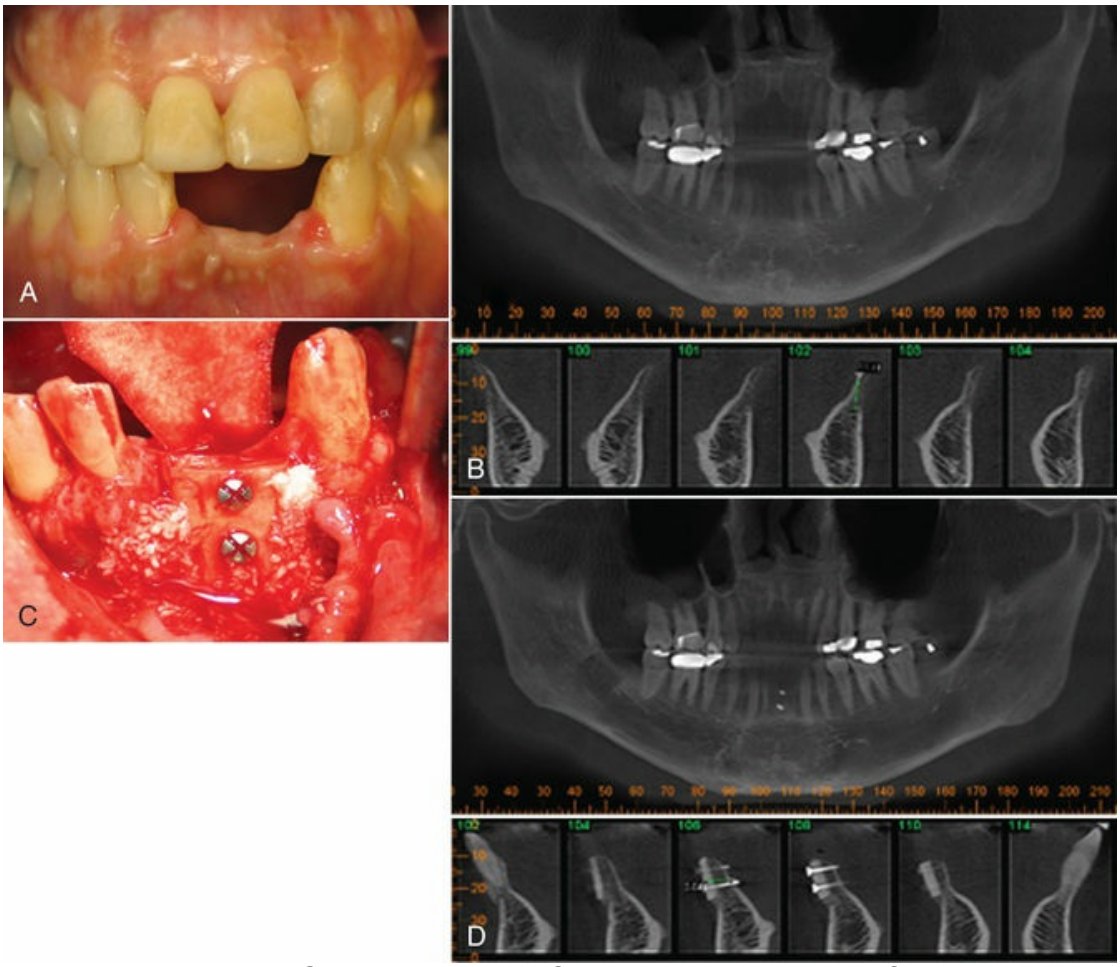

FIG. 5.38 (A) Clinical image of edentulous ridge defect. (B) Pretreatment CT image of defect. (C) Reconstructed ridge using ramus block graft. (D) CT scan of grafted site.

FIG. 5.39 (A) Clinical image of ridge 6 months after grafting. (B) Placement of implants in area of teeth #23 and #25. (C) Porcelain fused to metal (PFM) crowns for maxillary incisors and implant-supported bridge from teeth #23 to #25.

Occlusal Trauma

The causes of trauma from occlusion and the effect of this trauma on the periodontium[14] are discussed in detail in Chapters 26 and 55.

Case Scenario 5.1

Patient:

63 year-old male, former smoker (20 pack-years)

Chief Complaint:

Presents for scheduled quarterly maintenance visit.

Background Information

The patient was treated with repeated sessions of scaling and root planing as well as periodontal flap surgery several years ago. He has since been very compliant with a 3-month maintenance schedule.

Clinical Findings:

Intraoral evaluation reveals 2 to 7 mm of clinical attachment loss throughout his dentition with probing depth measurements ranging from 1 to 3 mm. The plaque control record was 20%, and localized bleeding on probing was noted on the distal of #7 and lingual of #30. The diagnosis was determined to be localized gingivitis on a reduced periodontium.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. If the patient's compliance becomes erratic and periodontitis relapses, how would you classify the patient's condition? A. Gingivitis B. Mild periodontitis C. Moderate periodontitis D. Severe periodontitis	**Answer: D** **Explanation:** In the case of reduced periodontium, it is critical to consider the extent of preexisting attachment loss. This attachment loss is definitive, and further progression can negatively affect teeth prognosis.

Case Scenario 5.2

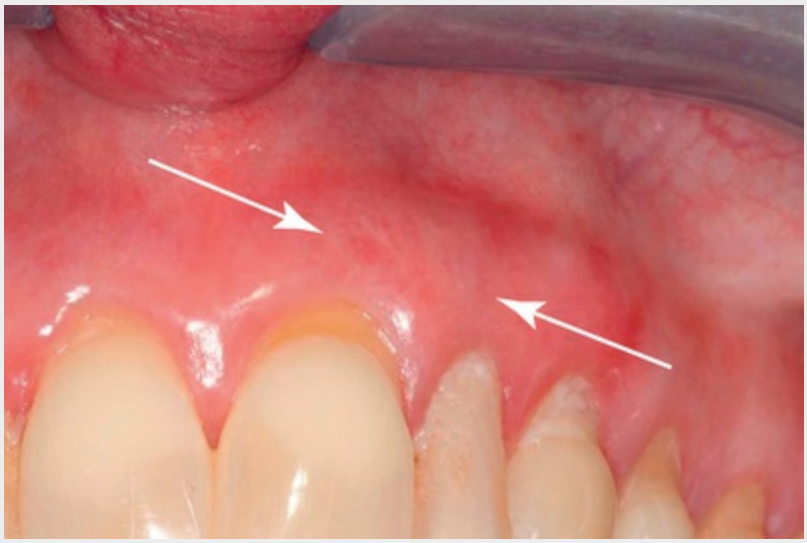
Patient:
55-year-old male, nonsmoker

Chief Complaint:
"My gum has receded and it's bleeding."

Background Information
The patient presents with aesthetic complaints associated with gingival recession and associated root exposure on the upper central incisors. The patient also reports occasional sensitivity and bleeding from the area.

The patient was treated with repeated sessions of scaling and root planing as well as periodontal flap surgery several years ago. He has since been very compliant with a 3-month maintenance schedule.

Current Findings:
White striations on the gingiva facial of #9 and #10 were noted. During clinical examination, gentle finger rubbing of the mucosa coronal to #9 led to exfoliation of the epithelium.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Do you expect scaling and root planing to treat this condition? A. Yes B. No	**Answer: B** **Explanation:** This mucocutaneous lesion was biopsied and the diagnosis of lichen planus was confirmed following clinical assessment and positive Nikolsky's sign. Appropriate corticosteroid treatment led to remission.

Case Scenario 5.3

Patient:
62-year-old postmenopausal female

Chief Complaint:
"I have noticed that I have halitosis, and my gums bleed."

Background Information
The patient says that she cannot brush her teeth because her gums have been painful for 6 months.

Current Findings:
Gingiva sloughs following the application of a cotton swab.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the most likely diagnosis? A. Acute necrotizing gingivitis B. Toothbrush abrasion C. Mucous membrane pemphigoid D. Sarcoidosis	**Answer: C** **Explanation:** Immunofluorescence-labelled antibodies are used to mark an antigen/antibody complex in the basement membrane where autoimmune reaction causes degeneration of basal lamina, hemidesmosomes, and anchoring fibrils, thereby resulting in sloughing of epithelium.

Case Scenario 5.4

Patient:
28-year-old male

Chief Complaint:
"My lower front teeth are mobile."

Background Information
Progressive recession through dentition over the past 2 years. Painful rampant recession in the anterior mandible recently.

Current Findings:
Cratered papillae, ulcerative gingiva with exposed interproximal bone.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. When you consult with the patient's physician, what is the most likely medical diagnosis? A. Osteoporosis B. Diabetes mellitus C. AIDS D. Medication-related osteonecrosis of the jaw	**Answer: C** **Explanation:** Necrotizing ulcerative periodontitis may be observed among HIV+ patients with very low CD4 counts (AIDS) and be manifested as local ulceration and necrosis of gingival tissue with exposed bone.

Case Scenario 5.5

Patient:
59-year-old postmenopausal female

Chief Complaint:
"My lower jaw is sore and aches."

Background Information
Lower first molar extracted ~ 4 months.

Current Findings:
Medication-related osteonecrosis of the jaw (MRONJ) with exposed alveolar bone.

Radiographic Findings:
Within normal limits.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the most likely medical diagnosis associated to MRONJ? A. Osteopenia B. Osteoporosis C. Malignant myeloma D. Localized osteomyelitis	**Answer: C** **Explanation:** Bisphosphonates (BPs) inhibit osteoclast-mediated bone resorption. BPs are used to manage osteolytic bone disorders such as osteoporosis, Paget disease, metastatic bone cancers, and multiple myeloma.

Case Scenario 5.6

Patient:

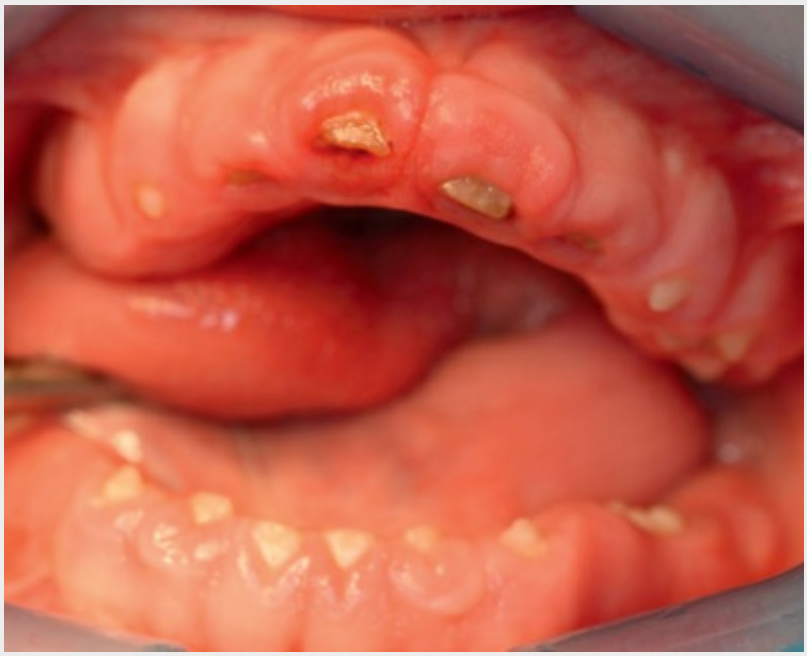
6-year-old male

Chief Complaint:
"My classmates tease me and call me 'gummy.' I have difficulty chewing my food and talking."

Background Information
Patient has had a kidney transplant.

Current Findings:
Severe gingival overgrowth.

Radiographic Findings:
Within normal limits.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. All of the following drug categories have been associated with gingival overgrowth EXCEPT which one? A. Antiarrhythmic, digoxin B. Anticonvulsant, phenytoin C. Calcium channel blocker, nifedipine D. Immunosuppressant, cyclosporine	**Answer: A** **Explanation:** Phenytoin, nifedipine, and cyclosporine have all been associated with gingival overgrowth, while digoxin has not been associated with overgrowth.

Case Scenario 5.7

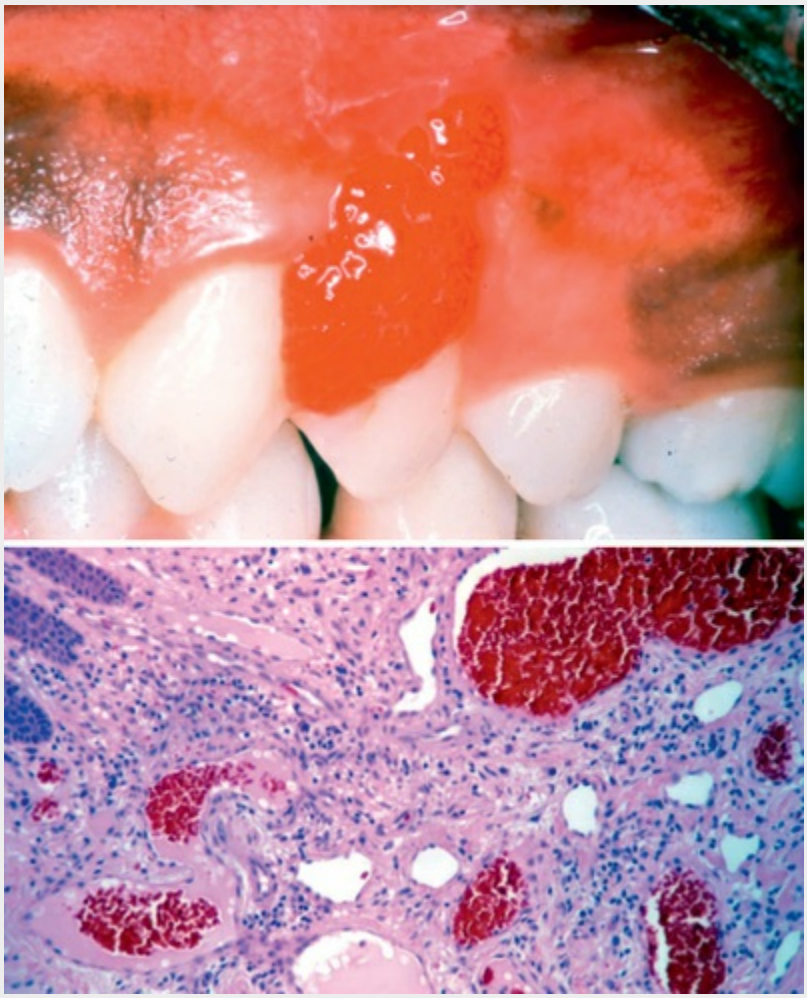
Patient:
27-year-old female

Chief Complaint:
"There is a bump on my gums that bleeds when I brush and floss."

Background Information
Lesion developed over past ~ 2 months.

Current Findings:
Biopsy depicted in lower image.

Radiographic Findings:
Within normal limits.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the most likely diagnosis? A. Fibroma B. Lateral periodontal abscess C. Epulis fissuratum D. Pyogenic granuloma	**Answer: D** **Explanation:** Biopsy depicts inflammatory cell infiltrate within the connective tissue and numerous capillaries engorged with erythrocytes.

CHAPTER 6

Fundamentals in the Methods of Periodontal Disease Epidemiology

Philippe P. Hujoel, Georgios A. Kotsakis

CHAPTER OUTLINE

The Need for Epidemiology
Epidemiologic Study Designs
Causes
Diagnosis

The Need for Epidemiology

The World Health Organization (WHO) defines epidemiology as "the study of the distribution and determinants of health-related

states or events (including disease), and the application of this study to the control of diseases and other health problems." Distinct study designs are employed to examine the distribution of periodontal diseases in populations and to determine its etiology and its association with other diseases; the ultimate goal is to determine evidence-driven preventive and therapeutic strategies. "Periodontal [gum] diseases, including gingivitis and destructive periodontal disease, are serious infections."[72] This 2009 statement from a professional dental organization reflected the dominating belief accepted since the 1960s that bacteria cause periodontal conditions.[19] This bacterial dogma had several consequences. Clinical management and research became largely focused on vaccines, microbial diagnosis, antimicrobials, antibiotics, dental plaque, and immunology. Clinical diagnoses that did not fit the infection paradigm (e.g., periodontal atrophy) were eliminated from some periodontal disease classifications, and it was hypothesized that periodontal infections caused systemic diseases.

But are periodontal diseases really infectious diseases? A reliable answer to this question requires epidemiologic evidence. This chapter focuses on the role of epidemiology in the study of human diseases. *Case–control studies* and *cohort studies* are two epidemiologic study designs that identify common causes of chronic disease, such as smoking, ionizing radiation, hepatitis B, and high blood pressure. *Randomized controlled trials* are study designs that assess the diagnosis, management, and prognosis of chronic diseases and that either confirm or refute the suspected causes of disease identified in case–control or cohort studies. Prostate surface antigen screening, polio vaccination, and hormone replacement therapy are examples of diagnoses and treatments for chronic diseases that were evaluated by means of randomized controlled trials.

Study Designs

Epidemiologic study designs fall within two broad categories: observational and interventional studies. As the terms imply, assigning a study to one of these categories depends on if the investigators assess the efficacy of an intervention (interventional)

or if the intervention is not under control of the investigators (observational). Examples of interventional studies in oral health research are randomized clinical trials and nonrandomized clinical trials. Examples of observational studies are cross-sectional studies, cohort studies, and case-control studies.

Some of the essential characteristics of epidemiologic studies are that they are conducted in humans, there is a control or a comparison group, and clinically relevant endpoints are evaluated. Such studies are available to support the direct effects that oral bacteria have on reversible gingival inflammation.[73] However, studies that are commonly cited in support of the periodontal infection hypothesis often lack these elements. For instance, is a "burst" of bone loss[21] subsequent to the implantation of *Bacteroides gingivalis* (now *Porphyromonas gingivalis*) in an animal model proof that "this microorganism [is] of great importance to the control of destructive periodontal disease"? Opponents of this hypothesis could argue that in similar animal models nicotine injections alone have a direct effect on periodontal bone loss, thus satisfying the biologic plausibility criterion for causality.[54] Nevertheless, in contemporary practice the strength of scientific evidence is formally ranked based on the study design. One widely used level of evidence classification by the Oxford Center for Evidence-Based Medicine (http://www.cebm.net/wp-content/uploads/2014/06/CEBM-Levels-of-Evidence-2.1.pdf) generally considers animal studies (i.e., mechanism-based reasoning) as having the lowest level of evidence to impact clinical thinking, whereas systematic reviews of randomized controlled trials are generally considered as having the highest available level of evidence.

Systematic Review versus Expert Opinion

A systematic review is considered a form of secondary research that aims to screen the entire breadth of information on a selected topic, identify relevant research studies, and summarize their findings. The key difference between an expert opinion review and a systematic review is that the latter is more objective in the sense

that it intends to summarize the available body of literature inclusively and not based on the author's opinion on which studies are noteworthy or impactful. It goes without saying that systematic reviews are considered to be high level and are often used to guide clinical decision-making, but the clinicians should be aware that their conclusions suffer from the shortcomings of the included studies.

Epidemiologic studies, which are at a higher level than case reports and animal studies, have had a powerful impact on reducing the incidence of some chronic diseases by reliably identifying their primary causes. Reliable evidence on what causes disease allows laboratory research to focus on elucidating the causal pathways of disease, which can then lead to clinical trials. "Medical science continually passes the baton of discovery from [epidemiologic] observation to laboratory studies to human clinical trials."[42] For example, epidemiologic observations identified hepatitis B as the main cause of liver carcinoma, which is one of the most common cancers in the world.[3] Subsequently, the baton of discovery was passed to basic science, with which a recombinant engineered vaccine for hepatitis B was developed. Then, the baton of discovery was passed to clinical trialists, who assessed the effectiveness of vaccinations and documented dramatic declines in mortality rates from liver cancer.[41] Similar success stories in the management of chronic diseases in which epidemiology played a critical role include coronary heart disease and blood pressure medication, dental caries and fluoride, and lung cancer and smoking intervention programs.

« Flash Back

Recall that well-designed interventional studies generally are higher level than observational studies.

The emerging epidemiologic evidence regarding the cause of periodontal diseases suggests that factors such as cigarette smoking, sugar, cereals, and chronic diseases such as diabetes could

be primary causes of periodontal disease.[5,22,64] Notably, the 2004 US Surgeon General report concluded that the evidence was sufficient to infer a causal relationship between smoking and periodontitis.[74] Organizations such as the WHO suggest that periodontal disease prevention be made an integral part of programs that focus on tobacco control, diet, and physical activity, which are also shared risk factors with other prevalent chronic diseases such as cardiovascular diseases.[56] Regardless of your current beliefs about the causes of periodontal disease, becoming familiar with the epidemiologic methodology may be important in order to judge this emerging evidence independently and critically.

Measuring the Occurrence of Conditions or Diseases

The fundamental tools of epidemiology are simple sums and divisions that reflect how many individuals or sites either have or develop a particular condition or disease.

The *prevalence* is the sum of all examined individuals or sites that exhibit the condition or disease of interest divided by the sum of the number of individuals or sites examined. The prevalence can range from 0% (no one has the condition or disease of interest) to 100% (everyone has the condition or disease of interest).

As an example of prevalence, the Centers for Disease Control and Prevention reported about the prevalence of individuals with at least one periodontal pocket depth of 4 mm or deeper. It was reported that, from 1988 to 1994, a little more than 1 in 5 Americans had such a condition, for a prevalence of a little more than 20%; from 1999 to 2004, only 1 in 10 Americans fell into this category,[15] for a prevalence of around 10%. These findings suggest a more than 50% decline in the prevalence of pocket depths greater than or equal to 4 mm for adults between the ages of 20 and 64 years, which occurred over approximately a decade. These epidemiologic data confirm another report of declining destructive periodontal disease prevalence in the United States.[7] Such information about prevalence measures of periodontal conditions may have implications for human resource needs in the United States and may provide clues with respect to the causative factors that drive such changes. Many

countries do not have prevalence surveillance systems,[56] which makes it difficult to determine whether these trends observed in the United States are isolated events or part of a more general trend.

The *risk* is the probability that an individual or a site will develop a particular condition or disease during follow-up. The risk for a condition or a disease is a number that ranges between 0% and 100%. The simplest way to estimate risk is to have a fixed number of persons or sites at risk at some defining moment (i.e., time zero [t_0]). Individuals or sites within individuals are followed up over time after this defining moment. After a follow-up period (i.e., from t_0 to t_n), the risk can be calculated as the proportion of persons or sites in which the clinical outcome of interest develops during the follow-up period. Because the risk is estimated as a proportion, it is without dimension, and it ranges between 0 and 1. When a risk is reported, it should be accompanied by a specific time period to which it is applied. A 5% risk for death may be considered small when it refers to a 20-year period but large when it refers to a 3-month period.

As an example, consider concerns about occupational human immunodeficiency virus (HIV) infection among dentists. It has been reported that the risk for developing an HIV infection within the year subsequent to an accidental needle stick with HIV-contaminated blood is 0.3%. Such a statistic has an intuitive appeal and can be related to patients or colleagues. A risk of 0.003 (0.3%) indicates that for every 1000 individuals who have an accidental HIV-contaminated needle stick, 3 are expected to develop an HIV infection within a year of the event.

The *odds* for an event is the probability that an event occurred divided by the probability that an event did not occur. Whereas probability is a value that has to range between 0 and 1, odds values range from 0 to infinity. If the probability for observing an event is small, then the odds and the probability are almost identical. For example, if the probability for a vertical root fracture after an endodontic procedure is 0.001, then the odds are 0.001/0.999 or 0.001001. Odds are commonly reported in studies because they are often easier to estimate with statistical models than probabilities. For example, the odds for developing an HIV infection after an accidental needle stick with HIV-contaminated

blood are 0.003 (0.003/0.997).

Incidence rates are an alternative measure to describe disease occurrence. One example of an incidence rate is the speedometer in a car that displays at any given time the number of kilometers being traveled per hour. In clinical trials or epidemiology, the rate reflects the number of disease occurrences per person-time or site-time. The disease rate is a ratio in which the numerator is the number of subjects or sites diagnosed with the disease of interest and the denominator is the sum of the time at risk over all subjects or sites in the population.

Incidence versus Prevalence

Recall that prevalence is the proportion of a population found to have a condition at a given point in time (e.g., 9% of the US population had severe periodontitis in the 2009-2010 NHANES survey), while incidence is the probability that a disease will occur in a previously healthy population over a period of time (e.g., the incidence of peri-implantitis for patients with mandibular over-dentures is 17% after 5 years).

Incidence rates—as opposed to the previously introduced measures of disease occurrence—imply an element of time. The denominator in the incidence rate has time as the dimension. Thus the dimension of incidence rate is 1/time. This dimension is often referred to as "person-time" or "site-time" to distinguish the time summation from ordinary clock-time. The magnitude of the incidence rate can vary between 0 and infinity. When there are no new disease onsets during the study period, the incidence rate is 0. When every person observed dies instantaneously at the start of the study (and thus the sum of the time periods is 0), then the incidence rate is infinity.

An example of the application of rates is provided in Fig. 6.1, in which the number of teeth lost per 1000 tooth-years is plotted as a function of the maximum probing depth at the start of follow-up. The plot suggests a nonlinear relationship between maximum pocket depth and tooth loss, with a substantial increase in tooth loss rate for teeth that have periodontal pockets of 7 mm or deeper.

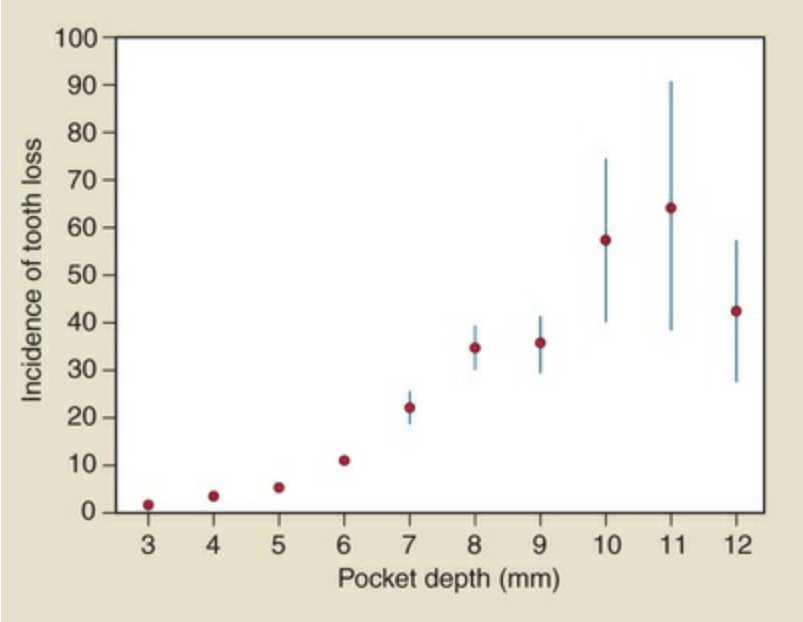

FIG. 6.1 Rate of tooth loss per 1000 tooth-years as a function of maximum probing depth per tooth in a cohort of 1021 patients between the ages of 40 and 65 years under periodontal specialist care for destructive periodontal disease. (Data from Hujoel PP, Cunha-Cruz J, Selipsky H, et al: Abnormal pocket depth and gingival recession as distinct phenotypes. *Periodontol 2000* 39:22–29, 2005.)

For the study of risk, the population studied is usually limited to those individuals at risk for the outcome of interest. Thus if the outcome of interest is a disease, the following subjects are excluded from the cohort: persons who already have the disease, persons who have immunity to the disease, and persons who are biologically incapable of developing the disease.

Periodontal Measures Typically Recorded Clinically

A periodontal examination can measure various characteristics of the periodontium. Dental records of periodontal patients typically contain information about the teeth that are present, missing, or impacted as well as measurable information about the periodontal status of those teeth. Information such as clinical probing depth, bleeding on probing, gingival recession, mobility of teeth, and the presence of furcation involvements can be charted. In addition, some clinicians may collect information about the presence of

gingivitis by evaluating the color and form of the gingival tissues. These measures can be complemented with radiographic examinations that may provide information about marginal bone levels.

In research settings or in some selected private practices, additional periodontal measures may be collected, such as clinical attachment levels, microbiologic measures, gingival crevicular fluid volume, biomarkers in the crevicular fluid, and indices that measure the amount of gingival inflammation or dental plaque or debris accumulation.

Two common measures of gingival inflammation are the Gingival Index (GI) and bleeding on probing.[25] The GI was proposed in 1963 as a method for assessing the severity and quantity of gingival inflammation.[46,47] With this particular index, only gingival tissues are assessed. Each of the four gingival areas of the tooth (i.e., facial, mesial, distal, and lingual) are assessed for inflammation and rated as normal gingiva (a score of 0) to severely inflamed gingiva with a tendency to spontaneously bleed (a score of 3). Gingiva that is mildly inflamed but without bleeding on probing is given a score of 1, whereas moderately inflamed gingiva with bleeding is given a score of 2. The scores can be averaged for each patient to provide patient means. Alternatively, site-specific analyses can relate local and patient-specific factors to the GI that is measured at individual sites.[13]

Bleeding on Probing versus Gingival Index

In clinical settings the term *gingival index* is often misused in lieu of bleeding on probing (BOP). According to the existing nomenclature, gingival index is a categorical index that assesses the severity of gingival inflammation on a scale from 0 to 3. On the other hand, BOP is a binary index (Yes/No) that determines whether a site is bleeding on probing or not. The two should not be confused.

Bleeding on probing is another measure of periodontal inflammation. The specific approach to obtain a bleeding measure can vary from one study to the next as well as from one clinician to

another. For example, in the third National Health and Nutrition Examination Survey (NHANES III),[52] bleeding measures were obtained as follows. First, the facial and mesiofacial sites of teeth in two randomly selected quadrants—one maxillary and one mandibular—were selected. A special probe known as the *National Institute of Dental Research probe* was used in these assessments. This color-coded probe is marked at 2, 4, 6, 8, 10, and 12 mm. To begin the assessment, the examiner dried a quadrant of teeth with air. Then, starting with the most posterior tooth in the quadrant (excluding the third molar), the examiner placed a periodontal probe 2 mm into the gingival sulcus at the facial site and carefully swept the probe from the mesiofacial to the mesial interproximal area. After probing the sites in the quadrant, the examiner assesses the presence or absence of bleeding at each probed site. The same procedure was repeated for the remaining quadrant.

Commonly used measures of periodontal tissue destruction include mean probing depth, mean attachment loss, and mean recession level.[32] The clinical protocols regarding how such mean values are collected and calculated can vary considerably. One example of how such values can be ascertained clinically is described in the National Institute of Dental and Craniofacial Research "periodontal destruction" examination.[52] This examination includes an assessment of periodontal attachment loss[60] as the distance in millimeters from the cemento-enamel junction to the bottom of the gingival sulcus. This distance was measured at the facial and mesiofacial sites of teeth in a randomly selected maxillary and mandibular quadrant with the use of the indirect measurement method developed by Ramfjord.[60]

Sensitivity versus Specificity

Sensitivity is defined as the number of diseased patients who are correctly identified as having disease—that is, the diagnostic marker leads to a minimum number of false negative diagnoses. Specificity is defined as the number of healthy persons who are correctly determined to not have the disease—that is, the diagnostic marker leads to a minimum number of false positive diagnoses.

Translating Periodontal Measures Into Traditional Epidemiologic Measures of Disease Occurrence

The application of the traditional epidemiologic methods of risk, prevalence, and rate was challenging, because medical epidemiologists typically deal with patients. Dental epidemiologists deal with as many as 188 sites per patient. These periodontal sites within patients are correlated with many host-related factors. For example, gingival bleeding is suppressed in smokers.[6] Therefore bleeding on probing in periodontal sites in smokers tends to be more alike than bleeding on probing in periodontal sites among nonsmokers. Sites within patients are not statistically independent. The statistical methodology that is used to deal with correlated observations can be complex, and for most of the 20th century it was challenging to calculate the confidence intervals for site-specific risks or prevalence.[34] As a result, clinicians could not obtain reliable information about whether a periodontal site colonized with a particular microbiologic species was at an increased risk for periodontal attachment loss. These challenges may have hampered progress in the building of causal models of periodontal disease.

A common approach to dealing with this challenge of correlated observations was to summarize site-specific periodontal data at the patient level. These summaries could be calculated in a variety of ways. The information about the presence of bleeding in up to 188 periodontal sites in a patient could be summarized as the presence of at least 1 bleeding site, the presence of at least 5 bleeding sites, or a patient mean value.

The advent of modern statistical techniques to deal with the problem of correlated data made it possible to avoid summarizing site-specific information at a patient level.[13,14,28,33,34] These methods allow for the exploration of the role of patient- and site-specific factors in local site-specific events. For example, this can be used to determine whether the 3-mm loss of attachment at a site is related to site-specific factors (e.g., microflora present at that site), host factors (e.g., serum cotinine levels), or an interaction between a site-specific factor and a host factor.

True and Surrogate Measures of the Periodontal Condition

The epidemiology of true and surrogate endpoints of periodontal disease do not necessarily coincide. *True endpoints* are tangible outcomes that directly measure how a patient feels, functions, or survives.[17] True endpoints include oral health–related quality-of-life measurements[40,48,68] and self-reported problems, such as a positive answer to the following question: "When you brush or floss your teeth, do you notice bleeding that is both regular and that involves spitting blood-stained saliva?" *Surrogate endpoints* are intangible to the patient.[71] Surrogate endpoints in periodontal research include anatomic measures (e.g., probing depth), measures of inflammation (e.g., bleeding), microbiologic measures, and immunologic measures.[13] Surrogate endpoints are often objective, because they can be measured by the clinician (rather than relying on self-report by patients) or by laboratory methods.

Surrogate endpoints can be misleading when the goal is to provide reliable information about clinical decisions related to diagnosis, etiology, treatment, or prognosis. An overview of situations in clinical research in which surrogate endpoints have led to misleading conclusions is provided in Table 2.1 on the Expert Consult website. One periodontal example is the use of systemic antibiotics that may have a beneficial impact on attachment gain[19] but a potential increased risk for tooth loss.[11]

Periodontal Endpoints: Examples

True endpoints: Tooth loss, patient's quality of life, and oral function

Surrogate endpoints: Probing depths, bleeding on probing, microbial measures

Challenges of Obtaining Epidemiologic Measures of Periodontal Conditions and Diseases

Among the challenges that periodontal epidemiologists face are the continuous changes in the type of surrogate data collected, the paucity of information about whether surrogate information provides reliable information regarding outcomes of tangible patient benefit (i.e., outcomes that the patient cares about), and the lack of diagnostic codes for the reasons for tooth loss. In fact, accruing evidence points in the direction of commonly used surrogate measures being poor predictors of periodontal status.[51]

The diversity of measures used to assess periodontal condition or disease is staggering. One survey of periodontal clinical trials conducted over a mere 4-year period indicated that 153 distinct surrogate endpoints were defined and that more than 80% of these endpoints were used in fewer than 5 of the 82 trials.[25] Another survey similarly identified the diversity of methodologies and definitions as a challenging issue when systematically reviewing evidence.[65] This continuous creation of "new and improved" surrogate outcomes in periodontal research is likely an important driver of false-positive conclusions.[27]

The types of periodontal measures that are favored also depend on the era. Russell developed the Periodontal Index,[63] which scored the supporting tissues for each tooth in the mouth according to a progressive scale that gives little weight to gingival inflammation and relatively great weight to advanced periodontal disease. Although the Periodontal Index was used in the first National Health and Nutrition Examination Survey (NHANES), thereby gaining national prominence in the United States, it was never used again in any of the subsequent NHANES versions. Since then, most periodontal surveys in the United States have employed different examination protocols. The survey methodology has been changed yet again, leading to large variations in disease estimates.[16] Studies of decreases in the use of scaling and root planing procedures in the state of Washington and at a national level,[8,61] long-term trends in decreasing edentulism, and decreasing periodontitis prevalence estimates in national surveys with consistent methodology[15] suggest that periodontitis prevalence in the United States is dropping rapidly (Tables 6.1 and 6.2).

TABLE 6.1

Periodontal Status of the US Population Among Adults Between the Ages of 20 and 64 Years

Status	1988 to 1994	1999 to 2004
Number of teeth present	24	25
Edentulism	6%	4%
Periodontal disease (i.e., one site with ≥3-mm attachment loss and ≥4-mm pocket depth)	15%	9%
Periodontal disease among the poor	28%	14%
Dental visits	66%	6%
Mean pocket depth	1.47 mm	1.02 mm
Mean loss of attachment	1.07 mm	0.72 mm
≥2-mm recession in at least one site	32%	21%
≥4-mm pocket depth in at least one site	23%	10%
≥4-mm attachment loss in at least one site	25%	17%

TABLE 6.2

Periodontal Status of the US Population Among Seniors 65 Years Old and Older

Status	1988 to 1994	1999 to 2004
Number of teeth present	18	19
Edentulism	34%	27%
Periodontal disease (one site with ≥3-mm attachment loss and ≥4-mm pocket depth)	19.5%	10.5%
Periodontal disease among the poor	26.3%	16.6%
Dental visits	54%	55%
Mean pocket depth	1.47 mm	1.07 mm
Mean loss of attachment	2.04 mm	1.55 mm
≥2-mm recession in at least one site	73%	48%
≥4-mm pocket depth in at least one site	22%	12%
≥4-mm attachment loss in at least one site	59%	50%

A second challenge when interpreting periodontal statistics is the common lack of information about measures that matter to patients, such as tooth loss or quality-of-life issues related to oral health. This situation creates challenges when interpreting evidence. It is similar to tracking prostate cancer by measuring inflammation or swelling of the prostate gland without knowing how this information relates to prostate cancer mortality. This challenge is further compounded by the absence of diagnostic codes for tooth loss, which has largely prevented the obtaining of reliable information about how many teeth are lost as a result of periodontal disease as opposed to dental caries.

Finally, the attempt to track a disease by only collecting a

surrogate outcome measure such as probing depth from the teeth that are present leads to a type of bias that is typically referred to as *survival bias.* Most periodontal clinical trials performed during the 20th century evaluated the effect of periodontal therapies on those teeth that survived the treatment. The more teeth that are lost, the more meaningless such data become. The imputation of data can provide an understanding of the extent to which such biases may alter the conclusions of studies.

In summary, the fundamental tool of periodontal epidemiology is a measure of the occurrence of periodontal conditions. These measures include epidemiologic statistics, such as prevalence, risk, and rate, and they focus on either patient-specific or site-specific markers, such as oral health–related quality of life, tooth loss, anatomic measures, and measures of gingival inflammation. This wealth of possibilities when defining periodontal conditions in combination with statistical challenges when handling correlated data has made it difficult to answer even a simple question such as whether a hidden periodontal disease epidemic occurred during the 20th century.[29]

Epidemiologic Study Designs

The essence of epidemiology and clinical epidemiology is to relate measures of disease occurrence to suspected causes or interventions. Can the dramatic drop in destructive periodontal disease prevalence in the United States be attributed to a change in smoking prevalence? Can the presence of particular microbiologic species around a tooth be related to the risk of future tooth loss? Can the rate of tooth loss in a sample of elderly patients be related to the use of an antimicrobial rinse? With an evidence-based approach, these questions can be most reliably answered by three epidemiologic study designs. As mentioned earlier in this chapter and as briefly introduced in Chapter 2, these study designs (in order of decreasing reliability) are the randomized controlled trial, the cohort study, and the case–control study.

Randomized Controlled Trials

Randomized controlled trials in periodontics typically assign patients or some teeth within a patient randomly to a treatment. Patients are then monitored, and subsequent outcomes are assessed. Table 6.3 provides two examples of randomized controlled trials.

TABLE 6.3

Examples of Periodontal Randomized Controlled Trials

Periodontal Treatment	Outcome	Sample Size
Scaling and root planing for pregnant women[50]	Infants with low birth weights	823
Biphasic calcium phosphate ceramic[53]	Clinical attachment level	137

The randomized controlled trial is the only study design that can provide a probabilistic basis for the making of a causal inference between an intervention and an outcome. Reliable inference regarding the causality of associations can be obtained if the delicate machinery of clinical trial design and analysis is strictly respected. For example, there needs to be a pretrial hypothesis that specifies the endpoint, the treatments to be compared, the patient population, and the degree of required precision. Other factors that are important for obtaining reliable answers include a secure randomization process, the masking of patients and clinicians, the presence of an independent data and safety monitoring board, and strict adherence to the pretrial hypothesis, which must include an intent-to-treat analysis. Trials with exquisite attention to detail are referred to as *definitive trials,* and they are rare in any field, including periodontal research. Definitive trials are required to provide reliable answers about treatment efficacy. Most of the trials published in the literature are in the category of exploratory trials. These trials typically do not report a pretrial hypothesis, and they conclude that the intervention was successful when compared to the control.[26] These are almost always false-positive conclusions.[27]

Cohort Studies

Cohort studies can also be referred to as *exposure-based study designs.* Subjects who are free of the disease of interest are classified with respect to an exposure (e.g., cigarette smoking, diabetes) and

followed longitudinally for the assessment of periodontal outcomes. Table 6.4 provides two examples of cohort studies.

TABLE 6.4

Examples of Periodontal Cohort Studies

Periodontal Exposure	Outcome	Sample Size
Periodontal disease and tooth loss[35]	Coronary heart disease	51,529
Gingivitis[9]	Tooth loss	>500

Cohorts can be defined by a geographic area, records, exposure status, or a combination of different criteria. In one study of the causal factors of edentulism, the population of interest was defined as the inhabitants of the town of Tecumseh, Michigan. Persons within this community were examined in 1959 as part of a community-wide health study. Twenty-eight years later, a subset of these patients was reexamined to study the risk factors for edentulism.[52] Some natural disease history studies of destructive periodontal disease have been conducted on the basis of geographic location. Examples include the Norwegian Longitudinal Study,[1] the Veterans Administration Longitudinal Study,[39] and the Sri Lanka study.[2] A cohort can be defined by records (e.g., schools, health insurance plans, unions, industries, professional organizations). Many cohort studies of periodontal disease outcomes are performed in patients who belong to a particular dental insurance company[12] or to a professional group.[36] Finally, cohorts can be defined on the basis of a specific exposure. For example, different levels of fluoride concentrations in the water supply have been used for the definition of cohorts.

Case–Control Studies

Case–control studies are typically referred to as *outcome-based study designs.* Persons with a condition or outcome of interest (i.e., cases) are compared with persons without a condition of interest (i.e., controls) with respect to the history of the suspected causal factors. Many people intuitively think along the lines of a case–control study when evaluating disease causes. For example, if an individual suffers from food poisoning after a party, he or she is likely to

compare past food intake with those individuals who did *not* experience food poisoning. Similarly, if one is diagnosed with a serious illness, a common reaction is to ask, "Why me?" This is usually followed by a comparison of one's history of exposures with those of other individuals who did *not* develop the serious illness. The primary goal of a case–control study is to find out what *past* exposures or factors are different between patients with a disease versus those without the disease. Table 6.5 provides two examples of case–control studies.

TABLE 6.5

Examples of Periodontal Case–Control Studies

Case–Control Criteria	Investigated Risk Factors	Sample Size
Destructive periodontal disease[47a]	Smoking	177
Acute myocardial infarction[59a]	Dental health	202

The case–control study is a challenging type of study to conduct. Trying to minimize the role of bias in case–control studies requires careful planning, conduct, and analysis. Even when everything is done perfectly, one can come to the wrong conclusions in case–control studies. A review of the quality of periodontal case–control studies suggested that they are frequently inadequately conducted and reported.[45]

Two important elements of the case–control study design are the definitions of the terms *case* and *control.* A *case* is a person in the population or study group who has been identified as having a particular disease, health disorder, or condition.[10] The case definition should be rigorous to minimize bias and misclassification; it can be based on symptoms, signs, or the results of diagnostic tests. For example, the case definition for a myocardial infarction in a case–control study of the relationship between dental health and acute myocardial infarction was as follows[2]:

1. Symptoms start within 36 hours before the admission
2. No prior myocardial infarction
3. Residing in Helsinki or an immediate neighborhood
4. Age <60 years for men and <65 years for women
5. Blood samples available at admission and at 4 weeks

In a case–control study, the *controls* should be at risk for developing the investigated disease and come from the same population that generated the cases. For example, if the investigated disease is root caries, the controls should be at risk for developing root caries (i.e., have exposed root surfaces) and originate from the same population that generated the cases that have root caries.

Causes

Human chronic diseases such as cancer, diabetes, and destructive periodontal disease have complex causes. The terms *necessary cause, component cause,* and *sufficient cause* help to define the challenges of determining the cause of a disease and of verbalizing the complexity of chronic disease causes.[62]

The set of causes that initiate a chronic disease is referred to as a *sufficient cause.* Each sufficient cause consists of multiple component causes. Consider the hypothetical example in which four sufficient causes exist for noniatrogenic destructive periodontal disease (Fig. 6.2). The first sufficient cause in this example includes the following component causes: smoking, delayed neutrophil apoptosis, an interleukin-1 gene defect, dental plaque, a tooth, and an unspecified gene defect. These different elements of a sufficient cause are referred to as *component causes.* All component causes of a sufficient cause need to be present for the disease process to be initiated. Multiple sufficient causes may be responsible for a given disease. For example, two sufficient causes exist for destructive periodontal diseases that do not include smoking.

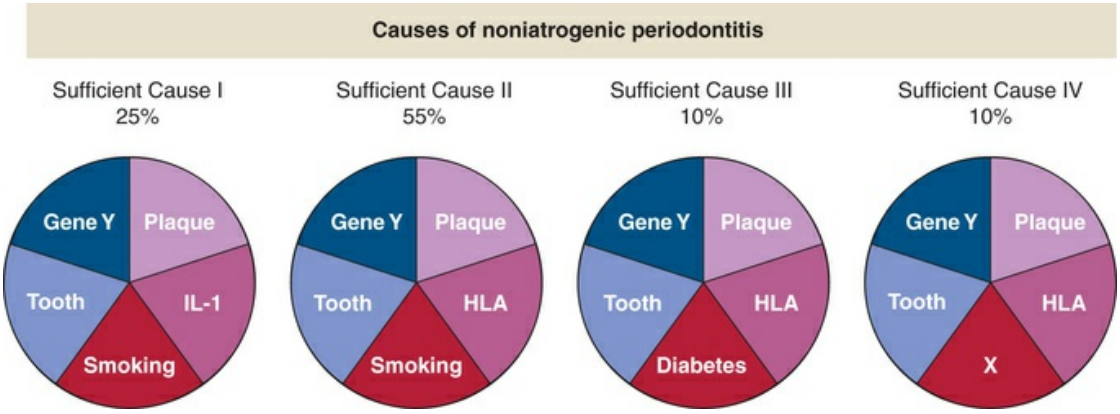

FIG. 6.2 Causes of noniatrogenic periodontitis. (Data from Rothman KJ: Causes. 1976. *Am J Epidemiol* 141:90–95, 1995.)

A component cause, which is an element of all the sufficient causes for a given disease, is referred to as a *necessary cause*. For example, fermentable carbohydrates are a necessary cause for dental caries. However, there are very few examples of necessary causes: smoking is not a necessary cause of lung cancer or destructive periodontal disease, hepatitis B infection is not a necessary cause of liver cancer, and *Streptococcus viridans* is not a necessary cause of bacterial endocarditis. The search for necessary causes of disease is important, because the elimination of such causes could eradicate a disease.

The proportion of disease that results from different component causes does not add up to 100%. The component cause "smoking" is responsible for 80% of destructive periodontal disease cases; plaque is responsible for 100%, and diabetes is responsible for 10%.

The complex causal web that leads to the initiation and progression of chronic disease makes the reliable identification of causal components difficult. Since the 1960s, epidemiology has succeeded in reliably identifying some of the causes of human chronic diseases. Now that those component causes responsible for a large proportion of cases for particular diseases (e.g., smoking for lung cancer) have been identified, the search for new causes is becoming significantly more challenging. For example, the hope existed that the Human Genome Project would lead to quick advances, but these hopes have not yet been fulfilled. Chronic diseases are typically caused not by one gene but rather by a set of many different genes, with each one responsible for only a small proportion of cases and acting in a variety of synergistic

mechanisms for disease initiation.

Suspected Modifiable Causative Factors for Periodontal Disease

Tobacco Smoking

Tobacco smoking is recognized by several organizations as one of the primary drivers of periodontal disease epidemiology.[5] Many criteria for causality have been satisfied,[18] and smoking cessation has been shown to slow the progression of periodontal disease.[38,39,57] The strong impact of tobacco smoking on periodontal disease has the potential to induce spurious causal associations in other suspected risk factors for periodontal disease. For example, smoking is a risk factor for both type 2 diabetes[75] and periodontal disease, thereby making associations between type 2 diabetes and periodontal disease susceptible to biases. To obtain reliable inferences about causal factors other than smoking, studies of periodontal disease epidemiology may need to be restricted to those who have never smoked.

Nutrition

Several studies have demonstrated relationships between periodontal disease and a variety of medical conditions that center on carbohydrate metabolism, including intake of dietary carbohydrates, exercise, obesity, prediabetes, and diabetes. A systematic review of randomized controlled trials involving carbohydrates suggested that the increased intake of fermentable carbohydrates may cause an increase in gingivitis.[26] Two systematic reviews suggested that diabetes was a risk factor for destructive periodontal disease.[64,67]

Dental Plaque

Several systematic reviews have provided evidence that chemotherapeutic and mechanical plaque control will reduce gingival inflammation. Essential oils[4] and cetylpyridinium-chloride–containing mouth rinses[20] may reduce gingival inflammation. Interdental brushes may reduce dental plaque,

bleeding, and probing pocket depth.[69] Power-driven toothbrushes may be more effective than manual toothbrushes for removing plaque and reducing inflammation.[66] Self-performed dental flossing may not be effective for reducing plaque and gingival inflammation.[4] Although these systematic reviews provide evidence about the role of dental plaque in gingival inflammation, they do not necessarily suggest that dental plaque is the primary cause of gingival inflammation.[24] Stomach acids may cause heartburn, and antacids may be effective at eliminating heartburn symptoms. However, this evidence does not make stomach acids a primary cause of heartburn. The primary cause of heartburn may, for instance, be a gluten allergy, and thus the cure of the heartburn requires the elimination of gluten from the diet. Antacids can be considered a palliative that is needed as long as the primary cause has not been identified.

Neither is there reliable evidence that gingival inflammation precedes destructive periodontal disease. There is no reliable randomized controlled trial evidence that oral hygiene has a beneficial impact on the prevention of periodontal destruction.[27,30]

The Cause of Periodontal Disease for the Patient Sitting in Your Chair

In clinical epidemiology, in a court of a law, and in modern-day clinical practice, uncertainty regarding the "cause" is an important consideration when discussing causality. The term *attributable risk percentage* is used to express the probability that a disease is caused by a suspected causative agent. For example, in a smoker with lung cancer, there may be a 20% probability that the lung cancer was caused by a factor other than smoking (e.g., radon). In an obese person with diabetes, there may be a 10% chance that obesity played no role in the onset of diabetes. For a worker with leukemia in the nuclear industry, there may be an 80% chance that the leukemia was not caused by the low-level protracted radiation exposures. One can almost never determine with certainty what caused a particular condition or disease to appear in a patient; all one can do is assign probabilities to the likelihood that a particular causal factor was responsible for the disease diagnosed in the patient. Destructive periodontal disease and periodontal

inflammation are no exception to this general rule of uncertainty for determining a disease's cause. As a result, diagnostic names (e.g., plaque-induced gingival disease, non–plaque-induced inflammatory gingival lesions[43]) can be considered misnomers, because such names imply diagnostic certainty that lead to circular reasoning.[2] The principle of diagnostic uncertainty is also important when it comes to the diagnosis of periodontal conditions.

Diagnosis

Periodontal Conditions Versus Periodontal Diseases

Disease is defined as an attribute or a characteristic of a person, and *diagnosis* is the clinician's belief that the person has the attribute.[70] The World Health Organization defined disease as those adverse health consequences that include physical or psychological impairment, activity restrictions, and role limitations.[70] Certain periodontal conditions have been associated with such adverse consequences, and thus certain periodontal conditions qualify as diseases according to the WHO's definition. In one study, about 1 in 5 patients who presented to a periodontal specialist reported that their teeth, gums, or dentures had an impact fairly often or very often on either eating; relaxing; avoiding going out; or feeling self-conscious, pain, or discomfort. In this same study, 4 out of 10 patients rated their oral health as fair or poor.[11] Other studies have shown that gingival conditions (e.g., necrotizing ulcerative gingivitis, attachment loss in high school students) are similarly related to oral health–related quality of life.[44]

An important thing to consider during periodontal diagnosis is to determine which periodontal conditions can be diagnosed as "diseased." Can a patient with a couple of sites with 1 or 2 mm of attachment loss be classified in this way? What about a patient with such subtle gingival inflammation that the majority of clinicians would not notice the inflammation and that even highly trained clinical examiners agree poorly about the presence of gingivitis? Disagreement regarding such questions is one of the reasons that the prevalence of gingivitis and destructive periodontal disease can

range widely, depending on which reference levels are considered to be the cutoff for normal as compared with diseased.

Diagnostic Tests Available to Assess Periodontal Conditions

Diagnostic tests for periodontal disease can include anatomic measures of tissue destruction, such as probing pocket depth and clinical attachment loss; measures of gingival inflammation, such as redness, suppuration, bleeding, bleeding on probing, elevated gingival temperature, and gingival crevicular fluid markers; radiographic measures of bone destruction and tooth mobility; and microbiologic measures. These test results—in combination with factors such as age, dental history, and systemic conditions—can be translated into a distinct set of periodontal diagnoses.

Translating Periodontal Diagnostic Test Results Into Periodontal Disease Diagnosis

Three different methods can be distinguished to translate clinical conditions into diseases: (1) normative or arbitrary values, (2) risk-based reference values, and (3) treatment-based reference values.[32]

Normative or Arbitrary Values to Diagnose Periodontal Disease

Diseases can be defined on the basis of normative or arbitrary reference values. If the normal periodontium is assumed to have no pockets deeper than 3 mm, then one could define destructive periodontal disease as being present in a patient with any pocket equal to or deeper than 4 mm, or a patient with three pockets equal to or deeper than 5 mm could be classified as having destructive periodontal disease.

Alternatively, normative values could be based on parametric or nonparametric percentage cutoff values as derived from national surveys. For instance, the 97.5th percentile of the age-specific number of pockets deeper than 5 mm could be used to define destructive periodontal disease. On the basis of the NHANES III

data, a 28-year-old individual with two pockets deeper than 5 mm could be diagnosed as having destructive periodontal disease, whereas five periodontal pockets deeper than 5 mm would be required in a 58-year-old individual.[31]

Diagnoses that are based on normative or arbitrary cutoffs result in normative or arbitrary disease prevalence levels, regardless of the distribution of underlying risk factors. Whether 5% or 95% of the population smoked two packs a day for 40 years, the prevalence of destructive periodontal disease would remain equal to the selected cutoff value. If all human chronic diseases were defined on the basis of an arbitrary 10th percentile cutoff value, the prevalence of all chronic disease would be equal to 5% (e.g., 5% of the population would have blood pressure that is too high, 5% would have a blood glucose level that is too high).

Risk-Based Reference Values to Diagnose Periodontal Disease

The diagnosis of disease can be set at the point on the diagnostic marker at which a steep increased risk for adverse health outcomes is present. The cutoff is still somewhat arbitrary, but it is connected to clinical realities in terms of the risk of adverse health outcomes. There is a tradeoff between the dangers of missed diagnoses when the cutoff is made too high (i.e., more specific) and the dangers of false-positive diagnoses when the cutoff is too low (i.e., more sensitive).

A risk-based diagnosis of destructive periodontal disease requires the conducting of longitudinal studies in which pocket depth at baseline is related to the risk of subsequent adverse outcomes (e.g., tooth loss). Fig. 6.1 represents such a plot and suggests that a pocket depth of 6 mm could be a diagnostic marker for destructive periodontal disease, because a distinctive increased risk for tooth loss is associated with pocket depth values of 6 mm or deeper.

The risk-based diagnosis of chronic diseases, much like the use of normative or arbitrary values, can do more harm than good. A diagnosis of obesity that is based on a body mass index of 28 may do more harm than good if weight loss treatments increase mortality risk.[37] A diagnosis of high blood pressure[59] or diabetes[49]

may cause more harm than good if the prescribed treatment further increases the mortality risk. Similarly, a diagnosis of destructive periodontal disease that is based on the presence of periodontal pockets 6 mm or deeper may cause more harm than good if the suggested periodontal treatments increase periodontal morbidity.

Therapeutic Reference Values to Diagnose Periodontal Disease

A more attractive definition of disease is the therapeutic or treatment-based diagnosis. With this definition, a person is defined as diseased only if the diagnosis of disease leads to tangible benefits. Most commonly, it is best to avoid diagnosing disease unless it can be shown that the diagnosis and the subsequent treatment actually provide tangible patient outcomes. With such an approach to diagnoses, periodontal disease should only be diagnosed if it leads to less morbidity.

Periodontal Disease Diagnoses

The Medical Subject Heading (MeSH) term headings for periodontal disease, the classification systems for periodontal diseases developed by professional organizations, and a sampling of English-language periodontal textbooks indicate that periodontal disease diagnoses come and go at a fast rate. On PubMed, seven different entry terms are currently listed under the MeSH heading of *Periodontitis*, which reflects some of the distinct periodontal diagnoses that have been used in the literature since 1965. However, a conference consensus[35] concluded that five of the seven terms listed were obsolete. The American Academy of Periodontology reported 10 different classification systems in 20 years.[2] Periodontal textbooks have similarly reported different sets of periodontal diagnoses every decade.

Periodontal dystrophies provide one example on the apparent arbitrariness by which periodontal diagnoses come and go. Periodontal dystrophies were commonly reported from the 18th century until the 1960s. However, this diagnosis was subsequently decided to be obsolete,[58] because it did not appear to fit the infection paradigm. Periodontal textbooks no longer referred to the

diagnosis of "periodontosis." However, an argument was made that this diagnosis should be resurrected.[55]

This example illustrates how profoundly the belief that periodontal disease is infectious has influenced all aspects of clinical periodontics, including the system for classifying periodontal conditions. Periodontal diagnoses in some circles are based on the premise that periodontal diseases "follow an infection/host paradigm in which it is held that noxious materials from dental plaque bacteria induce an inflammatory response in the adjacent periodontal tissue. … Central to this paradigm is the notion that the destruction of periodontal tissues is accompanied by an inflammatory response."[1]

There are two reasons why the diagnostic classification of periodontal diseases should not be based on the infection paradigm or on any other assumed cause. First, high-level evidence from epidemiologic studies is required to determine that periodontal disease is indeed an infection. Such evidence remains largely missing.[23] Smoking and diabetes appear to be associated with destructive periodontal disease independent of microbial colonization. Second, for chronic diseases with multiple causes, it is not possible to determine the cause of the disease; therefore it is of little clinical value to name the disease after a suspected cause. For example, periodontal disease in a diabetic patient cannot be referred to as "diabetic periodontitis." The clinician can only say that there is a certain probability that the periodontal disease in a diabetic patient is attributable to the diabetic condition.

From a clinical perspective, the ever-changing diagnostic classification systems that result from consensus conferences may be irrelevant, because no reliable evidence exists that the clinical use of such diagnostic systems improves patient outcomes. Simple diagnostic systems of periodontal disease can have several advantages for patient care, because they provide useful information about both the severity of the disease and its prognosis. The readers are referred to Chapter 5 for an in-depth discussion of periodontitis classification systems.

CHAPTER OUTLINE

Histopathology of Periodontal Disease
Inflammatory Responses in the Periodontium
Linking Pathogenesis to Clinical Signs of Disease
Resolution of Inflammation
Immune Responses in Periodontal Pathogenesis
Concept of Host Susceptibility

Understanding periodontal pathogenesis is key to improving management strategies for this common, complex disease. The first challenge is to understand exactly what is meant by the term *pathogenesis.* According to *Merriam Webster's Collegiate Dictionary,* the word *pathogenesis* is defined as "the origination and development of a disease." Essentially, this refers to the step-by-step processes that lead to the development of a disease and that result in a series of changes in the structure and function of, in this

case, the periodontium. In broad terms, the pathogenesis of a disease is the mechanism by which a causative factor (or factors) causes the disease. The word itself is derived from the Greek roots *pathos* (meaning "suffering") and *genesis* (meaning "generation or creation").

Our knowledge of periodontal pathogenesis has evolved over the years. It is important to be aware of this because treatment philosophies have changed in parallel with our improving understanding of the disease processes and will likely continue to change as our knowledge improves. During the late 1800s, Willoughby D. Miller[117] (an eminent dental researcher who established the important causal role of oral bacteria for dental caries) asserted that "during the last few years the conviction has grown continually stronger, among physicians as well as dentists, that the human mouth, as a gathering-place and incubator of diverse pathogenic germs, performs a significant role in the production of varied disorders of the body, and that if many diseases whose origin is enveloped in mystery could be traced to their source, they would be found to have originated in the oral cavity." This statement marked the beginning of an era of dental treatment strategies that aimed to treat systemic diseases by eliminating the so-called "foci of infection" in the mouth. As a result, many patients underwent unnecessary dental clearances to manage their systemic diseases.

By the 1930s, such approaches were beginning to be questioned. In an analysis of 200 patients with rheumatoid arthritis, of whom 92 had their tonsils removed as treatment for the arthritis (even though only about 15% gave any history of tonsillitis or sore throat) and of whom 52 had some or all of their teeth removed, no improvements in the rheumatoid arthritis symptoms were noted in any of the patients.[27] These authors wrote that "focal infection is a splendid example of a plausible medical theory which is in danger of being converted by its too enthusiastic supporters into the status of an accepted fact."[27] The end of the focal infection era was signaled by an editorial in the *Journal of the American Medical Association* in 1952, which stated that "many patients with diseases presumably caused by foci of infection have not been relieved of their symptoms by removal of the foci, many patients with these

same systemic diseases have no evident focus of infection, foci of infection are as common in apparently healthy persons as in those with disease."[165]

In more recent times, advances in the management of periodontitis have been driven by improved knowledge of the epidemiology, causation, and pathogenesis of the disease.[192] During the 1970s, the role of plaque as the sole causative factor for periodontitis was unquestioned. In those days, nonsurgical treatment was in its infancy, and most treatment options involved surgery (e.g., gingivectomy for the treatment of shallower pockets, access flap surgery for the treatment of deeper sites). When looking back, it becomes clear that the treatment strategies used during a given time period entirely depend on the prevailing understanding of pathogenesis at that particular point in time. It is therefore very likely that the management options that we take for granted now will change again in the future. This is to be welcomed because a progressive clinical discipline such as periodontology that is well founded in science and with benefit to the patient as its primary value should strive to improve therapeutic strategies in parallel with continued discovery.

Clinician's Corner

Why is studying periodontal pathogenesis important?

Pathogenesis refers to the processes that cause disease. In periodontitis, bacteria in the biofilm stimulate an immune–inflammatory response that causes the tissue damage that we recognize clinically as periodontitis. Understanding the disease processes is important because it may lead to the development of improved treatment strategies.

Periodontal disease results from a complex interplay between the subgingival biofilm and the host immune–inflammatory events that develop in the gingival and periodontal tissues in response to the challenge presented by the bacteria. The tissue damage that results from the immune–inflammatory response is recognized clinically as periodontitis. Gingivitis precedes periodontitis, but it is clear that

not all cases of gingivitis progress to periodontitis. In gingivitis, the inflammatory lesion is confined to the gingiva; however, with periodontitis, the inflammatory processes extend to additionally affect the periodontal ligament and the alveolar bone. The net result of these inflammatory changes is the breakdown of the fibers of the periodontal ligament, resulting in clinical loss of attachment together with resorption of the alveolar bone.

During the 1970s and 1980s, bacterial plaque was generally considered to be preeminent as the cause of periodontitis. It was clear (as it is now) that poor oral hygiene results in increased plaque accumulation, and it was accepted that this, in turn, resulted in periodontal disease. However, this model failed to take into account observations such as the finding that there are many individuals with poor oral hygiene who do not develop advanced periodontal disease, and conversely, some individuals, despite good oral hygiene and compliance with periodontal treatment protocols, present with advanced and progressing periodontitis. These findings were confirmed by the work of Löe and colleagues,[108] who studied Sri Lankan tea laborers who had no access to dental care and who could be divided into three main categories: (1) individuals (≈8% of the population studied) who had rapid progression of periodontal disease, (2) those (≈81%) who had moderate progression of such disease, and (3) those (≈11%) who demonstrated no progression of periodontal disease beyond gingivitis. All patients in this population displayed abundant plaque and calculus deposits, so clearly susceptibility to disease is influenced by more than just presence of dental plaque. The causative role of bacteria in the biofilm is clear in that the bacteria initiate and perpetuate the inflammatory responses that develop in the gingival tissues. However, the main determinant of susceptibility to disease is the nature of the immune–inflammatory responses themselves. It is paradoxical that these defensive processes, which are protective by intent (i.e., to prevent the ingress of the bacteria and their products into the tissues), result in the majority of tissue damage that leads to the clinical manifestations of disease.

Periodontal disease is therefore a unique clinical entity. It is not an infection in the classic sense of the word. With many infections, a

single infective organism causes the disease (e.g., human immunodeficiency virus, syphilis, tuberculosis), and the identification of that organism can provide the basis for the diagnosis. With periodontal disease, many species are identifiable in the periodontal pocket, and it is impossible to conclude that a single species or even a group of species causes periodontal disease. Many of the species that are considered important in periodontal pathogenesis may predominate in deep pockets because the pocket is a favorable environment in which they can survive (i.e., it is warm, moist, and anaerobic, with a ready supply of nutrients). Many of the unique features of periodontitis are derived from the anatomy of the periodontium, in which a hard, nonshedding surface (the tooth) is partly embedded within the body (within connective tissue), crosses an epithelial surface, and is partly exposed to the outside world (within the confines of the mouth). The bacteria that colonize this surface are effectively outside of the body (although they are in the gingival crevice or pocket), yet the inflammatory response that develops is located within the body (i.e., within the tissues). These factors add complexity to our understanding of the role of the biofilm and the immune–inflammatory responses that are part of periodontal tissue breakdown.

Histopathology of Periodontal Disease

To understand periodontal pathogenesis better, it is important to have an appreciation of the histology of clinically healthy tissues, as well as of inflamed gingival and periodontal tissues. Even gingival tissues that clinically would be considered to be noninflamed and healthy always have evidence of inflammatory responses occurring at the microscopic level. This is normal given the chronic low-grade challenge presented by the subgingival biofilm. The low-grade inflammatory response that results is not detectable macroscopically at the clinical level, but it is an essential protective mechanism for combating the microbial challenge and for preventing bacteria and their products from infiltrating tissues and

causing tissue damage. Our current understanding of susceptibility to periodontitis suggests that individuals who are susceptible to the disease mount an excessive or dysregulated immune–inflammatory response for a given bacterial challenge that leads to increased tissue breakdown as compared with those individuals who have a more normal inflammatory response.

Clinically Healthy Gingival Tissues

Clinically healthy gingival tissues appear pink, are not swollen or inflamed, and are firmly attached to the underlying tooth and bone, with minimal bleeding on probing. The dentogingival junction is a unique anatomic feature that functions to attach the gingiva to the tooth. It has an epithelial portion and a connective tissue portion, both of which are of fundamental importance for periodontal pathogenesis. The epithelial portion can be divided into three distinct epithelial structures: the gingival epithelium, the sulcular epithelium, and the junctional epithelium (Fig. 7.1). These epithelial structures are in continuity with each other, but they have distinct structures and functions, as indicated in Box 7.1.

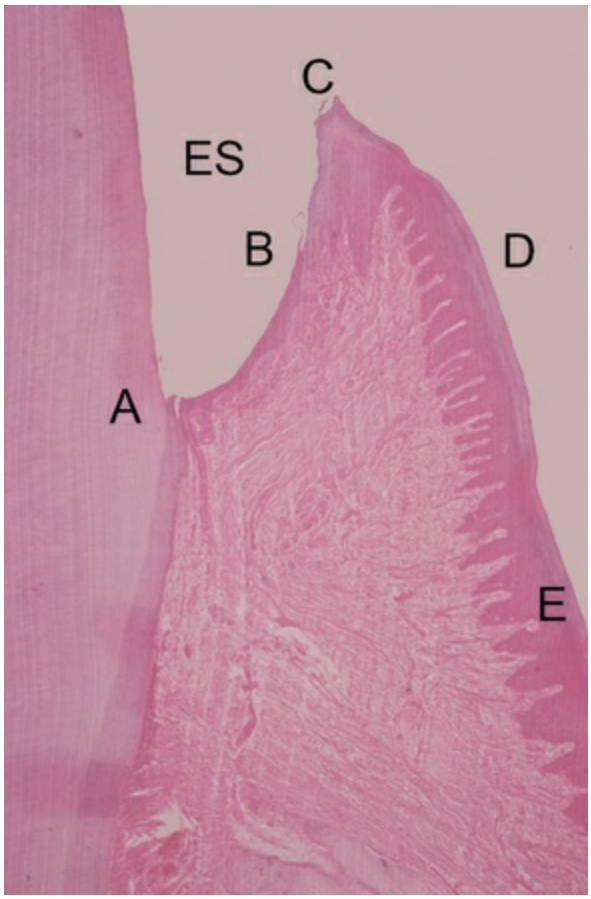

FIG. 7.1 **Histologic appearance of healthy gingiva. A photomicrograph of a demineralized tooth with the gingival tissues in situ (hematoxylin and eosin staining, low magnification). Cementoenamel junction *(A)*. Enamel space *(ES)*. Gingival health is characterized by the organization of the epithelium into distinct zones; junctional epithelium *(A-B)*, sulcular epithelium *(B-C)*, free gingiva *(C-D)*, and attached gingiva *(D-E)*. The gingival connective tissue is composed of densely packed, organized, and interlacing collagen bundles. A few scattered inflammatory cells are present but no significant inflammatory cell infiltrate.**

Box 7.1

Characteristics of the Epithelial Component of the Dentogingival Unit

Gingival Epithelium

- Stratified squamous keratinized and parakeratinized epithelium
- Continuous with the sulcular epithelium at the gingival

crest/gingival margin
- Covers the gingiva and forms the clinically visible gingival tissues
- Covers both the free and attached gingival tissues

Sulcular Epithelium

- Stratified squamous epithelium
- Nonkeratinized
- Faces the tooth surface but is not attached to it
- Forms the soft tissue lining of the gingival sulcus or the periodontal pocket

Junctional Epithelium

- Forms the epithelial attachment between the gingiva and the tooth
- Nonkeratinized
- Forms the floor of the sulcus/pocket
- Wraps around the tooth like a collar in health following the morphology of the cementoenamel junction
- Wider at the floor of the sulcus (i.e., 15 to 30 cells thick) and tapers apically to 3 to 4 cells thick
- Composed of layers of flattened squamous cells oriented parallel to the tooth surface
- Surface cells attach to the tooth surface through hemidesmosomes
- Basal lamina differs from other basal laminae that oppose connective tissue in that type IV collagen is absent

The junctional epithelium is a unique epithelial structure because the surface cells are specialized for the purpose of attachment to the tooth.[12] Therefore, unlike other epithelial tissues elsewhere in the body, no opportunity exists for the sloughing of cells from the surface. Instead, cells at the basal layer continually divide and move to within two or three cell layers of the tooth surface and then

migrate coronally and parallel to the tooth surface to reach the floor of the sulcus eventually and then be sloughed off into the gingival crevice. The spaces between cells of the junctional epithelium are also greater than those seen with other epithelial tissues, with the intercellular spaces comprising approximately 18% of the volume of the epithelium. This configuration is a result of a lower density of desmosomes in the junctional epithelium as compared with the gingival epithelium; the junctional epithelium is therefore intrinsically "leaky." This situation has great relevance for periodontal pathogenesis because the widened intercellular spaces in the junctional epithelium permit the migration of neutrophils (polymorphonuclear leukocytes); they also allow macrophages from the gingival connective tissues to enter the sulcus to phagocytose bacteria, and the ingress of bacterial products and antigens occurs as well.

The connective tissue component of the dentogingival unit contains densely packed collagen fiber bundles (a mixture of type I and III collagen fibers) that are arranged in distinct patterns that maintain the functional integrity of the tissues and the tight adaptation of the soft tissues to the teeth (see Chapter 3).

Even in clinically healthy gingiva, the gingival connective tissue contains at least some inflammatory cells, particularly neutrophils. Neutrophils continually migrate through the connective tissues and pass through the junctional epithelium to enter the sulcus or pocket. These findings were reported in the classic investigations of the histology of periodontal disease reported by Page and Schroeder in 1976.[135] This low-grade inflammation occurs in response to the continued presence of bacteria and their products in the gingival crevice. There is a continuous exudate of fluid from the gingival tissues that enters the crevice and flows out as gingival crevicular fluid (GCF). In addition to the continuous migration of neutrophils through the gingival tissues, lymphocytes and macrophages also accumulate. The presence of leukocytes in the connective tissues results from the chemotactic stimulus created by the subgingival biofilm and bacterial products, as well as from the chemoattractant factors produced by the host.

In clinically healthy tissues, this steady-state equilibrium between low-grade inflammation in the tissues and the continual presence of

the bacterial biofilm may persist for many years or indeed for the lifetime of the individual. Overt clinical signs of gingivitis (i.e., redness, swelling, and bleeding on probing) do not develop because of several innate and structural defense mechanisms, including the following:

- The maintenance of an intact epithelial barrier (the junctional and sulcular epithelium)
- The outflow of GCF from the sulcus (dilution effect and flushing action)
- The sloughing of surface epithelial cells of the junctional and sulcular epithelium
- The presence of neutrophils and macrophages in the sulcus that phagocytose bacteria
- The presence of antibodies in the GCF

However, if plaque accumulation increases, then inflammation and the classic clinical signs of gingivitis may develop. Although the development of gingivitis in response to the accumulation of plaque is fairly predictable, research has identified that a spectrum of responses may be observed, with some individuals developing more pronounced gingival inflammation for a given plaque challenge and others developing minimal gingival inflammation.[181] These observations underscore the importance of variations in host responses among individuals in terms of gingival inflammatory responses. Furthermore, many individuals may never develop periodontitis, despite having widespread gingivitis. The host's immune–inflammatory response is fundamental for determining which individuals may progress to developing periodontitis, and it is likely that inflammatory responses are different in those individuals who develop periodontitis as compared with those who never progress beyond gingivitis. The challenge that this presents clinically is that we do not yet know enough about susceptibility to periodontitis to identify these individuals before they actually develop signs of disease.

Histopathology of Gingivitis and Periodontitis

The development of gingivitis can be clearly observed from a clinical perspective. In addition, the changes that occur within the tissues are very obvious when examined under a microscope. In broad terms, infiltration of the connective tissues by numerous defense cells, particularly neutrophils, macrophages, plasma cells, and lymphocytes is noted. As a result of the accumulation of these defense cells and the extracellular release of their destructive enzymes, disruption of the normal anatomy of the connective tissues occurs and causes collagen depletion and subsequent proliferation of the junctional epithelium. Vasodilation and increased vascular permeability lead to increased leakage of fluid out of the vessels and facilitate the passage of defense cells from the vasculature into the tissues, thus resulting in enlargement of the tissues, which appear erythematous and edematous (i.e., the clinical appearance of gingivitis). These changes are all reversible if the bacterial challenge is substantially reduced by improved oral hygiene.

The landmark studies of Page and Schroeder[135] described the histologic changes that occur in the gingival tissues as the *initial, early, established,* and *advanced* gingival lesions (Box 7.2). In broad terms, the initial lesion corresponds with clinically healthy tissues (but nonetheless with transmigrating defense cells such as neutrophils if examined histologically), the early lesion corresponds with the early stages of (clinically evident) gingivitis, the established lesion corresponds with chronic gingivitis, and the advanced lesion marks the transition to periodontitis, with attachment loss and bone resorption. These are *histologic descriptions only,* and they should not form part of a clinical diagnosis. Moreover, these classic descriptions are primarily based on findings in experimental animals. The histologic appearances of gingivitis and periodontitis are shown in Figs. 7.2 and 7.3, respectively.

Box 7.2

Key Features of the Histologic Stages of Gingivitis and Periodontitis

Initial Lesion (Corresponds With Clinically Healthy Gingival Tissues)

- Slightly elevated vascular permeability and vasodilation
- Gingival crevicular fluid flows out of the sulcus
- Migration of leukocytes, primarily neutrophils, in relatively small numbers through the gingival connective tissue, across the junctional epithelium, and into the sulcus

Early Lesion (Corresponds With Early Gingivitis That Is Evident Clinically)

- Increased vascular permeability, vasodilation, and gingival crevicular fluid flow
- Large numbers of infiltrating leukocytes (mainly neutrophils and lymphocytes)
- Degeneration of fibroblasts
- Collagen destruction that results in collagen-depleted areas of the connective tissue
- Proliferation of the junctional and sulcular epithelium into collagen-depleted areas

Established Lesion (Corresponds With Established Chronic Gingivitis)

- Dense inflammatory cell infiltrate (i.e., plasma cells, lymphocytes, and neutrophils)
- Accumulation of inflammatory cells in the connective tissues
- Elevated release of matrix metalloproteinases and lysosomal contents from neutrophils
- Significant collagen depletion and proliferation of epithelium
- Formation of pocket epithelium that contains large numbers of

neutrophils

Advanced Lesion (Marks the Transition From Gingivitis to Periodontitis)

- Predominance of neutrophils in the pocket epithelium and in the pocket
- Dense inflammatory cell infiltrate in the connective tissues (primarily plasma cells)
- Apical migration of junctional epithelium to preserve an intact epithelial barrier
- Continued collagen breakdown that results in large areas of collagen-depleted connective tissue
- Osteoclastic resorption of alveolar bone

Note: These classic descriptions are primarily based on findings in experimental animals, and the correlation with the clinical situation in humans is approximate.

Adapted from Page RC, Schroeder HE: Pathogenesis of inflammatory periodontal disease: a summary of current work. *Lab Invest* 33:235–249, 1976.

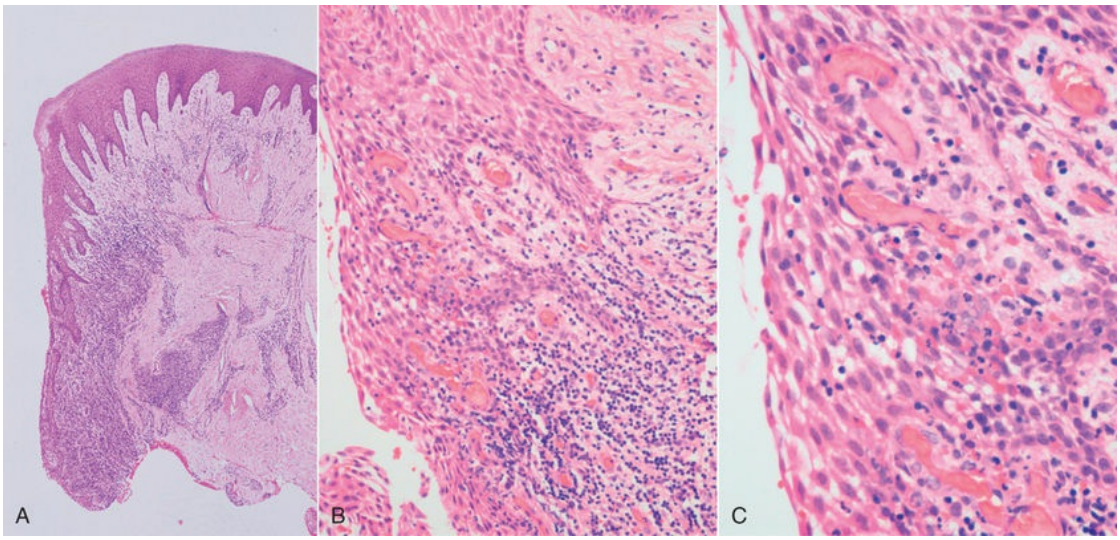

FIG. 7.2 **A series of photomicrographs illustrating the histologic appearance of gingivitis (hematoxylin and eosin staining). In all cases, the tooth is to the left side of the image. (A) Low magnification of the gingiva demonstrates hyperplastic junctional and sulcular epithelium with a dense inflammatory cell infiltrate in the adjacent connective tissue. (B) Medium magnification of the epithelial–connective tissue**

interface shows numerous intraepithelial inflammatory cells along with intercellular edema. The connective tissue contains dilated capillaries (hyperemia), and a dense inflammatory cell infiltrate is noted. (C) High magnification shows neutrophils and small lymphocytes transiting the sulcular epithelium.

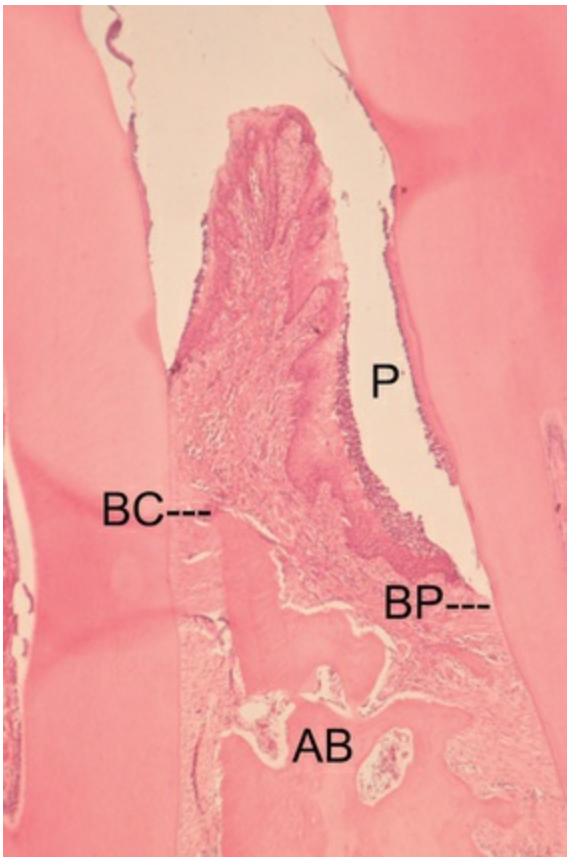

FIG. 7.3 Histologic appearance of periodontitis. A photomicrograph of adjacent demineralized teeth with the interproximal gingiva and periodontium in situ (hematoxylin and eosin staining, low magnification). The root of the tooth on the *right* is coated with a layer of dental biofilm or calculus, and attachment loss is noted with the formation of a periodontal pocket *(P)*. The periodontium is densely inflamed, and alveolar bone *(AB)* loss produces a triangular defect in addition to vertical bone loss. The base of the pocket *(BP)* is apical to the alveolar bone crest *(BC)*; this is called an *infrabony periodontal pocket.* (From Soames JV, Southam JC: *Oral pathology,* ed 4, Oxford, UK, 2005, Oxford University Press.)

The Initial Lesion

The initial lesion was reported to develop within 2 to 4 days of the accumulation of plaque at a site that was otherwise free of plaque and at which no inflammation was evident microscopically.

However, this situation is probably never encountered in reality, and the gingival tissues always have characteristics of a low-grade chronic inflammatory response as a result of the continual presence of the subgingival biofilm. In other words, the initial lesion corresponds to the histologic picture that is evident in clinically healthy gingival tissues. This low-grade inflammation is characterized by dilation of the vascular network and increased vascular permeability, thus permitting the neutrophils and monocytes from the gingival vasculature to migrate through the connective tissues toward the source of the chemotactic stimulus: the bacterial products in the gingival sulcus. The up-regulation of adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) and E-selectin in the gingival vasculature facilitates the migration of neutrophils from the capillaries into the connective tissues. The increased leakage of fluid from the vessels increases the hydrostatic pressure in the local microcirculation, and, as a result, GCF flow increases. Increased GCF flow has the effect of diluting bacterial products, and it also potentially has a flushing action to remove bacteria and their products from the crevice. However, given the nature of the bacterial biofilm, it is likely that mainly only planktonic (free-floating) bacteria are removed in this way.

The Early Lesion

The early lesion was said to develop after about 1 week of continued plaque accumulation and corresponds to the early clinical signs of gingivitis. The gingiva are erythematous in appearance as a result of the proliferation of capillaries, the opening up of microvascular beds, and continued vasodilation.[105] Increasing vascular permeability leads to increased GCF flow, and transmigrating neutrophils increase significantly in number. The predominant infiltrating cell types are neutrophils and lymphocytes (primarily thymic lymphocytes [T cells]),[137] and the neutrophils migrate through the tissues to the sulcus and phagocytose bacteria. Fibroblasts degenerate, primarily by apoptosis (programmed cell death), which increases the space available for infiltrating leukocytes. Collagen destruction occurs, which results in collagen depletion in the areas apical and lateral to the junctional and sulcular epithelium. The basal cells of these epithelial structures

begin to proliferate to maintain an intact barrier against the bacteria and their products, and the epithelium can then be seen proliferating into the collagen-depleted areas of the connective tissues (see Fig. 7.2).[153] As a result of edema of the gingival tissues, the gingiva may appear slightly swollen, and, accordingly, the gingival sulcus becomes slightly deeper. The subgingival biofilm exploits this ecologic niche and proliferates apically (thereby rendering effective plaque control more difficult). The early gingival lesion may persist indefinitely, or it may progress further.

The Established Lesion

The established lesion roughly corresponds to what clinicians would refer to as "chronic gingivitis." The progression from the early lesion to the established lesion depends on many factors, including the plaque challenge (the composition and quantity of the biofilm), host susceptibility factors, and risk factors (both local and systemic). In the initial work by Page and Schroeder,[135] the established lesion was defined as being dominated by plasma cells, and a significant inflammatory cell infiltrate in established gingivitis occupies a considerable volume of the inflamed connective tissues. Large numbers of infiltrating cells can be identified adjacent and lateral to the junctional and sulcular epithelium, around blood vessels, and between collagen fiber bundles.[22] Collagen depletion continues, with further proliferation of the epithelium into the connective tissue spaces. Neutrophils accumulate in the tissues and release their lysosomal contents extracellularly (in an attempt to kill bacteria that are not phagocytosed), thereby resulting in further tissue destruction. Neutrophils are also a major source of matrix metalloproteinase-8 (MMP-8; neutrophil collagenase) and MMP-9 (gelatinase B), and these enzymes are produced in large quantities in the inflamed gingival tissues as the neutrophils migrate through the densely packed collagen fiber bundles to enter the sulcus. The junctional epithelium and sulcular epithelium form a pocket epithelium that is not firmly attached to the tooth surface, that contains large numbers of neutrophils, and that is more permeable to the passage of substances into or out of the underlying connective tissue. The pocket epithelium may be ulcerated and less able to resist the

passage of the periodontal probe, so bleeding on probing is a common feature of chronic gingivitis. These inflammatory changes are still completely reversible if effective plaque control is reinstituted.

The Advanced Lesion

The advanced lesion, as described by Page and Schroeder,[135] marks the transition from gingivitis to periodontitis. This transition is determined by many factors, the relative importance of which is currently unknown but which includes the bacterial challenge (both the composition and the quantity of the biofilm), the host inflammatory response, and susceptibility factors, including environmental and genetic risk factors. Histologic examination reveals continued evidence of collagen destruction that extends into the periodontal ligament and the alveolar bone. Neutrophils predominate in the pocket epithelium and the periodontal pocket, and plasma cells dominate in the connective tissues. The junctional epithelium migrates apically along the root surface into the collagen-depleted areas to maintain an intact epithelial barrier. Osteoclastic bone resorption commences, and the bone retreats from the advancing inflammatory front as a defense mechanism to the prevent spread of bacteria into the bone (see Fig. 7.3). As the pocket deepens, plaque bacteria proliferate apically into a niche, which is very favorable for many of the species that are regarded as periodontal pathogens. The pocket presents a protected, warm, moist, and anaerobic environment with a ready nutrient supply, and because the bacteria are effectively outside of the body (even though they are in the periodontal pocket), they are not significantly eliminated by the inflammatory response. Thus a cycle develops in which chronic inflammation and associated tissue damage continue. The tissue damage is mainly caused by the inflammatory response, yet the initiating factor—the biofilm—is not eliminated. The destruction of collagen fibers in the periodontal ligament continues, bone resorption progresses, the junctional epithelium migrates apically to maintain an intact barrier, and as a result, the pocket deepens fractionally. This makes it even more difficult to remove the bacteria and to disrupt the biofilm through oral hygiene techniques, and thus the cycle is perpetuated.

Inflammatory Responses in the Periodontium

The molecules that play a role in the pathogenesis of periodontitis can be broadly divided into two main groups: those derived from the subgingival microbiota (i.e., microbial virulence factors) and those derived from the host immune–inflammatory response. In terms of the relative importance of each, it is now clear that most of the tissue breakdown results from the host's inflammatory processes.

Microbial Virulence Factors

The subgingival biofilm initiates and perpetuates inflammatory responses in the gingival and periodontal tissues. The subgingival bacteria also contribute directly to tissue damage by the release of noxious substances, but their primary importance in periodontal pathogenesis is that of activating immune–inflammatory responses that, in turn, result in tissue damage, which may well be beneficial to the bacteria located within the periodontal pocket by providing nutrient sources.

Lipopolysaccharide

Lipopolysaccharides (LPSs) are large molecules composed of a lipid component (lipid A) and a polysaccharide component. They are found in the outer membrane of gram-negative bacteria, they act as endotoxins (LPS is frequently referred to as *endotoxin*), and they elicit strong immune responses in animals. LPSs are highly conserved in gram-negative bacterial species, a finding that reflects their importance in maintaining the structural integrity of the bacterial cells. Immune systems in animals have evolved to recognize LPS through Toll-like receptors (TLRs), a family of cell surface molecules that are highly conserved in animal species ranging from *Drosophila* (a genus of fruit flies) to humans, thereby reflecting their importance in innate immune responses.[28] TLRs are cell surface receptors that recognize *microbe-associated molecular patterns* (MAMPs), which are conserved molecular structures located on pathogens. TLR-4 recognizes LPS from gram-negative

bacteria and functions as part of a complex of cell surface molecules, including CD14 and MD-2 (also known as *lymphocyte antigen 96*). The interaction of this CD14/TLR-4/MD-2 complex with LPS triggers a series of intracellular events, the net results of which are the increased production of inflammatory mediators (most notably cytokines) and the differentiation of immune cells (e.g., dendritic cells) for the development of effective immune responses against the pathogens. LPS is of key importance for initiating and sustaining inflammatory responses in the gingival and periodontal tissues. *Porphyromonas gingivalis* has an atypical form of LPS that is recognized by both TLR-2 and TLR-4.[38,45]

Biologic Properties of Lipopolysaccharide

- Located in the outer membrane of gram-negative bacteria
- Fundamental for maintaining structural integrity of the bacteria
- Elicits a strong response from animal immune systems
- Interacts with the CD14/TLR-4/MD-2 receptor complex on immune cells such as macrophages, monocytes, dendritic cells, and B cells, with resulting release of proinflammatory mediators such as cytokines from these cells

A component of gram-positive cell walls, lipoteichoic acid, also stimulates immune responses, although less potently than LPS. Lipoteichoic acid signals through TLR-2. Both LPS and lipoteichoic acid are released from the bacteria present in the biofilm and stimulate inflammatory responses in the tissues, thereby resulting in increased vasodilation and vascular permeability, the recruitment of inflammatory cells by chemotaxis, and the release of proinflammatory mediators by the leukocytes that are recruited to the area.

Bacterial Enzymes and Noxious Products

Plaque bacteria produce several metabolic waste products that contribute directly to tissue damage. These include noxious agents

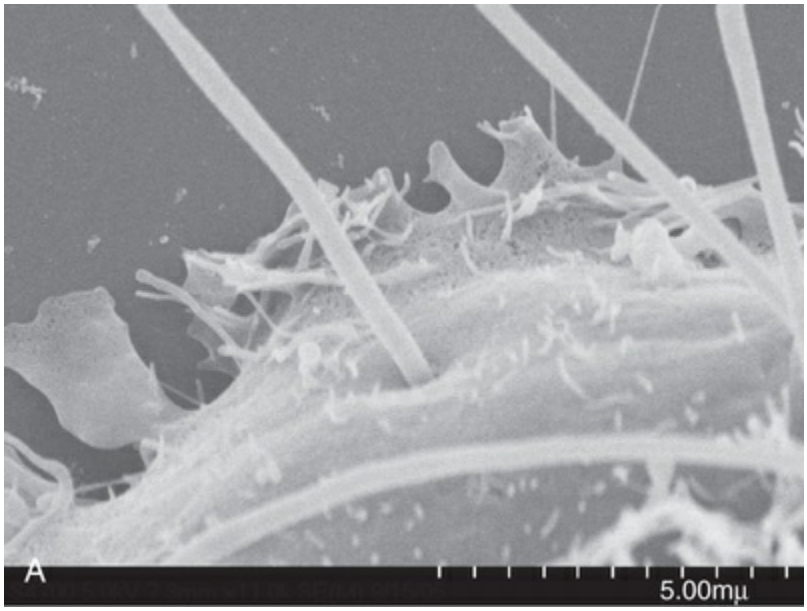
such as ammonia (NH_3) and hydrogen sulfide (H_2S), as well as short-chain carboxylic acids such as butyric acid and propionic acid. These acids are detectable in GCF and are found in increasing concentrations as the severity of periodontal disease increases. These substances have profound effects on host cells (e.g., butyric acid induces apoptosis in T cells, B cells, fibroblasts, and gingival epithelial cells).[95,96,166] The short-chain fatty acids may aid *P. gingivalis* infection through tissue destruction, and they may also create a nutrient supply for the organism by increasing bleeding into the periodontal pocket. The short-chain fatty acids also influence cytokine secretion by immune cells, and they may potentiate inflammatory responses after exposure to proinflammatory stimuli such as LPS, interleukin-1β (IL-1β), and tumor necrosis factor alpha (TNF-α).[125]

Plaque bacteria produce proteases, which are capable of breaking down structural proteins of the periodontium such as collagen, elastin, and fibronectin. Bacteria produce these proteases to digest proteins and thereby provide peptides for bacterial nutrition. Bacterial proteases disrupt host responses, compromise tissue integrity, and facilitate the microbial invasion of the tissues. *P. gingivalis* produces two classes of cysteine proteases that have been implicated in periodontal pathogenesis. These are known as *gingipains,* and they include the lysine-specific gingipain Kgp and the arginine-specific gingipains RgpA and RgpB. The gingipains can modulate the immune system and disrupt immune–inflammatory responses, thus potentially leading to increased tissue breakdown.[138] Gingipains can reduce the concentrations of cytokines in cell culture systems,[6] and they digest and inactivate TNF-α.[25] The gingipains can also stimulate cytokine secretion through the activation of protease-activated receptors (PARs). For example, RgpB activates two different PARs (PAR-1 and PAR-2), thereby stimulating cytokine secretion,[107] and both Rgp and Kgp gingipains stimulate IL-6 and IL-8 secretion by monocytes by the activation of PAR-1, PAR-2, and PAR-3.[182]

Microbial Invasion

Microbial invasion of the periodontal tissues has long been a contentious topic.[11] In histologic specimens, bacteria (including

cocci, filaments, and rods) have been identified in the intercellular spaces of the epithelium.[50] Periodontal pathogens such as *P. gingivalis* and *Aggregatibacter actinomycetemcomitans* have been reported to invade the gingival tissues,[30,73,148] including the connective tissues.[149] *Fusobacterium nucleatum* can invade oral epithelial cells, and bacteria that routinely invade host cells may facilitate the entry of noninvasive bacteria by coaggregating with them (Fig. 7.4).[47] It has also been shown that *A. actinomycetemcomitans* can invade epithelial cells and persist intracellularly.[49] The clinical relevance of these various findings is unclear, however, and more recent studies have reported that although species such as *P. gingivalis* can be found located within the tissues, they are mainly within the epithelium, and it is unusual for the bacteria to reach the connective tissue until extensive tissue destruction has occurred, and even then it is as a result of inflammation rather than "invading" bacteria.[11]



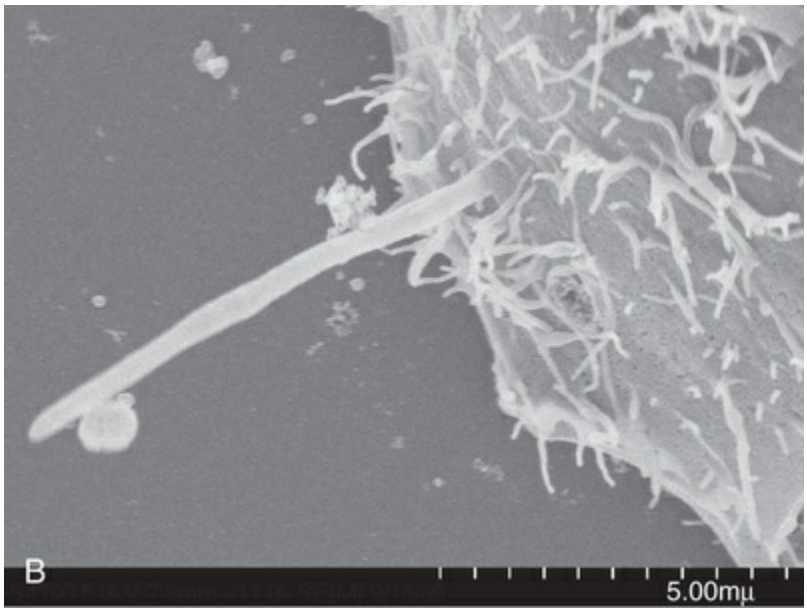


FIG. 7.4 **Invasion of epithelial cells by *Fusobacterium nucleatum*. In both images, a single epithelial cell is shown being penetrated by invading *F. nucleatum* bacteria; three or four bacteria are evident in (A), and one bacterium is evident in (B). (A) The ruffled surface of the epithelial cells (multiple small fingerlike projections that are much smaller than the *F. nucleatum* bacteria) is likely to be an artifact. (B) *F. nucleatum* may facilitate the colonization of epithelial cells by bacteria that are unable to adhere or invade directly as evidenced by the single coccoid bacterium *(Streptococcus cristatus)* that has coaggregated with the *F. nucleatum* bacterium as it penetrates the epithelial cell.** (A and B, Courtesy Dr. A.E. Edwards, Imperial College, London, UK; Dr. J.D. Rudney, Bath University, Bath, UK; and Dr. T.J. Grossman, the University of Minnesota, Minneapolis, Minn.)

Clinical Correlation

Is bacterial invasion of the tissues a valid concept, and does it have implications for therapy?

Good evidence indicates that certain species of subgingival bacteria are able to invade epithelial cells, thereby providing a shelter from the host defenses (and also highlighting the important role of epithelium in host defenses by release of cytokines to activate inflammatory responses). However, invasion of the deeper connective tissues by live bacteria such as *Porphyromonas gingivalis* seems to occur (if it occurs!) at a much later stage in advanced disease, probably as a result of inflammation and resultant tissue destruction. Reports of bacteria present in the tissues (described as a "reservoir of infection") have sometimes been used to justify the

use of antibiotics for treatment of periodontitis as a means to try to eliminate those organisms that are located in the tissues and that are therefore "protected" from mechanical disruption by root surface debridement. However, until the clinical relevance of the presence of bacteria in the tissues is better defined, it is inappropriate to make clinical treatment decisions (e.g., whether to use adjunctive systemic antibiotics) on this premise alone.

Fimbriae

The fimbriae of certain bacterial species, particularly *P. gingivalis,* may also play a role in periodontal pathogenesis. *P. gingivalis* fimbriae stimulate immune responses, such as IL-6 secretion,[97,129] and the major fimbrial structural component of *P. gingivalis,* FimA, has been shown to stimulate nuclear factor (NF)-κB and IL-8 in a gingival epithelial cell line through TLR-2.[5] Monocytes are also stimulated by *P. gingivalis* FimA, secreting IL-6, IL-8, and TNF-α.[48] *P. gingivalis* fimbriae also interact with complement receptor-3 (CR-3) to activate intracellular signaling pathways that inhibit IL-12 production mediated by TLR-2 signaling.[65] This may be of clinical relevance because IL-12 is important in the activation of natural killer (NK) cells and $CD8^+$ cytotoxic T cells, which themselves may be important in killing *P. gingivalis*–infected host cells, such as epithelial cells. Indeed, the blockade of the CR-3 receptor promotes IL-12–mediated clearance of *P. gingivalis* and negates its virulence.[65] Bacterial fimbriae are therefore important for modifying and stimulating immune responses in the periodontium.

Bacterial Deoxyribonucleic Acid and Extracellular Deoxyribonucleic Acid

Bacterial deoxyribonucleic acid (DNA) stimulates immune cells through TLR-9, which recognizes hypomethylated CpG regions of the DNA.[93] (CpG sites are regions of DNA at which a cytosine nucleotide is found next to a guanine nucleotide, separated by a phosphate molecule, which links the C and G nucleotides together, hence "CpG".) Extracellular DNA (eDNA) is a ubiquitous constituent of all biofilms and of particular interest in biofilms associated with chronic diseases such as periodontitis.[79] eDNA is

derived from the chromosomal DNA of bacteria in biofilms, and the majority of eDNA is released after bacterial cell lysis.[2,176] However, evidence also indicates that eDNA secretion may occur from bacterial cells by mechanisms that are independent of cell lysis.[66,143] The significance of this finding is not yet clear, but such "donated" DNA may be used by bacterial species as a means of increasing genetic diversity (if taken up by other bacteria), thereby contributing to antigenic variation and the spread of antibiotic resistance, and they may also modulate the host immune response. Thus eDNA may function as a source of genetic information for naturally transformable bacteria in the biofilm[189] or as a stimulus for host immunity. Perhaps more important, it is becoming increasingly clear that eDNA plays a number of important roles in biofilm integrity and formation on hard and soft tissues in the oral cavity. These include roles in adhesion and biofilm formation, protection against antimicrobial agents, and nutrient storage, as well as genetic exchange, and it is possible that eDNA may ultimately prove to be an important target for biofilm control.[79]

Host-Derived Inflammatory Mediators

The inflammatory and immune processes that develop in the periodontal tissues in response to the long-term presence of the subgingival biofilm are protective by intent but can result in considerable tissue damage, thereby leading to the clinical signs and symptoms of periodontal disease. It is paradoxical that the host response causes most of the tissue damage, although this is not unique to periodontal disease. For example, the tissue damage that occurs in the joints in patients with rheumatoid arthritis results from prolonged and excessive inflammatory responses, and it is characterized by the increased production of many of the cytokines that are also known to be important in periodontal pathogenesis. In the case of rheumatoid arthritis, the initiating factor is an autoimmune response to structural components of the joint; in periodontitis, the initiating factor is the subgingival biofilm. In both cases, the destructive inflammatory events are remarkably similar, although the pathogenesis varies as a result of the different anatomy. Key types of mediators that orchestrate the host

responses in periodontitis are summarized in the following subsections.

Cytokines

Cytokines play a fundamental role in inflammation, and they are key inflammatory mediators in periodontal disease.[141] They are soluble proteins, and they act as messengers to transmit signals from one cell to another. Cytokines bind to specific receptors on target cells and initiate intracellular signaling cascades that result in phenotypic changes in the cell by altered gene regulation.[17,174] Cytokines are effective in very low concentrations, they are produced transiently in the tissues, and they primarily act locally in the tissues in which they are produced. Cytokines are able to induce their own expression in either an autocrine or paracrine fashion, and they have pleiotropic effects (i.e., multiple biologic activities) on a large number of cell types. (Autocrine signaling means that the autocrine agent [in this case cytokines] binds to receptors on the cell that secreted the agent, whereas paracrine signaling affects other nearby cells.) Simply put, cytokines bind to cell surface receptors and trigger a sequence of intracellular events that lead ultimately to the production of protein by the target cell that alters that cell's behavior and could result in, for example, the increased secretion of more cytokines in a positive feedback loop.

Cytokines are produced by a large number of cell types, including infiltrating inflammatory cells (e.g., neutrophils, macrophages, lymphocytes), as well as resident cells in the periodontium (e.g., fibroblasts, epithelial cells). Cytokines signal, broadcast, and amplify immune responses, and they are fundamentally important for regulating immune–inflammatory responses and for combating infections. They have profound biologic effects that also lead to tissue damage with chronic inflammation; the prolonged and excessive production of cytokines and other inflammatory mediators in the periodontium leads to the tissue damage that characterizes the clinical signs of the disease. For example, cytokines mediate connective tissue and alveolar bone destruction through the induction of fibroblasts and osteoclasts to produce proteolytic enzymes (i.e., MMPs) that break down structural components of these connective tissues.[10]

Significant overlap and redundancy exist in the functions of individual cytokines. Cytokines do not act in isolation; rather, they function in flexible and complex networks that involve both proinflammatory and antiinflammatory effects and that bring together aspects of both innate and acquired immunity.[7] Cytokines play a key role at all stages of the immune response in periodontal diseases.[141]

Prostaglandins

The prostaglandins (PGs) are a group of lipid compounds derived from arachidonic acid, a polyunsaturated fatty acid found in the plasma membrane of most cells. Arachidonic acid is metabolized by cyclooxygenase-1 and 2 (COX-1 and COX-2) to generate a series of related compounds called the *prostanoids,* which include the PGs, the thromboxanes, and the prostacyclins. PGs are important mediators of inflammation, particularly prostaglandin E_2 (PGE_2), which results in vasodilation and induces cytokine production by a variety of cell types. COX-2 is up-regulated by IL-1β, TNF-α, and bacterial LPS, thus resulting in increased production of PGE_2 in inflamed tissues. PGE_2 is produced by various types of cells and most significantly in the periodontium by macrophages and fibroblasts. PGE_2 results in the induction of MMPs and osteoclastic bone resorption, and it has a major role in contributing to the tissue damage that characterizes periodontitis.

Matrix Metalloproteinases

MMPs are a family of proteolytic enzymes that degrade extracellular matrix molecules such as collagen, gelatin, and elastin. They are produced by a variety of cell types, including neutrophils, macrophages, fibroblasts, epithelial cells, osteoblasts, and osteoclasts. The names and functions of key MMPs are shown in Table 7.1. The nomenclature of MMPs has been based on the perception that each enzyme has its own specific substrate; for example, MMP-8 and MMP-1 are both collagenases (i.e., they break down collagen). However, it is now appreciated that MMPs usually degrade multiple substrates, with significant substrate overlap among individual MMPs.[68] The substrate-based classification is still

used, however, and MMPs can be divided into collagenases, gelatinases/type IV collagenases, stromelysins, matrilysins, membrane-type metalloproteinases, and others.

TABLE 7.1
Classification of Matrix Metalloproteinases

Group	Enzyme	Name
Collagenases	MMP-1	Collagenase 1, fibroblast collagenase
	MMP-8	Collagenase 2, neutrophil collagenase
	MMP-13	Collagenase 3
Gelatinases	MMP-2	Gelatinase A
	MMP-9	Gelatinase B
Stromelysins	MMP-3	Stromelysin 1
	MMP-10	Stromelysin 2
	MMP-11	Stromelysin 3
Matrilysins	MMP-7	Matrilysin 1, pump-1
	MMP-26	Matrilysin 2
Membrane-type MMPs	MMP-14	MT1-MMP
	MMP-15	MT2-MMP
	MMP-16	MT3-MMP
	MMP-17	MT4-MMP
	MMP-24	MT5-MMP
	MMP-25	MT6-MMP
Others	MMP-12	Macrophage elastase
	MMP-19	—
	MMP-20	Enamelysin

MMPs, Matrix metalloproteinases; *MT,* membrane type.

Adapted from Hannas AR, Pereira JC, Granjeiro JM, et al: The role of matrix metalloproteinases in the oral environment. *Acta Odontol Scand* 65:1–13, 2007.

MMPs are secreted in a latent form (inactive) and are activated by the proteolytic cleavage of a portion of the latent enzyme. This is achieved by proteases, such as cathepsin G, produced by neutrophils. MMPs are inhibited by proteinase inhibitors, which have antiinflammatory properties. Key inhibitors of MMPs found in the serum include the glycoprotein α_1-antitrypsin and α_2-macroglobulin, a large plasma protein produced by the liver that is capable of inactivating a wide variety of proteinases. Inhibitors of MMPs that are found in the tissues include the tissue inhibitors of metalloproteinases (TIMPs), which are produced by many cell types; the most important in periodontal disease is TIMP-1.[18]

MMPs are also inhibited by the tetracycline class of antibiotics, which has led to the development of a subantimicrobial

formulation of doxycycline as an adjunctive systemic drug treatment for periodontitis. Doxycycline, like all the tetracyclines, possesses the ability to down-regulate MMPs, and this was recognized as representing a potential novel treatment strategy for periodontitis. The subantimicrobial formulation has been shown to inhibit collagenase activity in the gingival tissues and GCF of patients with chronic periodontitis,[59] and some clinical trials have investigated the clinical effect of using this formulation of doxycycline as an adjunct to periodontal therapy.[139]

Properties of Key Types of Inflammatory Mediators in Periodontitis

Cytokines	Proteins that transmit signals from one cell to another Bind to cell surface receptors to trigger production of protein by the cell There are proinflammatory and antiinflammatory cytokines. A key proinflammatory cytokine is interleukin-1β, which up-regulates inflammatory responses and is produced by multiple cell types in the periodontium.
Prostaglandins	Lipid compounds derived from arachidonic acid Prostaglandin E_2 (PGE_2) is a key inflammatory mediator, stimulating production of other inflammatory mediators and cytokine production. PGE_2 also stimulates bone resorption and plays a key role in periodontitis progression.
Matrix metalloproteinases (MMPs)	A group of enzymes that break down structural proteins of the body MMPs include collagenases, which break down collagen. Key MMPs in periodontitis include MMP-8 and MMP-9, which are produced by neutrophils as they migrate through the periodontal tissues, thus contributing to periodontal tissue breakdown.

Role of Specific Inflammatory Mediators in Periodontal Disease

Interleukin-1 Family Cytokines

The IL-1 family of cytokines comprises at least 11 members, including IL-1α, IL-1β, IL-1 receptor antagonist (IL-1Ra), IL-18, and IL-33.[141]

IL-1β plays a key role in inflammation and immunity; it is closely linked to the innate immune response, and it induces the synthesis and secretion of other mediators that contribute to inflammatory

changes and tissue damage. For example, IL-1β stimulates the synthesis of PGE_2, platelet-activating factor, and nitrous oxide, thereby resulting in vascular changes associated with inflammation and increasing blood flow to the site of infection or tissue injury. IL-1β is mainly produced by monocytes, macrophages, and neutrophils and also by other cell types such as fibroblasts, keratinocytes, epithelial cells, B cells, and osteocytes.[40] IL-1β increases the expression of ICAM-1 on endothelial cells and stimulates the secretion of the chemokine CXCL8 (IL-8), thereby stimulating and facilitating the infiltration of neutrophils into the affected tissues. IL-1β also synergizes with other proinflammatory cytokines and PGE_2 to induce bone resorption. IL-1β has a role in adaptive immunity; it regulates the development of antigen-presenting cells (APCs) (e.g., dendritic cells), stimulates IL-6 secretion by macrophages (which, in turn, activates B cells), and has been shown to enhance the antigen-mediated stimulation of T cells.[13] GCF concentrations of IL-1β are increased at sites affected by gingivitis[70] and periodontitis,[99] and tissue levels of IL-1β correlate with clinical periodontal disease severity.[167] Studies in experimental animals have shown that IL-1β exacerbates inflammation and alveolar bone resorption.[88] It is clear from the multiplicity of studies that have investigated this cytokine that IL-1β plays a fundamental role in the pathogenesis of periodontal disease.[92]

IL-1α is primarily an intracellular protein that is not normally secreted and that therefore is not usually found in the extracellular environment or in the circulation.[43] Unlike IL-1β, biologically active IL-1α is constitutively expressed and likely mediates inflammation only when it is released from necrotic cells, thus acting as an "alarmin" to signal the immune system during cell and tissue damage.[16] The precise role of IL-1α in periodontal pathogenesis is not well defined, although studies have reported elevated IL-1α levels in GCF and gingival tissues in patients with periodontitis.[142] IL-1α is a potent bone-resorbing factor involved in the bone loss that is associated with inflammation.[172] It is possible that the measured level of IL-1α in gingival tissues represents intracellular IL-1α that has been released from damaged or necrotic cells, and it is probable that IL-1α plays a role in periodontal pathogenesis, possibly as a signaling cytokine (signaling tissue damage) and

contributing to bone resorptive activity.

IL-1Ra has structural homology to IL-1β, and it binds to the IL-1 receptor (IL-1R1). However, the binding of IL-1Ra does not result in signal transduction; therefore, IL-1Ra antagonizes the action of IL-1β.[42] IL-1Ra is important for the regulation of inflammatory responses, and it can be considered an antiinflammatory cytokine. IL-1Ra levels have been reported to be elevated in the GCF and tissues of patients with periodontal disease, thereby suggesting that it has a role in immunoregulation in cases of periodontitis.[145]

IL-18 interacts with IL-1β and shares many of the proinflammatory effects of IL-1β.[141] It is mainly produced by stimulated monocytes and macrophages.[61] Increasing evidence suggests that IL-18 plays a significant role in inflammation and immunity. IL-18 results in proinflammatory responses, including the activation of neutrophils.[102] It is a chemoattractant for T cells,[89] and it interacts with IL-12 and IL-15 to induce interferon gamma (IFN-γ), thereby inducing T-helper (Th1) cells, which activate cell-mediated immunity.[197] Very limited direct evidence exists for a role of IL-18 in periodontal pathogenesis. Oral epithelial cells secrete IL-18 in response to stimulation with LPS,[146] and a correlation between GCF IL-18 levels and sulcus depth has been reported.[81] IL-18 levels have been reported to be higher than those of IL-1β in patients with periodontitis, thereby suggesting that IL-18—along with IL-1β—is predominant in periodontitis lesions.[131] Because IL-18 has the ability to induce either Th1 or Th2 differentiation, it is likely to play an important role in periodontal disease pathogenesis.[132]

Other Interleukin-1 Family Cytokines

Six new members of the IL-1 family (IL-1F) of cytokines have been identified on the basis of their sequence homology, structure, gene location, and receptor binding.[4,9] Several of these cytokines were identified by different research groups, who gave them a variety of names, and proposals were suggested for renaming all the IL-1F cytokines in a more consistent manner, as indicated in Table 7.2. Our knowledge of the role of these cytokines in inflammation and immunity is very limited at present, and some of these cytokines may be evolutionarily redundant. IL-1F6, IL-1F8, and IL-1F9 are potential agonists (stimulating proinflammatory responses),[19,180]

whereas IL-1F5 and IL-1F10 are potential antagonists.[19,33,103] IL-1F7 appears to have antiinflammatory action.[44] It has five splice variants and one isoform, IL-1F7b, which is highly expressed by monocytes and up-regulated by LPS.[23] An intracellular mode of action has been suggested for IL-1F7b; it translocates to the nucleus of macrophages, and it may act as a transcriptional modulator by reducing the production of LPS-stimulated proinflammatory cytokines, thus supporting an antiinflammatory role for this cytokine.[163]

TABLE 7.2

Nomenclature of Interleukin-1 Family Cytokines

Cytokine	Systematic Name	Function
IL-1α	IL-1F1	Intracellular protein, proinflammatory, contributes to bone resorption, functions as an intracellular transcriptional regulator
IL-1β	IL-1F2	Key role in inflammation and innate immunity, synergizes with other proinflammatory mediators, major role in adaptive immunity (i.e., regulation of T cells and myeloid cells), stimulates connective tissue breakdown and bone resorption
IL-1Ra	IL-1F3	Inhibits the action of IL-1α and IL-1β
IL-18	IL-1F4	Similar proinflammatory profile to IL-1β, activates neutrophils, synergizes with IL-12 to activate T-helper 1 cells
IL-1F5	IL-1F5	Antiinflammatory effects via IL-4 induction, antagonizes IL-1F6 action
IL-1F6	IL-1F6	Proinflammatory but restricted expression (e.g., localized to skin)
IL-1F7	IL-1F7	Antiinflammatory, acts as an intracellular regulator, reduces production of lipopolysaccharide-stimulated proinflammatory cytokines
IL-1F8	IL-1F8	Proinflammatory but restricted expression (e.g., localized to skin and synovial tissues)
IL-1F9	IL-1F9	Proinflammatory but restricted expression (e.g., localized to skin, placenta, and esophagus)
IL-1F10	IL-1F10	Putative antagonist with antiinflammatory action
IL-33	IL-1F11	Activation of T-helper 2 cells and mast cells, functions as an intracellular transcriptional regulator but restricted expression (e.g., endothelial cells, smooth muscle cells, and fibroblasts)

IL, Interleukin; *IL-1F*, interleukin-1 family.

The novel IL-1F cytokines have limited tissue expression. For example, the agonists IL-1F6, IL-1F8, and IL-1F9 are mainly expressed in skin.[180] Therefore, although the primary cellular sources of IL-1β and IL-18 are hematopoietic cells (e.g., neutrophils, macrophages, monocytes, lymphocytes), IL-1F5 through IL-1F10 are mainly expressed outside of these lineages. At present, no clear data support a role for IL-1F5 through IL-1F10 in periodontal

pathogenesis. However, given that they are expressed mainly by epithelial cells, it will be interesting to learn whether they may play a role in inflammatory responses in the gingiva. This is relevant given the continual exposure of gingival epithelial cells to bacterial challenge, and these cytokines also have properties similar to the primary cytokines (e.g., IL-1β). For example, LPS results in the up-regulation of IL-1F6, IL-1F8, and IL-1F9, and these cytokines also stimulate the secretion of IL-6 and IL-8.[180] *P. gingivalis* LPS up-regulates IL-1F9 mRNA expression in monocytes, although it does not have an effect on IL-1F6, IL-1F7, IL-1F8, or IL-1F10.[9]

IL-33, which is also known as IL-1F11, is of interest because, uniquely among the IL-1 cytokines, it stimulates the production of Th2 cytokines (e.g., IL-5, IL-13), it activates Th2 cells, and it plays a role in mast cell development and function.[1,74,90,118,152] IL-33 is mainly found in nonimmune cells such as bronchial and arterial smooth muscle cells and epithelial cells from the bronchus.[152] It is constitutively expressed in the endothelial cells of small and large blood vessels, in the fibroblastic reticular cells of lymphoid tissues, and in epithelial cells.[26,119] Our knowledge of the expression of IL-33 in myeloid immune cells and of any role in periodontitis pathogenesis is very limited. However, it has been reported that IL-33 activates Th2 cells[152] and is chemoattractant for these cells.[90] Given that Th2 cells are likely to play a role in the destructive phases of periodontal disease and that the balance of T-cell subsets is an important factor in determining disease progression,[56] IL-33 may yet prove to play a role in periodontal pathogenesis.

Tumor Necrosis Factor Alpha

TNF-α is a key inflammatory mediator in periodontal disease, and it shares many of the cellular actions of IL-1β.[62] It plays a fundamental role in immune responses, it increases neutrophil activity, and it mediates cell and tissue turnover by inducing MMP secretion. TNF-α stimulates the development of osteoclasts and limits tissue repair by the induction of apoptosis in fibroblasts. TNF-α is secreted by activated macrophages, as well as by other cell types, particularly in response to bacterial LPS. The proinflammatory effects of TNF-α include the stimulation of endothelial cells to express selectins that facilitate leukocyte

recruitment, the activation of macrophage IL-1β production, and the induction of PGE_2 by macrophages and gingival fibroblasts.[133] TNF-α—although possessing similar activity to IL-1β—has a less potent effect on osteoclasts, and it is present at lower levels in inflamed gingival tissues than IL-1β.[168] GCF levels of TNF-α increase as gingival inflammation develops, and higher levels are found in individuals with periodontitis.[62,70]

Interleukin-6 and Related Cytokines

The cytokines in this group—which include IL-6, IL-11, leukemia-inhibitory factor (LIF), and oncostatin M—share common signaling pathways through signal transducers glycoprotein (gp) 130.[71] IL-6 is the most extensively studied of this group, and it has pleiotropic proinflammatory properties.[86] IL-6 secretion is stimulated by cytokines such as IL-1β and TNF-α, and it is produced by a range of immune cells (e.g., T cells, B cells, macrophages, dendritic cells), as well as resident cells (e.g., keratinocytes, endothelial cells, fibroblasts).[186] IL-6 is also secreted by osteoblasts, and it stimulates bone resorption and the development of osteoclasts.[78,94] IL-6 is elevated in the cells, tissues, and GCF of patients with periodontal disease.[55,104] IL-6 may have an influence on monocyte differentiation into osteoclasts and a role in bone resorption in patients with periodontal disease.[130] IL-6 also has a key role in regulating the proliferation and differentiation of B cells and T cells, particularly the Th17 subset.[86] IL-6 therefore has an important role in periodontal pathogenesis, although less than that of IL-1β or TNF-α.

IL-6 also has many activities outside of the immune system, such as in the cardiovascular and nervous systems. It has an important role in hematopoiesis and in signaling the production of C-reactive protein (CRP) in the liver. Furthermore, IL-6 stimulates T-cell differentiation and function, and it is important in the regulation of the balance of T-cell subsets, particularly the activation of Th17 cells (a subset of T cells that produce IL-17) and the balance with regulatory T cells (T_{reg} cells).[14]

Prostaglandin E_2

The cells primarily responsible for PGE_2 production in the periodontium are macrophages and fibroblasts. PGE_2 levels are increased in the tissues and in GCF at sites undergoing periodontal attachment loss. PGE_2 induces the secretion of MMPs, as well as osteoclastic bone resorption, and it contributes significantly to the alveolar bone loss seen with periodontitis. PGE_2 release from monocytes from patients with severe or aggressive periodontitis is greater than that from monocytes from patients who are periodontally healthy.[54,128] A large body of evidence has demonstrated the importance of PGE_2 in periodontal pathogenesis, and given that prostaglandins are inhibited by nonsteroidal antiinflammatory drugs (NSAIDs), researchers have investigated the use of NSAIDs as potential host–response modulators in the management of periodontal disease.[193,194] However, daily administration for extended periods is necessary for the periodontal benefits to become apparent, and NSAIDs are associated with significant unwanted side effects, including gastrointestinal problems, hemorrhage (from impaired platelet aggregation resulting from inhibition of thromboxane formation), and renal and hepatic impairment. NSAIDs are therefore not indicated as adjunctive treatments for the management of periodontitis (see Chapter 54).

The prostaglandins, including PGE_2, are derived from the COX pathway of arachidonic acid metabolism. The two main isoforms of the COX enzyme are COX-1 and COX-2. COX-1 is constitutively expressed and has antithrombogenic and cytoprotective functions. COX-2 is induced after stimulation with various cytokines, growth factors, and LPS. The inhibition of COX-1 by nonselective NSAIDs results in the majority of the unwanted side effects associated with NSAID usage, such as gastrointestinal ulceration and impaired hemostasis. The induction of COX-2 results in the production of elevated quantities of prostaglandins (e.g., PGE_2); therefore, the inhibition of COX-2 by NSAIDs that selectively inhibit COX-2 results in a reduction of inflammation without the unwanted effects commonly seen after long-term NSAID use. Preliminary studies in animal models have shown that selective COX-2 inhibitors slowed alveolar bone loss,[15,75] and human studies confirmed that

prostaglandin production in the periodontal tissues was modified.[187] However, in a dramatic and unfortunate development, the selective COX-2 inhibitors were later identified to be associated with significant and life-threatening adverse events, thereby resulting in several of these drugs being withdrawn from the market.[46] The selective COX-2 inhibitors therefore cannot be considered as adjunctive treatments for periodontal disease.

Matrix Metalloproteinases

MMPs are a family of zinc-dependent enzymes that are capable of degrading extracellular matrix molecules, including collagens.[18,147] MMPs play a key role in periodontal tissue destruction and are secreted by the majority of cell types in the periodontium, including fibroblasts, keratinocytes, endothelial cells, osteoclasts, neutrophils, and macrophages. In healthy tissues, MMPs are mainly produced by fibroblasts, which produce MMP-1 (also known as *collagenase-1*), and these have a role in the maintenance of the periodontal connective tissues. The transcription of genes coding for MMPs is up-regulated by cytokines such as IL-1β and TNF-α.[109] MMP activity is regulated by specific endogenous TIMPs and serum glycoproteins such as α-macroglobulins, which form complexes with active MMPs and their latent precursors.[144] TIMPs are produced by fibroblasts, macrophages, keratinocytes, and endothelial cells; they are specific inhibitors that bind to MMPs in a 1 : 1 stoichiometry.[68] MMPs are also produced by some periodontal pathogens, such as *A. actinomycetemcomitans* and *P. gingivalis*, but the relative contribution of these bacterially derived MMPs to periodontal pathogenesis is small. Most MMP activity in the periodontal tissues is derived from infiltrating inflammatory cells.

In healthy periodontal tissues, collagen homeostasis is a controlled process that is mediated extracellularly by MMP-1 (expressed by resident cells, primarily fibroblasts) and intracellularly by a variety of lysosomal-acid–dependent enzymes. In inflamed periodontal tissues, excessive quantities of MMPs are secreted by resident cells and by the large numbers of infiltrating inflammatory cells (particularly neutrophils) as they migrate through the tissues. As a result, the balance between MMPs and their inhibitors is disrupted, resulting in breakdown of the

connective tissue matrix[18,175] and leading to the development of collagen-depleted areas within the connective tissues, as described previously. Neutrophils are key infiltrating cells in periodontitis that accumulate in large numbers in inflamed periodontal tissues (see Fig. 7.2). Neutrophils have evolved to respond rapidly and aggressively to external stimuli, such as bacterial LPS, and they release large quantities of destructive enzymes very rapidly.[124] The predominant MMPs in periodontitis, MMP-8 and MMP-9, are secreted by neutrophils,[60] and they are very effective at degrading type 1 collagen, which is the most abundant collagen type in the periodontal ligament.[111] MMP-8 and MMP-9 levels increase with increasing severity of periodontal disease and decrease after treatment.[59,60,84] The prolonged and excessive release of large quantities of MMPs in the periodontium leads to the significant breakdown of structural components of the connective tissues, thereby contributing to the clinical signs of disease.

MMPs play a fundamental role in connective tissue homeostasis, as well as disease pathogenesis, and they possess a wide range of biologic effects that are relevant in periodontitis (Table 7.3). MMPs are important in alveolar bone destruction. They are expressed by osteoclasts, which also express cathepsin K. Cathepsin K is a lysosomal cysteine protease that is mainly expressed in osteoclasts and that plays a key role in bone resorption and remodeling. This enzyme can catabolize collagen, gelatin, and elastin and can therefore contribute to the breakdown of bone and cartilage.

TABLE 7.3

Biologic Activities of Selected Matrix Metalloproteinases Relevant to Periodontal Disease

MMP Type	Enzyme	Biologic Activity
Collagenases	All	Degrade interstitial collagens (types I, II, and III)
		Digest ECM and non-ECM molecules
	MMP-1	Keratinocyte migration and re-epithelialization
		Platelet aggregation
	MMP-13	Osteoclast activation
Gelatinases	All	Degrade denatured collagens and gelatin
	MMP-2	Differentiation of mesenchymal cells with inflammatory phenotype
		Epithelial cell migration
		Increased bioavailability of MMP-9

Stromelysins	All	Digest ECM molecules
	MMP-3	Activate pro-MMPs
		Disrupted cell aggregation
		Increased cell invasion
Matrilysins	MMP-7	Disrupted cell aggregation
		Increased cell invasion
Membrane-type MMPs	All	Digest ECM molecules
		Activate pro-MMP-2 (except MT4-MMP)
	MT1-MMP	Epithelial cell migration
		Degrade collagen types I, II, and III

ECM, Extracellular matrix; *MMPs,* matrix metalloproteinases; *MT,* membrane type.

Adapted from Hannas AR, Pereira JC, Granjeiro JM, et al: The role of matrix metalloproteinases in the oral environment. *Acta Odontol Scand* 65:1–13, 2007.

MMPs are critical for osteoclast access to the resorption site, particularly for MMP-9 and MMP-14. MMP-14 is located in the ruffled border of osteoclasts, and osteoblasts and osteocytes (but not osteoclasts) express MMP-13, which is present in resorption lacunae and functions to remove collagen remnants left over by osteoclasts.[68] MMPs also contribute to osteoclast recruitment and activity by releasing cytokines and receptor activator of nuclear factor-κB ligand (RANKL; see later). MMPs are also important in osteoblastic bone formation, including MMP-2, MMP-9, MMP-13, and MMP-14. MMP-14 also contributes to normal bone homeostasis, and MMP-14–activated transforming growth factor beta (TGF-β) inhibits osteoblast apoptosis.

Chemokines

Chemokines are cytokine-like molecules that are characterized by their chemotactic activity.[28] This activity gave rise to the term *chemokine* (i.e., they are chemotactic cytokines). Chemokines orchestrate leukocyte recruitment in physiologic and pathologic conditions,[20] so they are important for periodontal pathogenesis, which results in the chemotactic migration of neutrophils through the periodontal tissues toward the site of the bacterial challenge in the periodontal pocket.[164] Chemokines play a key role in neutrophil recruitment and the recruitment of other adaptive and innate immune cells to the site of immune and inflammatory responses. The chemokines are divided into two subfamilies according to structural similarity: the CC subfamily and the CXC subfamily.[162] The chemokine CXCL8, which is more familiarly known as IL-8, has

been demonstrated to be localized in the gingival tissues in areas of plaque accumulation and in the presence of neutrophilic infiltration,[178] and it has also been found in GCF.[112] Interaction between bacteria and keratinocytes results in the up-regulation of IL-8 and ICAM-1 expression in the gingival epithelium and the development of a chemotactic gradient of these molecules in the gingiva, thereby stimulating neutrophil migration into the tissues and the gingival sulcus.[177,179] Similar chemotactic gradients are also present in the gingiva of periodontally healthy individuals; this suggests a role for this process in the maintenance of periodontal health and supports the findings of infiltrating neutrophils being present even in clinically healthy tissues.[179]

It is becoming clear that chemokines play an important role in leukocyte migration in periodontal disease. CCL2 and CCL5 (also known as *regulated on activation, normal T-cell expressed and secreted* [RANTES]) play a role in macrophage migration, and CCL3 (also known as *macrophage inflammatory protein-1α* [MIP-1α]) and CXCL10 play a role in T-cell migration in inflamed periodontal tissues.[164] Chemokines play important roles in immune responses, repair, and inflammation, and they regulate osteoclast activity by influencing myeloid cell differentiation into osteoclasts, which may be of particular importance in the context of periodontitis.

Antiinflammatory Cytokines

The balance between proinflammatory and antiinflammatory events is crucial for determining disease progression, and it is now clear that individual cytokines do not act in isolation but rather as part of complex networks of mediators that have different functional activities. Antiinflammatory cytokines include IL-10, TGF-β, IL-1Ra, IL-1F5, and possibly IL-1F10.

The IL-10 family of cytokines has multiple pleiotropic effects and possesses immunosuppressive properties.[32,34] IL-10 is produced by T_{reg} cells, monocytes, and B cells, and it suppresses cytokine secretion by Th1 cells, Th2 cells, monocytes, and macrophages. The role of IL-10 in periodontal disease has been minimally studied, but animal models support that IL-10 down-regulates inflammatory responses. For example, IL-10 knockout mice are more susceptible to alveolar bone loss than wild-type mice.[150] IL-10 is also present in

GCF and periodontal tissues.[76]

TGF-β is a growth factor that functions as a cytokine and has immunoregulatory roles, such as the regulation of T-cell subsets and the action of T_{reg} cells, and it also plays a role in repair and regeneration.[195] It has multifunctional roles in various cellular functions, including angiogenesis, the synthesis of the extracellular matrix, apoptosis, and the inhibition of cell growth. TGF-β levels are higher in the GCF and periodontal tissues of patients with periodontitis and gingivitis than in patients who are periodontally healthy.[67]

Linking Pathogenesis to Clinical Signs of Disease

Advanced forms of periodontal disease are characterized by the symptoms of tooth mobility, tooth loss, and tooth migration. These result from the loss of attachment between the tooth and its supporting tissues after the breakdown of the inserting fibers of the periodontal ligament and the resorption of alveolar bone. Having reviewed the histopathology and the inflammatory processes that develop in the periodontal tissues as a result of prolonged accumulation of dental biofilm, it is now necessary to link these changes to the structural damage that occurs in the periodontium, thereby leading to the well-defined signs of disease.

Even clinically healthy tissues demonstrate signs of inflammation when histologic sections are examined. For example, transmigrating neutrophils are evident in clinically healthy gingival tissues moving toward the sulcus for the purpose of eliminating bacteria. If the inflammation becomes more extensive, then vasodilation and increased vascular permeability lead to edema of the tissues, as well as erythema, thereby causing gingival swelling and a slight deepening of the sulcus and further compromising plaque removal. The increased infiltration of inflammatory cells (particularly neutrophils) and the breakdown of collagen result in the development of collagen-depleted areas below the epithelium; as a result, the epithelium proliferates to maintain tissue integrity.

The epithelium provides a physical barrier to impede the ingress

of bacteria and their products; therefore, the disruption of the epithelial barrier can lead to further bacterial invasion and inflammation. Antimicrobial peptides, which are also called *defensins,* are expressed by epithelial cells, and gingival epithelial cells express two human β-defensins (hBD-1 and hBD-2). Furthermore, a cathelicidin class antimicrobial peptide, LL-37, which is found in the lysosomes of neutrophils, is also expressed in gingiva. These antimicrobial peptides are important for determining the outcomes of the host–pathogen interactions at the epithelial barrier.[190] The epithelium is therefore more than simply a passive barrier: it also has an active role in innate immunity.[37] Epithelial cells in the junctional and sulcular epithelium are in constant contact with bacterial products and respond to these products by secreting chemokines (e.g., IL-8, CXCL8) to attract neutrophils, which migrate up the chemotactic gradient toward the pocket. Epithelial cells are therefore active in responding to infection and signaling further host responses.

If the bacterial challenge persists, the cellular and fluid infiltrate continues to develop, and neutrophils and other inflammatory cells soon occupy a significant volume of the inflamed gingival tissues. Neutrophils are key components of the innate immune system, and they play a fundamental role in maintaining periodontal health, despite the constant challenge presented by the plaque biofilm.[124] Neutrophils are protective leukocytes that phagocytose and kill bacteria, and deficiencies in neutrophil functioning result in increased susceptibility to infections in general, as well as periodontal disease.[100] Neutrophils also release large quantities of destructive enzymes (e.g., MMPs) as they migrate through the tissues (particularly MMP-8 and MMP-9), a process that results in the breakdown of structural components of the periodontium and the development of collagen-depleted areas. Neutrophils also release their potent lysosomal enzymes, cytokines, and reactive oxygen species (ROS) extracellularly, thereby causing further tissue damage.[82] Neutrophil hyperactivity in periodontitis has also been suggested, which leads to the overproduction of damaging ROS and other mediators.[52] Patients with periodontitis have been reported to have neutrophils that demonstrate enhanced enzymatic activity and that produce increased levels of ROS.[113,114] However, it

is not yet clear whether the enhanced responsiveness of neutrophils is the result of the innate properties of the neutrophils in certain individuals, of priming by cytokines or bacteria, or of a combination of these factors. It is certainly clear, however, that the extracellular release of lysosomal enzymes contributes to continued tissue damage and collagen depletion in the periodontal tissues. The degeneration of fibroblasts limits opportunities for repair, and the epithelium continues to proliferate apically, thus deepening the pocket further; the pocket is then rapidly colonized by the subgingival bacteria.

The very first steps in the development of the pocket result from a combination of factors, including the detachment of cells at the coronal aspect of the junctional epithelium, whereas cells at the apical aspect migrate apically into the collagen-depleted areas; intraepithelial cleavage occurs within the junctional epithelium.[106,155,171] Epithelial tissues do not have their own blood supply and must rely on the diffusion of nutrients from the underlying connective tissues. Thus, as the epithelium proliferates and thickens, necrosis of epithelial cells that are more distant from the connective tissues can lead to intraepithelial clefts and splits, which also contribute to the early stages of pocket formation.

Clinician's Corner

How does a pocket develop?

The bacterial biofilm causes inflammation in the gingival tissues that causes swelling, and therefore the sulcus deepens slightly. The inflammatory response may subsequently spread to the deeper tissues and is characterized by infiltration by defense cells and breakdown of collagen in the connective tissues. The junctional epithelium migrates apically to maintain an intact epithelial barrier, and thus the sulcus becomes deeper again and is now referred to as a pocket. Bacteria in the biofilm proliferate apically, exploiting and perpetuating this environmental niche. The bacteria are never completely eradicated by the host response, and thus they continue to provoke an immune–inflammatory response, leading to progressing tissue breakdown, continued apical

migration of the junctional epithelium, resorption of alveolar bone, and gradual deepening of the pocket.

A cycle of chronic inflammation is therefore established in which the presence of subgingival bacteria drives inflammatory responses in the periodontal tissues; this is characterized by infiltration by leukocytes, the release of inflammatory mediators and destructive enzymes, connective tissue breakdown, and the breakdown and proliferation of the epithelium in an apical direction. The junctional and pocket epithelia become thin and ulcerated and bleed more readily, a condition that results in bleeding on probing. The bacteria in the pocket are never fully eliminated because they are effectively outside the body, but their continued presence drives the destructive inflammatory response in the periodontal tissues. Attempts at effective oral hygiene are rendered more difficult by the deepening of the pocket, and the cycle continues.

Alveolar Bone Resorption

As the advancing inflammatory front approaches the alveolar bone, osteoclastic bone resorption commences.[31] This is a protective mechanism to prevent bacterial invasion of the bone, but it ultimately leads to tooth mobility and even tooth loss. The resorption of alveolar bone occurs simultaneously with the breakdown of the periodontal ligament in the inflamed periodontal tissues. Two critical factors determine whether bone loss occurs: (1) the concentration of inflammatory mediators in the gingival tissues must be sufficient to activate the pathways that lead to bone resorption; and (2) the inflammatory mediators must penetrate to within a critical distance of the alveolar bone.[62]

Histologic studies have confirmed that the bone resorbs so that a width of noninfiltrated connective tissue of about 0.5 to 1.0 mm overlying the bone is always present.[188] It has also been demonstrated that bone resorption ceases when at least a 2.5-mm distance is present between the site of bacteria in the pocket and the bone.[136] Osteoclasts are stimulated by proinflammatory cytokines and other mediators of inflammation to resorb the bone, and the alveolar bone “retreats” from the advancing inflammatory front.

Osteoclasts are multinucleated cells that are formed from osteoclast progenitor cells and macrophages, and osteoclastic bone resorption is activated by a variety of mediators (e.g., IL-1β, TNF-α, IL-6, PGE_2).[122] Other mediators that also stimulate bone resorption include LIF, oncostatin M, bradykinin, thrombin, and various chemokines.[101]

Receptor Activator of Nuclear Factor-κB Ligand and Osteoprotegerin

A key system for controlling bone turnover is the receptor activator of nuclear factor-κB (RANK)/RANK ligand (RANKL)/osteoprotegerin (OPG) system. RANK is a cell surface receptor expressed by osteoclast progenitor cells, as well as by mature osteoclasts. RANKL is a ligand that binds to RANK and is produced as either a membrane-bound or secreted protein by a range of cells, including fibroblasts, osteoblasts, mesenchymal cells, and T- and B-lymphocytes. OPG is the inhibitor of RANKL and functions as a decoy receptor—that is, it binds to RANKL and prevents it from interacting with RANK. OPG is secreted primarily by osteoblasts, fibroblasts, and bone marrow stromal cells. The binding of RANKL to RANK results in osteoclast differentiation and activation, and thus bone resorption. The balance between RANKL and OPG activity (often referred to as the *RANKL:OPG ratio*) can therefore determine bone resorption or bone formation.

IL-1β and TNF-α regulate the expression of RANKL and OPG, and T cells express RANKL, which binds directly to RANK on the surfaces of osteoclast progenitors and osteoclasts, thereby resulting in cell activation and differentiation to form mature osteoclasts. In individuals with periodontitis, elevated levels of proinflammatory cytokines (e.g., IL-1β, TNF-α) and increasing numbers of infiltrating T cells result in the activation of osteoclasts by RANK, which results in alveolar bone loss. It has been reported that levels of RANKL are higher and that levels of OPG are lower in sites with active periodontal breakdown as compared with sites with healthy gingiva.[35] In addition, GCF RANKL/OPG ratios are higher in periodontitis than in healthy tissue.[21] It is clear that alterations in the relative levels of these key regulators of osteoclasts play a key

role in the bone loss that characterizes periodontal disease.

RANK/RANKL/OPG System

RANK (receptor activator of nuclear factor-κB)	Cell surface receptor on osteoclast progenitor cells
RANKL (RANK ligand)	Cytokine-like molecule that is the ligand for RANK (i.e., binds to RANK) and causes maturation into fully differentiated osteoclasts
OPG (osteoprotegerin)	Cytokine-like molecule that binds to RANKL and inhibits the interaction between RANKL and RANK
The RANK/RANKL/OPG signaling pathway plays a key role in regulating bone resorption. RANKL binds to RANK and stimulates osteoclast differentiation and activation. OPG antagonizes this action by binding to RANKL and preventing it from binding to RANK. The ratio of RANKL to OPG is important, with studies reporting higher levels of RANKL and lower levels of OPG in patients with advanced periodontitis compared with healthy controls.	

Resolution of Inflammation

Inflammation is an important defense mechanism to combat the threat of bacterial infection, but inflammation also results in tissue damage associated with the development and progression of most chronic diseases associated with aging, including periodontal disease.[183,185] It is becoming evident that the resolution of inflammation (i.e., "turning off" inflammation) is an active process that is regulated by specific mechanisms that restore homeostasis (see Chapter 10). It is possible that controlling or augmenting these mechanisms may lead to the development of new treatment strategies for managing chronic diseases such as periodontitis.[83] The resolution of inflammation is an active process that results in a return to homeostasis, and it is mediated by specific molecules, including a class of endogenous, proresolving lipid mediators that includes the lipoxins, resolvins, and protectins.[158] These molecules are actively synthesized during the resolution phases of acute inflammation; they are antiinflammatory, and they inhibit neutrophil infiltration. They are also chemoattractants, but they do not cause inflammation. For example, lipoxins stimulate infiltration by monocytes but without stimulating the release of inflammatory cytokines.

Lipoxins

The lipoxins include lipoxin A_4 (LXA_4) and lipoxin B_4 (LXB_4), and the appearance of these molecules signals the resolution of inflammation.[157] Lipoxins are lipoxygenase (LO)–derived eicosanoids that are generated from arachidonic acid. They are highly potent, they possess biologic activity at very low concentrations, and they inhibit neutrophil recruitment, chemotaxis, and adhesion.[170] Lipoxins also signal macrophages to phagocytose the remnants of apoptotic cells at sites of inflammation without generating an inflammatory response. Proinflammatory cytokines (e.g., IL-1β) released during acute inflammation can induce the expression of lipoxins, which promote the resolution of the inflammatory response.[115]

Resolvins and Protectins

Resolvins (i.e., resolution phase interaction products) are derived from the omega-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid; they are classified as E series resolvins (RvE) and D series resolvins (RvD).[159] Resolvins inhibit neutrophil infiltration and transmigration, as well as the production of proinflammatory mediators, and they have potent antiinflammatory and immunoregulatory effects.[156] Resolvins are highly potent and have been shown to reduce neutrophil transmigration by around 50% at concentrations of as low as 10 nM.[169] Protectins are also derived from docosahexaenoic acid. They are produced by glial cells, and they reduce cytokine expression.[77] They also inhibit neutrophil infiltration, and they have been reported to reduce retinal injury[120] and stroke damage.[110]

The release of endogenous proresolving molecules (e.g., lipoxins, resolvins, protectins) that "switch off" inflammation indicates that the control of inflammation is an active process rather than simply being a passive dwindling of proinflammatory signals. These molecules could potentially offer benefit for the management of chronic diseases such as periodontitis. This concept has been tested in animal models of periodontitis.[184] In a rabbit model of *P. gingivalis* and ligature-induced experimental periodontitis, periodontal inflammation was clearly evident after 6 weeks; this

was characterized by collagen breakdown and the resorption of alveolar bone. As the experiment progressed beyond 6 weeks, 4 μg/tooth of topical resolvin E1 (RvE1) was applied three times per week for an additional 6 weeks, whereas the control group continued to receive applications of topical *P. gingivalis.* In the control group, inflammation continued and led to further alveolar bone loss, with large increases in the numbers of osteoclasts and infiltrating neutrophils, as well as significant collagen breakdown. However, in the animals that received the topical RvE1, the progression of periodontitis was prevented, the resolution of inflammation occurred, and the bone loss that had occurred during the first 6 weeks of the study was reversed, with evidence of bone gain in the RvE1-treated animals.[69] These experiments suggest that the endogenous lipid mediators that resolve inflammation could offer potential for the development of new adjunctive treatments for the management of periodontitis.

Immune Responses in Periodontal Pathogenesis

The immune system is essential for the maintenance of periodontal health, and it is central to the host response to periodontal pathogens. However, if the immune response is dysregulated, inappropriate, persistent, or excessive in some way, then damaging chronic inflammatory responses such as those observed in periodontal disease can ensue. The immune response to plaque bacteria involves the integration at the molecular, cellular, and organ level of elements that are often categorized as being part of the innate immune system or the adaptive immune system. Furthermore, host responses in periodontal disease (and other major human diseases) were until recently represented as a linear progression from the host's recognition of microbial pathogens, to innate immune responses dominated by the action of phagocytic neutrophils, and culminating in the establishment of adaptive immune responses led by antigen-specific effector functions (e.g., cytotoxic T cells, antibodies). It is now widely appreciated that immune responses are complex biologic networks in which

pathogen recognition, innate immunity, and adaptive immunity are integrated and mutually dependent.[51] This complex network is flexible and dynamic, with aspects of positive and negative regulation, as well as feedback control; signals are amplified and broadcast, which leads to diverse effector functions. Furthermore, the immune system is integrated with other systems and processes, including the nervous system, hematopoiesis, and hemostasis, as well as elements of tissue repair and regeneration.[123]

Observational studies of periodontal tissues and investigations of animal models and cell and tissue systems have allowed us to identify aspects of the immune response that are relevant to periodontitis.[92,135] Immune responses, which underpin periodontal disease, have unique facets that must be considered before we can truly rationalize the detailed information that we have about individual immune cell functions and their responses to specific periodontal pathogens. Thus we need to understand how the polymicrobial biofilm (as opposed to individual species of periodontal pathogens) interacts with host immune defenses. We also need to appreciate specific immunologic properties that relate to the unique anatomy of the periodontium, to understand how immune responses contribute to the dynamic aspects of periodontal disease and its various clinical courses, and to gain a comprehension of how elements of host immunity contribute to tissue destruction, resolution, repair, and regeneration.

Innate Immunity

Defenses against infection include a wide range of mechanical, chemical, and microbiologic barriers that prevent pathogens from invading the cells and tissues of the body. Saliva, GCF, and the epithelial keratinocytes of the oral mucosa all protect the underlying tissues of the oral cavity and the periodontium. The commensal microbiota (e.g., in dental biofilm) may also be important for providing protection against infection by pathogenic microorganisms through effective competition for resources and ecologic niches and also by stimulating protective immune responses. The complex microanatomy of the periodontium, including the diversity of specialized epithelial tissues, presents

many interesting challenges for the study of the immunopathogenesis of periodontal disease.

If bacterial products enter the tissues, then the cellular and molecular elements of the innate immune response are activated. The term *innate immunity* refers to the elements of the immune response that are determined by inherited factors (and therefore "innate"), that have limited specificity, and that are "fixed" in that they do not change or improve during an immune response or as a result of previous exposure to a pathogen. The recognition of pathogenic microorganisms and the recruitment of effector cells (e.g., neutrophils) and molecules (e.g., the complement system) are central to effective innate immunity. Innate immune responses are orchestrated by a broad range of cytokines, chemokines, and cell surface receptors, and the stimulation of innate immunity leads to a state of inflammation. If innate immune responses fail to eliminate infection, then the effector cells of adaptive immune responses (lymphocytes) are activated. It is increasingly appreciated that the immune response functions as a network of interacting molecular and cellular elements in which innate immunity and adaptive (antigen-specific) immunity work together toward a common purpose. Aspects of innate immunity that are relevant to periodontal disease are now considered.

Innate Immunity	**Adaptive Immunity**
Refers to nonspecific defense mechanisms that act as barriers to infection. Components include: • Barriers to infection such as skin, mucosa, acid pH in the stomach • Antimicrobial molecules such as lysozyme, antimicrobial peptides • Immune system cells such as neutrophils and macrophages that kill infecting organisms • Receptors (e.g., Toll-like receptors) that recognize pathogen-derived molecules and activate immune–inflammatory responses • Antigen presentation to activate adaptive immune responses	Refers to antigen-specific immune responses. Components include: • Recognition of specific molecules on infecting organisms at the species and strain level • Cellular immune responses focused on defense from intracellular pathogens (e.g., viruses), involving cytokines from T helper cells, macrophages, and natural killer cells • Humoral immune responses focused on defense from extracellular pathogens (e.g., bacteria), involving B cells that differentiate into antibody-producing plasma cells

Innate and adaptive immunity do not function in isolation; close integration exists between the innate and adaptive arms of the

immune response.

Saliva

Saliva that is secreted from the three major salivary glands (i.e., parotid, submandibular, and sublingual), as well as from the numerous minor salivary glands, has an important role in the maintenance of oral and dental health. The action of shear forces associated with saliva flow is important for preventing the attachment of bacteria to the dentition and oral mucosal surfaces. Human saliva also contains numerous molecular components that contribute to host defenses against bacterial colonization and periodontal disease (Table 7.4). These components include molecules that non-specifically inhibit the formation of the plaque biofilm by inhibiting adherence to oral surfaces and promoting agglutination (e.g., mucins), those that inhibit specific virulence factors (e.g., histatins that neutralize LPS), and those that inhibit bacterial cell growth (e.g., lactoferrin) and that may induce cell death.[58,98] Saliva also contains specific immunoglobulin A (IgA) antibodies to periodontal pathogens that target specific antigens and that inhibit bacterial adherence.

TABLE 7.4

Constituents of Saliva That Contribute to Innate Immunity

Saliva Constituent	Host Defense Function
Antibodies (e.g., immunoglobulin A)	Inhibit bacterial adherence, promote agglutination
Histatins	Neutralize lipopolysaccharides, inhibit destructive enzymes
Cystatins	Inhibit bacterial growth
Lactoferrin	Inhibits bacterial growth
Lysozyme	Lyses bacterial cell walls
Mucins	Inhibits bacterial adherence, promotes agglutination
Peroxidase	Neutralizes bacterial hydrogen peroxide

Epithelial Tissues

The epithelial tissues play a key role in host defense because they are the main site of the initial interactions between plaque bacteria and the host, and they are also the site of the invasion of microbial pathogens. The keratinized epithelium of the sulcular and gingival

epithelial tissues provides protection for the underlying periodontal tissue in addition to acting as a barrier against bacteria and their products.[12,154] By contrast, the junctional epithelium has significant intercellular spaces, it is not keratinized, and it exhibits a higher cellular turnover rate. These properties render the junctional epithelium permeable, thereby allowing for the inward movement of microbes and their products and the outward movement of GCF and the cells and molecules of innate immunity. Furthermore, the spaces between the cells of the junctional epithelium widen with inflammation, which results in increased GCF flow.[154]

Some species of periodontal bacteria invade host epithelial tissues; at the molecular level, the processes of adhesion and invasion are coupled. Studies of the invasion of gingival epithelial cells by *P. gingivalis* have served as a paradigm for the study of this process; the infection of host cells by *P. gingivalis* involves the action of proteases and cell surface fimbriae.[3,97] Invasion by *P. gingivalis* is initiated through signaling by interaction of bacterial components with surface integrins PAR-1 and PAR-2, as well as TLRs.[64,97,196] This, in turn, activates intracellular signaling pathways (e.g., mitogen-activated protein kinase) and results in the reorganization of actin filaments and microtubules and a modulation of calcium cation (Ca^{2+}) influx. It is thought that the inhibition of host cell apoptosis may facilitate the survival of intracellular bacteria and that bacteria inside of the cell are protected from the host immune response. The invasion of host cells could therefore be relevant to the spread and persistence of certain periodontal bacteria. In addition, in vivo analysis and the studies of a three-dimensional–engineered human oral mucosa model demonstrated that *P. gingivalis* can migrate through the basement membrane of epithelial layers and invade connective tissue.[3] Histologic analysis reveals that, in the presence of periodontitis, epithelial cells become more rounded and tend to detach from the underlying connective tissue.[154] Proteases break down cell-to-cell junctions in epithelial tissues by digesting transmembrane proteins and adhesion molecules (e.g., E-cadherin). Microanatomic changes associated with the onset of periodontitis, such as the widening of the spaces between the cells of the junctional epithelium and the development of the pocket epithelium, further facilitate bacterial invasion.

Bacterial spread through the basement membrane and into the underlying connective tissues is facilitated by bacterially derived proteases and host proteases derived from infiltrating neutrophils (e.g., MMPs).

At the cellular and molecular levels, most in vitro studies of epithelial cell responses to periodontal bacteria have been carried out in primary gingival epithelial cells or various immortalized cell lines derived from oral epithelial tissue; these studies have provided insight into host cell responses to periodontal bacteria.[3,64,67,196] Epithelial cells also constitutively express antimicrobial peptides (e.g., hBDs, LL-37), and the synthesis and secretion of these molecules is up-regulated in response to periodontal bacteria. Neutrophils are also a source of antimicrobial peptides (i.e., α-defensins). Antimicrobial peptides are small, polycationic peptides that disrupt bacterial cell membranes and thereby directly kill bacteria with broad specificity.

The different categories of antimicrobial peptides are defined on the basis of structural homology. The α-defensins (e.g., human neutrophil peptides 1 through 4) are expressed by neutrophils and as such are commonly found in GCF. The hBDs (e.g., hBDs 1 through 3) are expressed in the gingival epithelial cells, the salivary glands, and the tongue, as well as in immune cells (e.g., macrophages, dendritic cells); some hBDs are constitutively expressed, and others are expressed only in response to cytokines and bacterial products (e.g., gingipains of *P. gingivalis*).[3,37] A third class of antimicrobial peptides are the cathelicidins, of which LL-37 is expressed in high levels in the junctional epithelium. Like the hBDs, LL-37 has a widespread expression pattern in the mouth; it is found in the salivary glands, the tongue, and the leukocytes as well as in the connective tissue. Antimicrobial peptides have more recently assumed greater importance because it has been recognized that they have a wider role in regulating innate and adaptive immune responses to infection.[41] Thus these molecules have chemokine-like activity in that they stimulate the chemotaxis of a range of leukocytes involved in innate and acquired immunity. Antimicrobial peptides also stimulate mast cell degranulation and cytokine production, and they likely have a role in wound healing through their effect on keratinocyte differentiation. Furthermore,

some interest has been expressed in their possible role in therapy for oral inflammatory diseases.[41]

Epithelial cells that are directly stimulated with bacterial components and cytokines can produce MMPs, which contribute to a loss of connective tissue. Epithelial cells also secrete a range of cytokines in response to periodontal bacteria (e.g., *P. gingivalis, A. actinomycetemcomitans, F. nucleatum, Prevotella intermedia*), which signal immune responses. These include the proinflammatory cytokines IL-1β, TNF-α, and IL-6, as well as the chemokine IL-8 (CXCL8) and the monocyte chemoattractant protein-1 (MCP-1), which serve to signal neutrophil and monocyte migration from the vasculature into the periodontal tissue. In some (but not all) experimental systems, *P. gingivalis* has been shown to inhibit IL-8; it has been suggested that this may result in a temporary local immune suppression in the periodontium and facilitate the accumulation and invasion of pathogenic periodontal bacteria and the initiation of periodontitis.[39,64] *P. gingivalis* is an example of one periodontal pathogen with a range of virulence factors that affect host immune defenses,[64,97] as indicated in Table 7.5.

TABLE 7.5

Virulence Factors of *Porphyromonas gingivalis* That Interact With the Immune System

Virulence Factor	Effect on Immune System
Proteases (gingipains)	Degradation of signaling molecules (CD14) and cytokines (e.g., interleukin-1β, interleukin-6)
Cell invasion capabilities	Inhibition of interleukin-8 secretion
Lipopolysaccharides	Antagonism of the stimulatory effects of lipopolysaccharides from other species; no up-regulation of E-selectin
Fimbriae	Inhibition of interleukin-12 secretion in macrophages
Cell surface polysaccharides	Resistance to complement
Short-chain fatty acids	Induction of apoptosis in host cells

Gingival Crevicular Fluid

GCF originates from the postcapillary venules of the gingival plexus. It has a flushing action in the gingival crevice, but it also likely functions to bring the blood components (e.g., neutrophils,

antibodies, complement components) of the host defenses into the sulcus.[63] The flow of GCF increases in inflammation, and neutrophils are an especially important component of GCF in periodontal health and disease.[92]

Pathogen Recognition and Activation of Cellular Innate Responses

If plaque bacteria and their products penetrate the periodontal tissues, specialized "sentinel cells" of the immune system recognize their presence and signal protective immune responses. These cells include macrophages and dendritic cells, which express a range of pattern recognition receptors (PRRs) that interact with microbe-associated molecular patterns (MAMPs). The activation of PRRs activates innate immune responses to provide immediate protection, and adaptive immunity is also activated with the aim of establishing a sustained antigen-specific defense. Excessive and inappropriate or dysregulated immune responses lead to chronic inflammation and the concomitant tissue destruction associated with periodontal disease.

eTABLE 7.1

Glossary of Terms Relevant to Periodontal Immunobiology

Term	Definition
Arginine-specific gingipains A (RgpA) and B (RgpB)	Enzymes secreted by the periodontal pathogen *Porphyromonas gingivalis* and that are important virulence factors
Cluster of differentiation (CD)	Molecules that define different immune cell lineages, functional phenotypes, and stages of development
CD4	Characteristic coreceptor molecule of T-helper cells
CD8	Characteristic coreceptor molecule of cytotoxic T-cells
CD14	Binds to LPS, facilitates interaction with TLRs, exists in soluble and membrane-bound forms
Cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2)	Enzymes responsible for synthesis of inflammatory mediators (e.g., PGE_2) from arachidonic acid
Complement receptor-3 (CR-3)	Cellular receptor for complement that interacts with *Porphyromonas gingivalis* fimbriae to signal cytokines
CXCL and CCL	Two structurally distinct groups of chemokines, which are small proteins that activate and stimulate the movement of leukocytes
Dendritic cell-specific intercellular adhesion molecule (ICAM)-3–grabbing nonintegrins	Cell surface molecule on dendritic cells that has a role in cell-to-cell interactions and antigen presentation

(DC-SIGN)	
Extracellular DNA (eDNA)	Bacterial DNA found extracellularly within the plaque biofilm
Gingival crevicular fluid (GCF)	Serum exudate that flows from the gingival sulcus (particularly in individuals with periodontitis) and that contains molecular and cellular elements of the immune response
GroEl	Bacterial heat shock proteins that stimulate immune responses
Human β-defensins (hBD)	Antimicrobial peptides synthesized by epithelial cells that kill bacterial cells but that have other functions in immune responses
Intercellular adhesion molecule-1 (ICAM-1)	Expressed on endothelial molecules during inflammation; interacts with integrins on neutrophils to facilitate neutrophil movement
Interleukin (IL)	Generic term for cytokines produced by leukocytes that are grouped into families on the basis of structural and functional similarities (e.g., IL-1 family)
Lysine-specific gingipain A (KgpA)	Enzyme secreted by the periodontal pathogen *Porphyromonas gingivalis,* which is an important virulence factor
Leukemia-inhibitory factor (LIF)	Cytokine of the IL-6 family
Peptide cleavage product of human cathelicidin (LL-37)	An antimicrobial peptide widely expressed in tissues that kills bacterial cells and that has other functions in immune responses
Lipopolysaccharide (LPS)	A bacterial cell surface molecule that is characteristic of gram-negative bacteria and that stimulates innate cells via TLRs
Lipoteichoic acid (LTA)	Characteristic molecule of gram-positive bacterial cell walls that activates innate immune cells via TLRs
Lipoxin A_4 (LXA_4), lipoxin B_4 (LXB_4)	Arachidonic acid derivatives involved in the resolution of inflammation
Microbe-associated molecular pattern (MAMP)	Molecules associated with microorganisms that activate innate immunity through specific signaling pathways; MAMPs are sometimes also referred to as PAMPs (pathogen-associated molecular patterns); LPS is an example of an MAMP
MD-2	Part of the LPS receptor complex; binds to TLR as a prerequisite for binding LPS
Matrix metalloproteinases (MMPs)	Family of proteolytic enzymes that degrade extracellular matrix molecules
Natural killer (NK) cells	Large granular lymphocytes; distinct from T cells and B cells, which are important for innate immunity to intracellular pathogens
Nucleotide oligomerization domain receptors 1 (NOD 1) and 2 (NOD 2)	Intracellular PRRs that interact with intracellular bacteria and stimulate innate immunity
Osteoprotegerin (OPG)	Cytokine-like molecule that binds to RANKL and inhibits the interaction between RANKL and RANK, thereby acting as a decoy receptor for RANKL and antagonizing its action
Protease activated receptors 1 (PAR-1) and 2 (PAR-2)	Cellular receptors that, when activated by bacterial enzymes, can signal cytokine secretion
Prostaglandin E_2 (PGE_2)	Inflammatory mediator derived from arachidonic acid
Pattern-recognition receptors (PRRs)	Integrated membrane proteins and intracellular molecules of immune cells that interact with MAMPs and that signal innate immunity
Receptor activator of nuclear factor-κB (RANK)	Osteoclast cell surface receptor important for bone regulation
Receptor activator of nuclear factor-κB ligand (RANKL)	Cytokine-like molecule that is the ligand for RANK

Regulatory T-cell subset (T_{reg} cells)	A subset of $CD4^+$ T cells that are characterized by the secretion of TGF-α and IL-10 and that inhibit immune responses
T-helper 1 subset (Th1 cells)	A subset of $CD4^+$ T cells that are characterized by their cytokine secretion profile and that activate cellular immunity
T-helper 2 subset (Th2 cells)	A subset of $CD4^+$ T cells that are characterized by their cytokine secretion profile and that activate humoral (antibody) immunity
T-helper 17 subset (Th17 cells)	A subset of $CD4^+$ T cells that are characterized by the secretion of IL-17 and that activate inflammatory responses (e.g., neutrophils)
Tissue inhibitors of matrix metalloproteinases (TIMPs)	Molecules concerned with the regulation of MMPs
Toll-like receptors (TLRs)	A class of PRRs that recognizes MAMPs (e.g., LPS) and that signals cytokine secretion in innate cells
Tumor necrosis factor alpha (TNF-α)	Classic proinflammatory cytokine that activates innate immunity and shares many actions with IL-1β

The best studied of the signaling systems involved in the recognition of plaque bacteria is the interaction of bacterial LPS with TLRs: *P. gingivalis, A. actinomycetemcomitans,* and *F. nucleatum* all possess LPS molecules that interact with TLR-4 to activate myeloid immune cells. However, individual species of plaque bacteria have a wide variety of MAMPs, which may interact with PRRs. For example, *P. gingivalis* LPS signals via TLRs (predominantly TLR-2), and fimbriae, proteases, and DNA from *P. gingivalis* are all recognized by host cells through interaction with specific PRRs. Certain nonimmune cells in the periodontium (e.g., epithelial cells, fibroblasts) also express PRRs and may recognize and respond to MAMPs from plaque bacteria.

Although the signaling pathways activated by PRRs may be diverse, in general terms, they converge to elicit similar host cell responses in the form of the up-regulation of cytokine secretion and, in the case of APCs such as dendritic cells, cell differentiation that leads to enhanced signaling of the adaptive immune response.

The signaling of cytokine responses by PRRs influences innate immunity (e.g., neutrophil activity), adaptive immunity (e.g., T-cell effector phenotype), and the development of destructive inflammation (e.g., the activation of fibroblasts and osteoclasts). Some cytokines are particularly important to innate immune signaling, and good evidence indicates that they have a role in immune responses in the periodontium. The archetypal proinflammatory cytokine is IL-1β, which exerts its action directly by activating other cells that express the IL-1R1 receptor (e.g., endothelial cells) or by stimulating the synthesis and secretion of

other, secondary mediators such as PGE_2. The effect of IL-1β is amplified by a synergistic action with other cytokines such as TNF-α. The up-regulation of ICAM-1 and E-selectin on endothelial cells is central to the migration of neutrophils into the periodontium, and this is stimulated by IL-1β and TNF-α. IL-1β also stimulates the secretion of the chemokine IL-8, which stimulates neutrophil chemotaxis. IL-1β and TNF-α also activate MMP secretion from fibroblasts and osteoclasts; this facilitates the movement of neutrophils through the connective tissues (and thus protective innate responses), but it also contributes to the tissue destruction associated with periodontal disease, along with MMPs from neutrophils.

Other cytokines that are up-regulated as a result of the activation of PRRs include IL-6, which influences the development of a number of immune cells (e.g., B cells, dendritic cells) and stimulates osteoclast differentiation and thus bone turnover. Other cytokines provide specific signals that contribute to the development of specific $CD4^+$ T-helper cell subsets (e.g., IL-4, IL-12, IL-18). In addition to cytokines that activate immune responses, other cytokines are up-regulated that have a role in immune regulation by suppressing cytokine activity; these include IL-1Ra, IL-10, and TGF-β. Cytokines from T-cell subsets feed back to and modify innate immune responses; for example, IFN-γ from Th1 cells activates macrophages, IL-17 from Th17 cells synergizes with IL-1β and TNF-α to reinforce inflammatory reactions, and IL-10 and TGF-β suppress immune responses. The action of many cytokines produced in the periodontium is not limited to one aspect of the host immune response; in other words, cytokines are pleiotropic (i.e., they have multiple effects).

Neutrophil Function

Neutrophils are the "professional" phagocytes that are critical to the clearance of bacteria that invade host tissues.[124] Neutrophils are present in clinically healthy gingival tissues, and they migrate through the intercellular spaces of the junctional epithelium into the sulcus.[90,154] This is part of a "low-grade defense" against plaque bacteria, and it is necessary to prevent infection and periodontal tissue damage.[154] The importance of neutrophils to the maintenance

of periodontal health is demonstrated clinically by the observations of severe periodontitis in patients with neutrophil defects.[124]

A small proportion (1% to 2%) of the intercellular spaces in healthy junctional epithelium is occupied by neutrophils (and other leukocytes at various stages of differentiation), but this can increase to 30% with even modest inflammation. In the inflammatory state, changes to the local vasculature occur in the gingiva: high endothelial venules develop from the postcapillary venules of the gingival plexus, which facilitates leukocyte emigration and increases the flow of GCF into the pocket.[154]

Neutrophils migrate from the gingival plexus to the extravascular connective tissue and then into the junctional epithelium through the basement membrane. The presence of a layer of neutrophils in the junctional epithelium forms a host defense barrier between subgingival biofilm and the gingival tissue. At the molecular level, the interaction of adhesion molecules (e.g., ICAM-1) on endothelial and epithelial cells with β2 integrins on neutrophils facilitates neutrophil migration. Indeed, evidence from immunohistochemistry studies indicate the existence of gradients of IL-8 (a "chemotactic gradient"), as well as gradients of ICAM-1, which direct the neutrophils from the vasculature into the tissues and toward the junctional epithelium.[179] The migration of neutrophils contributes to the disruption of the junctional epithelium by the degradation of the basement membrane through protease release and the action of ROS. An aspect of neutrophil-mediated immunity is the formation of neutrophil extracellular traps (NETs).[191] NETs constitute a highly conserved antimicrobial strategy in which decondensed nuclear DNA and associated histones are extruded from the neutrophil, thus forming weblike strands of DNA in the extracellular environment. These strands, in conjunction with antimicrobial peptides (AMPs), facilitate the extracellular killing of microorganisms that become trapped within the NETs. NETs can be released by viable neutrophils and also following a form of programmed cell death called NETosis. NETs are produced in response to a wide range of infecting pathogens and likely constitute an important defense strategy, but due to the concomitant release of cytotoxic molecules they can also contribute to host tissue damage. The potential role of NETs in periodontal

pathogenesis is an area of ongoing research.

Adaptive Immunity

Adaptive immunity has evolved to provide a focused and intense defense against infections that overwhelm innate immune responses. Adaptive immunity is particularly important as ecologic, social, and demographic changes—which alter susceptibility to existing and emerging infective microorganisms—outpace the natural evolution of biologic systems. Furthermore, the development of effective vaccination is, along with the identification of antibiotics, perhaps one of the greatest triumphs of medical science; this success is based on knowledge of the elements and principles of adaptive immunity.

Adaptive immunity contrasts with innate immunity with regard to the dynamic of the underlying cellular and molecular responses: adaptive immunity is slower and reliant on complex interactions between APCs and T and B lymphocytes. A key element is the antigen specificity of the responses that facilitates the specific targeting of a diverse range of effector elements, including cytotoxic T cells and antibodies. Another facet is the ability of adaptive immune responses to improve during exposure to antigen and on subsequent reinfection events.[24] Our current understanding suggests that the cellular and molecular elements of adaptive immunity are more diverse than those of innate immunity, and although a role for many of these factors in periodontal disease has been identified, our knowledge is far from complete. The importance of adaptive immune responses in periodontal pathogenesis is endorsed by histologic studies of established lesions in periodontal disease.[92,135] The population of leukocytes in the periodontium in gingivitis (i.e., the early stages of responses to the plaque biofilm) and in stable periodontal lesions (i.e., those in which tissue destruction is apparently not progressing) has been reported to be dominated by T cells, and these cells are clustered mainly around blood vessels. Cell surface marker studies suggest that these cells are activated but not proliferating.[57] In addition, a predominance of the helper T-cell subset (i.e., CD4-expressing T cells) over the cytotoxic T-cell subset (i.e., CD8-expressing T cells) is

observed. These T cells are considered to be proactively maintaining tissue homeostasis in the presence of the microbial challenge of the plaque biofilm.[57] By contrast, in active (progressing) periodontitis, B cells and plasma cells predominate and are associated with pocket formation and the progression of disease.

Antigen-Presenting Cells

Central elements of the activation and function of T cells and B cells are the presentation of antigen by specialized APCs to T cells and the development of a specific cytokine milieu that influences the development of T cells with particular effector functions. APCs detect and take up microorganisms and their antigens, after which they may migrate to lymph nodes and interact with T cells to present antigen. The periodontium contains a number of APCs, including B cells, macrophages, and at least two types of dendritic cells (i.e., dermal dendritic cells and Langerhans cells).[36] It is increasingly recognized that the engagement of PRRs (and in particular TLRs) by MAMPs from pathogenic microorganisms is not only central to signaling innate immunity in the form of cytokine up-regulation but also a critical element of the activation of APCs and the elaboration of T-cell effector function. Thus TLR activation increases the expression of costimulatory molecules on APCs, which are critical to the interaction of these cells with T cells. In addition, TLR activation enhances antigen uptake and processing. Different APCs process and present antigens by different pathways and mechanisms, and this variation is one of the factors—along with the presence of specific combinations of cytokines—that influences the phenotype of T-cell effector function produced during specific immune responses.[57]

T Cells

Several different subsets of thymic lymphocytes (i.e., T cells) develop in the bone marrow and thymus and migrate to the peripheral tissues to participate in adaptive immune responses. The expression of the cell surface molecules (CD4 or CD8) or particular T-cell antigen receptors ($\alpha\beta$ or $\gamma\delta$) broadly defines functional T-cell subsets that emerge from the thymus. The role of T cells in

periodontal disease has been established through immunohistologic studies of diseased tissues.[161] $CD4^+$ helper T cells are the predominant phenotype in the stable periodontal lesion, and it is thought that alterations in the balance of effector T-cell subsets within the $CD4^+$ population may lead to progression toward a destructive, B-cell–dominated lesion.[57] $CD4^+$ T-cell subsets are defined on the basis of their phenotypic characteristics and effector functions. The nature of the APCs, which present antigen to cognate T-cell receptors on T cells, and the presence of specific combinations of cytokines and chemokines locally influence the nature of the $CD4^+$ T-cell effector subset that develops from naive T cells (Fig. 7.5). $CD4^+$ T-cell subsets are defined by the expression of specific transcription factors, and their functional characteristics are associated with their cytokine secretion profile.

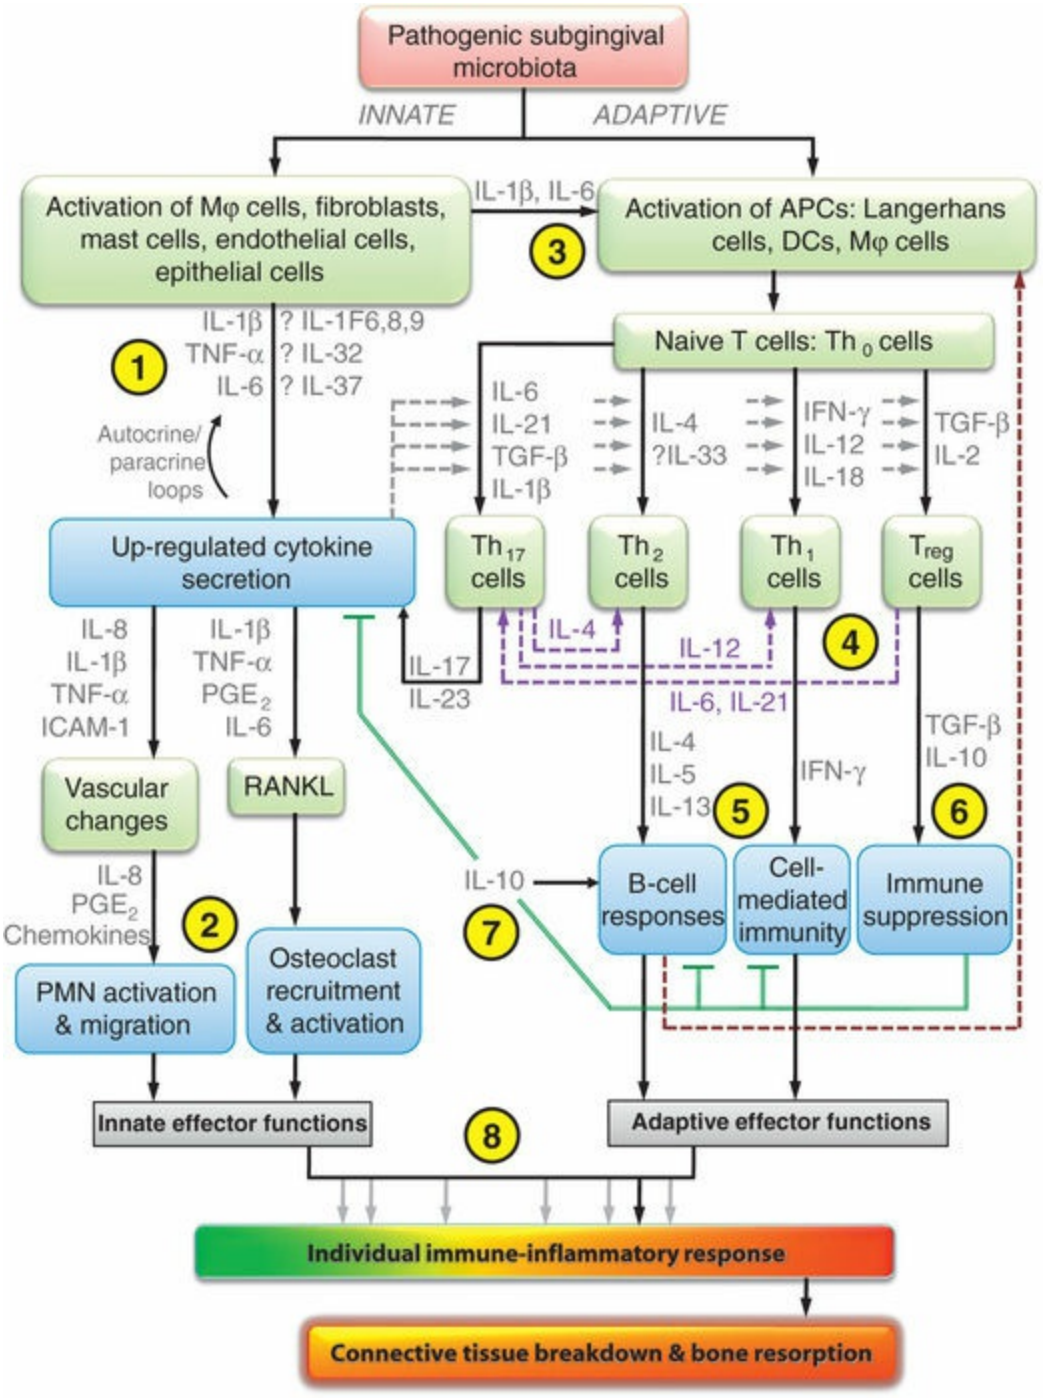

FIG. 7.5 **Cytokine networks in periodontal diseases. Schematic to illustrate the multiple interactions between cytokines and cellular functions in periodontal diseases. *(1)* Resident and infiltrating cells in the periodontium respond to microbe-associated molecular patterns *(MAMPs)* signaling through pattern-recognition receptors *(PRRs)* by the production of cytokines as an early step in innate immune responses. Cytokine up-regulation is sustained by autocrine and paracrine feedback loops. (Note: *Question marks* indicate more speculative suggestions about the role of specific cytokines in periodontal pathogenesis than are known at present.) *(2)* Up-regulated cytokine activity leads to vascular changes, polymorphonuclear leukocyte *(PMN)* activation and migration, and, ultimately, osteoclastogenesis and osteoclast activation. *(3)* Cytokines produced in innate responses contribute to the activation of antigen-presenting**

cells *(APCs).* These present specific antigens to naive $CD4^+$ T cells *(Th_0 cells),* which differentiate into $CD4^+$ effector T cells (e.g., T-helper cells *[Th_1, Th_2, Th_{17}],* and T-regulatory *[T_{reg}] cells*) according to the local cytokine milieu (as indicated by the groups of *four parallel horizontal gray dashed arrows*). For example, Th_0 cells differentiate into Th_{17} cells under the influence of interleukin-6 *(IL-6)*, IL-21, transforming growth factor beta *(TGF-β),* and IL-1β. (APCs are also activated by B cells, which are themselves activated at a later stage in the cytokine network [indicated by the *brown dashed arrow at the right edge of the figure*]; this is an example of the complexities of sequential feedback loops that develop). *(4)* Th_1 and Th_2 cells have a relatively stable phenotype, but other T-cell subsets can exhibit functional plasticity under the influence of different cytokine environments (indicated by *purple dashed arrows*). For example, Th_{17} cells can develop into Th_1 cells under the influence of IL-12 and into Th_2 cells under the influence of IL-4. *(5)* Different T-cell subsets are associated with various cytokine secretion profiles that regulate different aspects of immune responses and that contribute to up-regulated cytokine activity. For example, Th_1 cells secrete interferon gamma *(IFN-γ)* (which activates cell-mediated immunity), and Th_2 cells regulate antibody-mediated (humoral) immunity through the secretion of cytokines IL-4, IL-5, and IL-13. Cytokines produced by different T-cell subsets increase their further secretion in positive feedback loops and also inhibit the development of other T-cell subsets (e.g., IL-4 from Th_2 cells inhibits Th_1 development, and IFN-γ from Th_1 cells inhibits Th_2 T-cell subsets). *(6)* T_{reg} cells secrete TGF-β and IL-10, which have immunosuppressive functions. For example, IL-10 suppresses Th_1 and Th_2 responses, as well as cells of monocyte/macrophage lineage *(Mφ)* and dendritic cell *(DC)* function, and it also down-regulates cytokine production in various cells (i.e., Th_1 cells, Th_2 cells, PMNs, and natural killer *[NK]* cells). (Suppressive effects are indicated by *flat-ended green lines.*) *(7)* IL-10 functions as a regulatory mediator, but it can also exhibit other activities (e.g., the activation of B cells). The different aspects of IL-10 biology (i.e., immunosuppressive vs. immunostimulatory) likely depend on the local cytokine environment. These dual roles of IL-10 are indicated by the *green (inhibitory) line* and the *black (stimulatory) arrow. (8)* The sum total of innate and adaptive effector functions results in an immune–inflammatory response, the precise nature of which will vary from person to person (as indicated by the *multiple gray arrows,* with some patients being more susceptible to disease than others), as well as over time within an individual. In this case, the *black arrow* indicates an individual who has a proinflammatory response that leads to connective tissue breakdown and bone resorption. *ICAM-1,* intercellular adhesion molecule-1; *PGE_2,* prostaglandin E_2; *RANKL,* receptor activator of nuclear factor-κB ligand; *TNF-α,* tumor necrosis factor alpha. (Reproduced with permission from Kinane DF, Preshaw PM, Loos BG: Host-response: understanding the cellular and molecular mechanisms of host-microbial interactions—consensus of the Seventh European Workshop on Periodontology. *J Clin Periodontol* 38[Suppl 11]:44–48, 2011.)

The best-defined functional subsets of $CD4^+$ T cells are the Th1 and Th2 cells, and a dynamic interaction between Th1 and Th2 cells may provide, in part, an explanation for fluctuations in disease activity and the progression of periodontal disease (Box 7.3). Th1

cells secrete IFN-γ, which activates cell-mediated immunity (i.e., macrophages, NK cells, and $CD8^+$ cytotoxic T cells) against pathogenic microorganisms. The activation of macrophages promotes phagocytosis and killing of microbial pathogens, whereas NK cells and $CD8^+$ T cells are cytotoxic T cells that kill infected host cells. Conversely, Th2 cells regulate humoral (antibody-mediated) immunity and mast cell activity through the secretion of the cytokines IL-4, IL-5, and IL-13. Thus the predominance of Th2 cells leads to a B-cell response. The B-cell response may be protective, for example, as a result of the production of specific antibodies that would serve to clear tissue infections through interaction with the complement system and by enhancing neutrophil phagocytosis. However, B cells are also a source of proinflammatory cytokines that contribute to tissue destruction.

Box 7.3

The T-Helper 1/T-Helper 2 Concept of Periodontal Disease Progression

A dynamic interaction between T-helper 1 (Th1) and T-helper 2 (Th2) cells represents a possible explanation for aspects of the fluctuations in disease activity and clinical progression seen with periodontal disease. It has been hypothesized that a strong innate response results in interleukin-12 synthesis (e.g., by tissue macrophages) that leads to a Th1 response that provides protective cell-mediated immunity that would be manifested as a "stable" periodontal lesion. Conversely, a poor innate response would lead to reduced interleukin-12, which would permit the development of Th2 responses and lead to the activation of B cells; this, in turn, would mediate a destructive lesion, possibly through enhanced B-cell–derived interleukin-1β.[57,160] However, definitive evidence to support associations of Th1 and Th2 cells with different clinical presentations of periodontal disease has been difficult to obtain. Investigators have suggested that this is a result of variations among experimental studies, which have differed with respect to the material that has been used, the definitions of disease stages, the experimental designs, and analytic methods used.[53,57,160] In

addition, in general terms, the Th1/Th2 dichotomy does not explain all aspects of the regulation of adaptive immune responses. More recently, other T-cell subsets have been identified and defined. For example, regulatory T cells secrete interleukin-10 and transforming growth factor beta and thereby suppress immune responses. Th17 cells have a proinflammatory action through the secretion of interleukin-17, a cytokine that synergizes with interleukin-1β and tumor necrosis factor alpha. Therefore, although it is widely accepted that Th1 and Th2 cells are likely to be important in the immunopathogenesis of periodontal disease, it is increasingly recognized that the Th1/Th2 model alone is probably inadequate to explain the role of T cells in this process.

T_{reg} cells have an immunosuppressive action that is mediated by the secretion of TGF-β and that is important to the prevention of autoimmune disease. These cells are increased in periodontitis lesions and may therefore have a role in disease pathogenesis.[121] Certain lines of evidence suggest that the pathogenesis of periodontal disease may involve some elements of autoimmunity.[57] For example, immunologic cross-reactivity occurs between HSP60 expressed on human cells and the GroEL molecule of *P. gingivalis*, and specific serum antibodies and antigen-specific T cells to these molecules have been detected in periodontal disease. Similarly, autoantibodies and specific T cells against other host (i.e., self) molecules, such as type I collagen, have been identified in periodontal disease.

Th17 cells comprise another subset of T cells, and they have a proinflammatory action that is important in immune responses against extracellular infections mediated by the cytokine IL-17. Infections with a diverse range of pathogens have been shown to activate strong Th17 cell responses, and Th17 cells are thought to provide a substantial inflammatory response to clear microorganisms that Th1/Th2 cells have failed to eradicate. IL-17 has a number of activities in common with IL-1β and TNF-α, and it has a synergistic activity with these cytokines, particularly TNF-α. IL-17 induces proinflammatory cytokine expression (including IL-1β and TNF-α) in macrophages, stimulates chemokine expression, and thereby activates neutrophil infiltration. Increasing evidence

indicates a role of IL-17 and Th17 cells in periodontal disease.[53] IL-17 has been detected in periodontal tissues at sites of advanced disease. IL-17 induces IL-6 and IL-8 secretion by gingival fibroblasts and also up-regulates MMP-1 and MMP-3 in these cells. IL-17 also induces IL-1β and TNF-α secretion from macrophages and gingival epithelial cells. In a mouse model of periodontitis induced by *P. gingivalis,* IL-17 receptor deficiency (IL-17RA knockouts) resulted in increased susceptibility to alveolar bone loss, thereby suggesting a protective role of IL-17 in bone homeostasis, possibly by an effect on neutrophil function.

Several other effector $CD4^+$ T-cell subsets have been defined on the basis of their cytokine secretion profile: these include Th9 cells and Th22 cells. In addition, T-cell subsets have been defined on the basis of their specific anatomic location. For example, Th22 cells home to the skin, in which they likely stimulate antimicrobial peptide (AMP) production and the differentiation of keratinocytes. In addition, T follicular helper cells are located in germinal centers in lymph nodes in which they provide B-cell help and stimulate Ig class switching. The homing of particular T-cell subsets to specific anatomic locations is defined by the expression of chemokine receptors that confer responsiveness to specific chemotactic signals that are produced in those locations. However, thus far, the majority of the work on these novel T-cell subsets has been carried out in mouse models and in vitro systems; their relevance to human biology in vivo and in disease remains to be fully elucidated.

Cytokines produced by differentiated T-cell subsets feed back to stimulate differentiation and to sustain the activity of the cells from which they are derived (i.e., in a positive feedback loop). Simultaneously, they inhibit the development of other competing subsets. For example, IL-4 from Th2 cells inhibits the development of Th1 cells, and IFN-γ from Th1 cells inhibits Th2 cells.

It is increasingly appreciated that individual $CD4^+$ T-cell clones—after they have encountered antigen and differentiated in response under the influence of a specific cytokine environment (i.e., a milieu)—may not be terminally differentiated cells. Rather, functional flexibility appears to exist between T-cell subsets and in particular within the memory T-cell population (see Fig. 7.5). For example, Th17 and T_{reg} cells can interconvert, depending on the

local concentrations of cytokines such as IL-6, IL-23, and TGF-β.[173] It is thought that the plethora of functional subsets of T cells, their anatomic location, and their ability to switch phenotype are reflections of the requirement for effective responses against diverse pathogens.

The complexities of the interactions between cellular and molecular aspects of innate and adaptive immune functioning are presented in Fig. 7.5. It is clear that multiple proinflammatory and antiinflammatory pathways, positive and negative feedback loops, and agonists and antagonists all play a role in determining the nature of the immune–inflammatory response to the bacterial challenge and the degree of tissue damage that is experienced. Furthermore, the nature of the inflammatory response varies among individuals; this could explain why certain people appear to be more susceptible to periodontitis than others.

Clinician's Corner

What makes a person susceptible to periodontitis?

We have all seen patients with good oral hygiene yet advanced periodontitis and, conversely, patients with poor oral hygiene who may have gingivitis or mild periodontitis, but who do not develop advanced periodontitis. It is clear that immune functioning and inflammatory responses are highly complex processes that vary from person to person. Our understanding is that the sum total of all the immune–inflammatory events in the periodontal tissues (which are also influenced by environmental factors such as smoking or diabetes) is the main determinant of how much tissue damage occurs in response to the challenge presented by the bacterial biofilm. This tissue damage is what we recognize clinically as disease. Our challenge for the future is to learn how to identify susceptible patients at a much earlier stage in the disease process, before tissue damage occurs.

Antibodies

Specific antibodies are produced in response to the bacterial

challenge in periodontal disease and are the endpoint of B-cell activation. Commensurate with the appearance of antibodies against bacterial antigens is the appearance of differentiated plasma cells. High levels of antibodies appear in GCF (in addition to those in the circulation), and these are produced locally by plasma cells in periodontal tissues.[8] Antibodies to periodontal pathogens are primarily IgG, with few IgM or IgA types produced.

Many species of oral bacteria elicit a polyclonal B-cell response (with the consequent production of specific antibodies against those bacteria). However, these responses augment responses against nonoral bacteria and may lead to the production of autoantibodies (e.g., antibodies against collagen and connective tissue proteins), which may contribute to tissue destruction in periodontal disease.[8,57] The incidence and levels of specific serum and GCF IgG antibodies are raised in chronic periodontitis, a finding suggesting that local and peripheral generation of antibodies may be important in the immune response to periodontal pathogens. Antibodies (i.e., IgA) to periodontal pathogens are also found in saliva. Variations in the levels of specific antibodies to different species in different clinical presentations suggest differences in pathogenesis. For example, antibodies to *A. actinomycetemcomitans* of the IgG_2 subclass predominate in aggressive periodontitis.[151]

Other *P. gingivalis* molecules (i.e., fimbriae and hemagglutinin) also act as antigens. Specific antibodies are also generated by serotype-specific carbohydrate antigens (e.g., capsular polysaccharide of *P. gingivalis,* carbohydrate of *A. actinomycetemcomitans* LPS). The subclass distribution of antibodies is influenced by cytokines that are derived from monocytes.[151] For example, IgG_2 production is regulated by IL-1α, IL-1β, and PGE_2 from monocytes as well as by platelet-activating factor from neutrophils. PGE_2 and platelet-activating factor indirectly induce Th1 responses and therefore IFN-γ, which stimulates IgG_2 production. Individuals with aggressive periodontitis have monocytes that are hyperresponsive to LPS and that produce elevated quantities of PGE_2.[8] *A. actinomycetemcomitans* is commonly associated with aggressive periodontitis, which induces IL-12 production that regulates NK cells and Th1 cells. These cells are a

source of IFN-γ, which, in turn, regulates IgG_2.

Some studies have reported an effect of treatment on levels of specific antibodies to periodontal pathogens. For example, plaque removal reduces the titers of antibodies to *P. gingivalis* and *A. actinomycetemcomitans* in serum, GCF, and saliva.[8] Some studies have observed a transient increase in antibody titers after treatment, which may be due to the release of antigens into the tissue and circulation.

The significance of antibodies in periodontitis is not clear. It is not known whether these antibodies have a protective function or whether they participate in disease pathogenesis. Although some evidence indicates a correlation between clinical parameters of disease and titers of specific antibodies to periodontal pathogens, other studies report an inverse correlation of antibody levels and avidity with periodontal destruction. In addition, specific antibodies to periodontal pathogens are found in healthy individuals, as well as in persons with periodontal disease.

Concept of Host Susceptibility

The immune and inflammatory processes that result from the challenge presented by the subgingival biofilm are complex and are mediated by a large number of proinflammatory and antiinflammatory cytokines and enzymes that function as a network of mediators with overlapping roles and activity (see Fig. 7.5). Immune responses to the bacterial challenge do not occur in isolation, but rather take place in the context of other host and environmental factors that influence these responses and thereby determine the progression of disease. Certain risk factors increase susceptibility to periodontal disease, particularly smoking[126] and diabetes[140]; these are considered elsewhere in this book.

A feature of human development and evolution has been that quantitative and qualitative differences exist in immune responses among individuals.[72] Indeed, infectious agents (e.g., bacteria) exert evolutionary selection pressures on the species that they infect. This may be relevant in periodontal disease, and some studies have confirmed that immune cells from patients with periodontal disease secrete higher quantities of proinflammatory cytokines than do cells

from persons who are periodontally healthy.[174] Cytokine profiles are also different in those individuals with immune-mediated diseases as compared with healthy control subjects.

These observations have led to the concept of the "hyperinflammatory" or "hyperresponsive" trait in which certain individuals possess a hyperinflammatory phenotype that accounts for their increased susceptibility to chronic inflammatory conditions such as periodontitis.[29] Such a trait may also underpin shared susceptibility between conditions such as periodontitis and cardiovascular disease or diabetes. However, at present, it is not possible to identify with certainty those patients who are hyperresponders. The hyperresponder concept was originally proposed in the context of the responsiveness of monocytes to LPS challenge; this suggests that patients with disease possess an individual hyperresponsive monocytic trait that is characterized by elevated levels of inflammatory mediators released from monocytes in response to bacterial challenge.[128] It is likely that many reasons contribute to disease variations among individuals, such as variations in immune responses, pathogenesis, and the plaque biofilm; this situation results in an uneven disease experience in the population.

Fig. 7.6 is a schematic illustration of how increasing bacterial challenge can result in differing levels of inflammatory response according to the response profile of an individual patient.[128] Most individuals would be considered normal, and for a given bacterial challenge, they would produce a certain level of inflammatory mediators in the periodontal tissues. For those who are hyperresponders, the same bacterial challenge results in a greater inflammatory response, which over time would result in increased tissue breakdown, earlier presentation of the clinical signs of disease, and a clinical interpretation of having increased susceptibility to periodontitis. Those individuals who are hyporesponsive produce lower levels of inflammatory mediators and are therefore somewhat resistant to the development of periodontitis, even though plaque may be present and they may have widespread gingivitis and/or mild periodontitis. The nature of the immune–inflammatory response is governed by genetic factors and environmental factors, and it may vary over time within the

same individual (e.g., if environmental factors such as smoking status, stress, or systemic disease should change).[87]

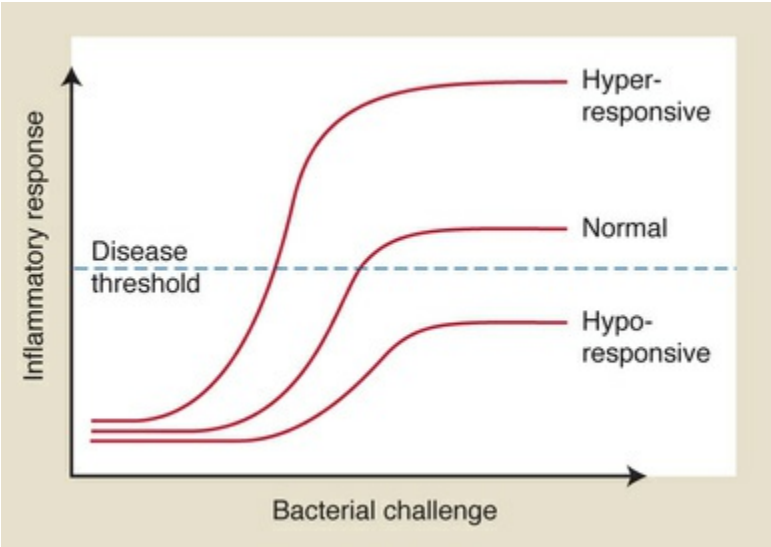

FIG. 7.6 Inflammatory response characteristics in relation to bacterial challenge. A given bacterial challenge results in differing levels of inflammatory response according to the response profile of an individual. Most people are close to normal and produce a certain level of inflammatory mediators for a given challenge. Those who are hyperresponders generate an excessive inflammatory response for the same bacterial challenge and cross the threshold into active disease at an earlier stage. Those who are hyporesponsive produce lower levels of inflammatory mediators and, despite a significant bacterial challenge, may never develop advanced periodontitis. (Modified from Champagne CM, Buchanan W, Reddy MS, et al: Potential for gingival crevice fluid measures as predictors of risk for periodontal diseases. *Periodontol 2000* 31:167–180, 2003.)

A similar dose–response curve can also be expressed in the context of stable or progressing disease, and, as shown in Fig. 7.7, a certain level of bacterial challenge results in a moderate release of inflammatory cytokines, mediators, and enzymes. These mediators, together with the infiltrating defense cells, have a protective role to eliminate bacteria in the sulcus and do not trigger periodontal disease breakdown. Such a steady-state scenario may persist indefinitely. However, if something changes (e.g., the quantity or quality of the biofilm alters, or the host defenses alter as a result of a change in an environmental exposure), then the secretion of cytokines, prostanoids, MMPs, and other mediators may increase in the tissues, thereby leading to the histopathologic changes described previously and a transition to periodontitis. Thus a threshold exists between stable and active disease, and this varies

from person to person. The dose–response curve for any individual can shift to the left or the right according to environmental changes. A shift to the left would result in an increase in the quantities of inflammatory mediators produced for a given bacterial challenge and potentially an exacerbation of disease; a shift to the right would have the opposite effect. In all cases, an increase in the bacterial challenge would have the tendency to increase the production of inflammatory mediators, which may tip the balance from a stable to a progressing periodontal lesion.

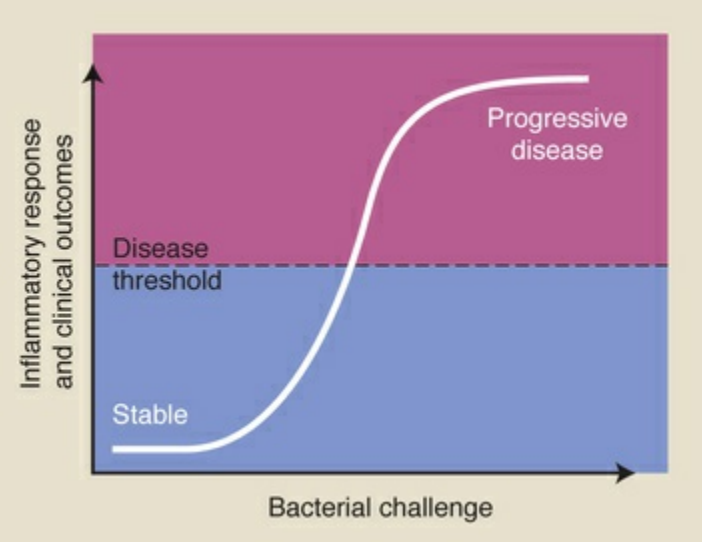

FIG. 7.7 Inflammatory response characteristics in relation to an individual's threshold for periodontitis. A certain level of bacterial challenge results in a moderate inflammatory response, which is protective by intent and may not be sufficient to transition to periodontal disease. This stable condition may persist for many years or even throughout the individual's lifetime. Changes in the bacterial burden (i.e., qualitative, quantitative, or both) or changes in the host response (e.g., as a result of a change in an environmental exposure) could result in an up-regulated inflammatory response characterized by marked cellular infiltrate and the increased secretion of inflammatory mediators leading to tissue damage and a transition from the stable situation to periodontitis. The location of the threshold between stable and active disease varies from person to person. In addition, the dose–response curve for any individual can shift to the left or the right in accordance with environmental changes. A shift to the left would result in an increased inflammatory response to a given bacterial challenge and potentially an exacerbation of disease. A shift to the right would have the opposite effect. (Modified from Champagne CM, Buchanan W, Reddy MS, et al: Potential for gingival crevice fluid measures as predictors of risk for periodontal diseases. *Periodontol 2000* 31:167–180, 2003.)

These are, of course, simplistic models to explain a highly

complex phenomenon, and it is clear that cytokines and inflammatory mediators function in complicated networks (see Fig. 7.5).[85,141] Therefore, although increases and decreases in the absolute levels of cytokines have been reported in disease states, it is clear that the dysregulation of cytokine networks and other mediators is the key determinant of disease progression. Thus the relative proportions of mediators within inflammatory networks are fundamental to determining disease progression, and changes in these proportions are driven by inflammatory challenges and the genetic and environmental factors that govern how the host responds to such challenges.[91,134] Schematic illustrations to explain the pathogenesis of periodontal disease, such as presented in Fig. 7.5, can be useful; however, given the complexity of the disease processes, they are inevitably simplistic. Earlier models were very simplistic indeed, being essentially linear and suggesting that periodontitis resulted directly from the microbial challenge.[91] This concept influenced periodontal treatment over the decades and resulted in treatment strategies that focused primarily on the biofilm. Modern concepts of periodontal pathogenesis describe a host response that transitions from being proportionate and proresolving (in terms of resolving inflammation) to one that is disproportionate and nonresolving and ultimately self-destructive as chronic inflammation develops. These changes occur in parallel with changes in the biofilm, the nature of which is influenced by the development of inflammation in the tissues, as it transitions from being health-promoting to dysbiosis, thus perpetuating the chronic inflammation.[116]

Increasing awareness of the importance of host factors in determining interindividual differences in disease progression has resulted in the realization that, although plaque bacteria initiate and perpetuate the inflammatory response, most of the tissue damage results from the host response, which is influenced by genetic factors, as well as environmental and acquired risk factors. Risk factors such as smoking alter the progression of the immune–inflammatory response and shift the balance toward increased periodontal breakdown.[80] This implies that the presence of plaque bacteria does not inevitably lead to tissue destruction, and this concept is supported by a large number of epidemiologic studies,

which confirm that more advanced disease is usually confined to a minority of the population.[108]

Our improved understanding of the disease processes in periodontitis has led to the development of a biologic systems model for representing periodontal pathogenesis. This involves bacterial components, environmental factors, specific inflammatory mechanisms, and host–genetic variations that are associated with disease.[91] A biologic systems approach provides a framework for viewing the contributions and relative importance of all the components that contribute to the clinical presentation of disease. Thus, in the context of periodontal disease, such a system would include a person level, a genetic/epigenetic level, the biologic phenotype, and, ultimately, the clinical phenotype (Fig. 7.8).[127] Such systems provide a more comprehensive view of the disease as a complex regulatory network in which aspects of the specific genetic factors, environmental exposures, and other modifying factors that an individual is exposed to determine the development of the disease state.

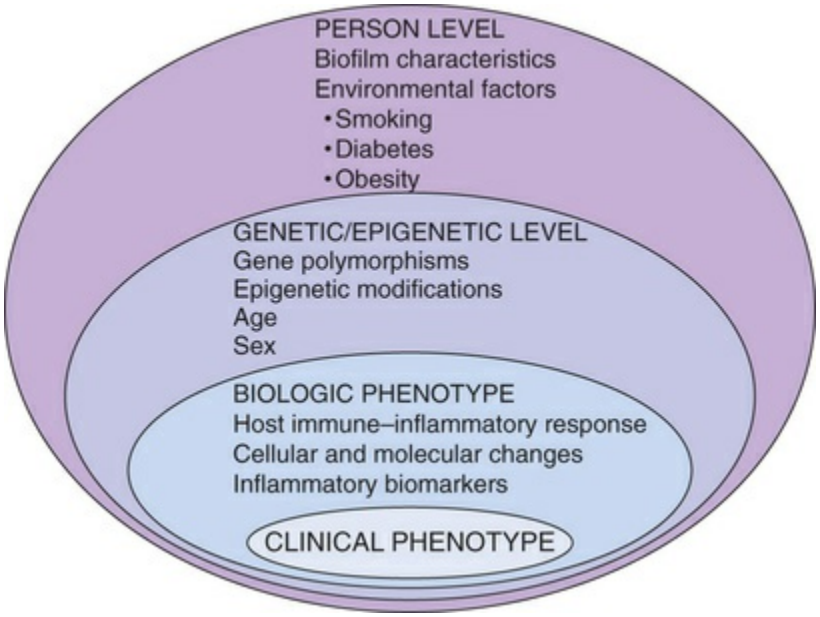

FIG. 7.8 A biologic systems model of periodontitis. The outermost level of this model is the *Person Level*, which represents an individual's unique characteristics as they are related to periodontitis. These include the compositional characteristics of the subgingival biofilm, as well as known risk factors and environmental exposures such as smoking and diabetes. The *Person Level* characteristics interact with the *Genetic/Epigenetic Level* characteristics, which include nonmodifiable factors such as age, sex, and genetic

composition. Gene polymorphisms are known to be associated with periodontal disease, and epigenetics refers to changes in phenotype (i.e., clinical disease expression) caused by mechanisms other than changes in the underlying DNA sequence. Epigenetics can be defined as all the meiotically and mitotically inherited changes in gene expression that are not encoded in the DNA sequence itself. Epigenetic modifications are important permissive and suppressive factors for controlling the expressed genome through gene transcription. Two major epigenetic mechanisms are the posttranslational modification of histone proteins in chromatin and the methylation of DNA. The *Genetic/Epigenetic Level* characteristics influence the *Biologic Phenotype,* which is characterized by the specific immune–inflammatory responses (i.e., cellular and molecular events and the production of inflammatory mediators) that are associated with the *Clinical Phenotype* (i.e., the clinical presentation of the disease). This model reflects how different individuals with the same presentation (e.g., periodontitis) may have very different predisposing and risk factors. The model depicts the different biologic factors that underpin the development of periodontal disease in different individuals and that ultimately may be used to classify disease by the contribution provided to the clinical phenotype at each level. (Modified from Offenbacher S, Barros SP, Beck JD: Rethinking periodontal inflammation. *J Periodontol* 79:1577–1584, 2008.)

To summarize, it is clear that the subgingival bacteria initiate and perpetuate the immune–inflammatory responses in the periodontal tissues. These responses are characterized by classic signs of inflammation that are modified as a result of the unique anatomy of the periodontium and the dentogingival apparatus. The inflammatory events that develop in response to the bacterial challenge are protective by intent, but they result in the majority of tissue damage and breakdown that lead to the clinical signs of periodontitis. Individuals vary with regard to their susceptibility to periodontal disease and also in the threshold level at which a stable periodontal site progresses to an active site. Such variations are genetically determined, and they are also influenced by environmental risk factors (e.g., smoking), some of which are modifiable and some of which are not. The challenge for the future is to identify at-risk individuals who possess the hyperinflammatory trait so that disease can be prevented by careful management strategies before tissue loss has occurred.

Case Scenario 7.1

Patient:

56-year-old male

Chief Complaint:

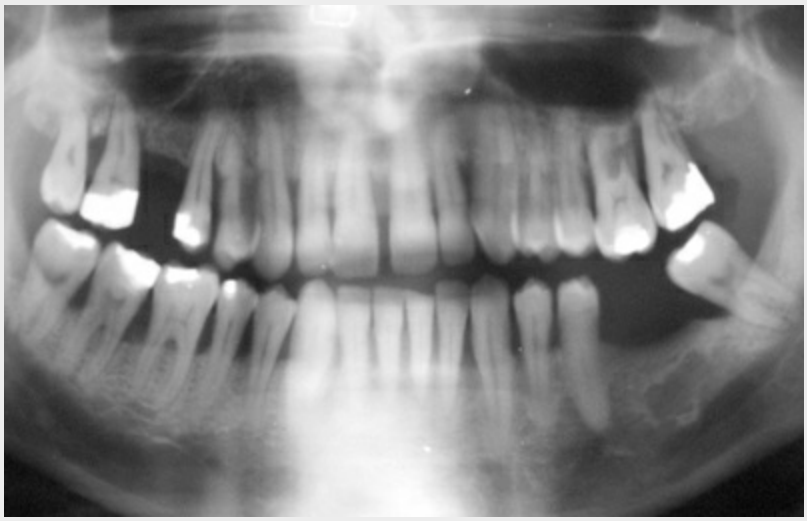
Bad breath and bleeding gums when brushing his teeth

Background Information

Clear medical history
Former smoker (quit 6 months ago, smoked 20 cigarettes per day for 15 years before this).
Irregular dental attender, with no previous history of periodontal treatment
Manual toothbrush user, twice per day, for at most 1 minute each time

Current Findings

Generalized probing depths of 5–8 mm with bleeding on probing (BOP score 70%).
Generalized alveolar bone loss (> 50% root length) throughout the dentition, with more advanced bone loss (>80%) at maxillary molars
Mobility of upper right central incisor (grade I)



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the most likely explanation for the high BOP score in this patient? A. Past smoking history B. Current nonsmoking status C. Plaque-induced inflammation D. Occlusal factors	**Answer: C** **Explanation:** Poor oral hygiene and presence of the subgingival biofilm result in inflammation in the gingival and periodontal tissues. The periodontal probe penetrates the inflamed junctional epithelium easily, causing bleeding on probing. Note: smoking can have an inhibitory effect on the microvasculature such that smokers, on quitting, often notice an increase in gingival bleeding as the vasculature recovers (see Chapter 12).
2. What is the most likely etiology for the periodontitis in this patient? A. Bacteria in plaque (e.g., *Porphyromonas gingivalis*) B. Inflammation in the periodontal tissues C. Smoking D. All of the above	**Answer: D** **Explanation:** All factors are likely to be relevant in this case. Poor oral hygiene and the long-term challenge of the bacterial biofilm result in chronic inflammation in the periodontal tissues. The immune–inflammatory response is protective by intent, but it causes the tissue damage that we recognize clinically as periodontitis. Smoking is a major risk factor for periodontitis and exacerbates the disease processes, leading to more severe periodontitis.
3. What is the specific periodontal diagnosis in this case?	**Answer: B** **Explanation:** The patient has generalized bone loss (therefore, this is periodontitis, not gingivitis). In view of the patient's age, smoking history, and the presence of local factors such as

A. Gingivitis B. Chronic periodontitis C. Aggressive periodontitis (localized) D. Aggressive periodontitis (generalized)	generalized biofilm deposits, this is a case of chronic periodontitis. Aggressive periodontitis is said to occur in younger patients (typically <35 years old), who are otherwise generally healthy, with a rapid rate of disease progression and a positive family history of disease (see Chapter 28).
4. Why is there more advanced bone loss in the maxillary molar regions than elsewhere in the dentition? A. Poor access for cleaning B. Multirooted teeth/complex anatomy C. A and B D. Past history of localized aggressive periodontitis	**Answer: C** **Explanation:** It can be difficult to explain why certain sites have more advanced disease than others. Maxillary molars often have more advanced bone loss, probably because of difficulties accessing these regions for cleaning (especially interproximal cleaning). Further difficulties in cleaning arise once furcation involvement occurs, leading to further progression of disease at these sites.
5. In conjunction with oral hygiene instruction and patient motivation, what is the likely initial therapy in this case? A. Root surface debridement B. Access flap surgery C. Gingivectomy D. Periodontal regeneration	**Answer: A** **Explanation:** Initial therapy focuses on behavior change, and patient motivation and support to enable a high standard of patient-performed plaque control to achieve excellent oral hygiene. This is coupled with nonsurgical periodontal therapy to disrupt and reduce the subgingival biofilm and remove plaque-retentive features such as calculus. Biofilm control is the vehicle by which we aim to reduce inflammation in the periodontal tissues, thus leading to shrinkage of the tissues as a result of resolution of inflammation, and reductions in probing depths, which are then easier to clean and maintain.

CHAPTER 8

Biofilm and Periodontal Microbiology

Wim Teughels, Isabelle Laleman, Marc Quirynen, Nicholas Jakubovics

CHAPTER OUTLINE

The Oral Cavity From a Microbe's Perspective
Bacteria and Their Biofilm Mode of Living
Characteristics of Biofilm Bacteria (Life in "Slime City")
Bacterial Transmission and Translocation
Nonbacterial Inhabitants of the Oral Cavity
Microbiologic Specificity of Periodontal Diseases
The Transition From Health to Disease
Virulence Factors of Periodontopathogens
Future Advances in Periodontal Microbiology

The human fetus inside the uterus is sterile, but as soon as it passes

through the birth canal, it acquires vaginal and fecal microorganisms.[83,112] Within 2 weeks, a nearly mature *microbiota* is established in the gut of the newborn baby. After weaning (>2 years), the entire human microbiota is formed and comprises a very complex collection of hundreds of different types of bacteria with approximately 10^{14} microbial cells.[262] From this moment on, our body contains *1.3* to *10 times more bacteria* than human cells.[361] It has been estimated that, for a normal, healthy human being, the bacterial population comprises 2 kg of the total body weight. This is fascinating if one realizes that the average human brain weighs only about 1.4 kg.

The colonization of the oral cavity also starts close to the time of birth (Fig. 8.1). Within hours after birth, the sterile oral cavity is colonized by low numbers of mainly facultative and aerobic bacteria.[388] At that time, the oral microbiota of newborns closely resembles the mother's vaginal microbiota or, for newborns delivered by cesarean section, the mother's skin microbiota.[83] From the second day, anaerobic bacteria can be detected in the infant's edentulous mouth.[96,337] The number of oral bacteria increases gradually as a result of exposure to external environmental microbial sources.[189,288,337] *Streptococcus salivarius* and *Streptococcus mitis* (Fig. 8.2A) have been identified as the first and most dominant oral microbes to colonize the oral cavity of newborn infants.[187,188,210] *Veillonella* spp. (Fig. 8.2B), *Neisseria* spp., *Actinomyces* spp. (Fig. 8.2C and D), and *Staphylococcus* spp. are also among the first colonizers of the oral cavity. After tooth eruption, a more complex oral microbiota is established. The species that colonize the teeth after eruption include *Streptococcus sanguinis* (Fig. 8.2D), *Lactobacillus* spp. (Fig. 8.2E), and *Streptococcus oralis.* Oral streptococci, including *S. oralis, Streptococcus anginosus,* mutans streptococci (*Streptococcus mutans* and *Streptococcus sobrinus*), and *Streptococcus gordonii* (Fig. 8.2F) are commonly reported to be present after the first year of life.[49,53,230,288] In addition, anaerobes, including *Fusobacterium* spp. (Fig. 8.2G) and *Prevotella* spp. (Fig. 8.2H and I), can also be detected in young children.[49,189] In later childhood, the bacterial diversity and numbers in the oral cavity increase as more teeth erupt and provide more areas for the adherence and retention of bacteria.[33]

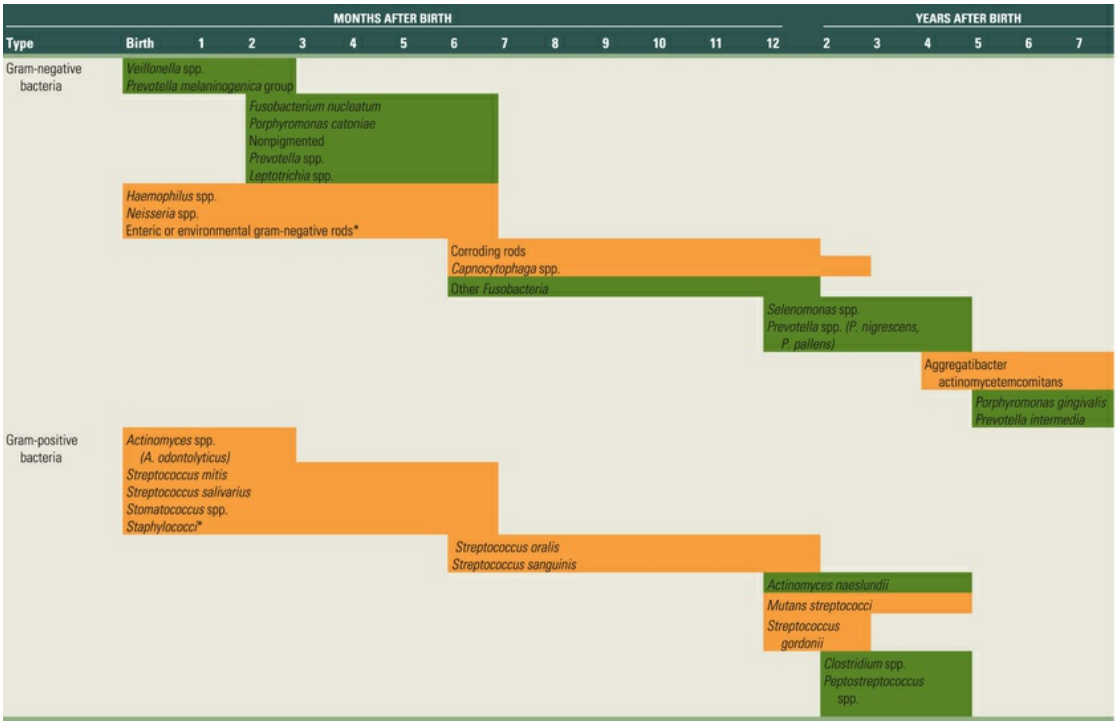

FIG. 8.1 Colonization of the oral cavity. Amenable periods for the establishment of the most frequent bacterial species or groups (prevalence, >25%) in infants' mouths. Anaerobic bacteria are indicated in green, and aerobic or facultative bacteria are indicated in orange. *Asterisk,* The prevalence of these bacteria decrease with age.

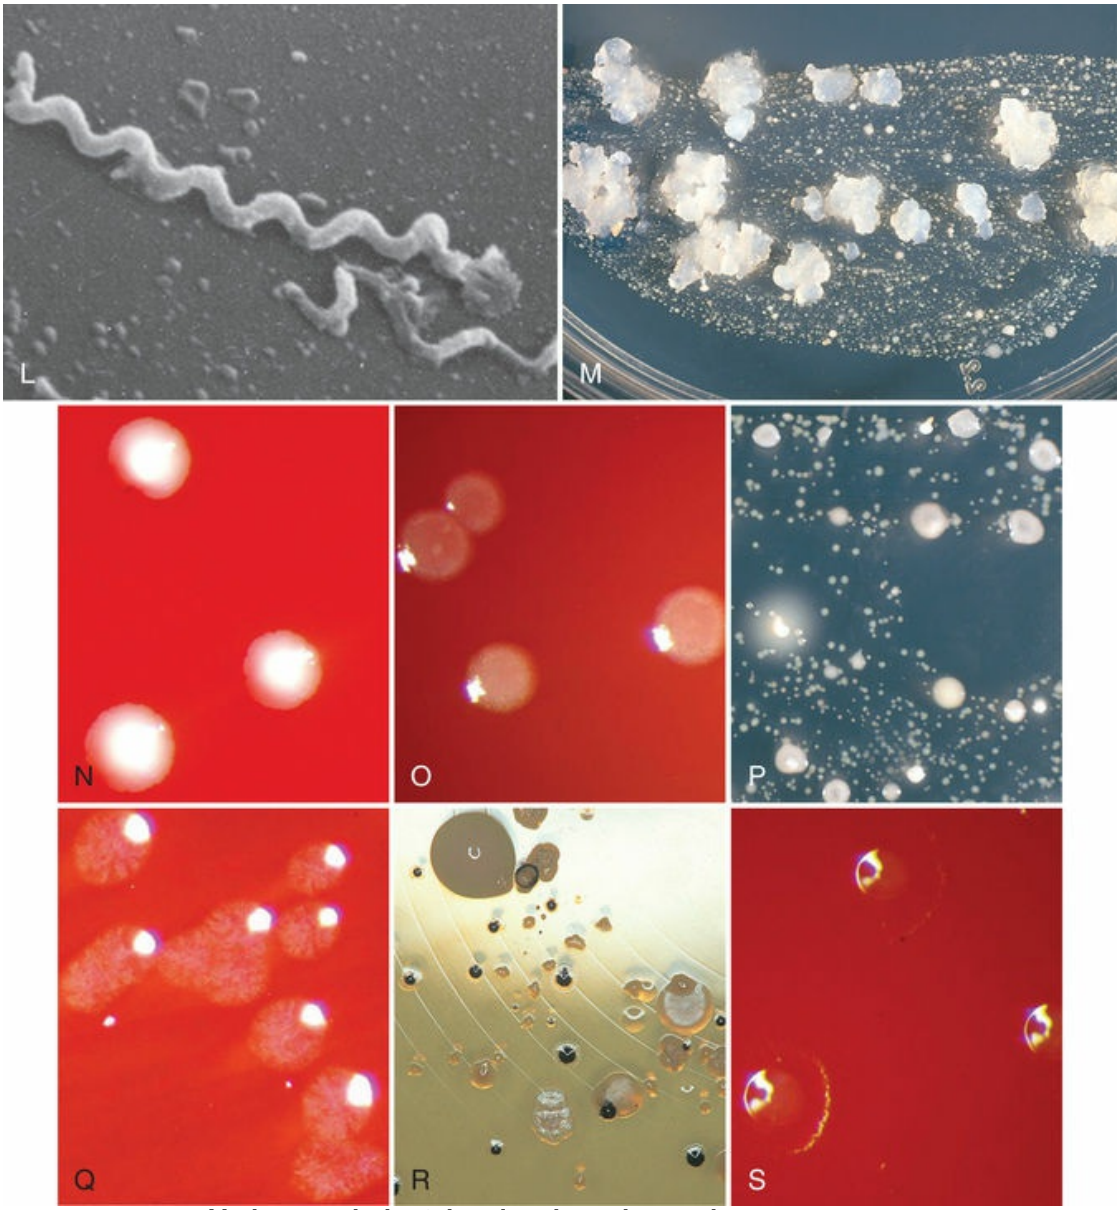

FIG. 8.2 **Various periodontal and cariogenic species grown on agar plates. (A) *Streptococcus mitis* are gram-positive, fast-growing, facultatively anaerobic bacteria that are easy to culture on a blood-agar plate. A clear halo surrounding the colonies appears through hemolytic activity. (B) *Veillonella parvula* are anaerobic, gram-negative, small cocci. They form small transparent colonies (<1.0 mm) after 48 hours of incubation. (C) *Actinomyces viscosus* are microaerophilic to anaerobic gram-positive rods with possible branches (pseudomycelium). They form slimy, white, spherical colonies in 48 hours. (D) The typical colony morphology of *Streptococcus sanguinis (right)* and *Actinomyces odontolyticus (left).* (E) *Lactobacillus* spp. typically grow on Rogosa agar as a sesame seed. (F) *Streptococcus gordonii* are facultative, anaerobic, gram-positive cocci. On a blood plate, colonies of 1 to 3 mm are formed within 48 hours. These bacteria are α-hemolytic, which results in the formation of a clear halo surrounding the colony. (G) This selective agar plate, which contains crystal violet and erythromycin (i.e., a CVE-agar plate), will allow *Fusobacterium nucleatum* to grow as a round, flat rhizoid, opaque purple colony. (H) A detailed picture of *Porphyromonas gingivalis* (green-brown colony) and *Prevotella***

intermedia **(black colony) on a classic nonspecific blood-agar plate. (I)** ***Prevotella nigrescens*** **forms like** ***P. intermedia*****, a black pigmented colony on a blood agar plate. It is a strictly anaerobic bacterium with growth that is limited to an oxygen-free environment. (J) A detailed picture of** ***Parvimonas micra*** **(small white colony) next to** ***Porphyromonas gingivalis*** **(green-brown colony) on a classic nonspecific blood-agar plate. (K) A detailed picture of** ***Aggregatibacter actinomycetemcomitans*** **grown on a selective agar plate that contains tryptic soy, horse serum, bacitracin, and vancomycin (i.e., a TSBV-agar plate). (L) It is extremely difficult to culture** ***Treponema denticola*** **(spirochete) on an agar plate and therefore not possible to identify this bacteria with classic culture. A phase-contrast microscope, a dark-field microscope, or an electron microscope is often used to visualize this bacterium. Identification and quantification are possible only through DNA analysis. (M) On a selective agar plate that contains trypticase yeast extract, cystine, sucrose, and bacitracin (i.e., a TYCSB agar plate),** ***Streptococcus mutans*** **will grow as a sugar cube. (N)** ***Eubacterium nodatum*** **colony morphology strongly depends on its substrate. Its growth is very slow, and it is an obligate anaerobic gram-positive rod. (O)** ***Tannerella forsythia*** **organisms are fastidious bacteria that are therefore difficult to culture. This organism grows on a blood-agar plate as a smooth white colony with a faded edge. The bacteria are strictly anaerobic. (P) The typical colony morphology of** ***Streptococcus sobrinus*** **on TYCSB agar (colony with a white halo). (Q)** ***Capnocytophaga*** **are slowly growing bacteria that require an elevated carbon dioxide concentration for their growth. They are facultative anaerobic rods. (R)** ***Campylobacter rectus*** **grows on a Hammond plate as small, smooth, opaque, round colonies that are black. (S)** ***Eikenella corrodens*** **has a variable colony morphology and shows different biochemical and serologic reactions. Because of the difficult determination with classic culture, identification and quantification through DNA techniques are very suitable for this organism.** ***E. corrodens*** **cells are facultative, anaerobic, gram-negative rods. ([A] to [C], [F], [I], [L], [N], [O], [Q], and [S] Courtesy ADD Clinident, Malden, the Netherlands.)**

Because of the paucity of longitudinal studies, relatively little is known about the initial colonization of key microbes found in the oral cavity of children and adults.[210] It is estimated that the oral bacterial microbiome of adults encompasses approximately 700 commonly occurring species, approximately half of which can be present at any time in any individual.[25,281] When one thinks about bacteria, one almost immediately associates them with different pathologic conditions. However, most oral bacteria are harmless commensals under normal circumstances. This means that this microbiota lives in harmony with its host but that, under specific conditions (i.e., increased mass and/or pathogenicity, suppression of commensal or beneficial bacteria, and/or reduced host response), disease can occur. The importance of the commensal microbiota is clearly illustrated by the development of *Candida* infections when

the normal oral microbiota is reduced, such as after a longer period of systemic antibiotic usage.[430] In addition, it has been shown that aggressive periodontitis is associated with a loss of colonization of *S. sanguinis*.[394] Conversely, investigators showed in mice that the commensal microbiota is required for *Porphyromonas gingivalis*–induced bone loss.[2,76]

It is obvious that the periodontal microbiota is extremely complex. Because it both affects and is affected by the host, the oral environment, and periodontal treatment, a profound knowledge of periodontal microbiology is necessary.

The Oral Cavity From a Microbe's Perspective

With the exception of those microorganisms that are present in feces and in secretory fluids, all bacteria maintain themselves within their host by adhering to a surface. This principle also applies to the oral cavity. From an ecologic viewpoint, the oral cavity, which communicates with the pharynx, should be considered as an "open growth system" with an uninterrupted ingestion and removal of microorganisms and their nutrients.

Key Fact

Most organisms can survive in the oropharynx only when they adhere to either the soft tissues or the hard surfaces. Otherwise, they may be removed by:

- Swallowing, mastication, or blowing the nose
- Tongue and oral hygiene implements
- The wash-out effect of the salivary, nasal, and crevicular fluid outflow
- The active motion of the cilia of the nasal and sinus walls

The ability of a bacterium to adhere to its host is crucial for the induction of infectious diseases, such as gingivitis or

periodontitis.[327] Oral bacteria and especially pathogenic bacteria, such as *Porphyromonas gingivalis* (Fig. 8.2H and J) and *Aggregatibacter actinomycetemcomitans* (Fig. 8.2K), have a large battery of virulence factors, one of which is the ability to adhere to hard intraoral surfaces and/or to the oral mucosae (Fig. 8.3).[56,58,110,377]

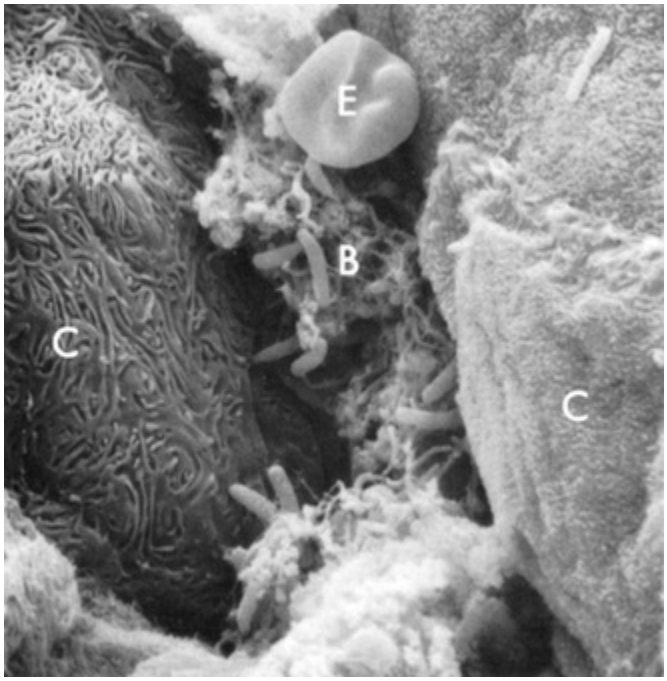

FIG. 8.3 Epithelial intercellular spaces containing plaque. Scanning electron micrograph of epithelial intercellular spaces that contain bacterial plaque *(B)* enmeshed in a fibrin-like material. *C*, Epithelial cells; *E*, erythrocyte. The cells to the *left* show signs of necrosis. ×4000.

On the basis of physical and morphologic criteria, the oral cavity can be divided into *six major ecosystems* (also called *niches*), each with the following distinct ecologic determinants:

1. The intraoral and supragingival hard surfaces (teeth, implants, restorations, and prostheses)
2. Subgingival regions adjacent to a hard surface, including the periodontal/peri-implant pocket (characterized by the presence of crevicular fluid, the root cementum or implant surface, and the pocket epithelium)
3. The buccal palatal epithelium and the epithelium of the floor of the mouth
4. The dorsum of the tongue

5. The tonsils
6. The saliva

In health, a core set of microorganisms is almost universally present in these ecosystems. This core microbiome includes members of the phyla Firmicutes (*Streptococcus* spp., *Veillonella* spp., and *Granulicatella* spp.), Proteobacteria (*Neisseria* spp., *Campylobacter* spp., and *Haemophilus* spp.), Actinobacteria (*Corynebacterium* spp., *Rothia* spp., and *Actinomyces* spp.), Bacteroidetes (*Prevotella* spp., *Capnocytophaga* spp., and *Porphyromonas* spp.), and Fusobacteria (*Fusobacterium* spp.).[156,211,457]

Table 8.1 summarizes several publications that discuss the detection frequency of periodontopathogens in these different niches. Most species (with the exception of spirochetes) (Fig. 8.2L) are able to colonize all of them. Some periodontopathogens (e.g., *Fusobacterium nucleatum* [see Fig. 8.2G] and *Prevotella intermedia* [see Fig. 8.2H]) are involved in the etiology of tonsillitis, and most periodontopathogens are able to colonize the maxillary sinus.[37,426]

[c]Number of "specific" positive sites in patients with advanced periodontitis.

[d]Number of "specific" positive sites in positive patients before/after full-mouth extraction (e.g., two patients tested positive for *A. a.* before extraction, and no patients tested positive for *A. a.* after full-mouth extraction).

[e]Number of "specific" positive sites in positive patients before/after periodontal therapy including surgery (e.g., nine patients tested positive for *A. a.* before periodontal therapy as compared with only four patients after periodontal therapy).

[f]Percentage of total flora cultivable in anaerobically incubated agar in nonspecific patients as estimated from several studies.

A. a., Aggregatibacter actinomycetemcomitans; E, full-mouth extraction; *L., Lactobacillus* spp.; *P. g., Porphyromonas gingivalis; P. i., Prevotella intermedia; Prev., Prevotella* spp. (e.g., *P. melaninogenica, P. denticola, P. loescheii, P. veroralis*); *R,* periodontal therapy including surgery; *S. m., Streptococcus mutans; Spi,* spirochetes.

The soft tissue surfaces are actively involved in the process of bacterial adhesion and colonization.[153] They use a variety of mechanisms to prevent the adhesion of pathogenic organisms, with shedding being one of the most important.

Clinician's Corner

Is it necessary to brush the gums?

In essence, not. The epithelial cells are shed twice a day in a process known as *desquamation*, which is considered to be a natural cleansing mechanism. However, due to the morphology of the tongue and under removable prostheses, desquamated epithelial cells will not be flushed away by removal forces within the oral cavity. Brushing of these areas may therefore be recommended.

The host vaginal epithelial cells, for example, supply glucose for

the colonized lactobacilli, which in turn produce acid. A lowering of the pH prevents the growth of many other species that have deleterious effects on the vaginal environment.[334] As such, these endogenous bacteria and their products can be considered necessary and beneficial components of a healthy body.

In periodontal pockets, studies have shown high numbers of bacteria attached to pocket epithelial cells in vivo. Areas of gingival inflammation are characterized by an increased number of adhering bacteria.[86,420] These adhering bacteria can also infiltrate the pocket wall in relatively large numbers and reach the underlying stroma (Fig. 8.4).[104,244,345] In general, a positive correlation exists between the adhesion rate of pathogenic bacteria to different epithelia and the susceptibility of the affected patient to certain infections.[277]

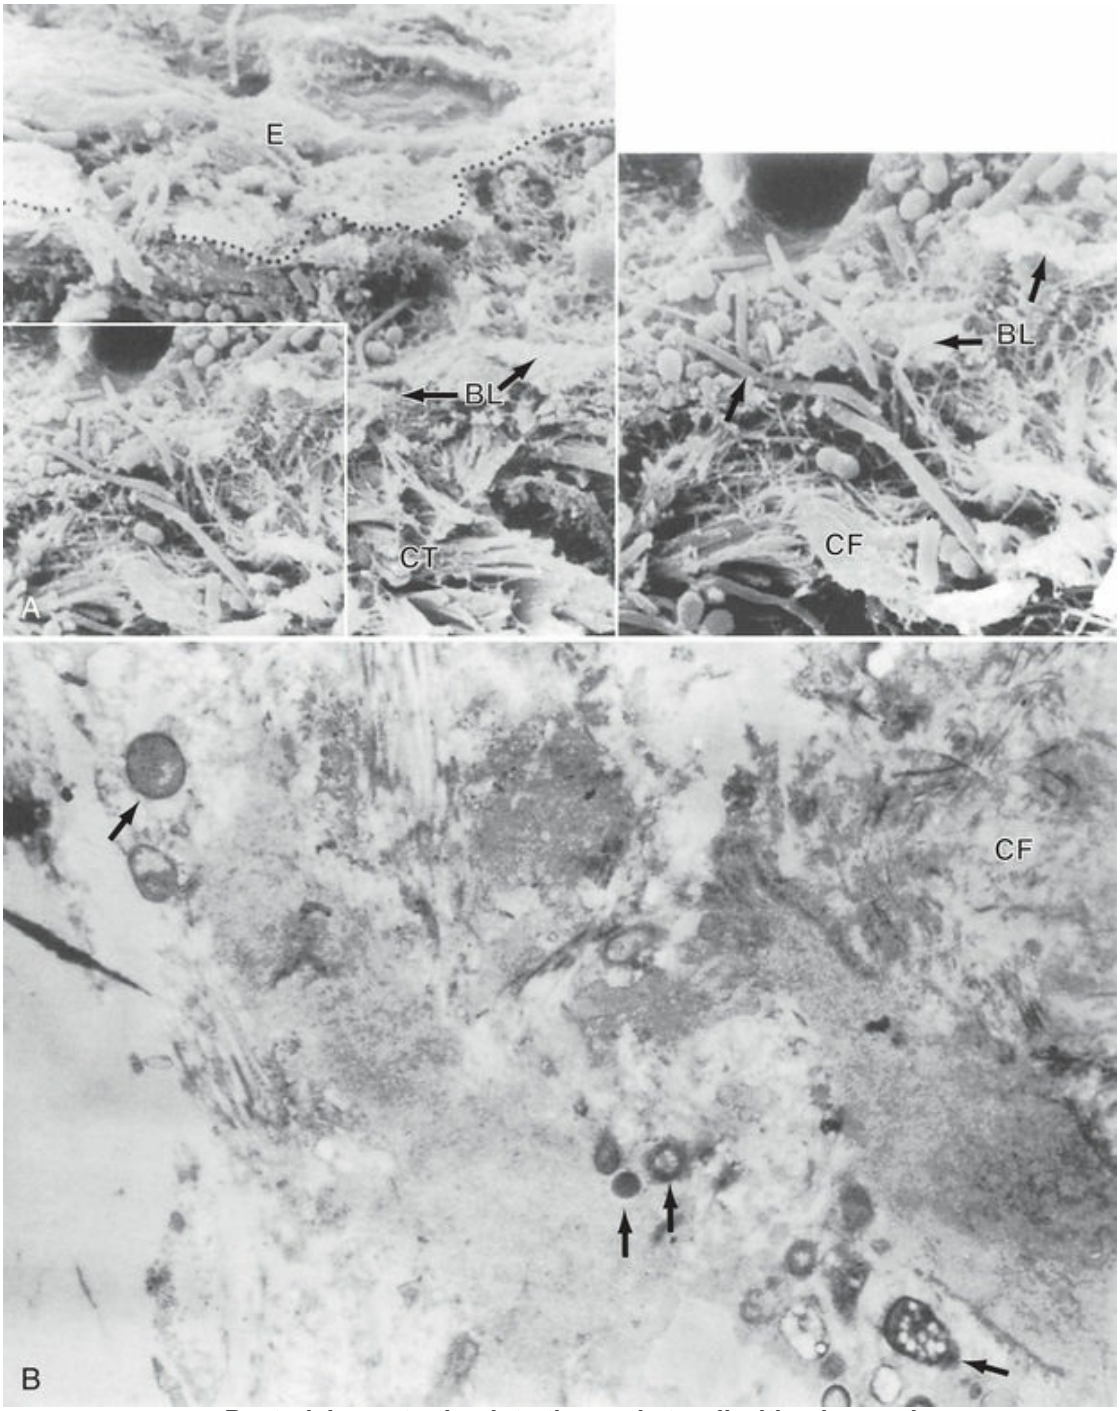

FIG. 8.4 Bacterial penetration into the pocket wall with advanced periodontitis. (A) Penetration through the pocket epithelium *(E)* and the basement lamina *(BL)* into the connective tissue *(CT) (arrows). CF,* Collagen fibers. (B) Connective-tissue–associated bacteria *(arrows)* in a patient with advanced periodontitis. ([A] Courtesy Dr. R. Saglie. [A] and [B] From Nissengard RJ, Newman MG: *Oral microbiology and immunology,* ed 2, Philadelphia, 1994, Saunders.)

Women prone to urinary tract infections, for example, harbor five times more bacteria per cell in adhesion assays of *Escherichia coli* to different epithelial cells of their urogenital tract (periurethral, vaginal, or uroepithelial cells). Similar observations have been

made regarding the adhesion of *Streptococcus pneumoniae* to nasopharyngeal epithelial cells of children prone to recurrent otitis media infections, as well as regarding the adhesion of *Haemophilus influenzae* to buccal cells of subjects prone to acute bronchitis.[71,403]

Some indications exist that the same may be true for periodontal infections. Isogai and coworkers[162] reported a significantly lower adherence rate of *P. gingivalis* and *P. intermedia* strains to gingival epithelial cells in rats that were resistant to gingivitis compared with susceptible rats. An in vitro study of cultured human pocket epithelial cells (Fig. 8.5) showed a similar tendency when patients who were resistant to periodontitis were compared with patients with severe periodontal breakdown.[314]

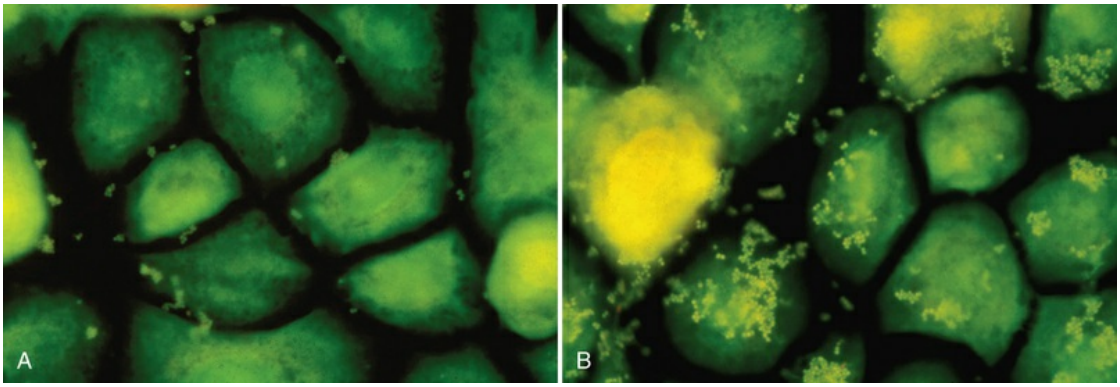

FIG. 8.5 ***Porphyromonas gingivalis*** **adhesion capacity differences. Microscopic confirmation of significant differences in the adhesion capacity of *P. gingivalis (small green dots)* to epithelial cells from (A) a resistant patient as compared with (B) a patient with severe periodontitis.**

Bacteria also adhere to hard tissues. In the human body, teeth and nails are the only naturally occurring nonshedding surfaces. Artificial nonshedding surfaces of medical importance include prosthetic devices such as catheters, artificial joints, dental implants, and heart valves. From a microbiologic viewpoint, teeth and implants are unique for two reasons: (1) they provide a hard, nonshedding surface that allows for the development of extensive structured bacterial deposits; and (2) they form a unique ectodermal interruption. A special seal of epithelium (junctional epithelium) and connective tissue is present between the external environment and the internal parts of the body. The accumulation and metabolism of bacteria on these hard surfaces are considered the

primary causes of caries, gingivitis, periodontitis, peri-implantitis, and, sometimes, bad breath.

In the periodontal pocket, different strategies contribute to bacterial survival, such as adhesion to the pocket epithelium and, when dentin is encountered, the colonization of the dentinal tubules.[305] The crevicular fluid with its constant outflow does not favor the maintenance of unattached bacteria in the periodontal pocket.

Investigators have suggested that teeth are the primary habitat for periodontopathogens because soon after a full-mouth tooth extraction in patients with severe periodontitis, key pathogens such as *A. actinomycetemcomitans* and *P. gingivalis* disappeared from the oral cavity, as determined by bacterial culturing techniques.[73] *P. intermedia* and other black-pigmented *Prevotella* spp. remained, but at lower detection frequencies and numbers (see Table 8.1).

The same applies to edentulous infants and wearers of full dentures in whom significant proportions of periodontopathogens have been recorded, with the exception of *A. actinomycetemcomitans* and *P. gingivalis*.[72,189] Therefore, teeth were considered as a "porte d'entrée" for periodontopathogens.

However, studies involving the use of molecular tools to detect and quantify oral bacteria seem to indicate that *A. actinomycetemcomitans* and *P. gingivalis* are not entirely eradicated after full-mouth extraction. They may remain colonizers of the oral cavity, but when teeth are lost, the relative numbers of these bacteria decrease.[318,320]

Key Fact

Hard surfaces such as teeth and dental implants are very important habitats for oral pathogens. However, they are by far not the only habitats.

Alternatively, cariogenic species were thought to be relatively restricted to solid surfaces (see Table 8.1). Therefore, *S. mutans* (Fig. 8.2M) was often considered an *obligate periphyte*.[402] In some studies, this species was detected only from the time that the deciduous teeth erupted in the oral cavity.[50] In a longitudinal observation of

adults with severe dental caries, the cariogenic species fell below detection level after full-mouth extraction but reappeared a few days after denture insertion.[51] On the basis of these reports and on their own observations, Caufield and Gibbons[54] concluded that most of the *S. mutans* cells in the saliva or on the tongue are derived from the biofilm present on the teeth and that the mucosae could not act as a reservoir for the infection of teeth by those organisms. These investigators suggested a "window of infectivity" for the acquisition of *S. mutans* at a mean age of 26 months (range, 9 to 44 months).[53] This observation has been supported by a few clinical studies, which showed that the initial colonization of *S. mutans* varied between 7 to 36 months, which is the time period that coincides with the eruption of the primary teeth.[7,49,106] Conversely, longitudinal studies by Wan and coworkers[431,432] and Law and Seow[209] showed that *S. mutans* colonization increased with the age of children, without any discrete window of infectivity. Clinical evidence now shows that *S. mutans* can be detected in the mouths of predentate children, before the eruption of the first tooth.[256,431,433]

Bacteria and Their Biofilm Mode of Living

To many people, the word *microbiologist* conjures images of someone in a laboratory coat swilling a flask of bacterial cells that are growing happily as pure cultures in nutrient-rich broth. In nature, bacteria rarely enjoy such an easy life. The major struggle faced by bacteria lies in obtaining sufficient nutrients to support growth. Competition is rife, and most microbial communities contain many different species, sometimes 100 or more, sharing the same site. Nutrients tend to concentrate at interfaces, and consequently the densest bacterial populations are located at interfaces of various kinds. In aquatic ecosystems, the major interfaces are the solid–liquid boundaries, such as the surfaces of submerged rocks or soil particles, and the air–water interface that is present in open systems, such as oceans or lakes. Bacteria grow well in the laboratory at the solid–gas interface on the surface of an agar plate. However, desiccation rapidly kills most bacterial cells, and

microbial growth at solid–gas interfaces is therefore generally restricted to areas where moisture is available. The human body provides several interfaces that support microbial populations, of which the most important in healthy individuals are the skin, gut, mouth, and female urogenital tract. As mentioned previously, the oral cavity is unusual in this regard because it provides hard, nonshedding surfaces (teeth) that are accessible for microbial colonization.

The importance of surfaces for microbial growth was recognized as early as the 1920s, when a number of workers independently noted that bacteria growing on glass slides submerged in soil were different from bacteria that could be cultured in broth.[208] However, it was not until around 50 years later that sessile microbial populations were considered to be sufficiently different from free-living microorganisms to merit their own name, and the term *biofilms* was coined (Fig. 8.6 and Fig. 8.7B and C). Biofilms are composed of microbial cells encased within a matrix of extracellular polymeric substances, such as polysaccharides, proteins, and nucleic acids.

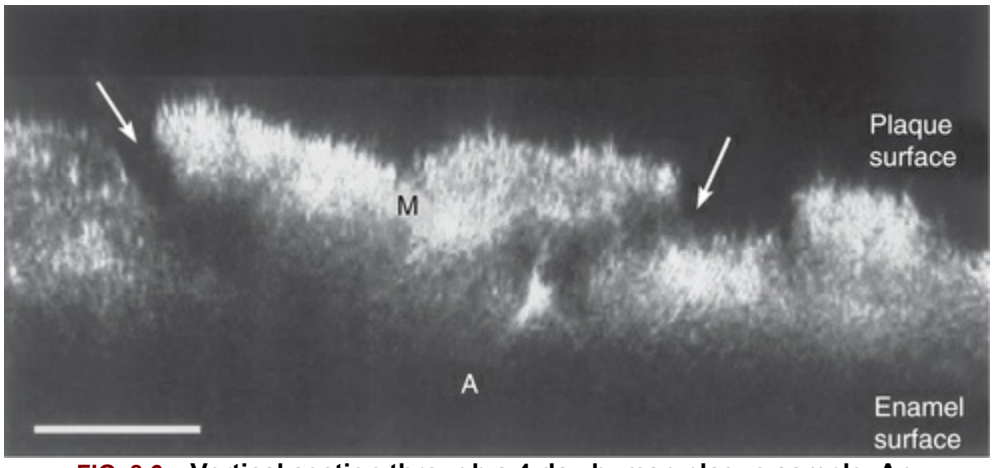

FIG. 8.6 Vertical section through a 4-day human plaque sample. An intraoral device designed for the in vivo generation of plaque biofilms on enamel was used. Confocal microscopy enabled the visualization of the section of plaque without the dehydration steps used in conventional histologic preparations. Notice the open fluid-filled channels *(arrows)* that traverse from the plaque surface through the bacterial mass (*M*; gray-white areas) to the enamel surface. An area in which the bacterial mass appears to attach to the enamel surface *(A)* is indicated. Scale bar = 25 µm. Biofilm bacteria are often up to 1000 times more resistant to antimicrobial agents than their planktonic counterparts.[9,96] Bacteria that grow in multispecies biofilms interact closely with neighboring

cells. Sometimes these interactions are mutually beneficial, as is the case when one organism removes another's waste products and uses them as an energy source.

In other instances, bacteria compete with their neighbors by secreting antibacterial molecules such as inhibitory peptides (bacteriocins) or hydrogen peroxide (H_2O_2) (Video 8.1). In addition, the biofilm mode of growth facilitates cell–cell signaling and deoxyribonucleic acid (DNA) exchange between bacteria. It is clear that microbial ecology within biofilm communities is highly complex and that, in many cases, knowledge is only emerging at this point.

Biofilms are heterogeneous: variations in biofilm structure exist within individual biofilms, between different types of biofilms, and between individuals[321] (Fig. 8.8). However, some structural features that are common to many biofilms have been noted. For example, biofilms frequently contain microcolonies of bacterial cells. Water channels are commonly found in biofilms, and these can form a primitive circulatory system that removes waste products and brings fresh nutrients to the deeper layers of the film. Surface structures, such as fronds, can dissipate the energy of fluid flowing over the biofilm and lead to the rapid blockage of vessels.[85] Mixed-species biofilms often have heterogeneity in the distribution of different species. Steep chemical gradients exist, such as those of oxygen or pH, and these produce distinct microenvironments within the biofilm.

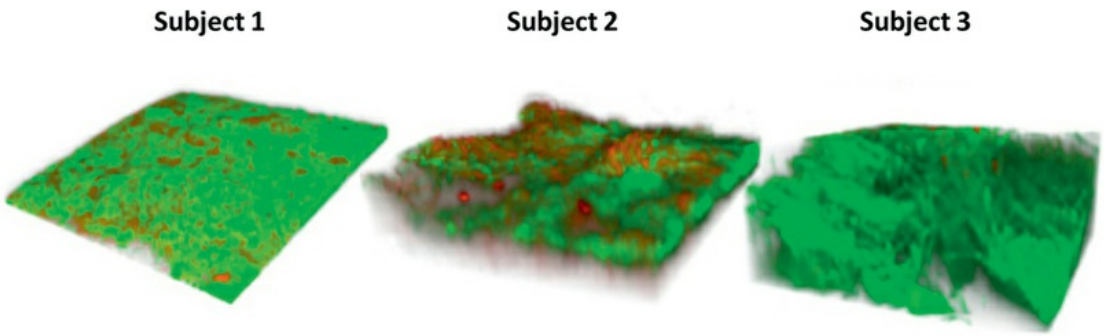

FIG. 8.8 Architecture of oral biofilms formed on enamel discs in situ in three subjects. Biofilms were allowed to develop on the enamel surfaces mounted on healing abutments in the oral cavity for 7 days. The abutments were then removed, stained with BacLight Live/Dead (ThermoFisher Scientific, Waltham, Mass.) staining, and visualized using confocal laser scanning microscopy. (Adapted from Rabe P, Twetman S,

Kinnby B, et al: Effect of fluoride and chlorhexidine digluconate mouthrinses on plaque biofilms. *Open Dent J* 31:106–11, 2015.)

Microbial populations on the surfaces of teeth (dental plaque) are excellent examples of biofilm communities (Fig. 8.9). The architecture of a dental plaque biofilm has many features in common with other biofilms. It is heterogeneous in structure, with clear evidence of open fluid-filled channels running through the plaque mass[64,65,449] (see Fig. 8.6). Nutrients make contact with the sessile (attached) microcolonies by diffusion from the water channels to the microcolony, rather than from the matrix. The bacteria exist and proliferate within the intercellular matrix through which the channels run. The matrix confers a specialized environment that distinguishes the bacteria that exist within the biofilm from those that are free floating; this is the so-called planktonic state in solutions such as saliva or crevicular fluid. The biofilm matrix functions as a barrier. Substances produced by bacteria within the biofilm are retained and concentrated, which fosters metabolic interactions among the different bacteria.

FIG. 8.9 Clinical picture of 10-day-old supragingival plaque. The first signs of gingival inflammation *(arrows)* are becoming visible.

The intercellular matrix consists of organic and inorganic materials derived from saliva, gingival crevicular fluid, and bacterial products.

Organic constituents of the matrix include polysaccharides, proteins, glycoproteins, lipid material, and DNA.[226] Albumin,

which probably originates from crevicular fluid, has been identified as a component of the plaque matrix. The lipid material consists of debris from the membranes of disrupted bacterial and host cells, bacterial vesicles, and possibly food debris. *Glycoproteins* from the saliva are important components of the pellicle that initially coats a clean tooth surface, but they also become incorporated into the developing plaque biofilm. Polysaccharides produced by bacteria also contribute to the organic portion of the matrix. They play a major role in maintaining the integrity of the biofilm.

The *inorganic components* of plaque are predominantly calcium and phosphorus, with trace amounts of other minerals such as sodium, potassium, and fluoride. The source of inorganic constituents of supragingival plaque is primarily saliva. As the mineral content increases, the plaque mass becomes calcified to form calculus (Fig. 8.10). Calculus is frequently found in areas of the dentition adjacent to salivary ducts (e.g., the lingual surface of the mandibular incisors and canines, the buccal surface of the maxillary first molars), and this reflects the high concentration of minerals available from saliva in those regions. The inorganic components of subgingival plaque are derived from crevicular fluid (a serum transudate). The calcification of subgingival plaque also results in calculus formation (Fig. 8.11). Subgingival calculus is typically dark green or dark brown, which probably reflects the presence of blood products that are associated with subgingival hemorrhage.

FIG. 8.10 **Supragingival calculus is depicted on the buccal surface of the maxillary molars adjacent to the orifice of the parotid duct.**

FIG. 8.11 **Dark-pigmented deposits of subgingival calculus on the distal root of an extracted lower molar.**

The importance of these biofilms for oral diseases, such as dental caries and periodontitis—together with the relative ease with which tooth surface biofilms can be accessed—has caused dental plaque to be one of the most highly studied biofilm systems. It is anticipated that, by understanding the mechanisms involved in the accumulation of dental plaque and the transition from health to disease, it will be possible to improve our control over these processes and to restrict plaque-associated oral diseases further.

Structure of a Mature Dental Plaque Biofilm

Dental plaque (see Fig. 8.9) is defined clinically as a structured, resilient, yellow-grayish substance that adheres tenaciously to the intraoral hard surfaces, including removable and fixed restorations.[30] The tough extracellular matrix makes it impossible to remove plaque by rinsing or with the use of sprays. Plaque can thus be differentiated from other deposits that may be found on the tooth surface, such as materia alba and calculus. *Materia alba* refers to soft accumulations of bacteria, food matter, and tissue cells that lack the organized structure of dental plaque and that are easily displaced with a water spray. *Calculus* is a hard deposit that forms via the mineralization of dental plaque and that is generally covered by a layer of unmineralized plaque (Table 8.2).

TABLE 8.2

Differences Between Tooth Deposits

Materia Alba	Dental Plaque	Calculus
• White, cheeselike accumulation	• Resilient clear to yellow-grayish substance	• Hard deposit that forms via the mineralization of dental plaque
• Soft accumulation of salivary proteins, some bacteria, many desquamated epithelial cells, and occasional disintegrating food debris	• Primarily composed of bacteria in a matrix of salivary glycoproteins and extracellular polysaccharides	• Generally covered by a layer of unmineralized dental plaque
• Lacks an organized structure and is therefore not as complex as dental plaque	• Considered to be a biofilm	
• Easily displaced with a water spray	• Impossible to remove by rinsing or with the use of sprays	

Dental plaque is composed primarily of microorganisms. One gram of plaque (wet weight) contains approximately 10^{11} bacteria.[358,380] The number of bacteria in supragingival plaque on a single tooth surface can exceed 10^9 cells. In a periodontal pocket, counts can range from 10^3 bacteria in a healthy crevice to more than 10^8 bacteria in a deep pocket. With the use of highly sensitive molecular techniques for microbial identification, it has been estimated that more than 750 distinct microbial phylotypes can be present as natural inhabitants of dental plaque.[1]

Any individual may harbor hundreds of different species. Next to bacteria, nonbacterial organisms can also be found in the dental plaque biofilm, including archaea, yeasts, protozoa, and viruses.[62,217]

Clinician's Corner

Is it possible to remove dental plaque by rinsing?

The biofilm nature of dental plaque means that it tenaciously adheres to surfaces. Therefore it cannot be removed by rinsing or sprays.

Dental plaque is broadly classified as supragingival or subgingival on the basis of its position on the tooth surface toward the gingival margin.

- *Supragingival plaque* is found at or above the

gingival margin; when in direct contact with the gingival margin, it is referred to as *marginal plaque.*
• *Subgingival plaque* is found below the gingival margin, between the tooth and the gingival pocket epithelium.

Supragingival plaque typically demonstrates the stratified organization of a multilayered accumulation of bacterial morphotypes (Fig. 8.12).[462] Gram-positive cocci and short rods predominate at the tooth surface, whereas gram-negative rods, filaments, and spirochetes predominate in the outer surface of the mature plaque mass.

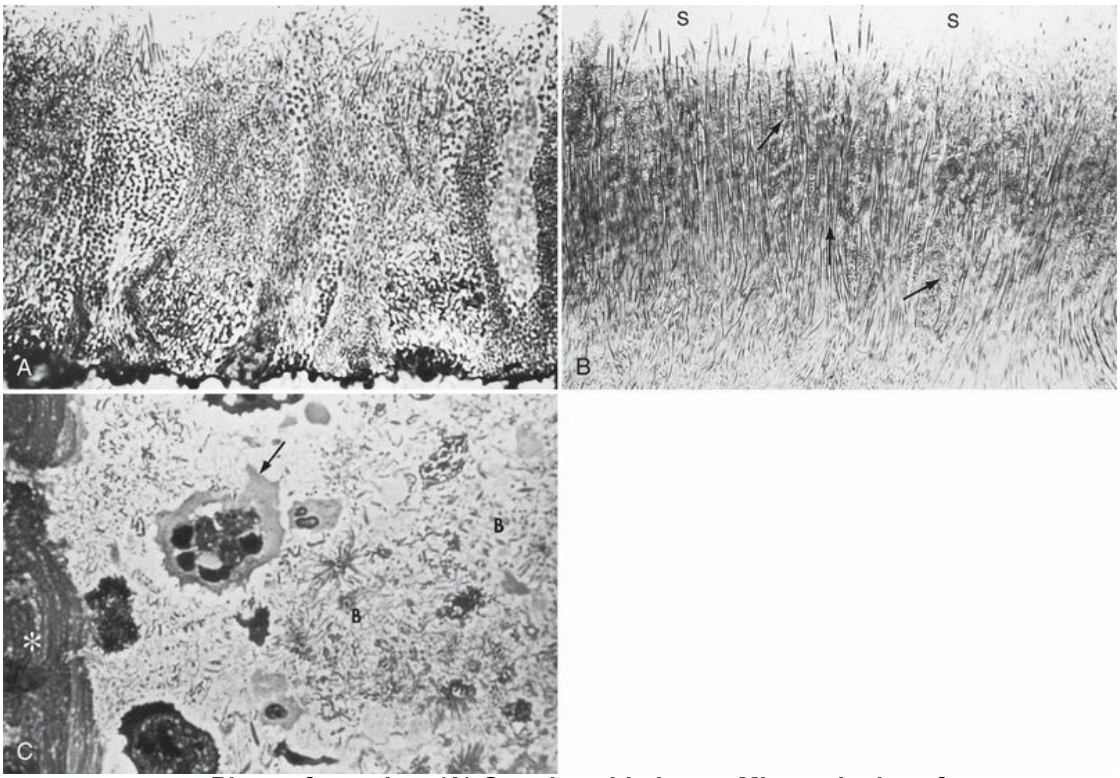

FIG. 8.12 Plaque formation. (A) One-day-old plaque. Microcolonies of plaque bacteria extend perpendicularly away from the tooth surfaces. (B) Developed supragingival plaque showing the overall filamentous nature and the microcolonies *(arrows)* that extend perpendicularly away from the tooth surface. The saliva–plaque interface is shown *(S).* (C) A histologic section of plaque showing nonbacterial components such as white blood cells *(arrow)* and epithelial cells *(asterisk)* interspersed among bacteria *(B).* (Courtesy Dr. Max Listgarten, Philadelphia, Pa.)

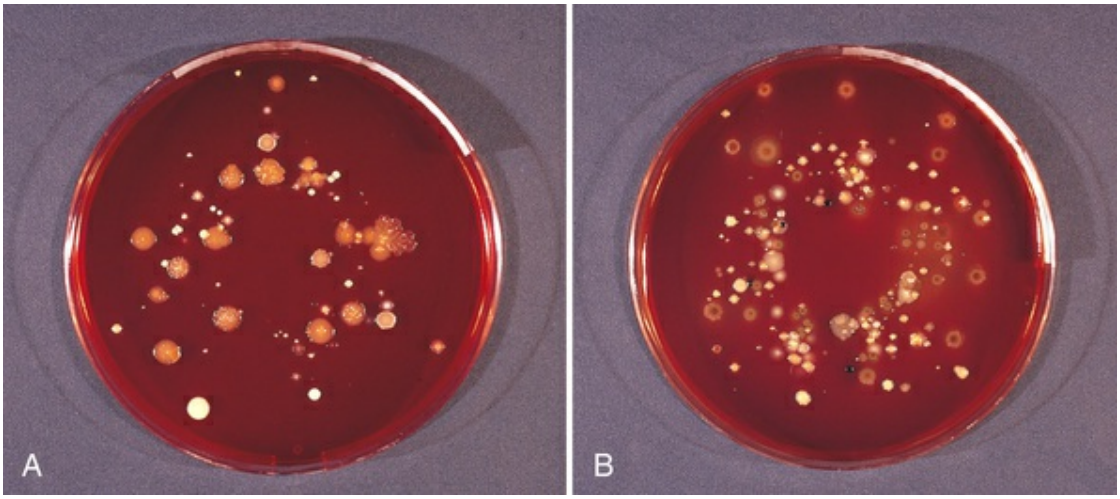
In general, the subgingival microbiota differs in composition from the supragingival plaque, primarily because of the local availability of blood products and a low reduction–oxidation (redox) potential, which characterizes the anaerobic environment.

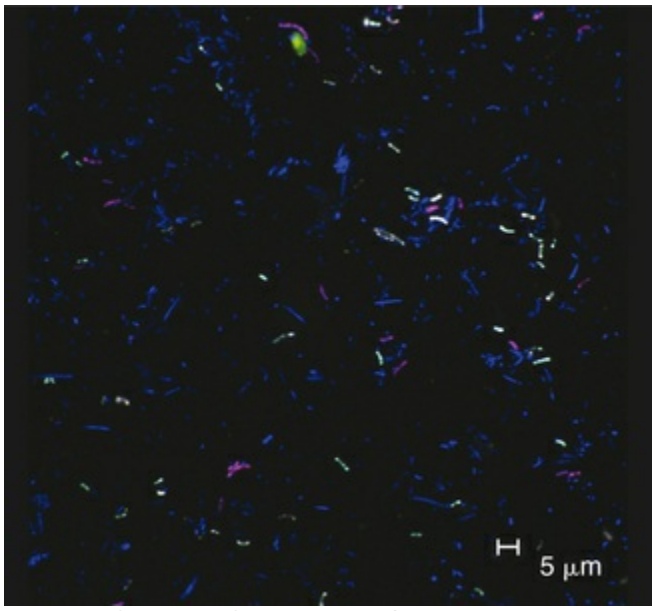
Many periodontopathogens are fastidious strict anaerobes and as such may contribute little to the initiation of disease in shallow gingival pockets. In deep periodontal pockets, however, they find their preferred habitat.

The identification of bacteria within intact dental plaque represents a significant challenge. Most of the previously cited studies of dental plaque microbiota used techniques that involved the disruption of the dental plaque matrix followed by microbial culture (eFig. 8.1) or culture-independent identification. Techniques have been developed that allow for the specific visualization of individual bacteria within mixed populations. With these methods, specific labeling is achieved by using nucleic acid probes (fluorescence in situ hybridization [FISH]) or specific antibodies (immunofluorescence). FISH has been applied to identify particular species within plaque samples scraped from periodontal pockets.[116,279,423] With this methodology, it is even possible to image bacteria that have never been cultured in the laboratory, such as members of the phylum Synergistetes (eFig. 8.2). Intact subgingival biofilms (eFig. 8.3) have also been analyzed by FISH and shown to be composed of a heterogeneous structure with organisms such as *Actinomyces* spp. at the base, *F. nucleatum* and *Tannerella forsythia* in the middle layers, and periodontopathogens including members of the *Cytophaga–Flavobacterium–Bacteroides* cluster in the outer layers.[462] Supragingival biofilms have proved somewhat easier to visualize than subgingival plaque (eFig. 8.4), and they have a somewhat different architecture.[462] Biofilms can be cultured on retrievable enamel chips held in intraoral devices in the mouths of volunteers. The enamel pieces can then be removed and processed for FISH or immunofluorescence. Images of biofilms can be captured by confocal laser scanning microscopy, which produces three-dimensional representations of the biofilm architecture. Labeling with nucleic acid probes requires the desiccation of the sample before hybridization, and therefore some structural information may be lost. Nevertheless, this technique has been

applied successfully to determine the spatial relationships between *Actinomyces naeslundii* and *Streptococcus* spp. in dental plaque.[82]

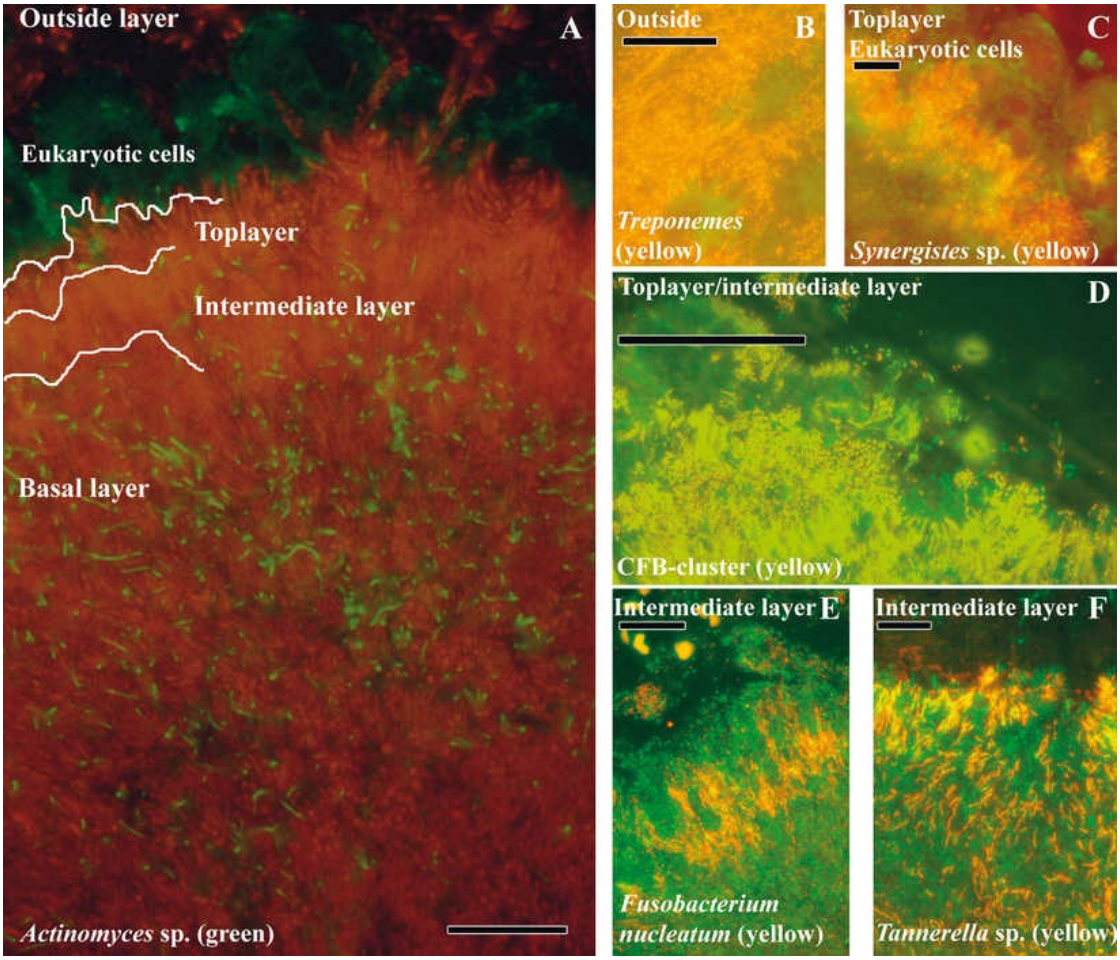


EFIG. 8.1 **Aerobic versus anaerobic plaque bacteria. A plaque sample grown under (A) aerobic and (B) anaerobic conditions. A comparison of the culture plates shows different bacteria and different colony morphologies.**

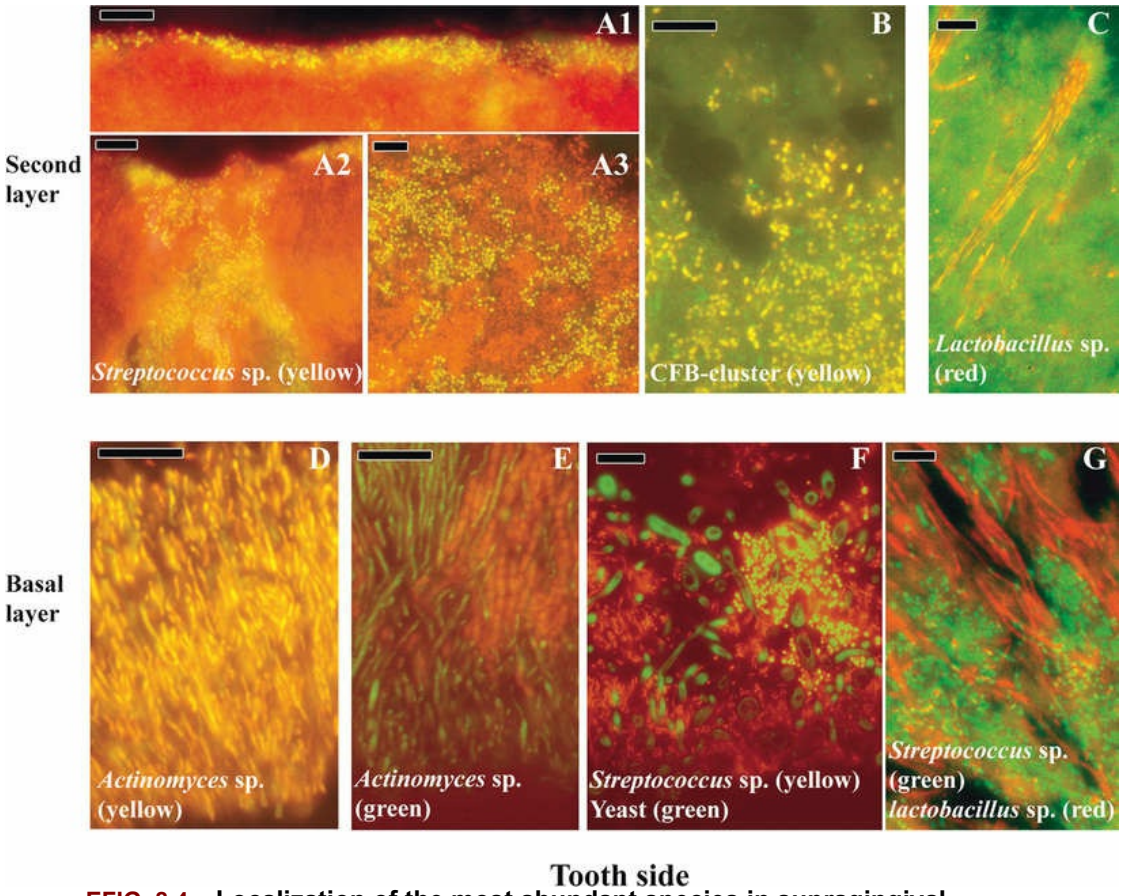


EFIG. 8.2 **Identification of uncultured Synergistetes in subgingival dental plaque. Plaque was removed from deep (6 to 10 mm) periodontal pockets of volunteers with localized or generalized severe periodontitis. Bacteria were transferred to microscope slides, and intracellular DNA was hybridized with nucleic acid probes for all eubacteria (blue), Synergistetes cluster A (red), or a specific member of the Synergistetes cluster A, "3.3/BH007" (green). Synergistetes 3.3/BH007 appear white (blue + red + green), whereas other members**

of Synergistetes cluster A appear purple (blue + red). Synergistetes cluster A members were commonly detected in healthy and periodontally diseased sites, even though these organisms have never been cultured in the laboratory. (Courtesy S.R. Vartoukian and W.G. Wade, King's College London Dental Institute, London. For more information, see Vartoukian SR, Palmer RM, Wade WG: Diversity and morphology of members of the phylum "synergistetes" in periodontal health and disease. *Appl Environ Microbiol* 75:3777, 2009.)



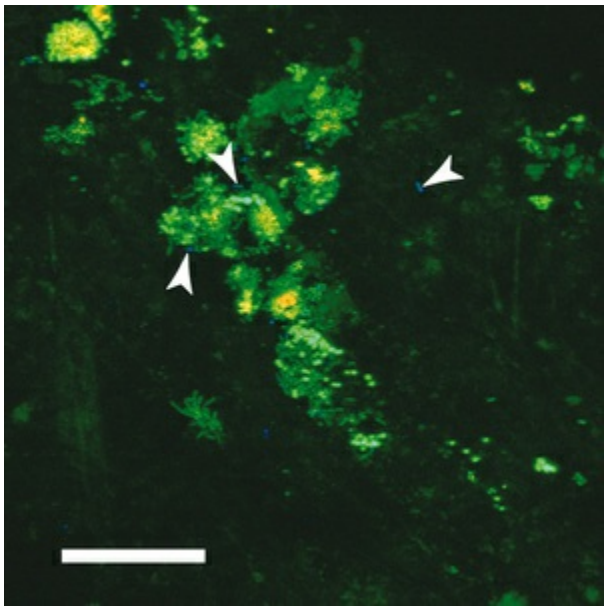
EFIG. 8.3 Localization of the most abundant species in subgingival biofilms. (A) Overview of the subgingival biofilm with *Actinomyces* spp. (green bacteria), bacteria (red), and eukaryotic cells (large green cells on top). (B) Spirochetes (yellow) outside the biofilm. (C) Detail of Synergistetes (yellow) in the top layer in close proximity to eukaryotic cells (green). (D) *Cytophaga–Flavobacterium–Bacteroides* cluster (CFB-cluster) (yellow) in the top and intermediate layer. (E) *Fusobacterium nucleatum* in the intermediate layer. (F) *Tannerella* spp. (yellow) in the intermediate layer. Each panel is double stained with probe EUB338 labeled with fluorescein isothyocyanate (FITC) or cyanine 3 (Cy3). The yellow color results from the simultaneous staining with FITC- and Cy3-labeled probes. Bars = 10 µm. (From Zijnge V, van Leeuwen MB, Degener JE, et al: Oral biofilm architecture on natural teeth, *PLoS ONE* 5[2]:e9321, 2010.)



EFIG. 8.4 **Localization of the most abundant species in supragingival biofilms. (A1) *Streptococcus* spp. (yellow) form a thin band on top of the biofilm that (A2) almost engulfs the biofilm or that (A3) manifests as small cells scattered throughout the top layer of the biofilm. (B) Cells from the *Cytophaga–Flavobacterium–Bacteroides* (CFB) cluster of bacteria in the top layer of the biofilm, without defined structure. (C) *Lactobacillus* spp. (red) forming long strings through the top layer. (D) *Actinomyces* spp. (yellow) plaque attached to the tooth. (E) *Actinomyces* spp. (green) and cocci forming initial plaque. (F) Multispecies initial plaque composed of *Streptococcus* spp. (yellow), yeast cells (green), and unidentified bacteria (red). (G) *Streptococcus* spp. (green) and *Lactobacillus* spp. (red) forming initial plaque. The black holes may be channels through the biofilm. A, B, C, E, and F are double stained with probe EUB338 labeled with fluorescein isothyocyanate (FITC) or cyanine 3 (Cy3). Bars = 10 µm.** (From Zijnge V, van Leeuwen MB, Degener JE, et al: Oral biofilm architecture on natural teeth, *PLoS ONE* 5[2]:e9321, 2010.)

In these studies, *A. naeslundii* cells were frequently observed juxtaposed to *Streptococcus* spp. cells. Many strains of *Actinomyces* coaggregate with oral streptococci, and therefore the spatial organization of these organisms within dental plaque may be influenced by adhesin–receptor interactions.[185] In fact, a protein adhesin of *A. naeslundii* has been shown to colocalize with a cognate oral streptococcal receptor polysaccharide in in situ biofilms using specific antibody (immunofluorescence) labeling (eFig. 8.5).[282] An

extended FISH technique, known as combinatorial labeling and spectral imaging FISH (CLASI-FISH), has been used to visualize interactions among 10 different taxa in dental plaque scraped from the surface of teeth.[245] From these images, *Corynebacterium* spp. were shown to form a framework for interactions in dental plaque, extending from the tooth surface through to outer layers of the biofilm. Overall, these studies clearly demonstrate that the interactions identified among bacteria isolated in the laboratory are relevant to the dental plaque biofilm.



EFIG. 8.5 Visualization of specific bacteria in dental plaque biofilms with the use of specific antisera. Biofilms were developed on the surface of enamel chips held in the mouths of volunteers for 8 hours. Samples were labeled with acridine orange (stains all bacteria green), antibodies against streptococcal cell surface polysaccharides (orange), and antibodies against *Actinomyces oris* type 1 fimbriae (blue). *A. oris* cells (some indicated by *white arrowheads*) and polysaccharide-bearing streptococci can be seen in juxtaposition with other bacteria, thus indicating that mixed-species interactions are common in dental plaque biofilms. Bar = 20 µm. (Courtesy R.J. Palmer Jr, National Institute of Dental and Craniofacial Research, Bethesda, Md.)

The environmental parameters of the subgingival region differ from those of the supragingival region. The gingival crevice or pocket is bathed by the flow of crevicular fluid, which contains many substances that bacteria may use as nutrients. Host inflammatory cells and mediators are likely to have considerable influence on the establishment and growth of bacteria in the

subgingival region. Both morphologic and microbiologic studies of subgingival plaque reveal distinctions between the tooth-associated regions and the soft tissue–associated regions of subgingival plaque (see Fig. 8.7A to C).[222,268]

Key Fact

The specific microbial composition and structure of dental biofilms are highly dependent on the region of the tooth and the local environmental parameters.

The tooth-associated cervical plaque that adheres to the root cementum does not markedly differ from that observed in gingivitis. At this location, filamentous microorganisms dominate, but cocci and rods also occur. This plaque is dominated by gram-positive rods and cocci, including *S. mitis*, *S. sanguinis*, *Actinomyces oris*, *Actinomyces naeslundii*, and *Eubacterium* spp. (see Fig. 8.2N). However, in the deeper parts of the pocket, the filamentous organisms become fewer in number; in the apical portion, they seem to be virtually absent. Instead, the microbiota is dominated by smaller organisms without a particular orientation.[222] The apical border of the plaque mass is separated from the junctional epithelium by a layer of host leukocytes, and the bacterial population of this apical-tooth–associated region shows an increased concentration of gram-negative rods (see Fig. 8.7D).

The layers of microorganisms that face the soft tissue lack a definite intermicrobial matrix and contain primarily gram-negative rods and cocci, as well as large numbers of filaments, flagellated rods, and spirochetes. Studies of plaque associated with crevicular epithelial cells indicate a predominance of species such as *S. oralis*, *S. intermedius*, *Parvimonas micra* (formerly *Micromonas micra* and *Peptostreptococcus micros*), *P. gingivalis*, *P. intermedia*, *Tannerella forsythia* (see Fig. 8.12), and *F. nucleatum*.[81,86] Host-tissue cells (e.g., white blood cells, epithelial cells) may also be found in this region (see Fig. 8.12C). Bacteria are also found within the host tissues, such as in the soft tissues (see Fig. 8.4), and within epithelial cells (Fig. 8.13), as well as in the dentinal tubules (Fig. 8.14).[344,345]

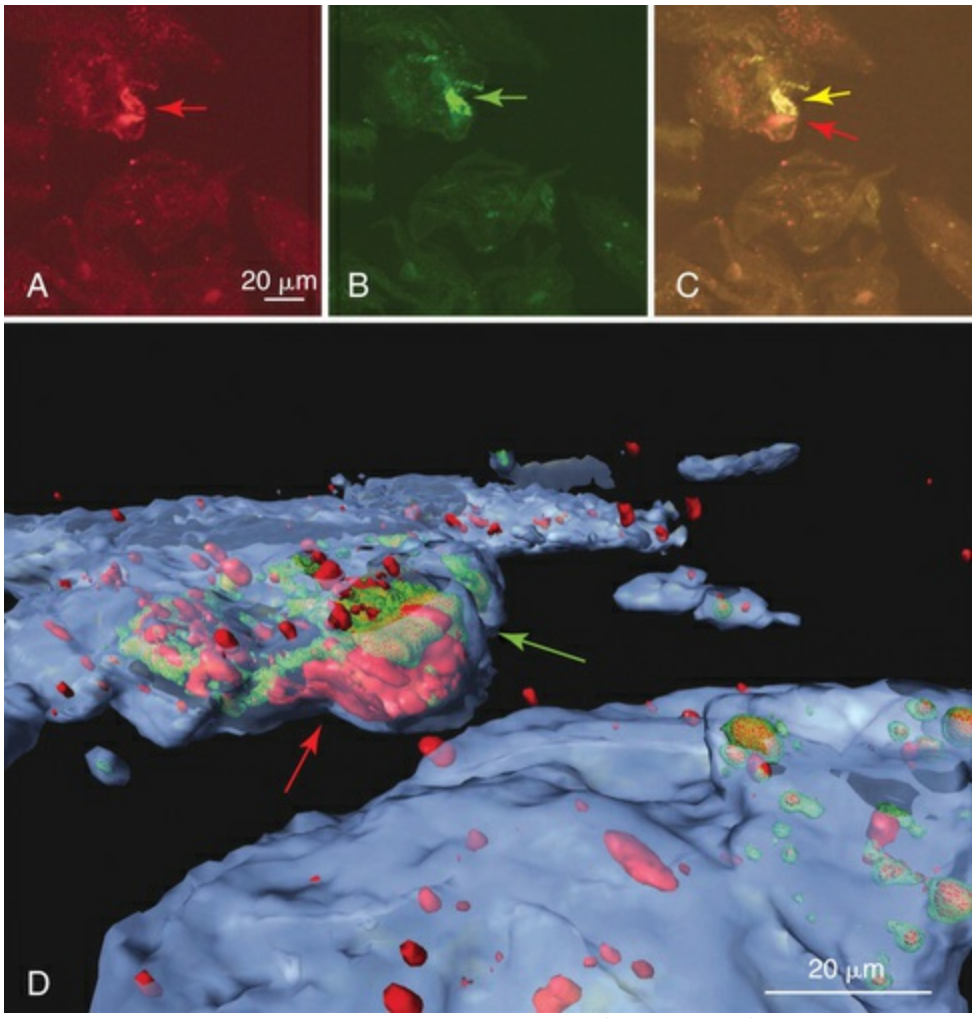


FIG. 8.13 **Bacteria in epithelial cells. (A) to (C) Images of z-section no. 39 from a stack of 74 0.2-μm z-sections (×600; the scale bar in [A] also applies to [B] and [C]). Buccal epithelial cells in this field were double-labeled with (A) the EUB338 universal probe and (B) the *Aggregatibacter actinomycetemcomitans*–specific probe. The cell in the center of (A) contained a large mass of brightly fluorescent intracellular bacteria *(red arrow).* Other cells in the field contained smaller bacterial masses (not marked). (B) A portion of the large mass labeled with the universal probe also hybridized with the *A. actinomycetemcomitans*–specific probe *(green arrow).* Images from (A) and (B) were superimposed in (C) to confirm that bacteria labeled with both probes *(yellow arrow)* were adjacent to other bacteria labeled only with the universal probe *(red arrow).* (D) Three-dimensional reconstruction of the same field. Bacteria recognized only by the universal probe are shown in solid red, whereas the colocalization of the *A. actinomycetemcomitans* and universal probes is depicted by a green wireframe over a red interior. Reconstructed buccal epithelial cell surfaces are presented in blue. The red and green colors are muted when bacterial masses are intracellular and brighter when bacteria appear to project out of the surface. The angle of view was rotated along the z-axis, and the image was zoomed. The large mass that appeared to have a lobular structure in z-section no. 39 was seen to be a cohesive unit that contained *A. actinomycetemcomitans* in direct proximity to other species *(red and green arrows).*** (From Rudney JD, Chen R, Sedgewick GJ: *Actinobacillus actinomycetemcomitans, Porphyromonas gingivalis*, and *Tannerella forsythensis* are components of a polymicrobial intracellular flora within human buccal

cells. *J Dent Res* 84:59–63, 2005.)

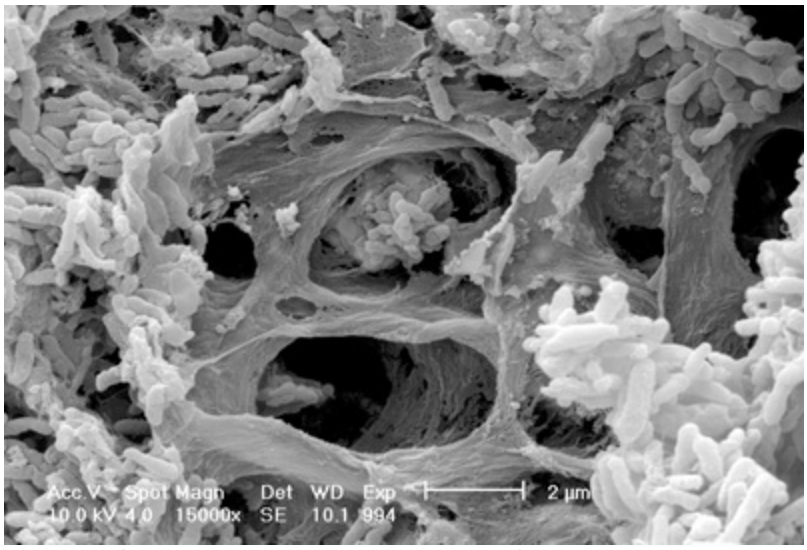

FIG. 8.14 **Scanning electron micrograph of bacteria within dentinal tubules.**

The composition of the subgingival plaque depends on the pocket depth. The apical part is more dominated by spirochetes, cocci, and rods, whereas in the coronal part more filaments are observed.

The site specificity of plaque is significantly associated with diseases of the periodontium. Marginal plaque, for example, is of prime importance during the initiation and development of gingivitis. Supragingival plaque and tooth-associated subgingival plaque are critical in calculus formation and root caries, whereas tissue-associated subgingival plaque is important in the tissue destruction that characterizes different forms of periodontitis. Biofilms also establish on artificial surfaces exposed to the oral environment, such as prostheses and implants.

Accumulation of a Dental Plaque Biofilm

The process of plaque formation can be divided into several phases: (1) the formation of the pellicle on the tooth surface, (2) the initial adhesion/attachment of bacteria, and (3) colonization/plaque maturation.

Formation of the Pellicle

All surfaces in the oral cavity, including the hard and soft tissues, are coated with a layer of organic material known as the acquired pellicle. The pellicle on tooth surfaces consists of more than 180 peptides, proteins, and glycoproteins, including keratins, mucins, proline-rich proteins, phosphoproteins (e.g., statherin), histidine-rich proteins, and other molecules that can function as adhesion sites (receptors) for bacteria.[366,367,453] The salivary pellicle can be detected on clean enamel surfaces within 1 minute after their introduction into the mouths of volunteers.[143] By 2 hours, the pellicle is essentially in equilibrium between adsorption and detachment, although further pellicle maturation can be observed for several hours.

Transmission electron microscopy shows the pellicle to be composed of two layers: a thin basal layer that is very difficult to remove, even with harsh chemical and mechanical treatments, and a thicker globular layer, up to 1 μm or more, that is easier to detach.[143,144] From these observations, it can be concluded that dental enamel is permanently covered with an acquired pellicle from the moment that teeth erupt.

Consequently, bacteria that adhere to tooth surfaces do not contact the enamel directly but interact with the acquired enamel pellicle. However, the pellicle is not merely a passive adhesion matrix. Many proteins retain enzymatic activity when they are incorporated into the pellicle, and some of these, such as peroxidases, lysozyme, and α-amylase, may affect the physiology and metabolism of adhering bacterial cells.[138,140–142]

In addition, a close ecologic relationship between the pellicle and its associated microbiology seems to exist. Walker and coworkers[429] reported that dental plaque samples produced in vitro biofilms only if the surface on which they were grown contained a salivary pellicle belonging to the patient who donated the plaque sample. No biofilm could be grown on a pellicle that came from a different subject.[429]

Initial Adhesion/Attachment of Bacteria

Colonization of a surface begins immediately after its introduction in the oral cavity. Colonizing bacteria can be detected within 3

minutes after the introduction of sterile enamel into the mouth.[139]

The initial steps of transport and interaction with the surface are essentially nonspecific (i.e., they are the same for all bacteria). The proteins and carbohydrates that are exposed on the bacterial cell surface become important when the bacteria are in loose contact with the acquired enamel pellicle. The specific interactions between microbial cell surface "adhesin" molecules and receptors in the salivary pellicle determine whether a bacterial cell will remain associated with the surface. Only a relatively small proportion of oral bacteria possess adhesins that interact with receptors in the host pellicle, and these organisms are generally the most abundant bacteria in biofilms on tooth enamel shortly after cleaning. Over the first 4 to 8 hours, the genus *Streptococcus* tends to dominate, usually accounting for >20% of bacteria present.[82,273,427] Other bacteria that commonly present at this time include species that cannot survive without oxygen (obligate aerobes), such as *Haemophilus* spp. and *Neisseria* spp., as well as organisms that can grow in the presence or absence of oxygen (facultative anaerobes), including *Actinomyces* spp. and *Veillonella* spp.[1,79] These species are considered the "primary colonizers" of tooth surfaces. The primary colonizers provide new binding sites for adhesion by other oral bacteria. The metabolic activity of the primary colonizers modifies the local microenvironment in ways that can influence the ability of other bacteria to survive in the dental plaque biofilm. For example, by removing oxygen, the primary colonizers provide conditions of low oxygen tension that permit the survival and growth of obligate anaerobes.

The initial steps in colonization of teeth by bacteria occur in three phases. Phase 1 is transport to the surface, phase 2 is initial reversible adhesion, and phase 3 is strong attachment.

Phase 1: Transport to the Surface

The first stage involves the initial transport of the bacterium to the tooth surface. Random contacts may occur, for example, through Brownian motion (average displacement, 40 μm/hour), through sedimentation of microorganisms, through liquid flow (several orders of magnitude faster than diffusion), or through active bacterial movement (chemotactic activity). However, relatively few

oral bacteria are motile, and forces such as saliva flow or mechanical contact between oral soft tissues and teeth are almost certainly more important than swimming for bringing the primary colonizing bacteria into contact with teeth.

Phase 2: Initial Adhesion

The second stage results in an initial reversible adhesion of the bacterium. This is initiated when the bacterial cell comes into close proximity to the surface (separation distance, ≈50 nm). Long- and short-range forces, including van der Waals attractive forces and electrostatic repulsive forces, operate at this distance. The behavior of bacterial cells can be reasonably described by the Derjaguin–Landau–Verwey–Overbeek theory of colloid stability.[148] According to this theory, the total interaction energy (also called the *total Gibbs energy* [G_{TOT}]), is the sum of the attractive forces (G_A) and the electrostatic repulsion (G_R). At the physiologic ionic strength of saliva, the van der Waals forces result in a net attraction of bacterial cells at distances of tens of nanometers from the surface. Approximately 10 nm from the surface is a secondary net energy minimum. Electrostatic repulsion prevents bacterial cells from being even closer to the surface. At distances of approximately 10 nm from the surface, bacterial cells are reversibly bound. It is thought that stronger binding at this point is the consequence of interactions between bacterial adhesins and receptors in the salivary pellicle. It has been estimated that 10 to 50 ligand-receptor interactions are required to attain essentially irreversible binding of a bacterial cell to the pellicle.[44]

Although the Derjaguin–Landau–Verwey–Overbeek theory presents a neat picture of the initial stages of bacterial adhesion, in reality even these early steps in adhesion are extremely complex. Bacteria are not perfect spheres, and many cells possess structures, such as fimbriae, that protrude from the cell surface. Lewis acid–base interactions (hydrophobicity) also influence cell surface interactions.[148] In addition, microbial cell surfaces are not uniformly coated with a negative charge. Some regions of the cell surface may be positively charged, and, for these areas, electrostatic interactions with a negatively charged surface will tend to be attractive. Finally, observations of early dental plaque often show bacteria associated

with shed epithelial cells, thus indicating that host cells may act as transporters to bring bacteria into close proximity with the teeth. Therefore, it is difficult to predict how initial attachment will be affected by modifying the prevailing environment.

Phase 3: Strong Attachment

After initial adhesion, a firm anchorage between the bacterium and the surface is established. On a rough surface, bacteria are more protected against shear forces so that a change from reversible to irreversible binding may occur more easily and more frequently. The substratum surface free energy becomes important because the water film between the interacting surfaces has to be removed before short-range forces can be involved. The binding between the bacteria and the pellicle is mediated by specific adhesins on the bacterial cell surface (usually proteins) and complementary receptors (proteins, glycoproteins, or polysaccharides) in the acquired pellicle. Many proteins in the acquired pellicle can act as receptors for streptococci, including α-amylase, acid proline-rich proteins, statherin, and salivary agglutinin glycoprotein gp340.[353] The specific adhesins of primary colonizing bacteria have been the subject of many investigations because these represent potential targets for interference with the formation of dental plaque. One of the best-characterized interactions is the binding between the antigen I/II family adhesins of oral streptococci and gp340.[166,167,301] Antigen I/II family adhesins are 160- to 180-kDa proteins expressed on the surfaces of many oral streptococci, including *S. mutans, S. sobrinus* (see Fig. 8.2P), *S. gordonii,* and *S. intermedius.* Gp340 is present in fluid-phase saliva, and it is a component of the salivary pellicle. In the fluid phase, interactions between antigen I/II proteins and gp340 result in the aggregation of bacteria. Large clumps of bacterial cells do not stick well to surfaces, and they are probably removed by swallowing.[220] By contrast, bacterial binding to immobilized gp340 results in the retention of cells within the biofilm. Interestingly, the recognition of fluid-phase and immobilized gp340 by streptococci appears to involve different mechanisms.[235] It is likely that gp340 changes its conformation after adhesion to a surface and thus exposes different receptors for bacterial binding. Similar conformational changes have been noted

for a number of host proteins, including proline-rich proteins and statherin.[93,117] The selective binding of fluid-phase or surface-bound proteins may modulate the ability of bacterial cells to colonize salivary pellicle-coated surfaces.

Colonization and Plaque Maturation

The primary colonizing bacteria (Table 8.3) adhered to the tooth surface provide new receptors for attachment by other bacteria as part of a process known as *coadhesion*.[185] Together with the growth of adherent microorganisms, coadhesion leads to the development of microcolonies (Fig. 8.15) and eventually to a mature biofilm.

TABLE 8.3
Overview of Primary and Secondary Colonizers in Dental Plaque

Primary colonizers	*Streptococcus gordonii*
	Streptococcus intermedius
	Streptococcus mitis
	Streptococcus oralis
	Streptococcus sanguinis
	Actinomyces gerencseriae
	Actinomyces israelii
	Actinomyces naeslundii
	Actinomyces oris
	Aggregatibacter actinomycetemcomitans serotype a
	Capnocytophaga gingivalis
	Capnocytophaga ochracea
	Capnocytophaga sputigena
	Eikenella corrodens
	Actinomyces odontolyticus
	Veillonella parvula
Secondary colonizers	*Campylobacter gracilis*
	Campylobacter rectus
	Campylobacter showae
	Eubacterium nodatum
	Aggregatibacter actinomycetemcomitans serotype b
	Fusobacterium nucleatum spp. *nucleatum*
	Fusobacterium nucleatum spp. *vincentii*
	Fusobacterium nucleatum spp. *polymorphum*
	Fusobacterium periodonticum
	Parvimonas micra
	Prevotella intermedia
	Prevotella loescheii
	Prevotella nigrescens
	Streptococcus constellatus
	Tannerella forsythia
	Porphyromonas gingivalis

	Treponema denticola

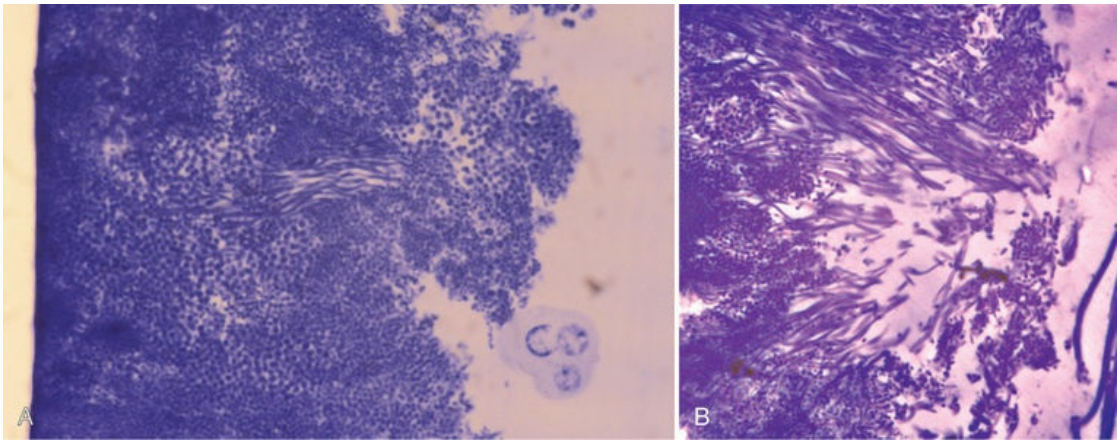

FIG. 8.15 **Dental plaque. (A) and (B) When a single microorganism adheres to the tooth surface, it can start to multiply, and it slowly forms a microcolony of daughter cells. These views were taken after plaque formation on a plastic strip (e.g., as shown in Fig. 8.20) glued to a tooth surface.**

Cell–cell adhesion between genetically distinct oral bacteria also occurs in the fluid phase (i.e., in saliva). In the laboratory, interactions between genetically distinct cells in suspension result in clumps or coaggregates that are macroscopically visible (Fig. 8.16).

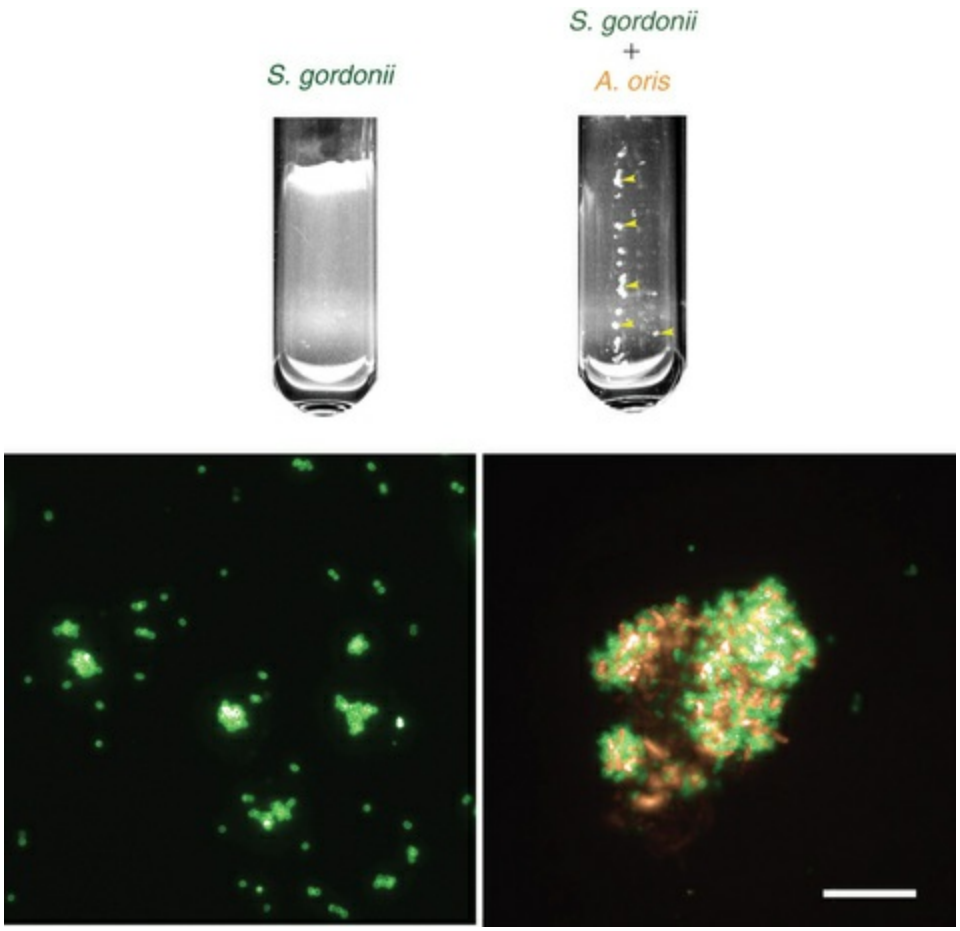

FIG. 8.16 Coaggregation. Coaggregation between *Streptococcus gordonii* DL1 and *Actinomyces oris* MG1 in vitro. A monoculture of *S. gordonii* appears uniformly turbid. Microscopically, cells labeled with specific anti-DL1 antibodies (green) are in small chains or clumps. After the addition of *A. oris,* cells clump together to form macroscopic coaggregates *(yellow arrowhead).* Under the microscope, *S. gordonii* (green) are evenly distributed throughout the coaggregates with *A. oris* (orange). Bar = 20 µm. (Image reproduced in part from Jakubovics NS, Gill SR, Iobst SE, et al: Regulation of gene expression in a mixed-genus community: stabilized arginine biosynthesis in *Streptococcus gordonii* by coaggregation with *Actinomyces naeslundii. J Bacteriol* 190:3646, 2008.)

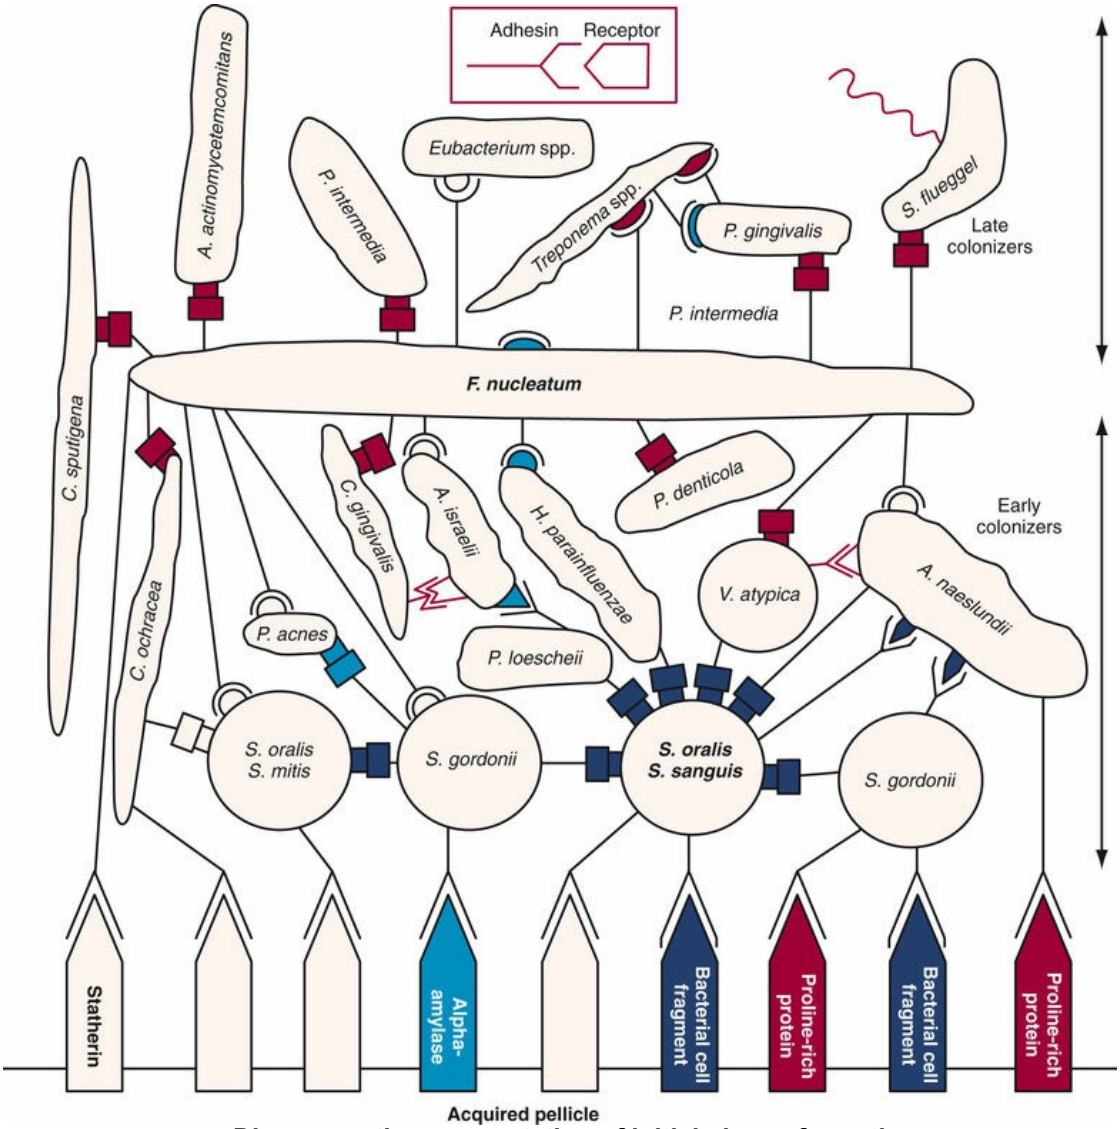
Coaggregation is a direct interaction; it is distinct from agglutination, which occurs when cells are stuck together by molecules in solution. At least 18 genera from the oral cavity have shown some form of coaggregation.[183] All oral bacteria possess surface molecules that foster some sort of cell–cell interaction (eFig. 8.6).[184] The initial stages of coaggregation or coadhesion are essentially the same as the first steps involved in bacterial binding to surfaces: bacterial cells come into contact through passive or active transport and bind weakly through nonspecific hydrophobic, electrostatic, and van der Waals forces.[84,102,179,184] These steps can be dramatically accelerated in vitro by vigorously mixing dense

suspensions of bacterial cells.[185] Strong cell–cell binding is then determined by the presence of adhesin proteins or carbohydrates on one partner and complementary receptor proteins or carbohydrates on the other. Note that adhesin–receptor interactions are mediated by the fundamental physicochemical forces (i.e., hydrophobic, electrostatic, and van der Waals), but they are highly specific.



EFIG. 8.6 **Diagrammatic representation of initial plaque formation. Early colonizers bind to receptors in the pellicle. Each adherent cell becomes in turn the nascent surface and bridge for additional species (secondary colonizers). The complementary sets of adhesin receptor symbols (example in box) represent the various kinds of coaggregations as well as the interactions with molecules in the pellicle. The symbol with a stem (adhesin) represents a cellular component that is heat inactivated (cell suspension heated to 85°C for 30 minutes) and sensitive to protease treatment. The cell type that**

exhibits the complementary symbol (receptor) is insensitive to either treatment. The symbols with a rectangular shape represent lactose-inhibitable coaggregations; the others are lactose noninhibitable. A. actinomycetemcomitans, *Aggregatibacter actinomycetemcomitans;* A. israelii, *Actinomyces israelii;* A. naeslundii, *Actinomyces naeslundii;* C. gingivalis, *Capnocytophaga gingivalis;* C. ochracea, *Capnocytophaga ochracea;* C. sputigena, *Capnocytophaga sputigena;* F. nucleatum, *Fusobacterium nucleatum;* H. parainfluenzae, *Haemophilus parainfluenzae;* P. acnes, *Propionibacterium acnes;* P. denticola, *Prevotella denticola;* P. gingivalis, *Porphyromonas gingivalis;* P. loescheii, *Prevotella loescheii;* S. flueggel, *Selenomonas flueggei;* S. gordonii, *Streptococcus gordonii;* S. mitis, *Streptococcus mitis;* S. oralis, *Streptococcus oralis;* S. sanguis, *Streptococcus sanguis;* V. atypica, *Veillonella atypica*. (Adapted from Kolenbrander PE, London J: Adhere today, here tomorrow: oral bacterial adherence. *J Bacteriol* 175:3247, 1993.)

Different species—or even different strains of a single species—have distinct sets of coaggregation partners (see eFig. 8.6 online). Fusobacteria coaggregate with all other human oral bacteria, whereas *Veillonella* spp., *Capnocytophaga* spp. (see Fig. 8.2Q), and *Prevotella* spp. bind with streptococci and/or actinomyces.[184,186,442] Each newly accreted cell becomes itself a new surface and therefore may act as a coaggregation bridge to the next potentially accreting cell type that passes by.

Many coaggregations among strains of different genera are mediated by lectin-like adhesins (proteins that recognize carbohydrates) and can be inhibited by lactose and other galactosides or by amino acids such as L-arginine. The significance of coaggregation in oral colonization has been documented in studies of biofilm formation in vitro as well as in animal model studies.[32,249]

Well-characterized interactions of secondary colonizers (see Table 8.3) with early colonizers include the coaggregation of *F. nucleatum* with *S. sanguinis, Prevotella loescheii* with *A. oris,* and *Capnocytophaga ochracea* with *A. oris.*[170,172,437–439] Streptococci show intrageneric coaggregation, which allows them to bind to the nascent monolayer of already bound streptococci.[155,181,274,368]

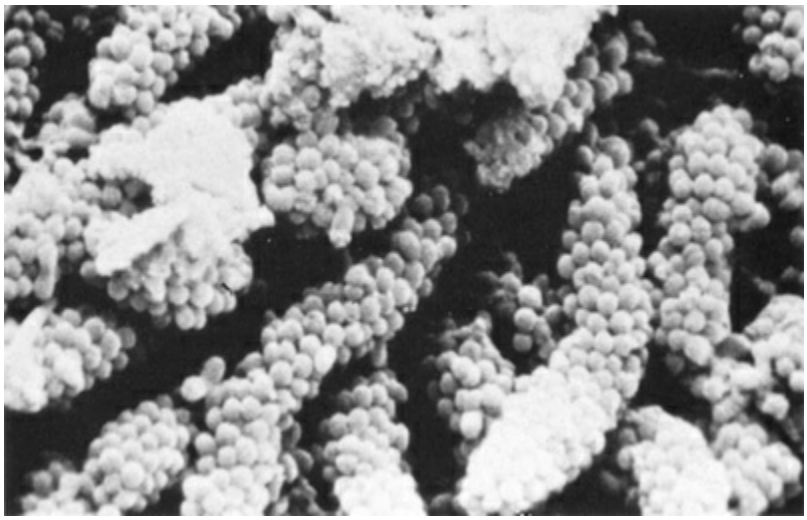
Secondary colonizers (see Table 8.3) such as *P. intermedia, P. loescheii, Capnocytophaga* spp., *F. nucleatum,* and *P. gingivalis* do not initially colonize clean tooth surfaces but rather adhere to bacteria that are already in the plaque mass.[184] The transition from early supragingival dental plaque to mature plaque growing below the gingival margin involves a shift in the microbial population from

primarily gram-positive organisms to high numbers of gram-negative bacteria. Therefore, during the later stages of plaque formation, coaggregation among different gram-negative species is likely to predominate. Examples of these types of interactions are the coaggregation of *F. nucleatum* with *P. gingivalis* or *Treponema denticola* (see Fig. 8.2L).[173,180,186]

Key Fact

Biofilm maturation is a highly specific event that involves a nonrandom aggregation of different bacteria.

The idea that coaggregation is important during the formation of oral biofilms opens new perspectives, especially for the use of probiotics. Special examples of coaggregations are the corn cob formation (eFig. 8.7), in which streptococci adhere to filaments of *Corynebacterium matruchotii* or *Actinomyces* spp., and the test-tube brush formation, composed of filamentous bacteria to which gram-negative rods adhere.[60,222,265]



EFIG. 8.7 Long-standing supragingival plaque near the gingival margin demonstrating a "corn cob" arrangement. A central gram-negative filamentous core supports the outer coccal cells, which are firmly attached by interbacterial adherence or coaggregation.

An analysis of more than 13,000 plaque samples that looked for 40 subgingival microorganisms using a DNA-hybridization

methodology defined color-coded "complexes" of periodontal microorganisms that tend to be found together in health or disease. The composition of the different complexes was based on the frequency with which different clusters of microorganisms were recovered, and the complexes were color coded for easy conceptualization (eFig. 8.8).[384] Interestingly, the early colonizers are either independent of defined complexes *(A. naeslundii, A. oris)* or members of the yellow (*Streptococcus* spp.) or purple complexes *(A. odontolyticus)* (see Fig. 8.2D). The microorganisms primarily considered secondary colonizers fell into the green, orange, and red complexes. The green complex includes *Eikenella corrodens, A. actinomycetemcomitans* serotype a, and *Capnocytophaga* spp. The orange complex includes *Fusobacterium, Prevotella,* and *Campylobacter* spp. (see Fig. 8.2R). The green and orange complexes include species recognized as pathogens in periodontal and nonperiodontal infections. The red complex consists of *P. gingivalis, T. forsythia,* and *T. denticola.* This complex is of particular interest because it is associated with bleeding on probing.[384] The existence of complexes of species in plaque is another reflection of bacterial interdependency in the biofilm environment.

EFIG. 8.8 Associations among subgingival species The data were derived from 13,261 subgingival plaque samples taken from the mesial aspect of each tooth in 185 adult subjects. Each sample was individually analyzed for the presence of 40 subgingival species with the use of checkerboard DNA–DNA hybridization. Associations were sought among species via cluster analysis and community ordination techniques. The complexes to the left consist of species that are thought to colonize the tooth surface and to proliferate at an early stage. The orange complex becomes numerically dominant later; it is thought to bridge the early colonizers and the red complex species, which become numerically more dominant during the later stages of plaque development. *A. actinomycetemcomitans, Aggregatibacter actinomycetemcomitans; A. odontolyticus, Actinomyces odontolyticus; C. concisus, Campylobacter concisus; C. gingivalis, Capnocytophaga gingivalis; C. gracilis, Campylobacter gracilis; C. ochracea, Capnocytophaga ochracea; C. rectus, Campylobacter rectus; C. showae, Campylobacter showae; C. sputigena, Capnocytophaga sputigena; E. corrodens, Eikenella corrodens; F. nuc., Fusobacterium nucleatum; F. periodonticum, Fusobacterium periodonticum; P. gingivalis, Porphyromonas gingivalis; P. micra, Parvimonas micra; P. nigrescens, Prevotella nigrescens; S. constellatus, Streptococcus constellatus; S. mitis, Streptococcus mitis; S. noxia, Selenomonas noxia; S. oralis, Streptococcus oralis; S. sanguis, Streptococcus sanguis; T. denticola, Treponema denticola; T. forsythia, Tannerella forsythia; V. parvula, Veillonella parvula.* (Adapted from Socransky SS, Haffajee AD, Cugini MA, et al: Microbial complexes in subgingival plaque. *J Clin Periodontol* 25:134, 1998.)

Factors That Affect Supragingival Dental Plaque Formation

Clinically, early undisturbed plaque formation on teeth follows an exponential growth curve when measured planimetrically.[313] During the first 24 hours when starting with a clean tooth surface, plaque growth is negligible from a clinical viewpoint (i.e., <3% coverage of the vestibular tooth surface, which is an amount nearly undetectable clinically). This "lag time" is a result of the fact that the microbial population must reach a certain size before it can easily be detected by a clinician. During the following 3 days, coverage progresses rapidly to the point at which, after 4 days, an average of 30% of the total coronal tooth area will be covered with plaque (Video 8.2: Plaque growth).

Several reports have shown that the microbial composition of the dental plaque will change, with a shift toward a more anaerobic and a more gram-negative flora, including an influx of fusobacteria, filaments, spiral forms, and spirochetes (Fig. 8.17). This was clearly

illustrated in experimental gingivitis studies.[398,409] For example, using next-generation sequencing, the microbiota was shown to shift from baseline to a significantly different community within 1 week of withdrawing oral hygiene.[175] With this ecologic shift within the biofilm, a transition occurs from the early aerobic environment, which is characterized by gram-positive facultative species, to a highly oxygen-deprived environment, in which gram-negative anaerobic microorganisms predominate. Bacterial growth in older plaque is much slower than in newly formed dental plaque, presumably because nutrients become limiting for much of the plaque biomass.[436]

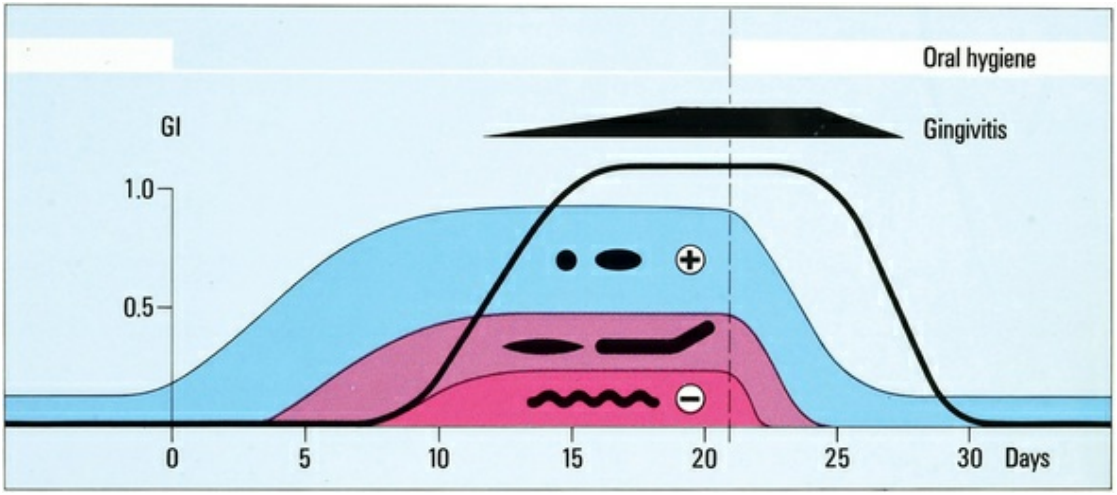


FIG. 8.17 **Artistic impression of the 1965 published classic experimental proof of the bacterial etiology of gingivitis using the experimental gingivitis model. In plaque-free subjects with clinically noninflamed gingiva, plaque will slowly develop on the teeth when all mechanical plaque control is stopped. With time, the plaque composition changes. During the first few days, the plaque is mainly composed of gram-positive (+) cocci and rods. Later on, the composition is shifted toward more gram-negative species and more rods and filaments; finally, gram-negative (−) spirochetes appear (see morphotypes in *black*). Within a few days, mild gingivitis ensues (*black line;* gingival index [GI] of 1 according to Löe and Silness). From the moment that proper plaque control is reestablished *(vertical line)*, the plaque composition returns to the initial situation, and the symptoms of gingivitis disappear.** (From Löe H, Theilade E, Jensen SB: Experimental gingivitis in man. *J Periodontol* 36:177, 1965.)

Topography of Supragingival Plaque

Early plaque formation on teeth follows a typical topographic

pattern (Fig. 8.18), with initial growth along the gingival margin and from the interdental spaces (i.e., the areas protected from shear forces). Later, a further extension in the coronal direction can be observed.[254,317] This pattern may change severely when the tooth surface contains irregularities that offer a favorable growth path (Fig. 8.19). Plaque formation may also originate from grooves, cracks, perikymata, or pits. Scanning electron microscopy studies clearly revealed that the early colonization of the enamel surface starts from surface irregularities in which bacteria shelter from shear forces, thereby permitting them the time needed to change from reversible to irreversible binding.

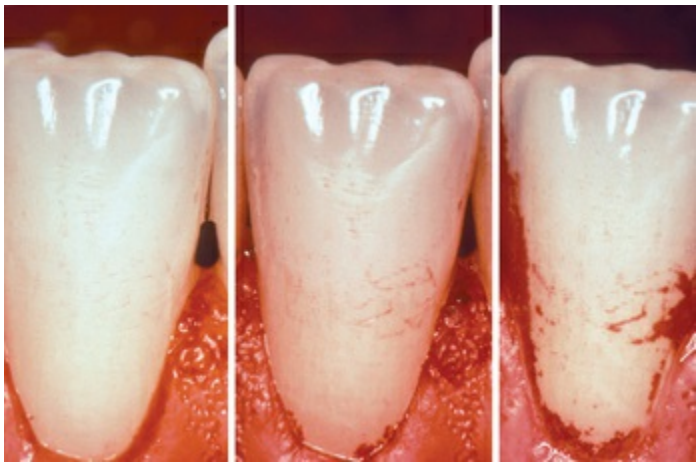

FIG. 8.18 Typical topography of plaque growth. Initial growth starts along the gingival margins and from the interdental spaces (i.e., areas protected from shear forces) to extend farther in a coronal direction. This pattern may fundamentally change, for example, if the tooth surface contains irregularities, such as those evident in Fig. 8.19.

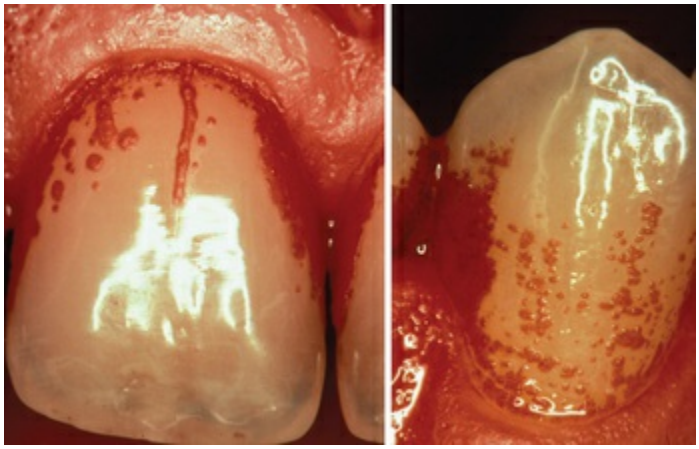

FIG. 8.19 **Surface irregularities and plaque growth. Important surface irregularities (i.e., a crack on the central upper incisor, several small pits on the canine) are also responsible for the so-called individualized plaque growth pattern.**

Key Fact

Dental plaque growth starts at areas that are protected from shear forces such as the gingival margin, the interdental space, and along grooves, cracks, pits, and fissures.

By multiplication, the bacteria subsequently spread out from these starting-up areas as a relatively even monolayer. Surface irregularities are also responsible for the so-called individualized plaque growth pattern (see Fig. 8.19), which is reproduced in the absence of optimal oral hygiene.[254,255] This phenomenon illustrates the importance of surface roughness in plaque growth, which should lead to proper clinical treatment options.

Surface Microroughness

Rough intraoral surfaces (e.g., crown margins, implant abutments, denture bases) accumulate and retain more plaque and calculus in terms of thickness, area, and colony-forming units.[305] Ample plaque also reveals an increased maturity or pathogenicity of its bacterial components, which is characterized by an increased proportion of motile organisms and spirochetes and/or a denser packing of them (Figs. 8.20 and 8.21). Smoothing an intraoral surface decreases the rate of plaque formation. Below a certain surface roughness ($R_a < 0.2$ μm), however, further smoothing does not result in an additional reduction in plaque formation.[28,306] There seems to be a threshold level for surface roughness ($R_a \approx 0.2$ μm) above which bacterial adhesion will be facilitated.[27] Although surface free energy and surface roughness are two factors that influence plaque growth, the latter predominates (see Figs. 8.20 and 8.21).

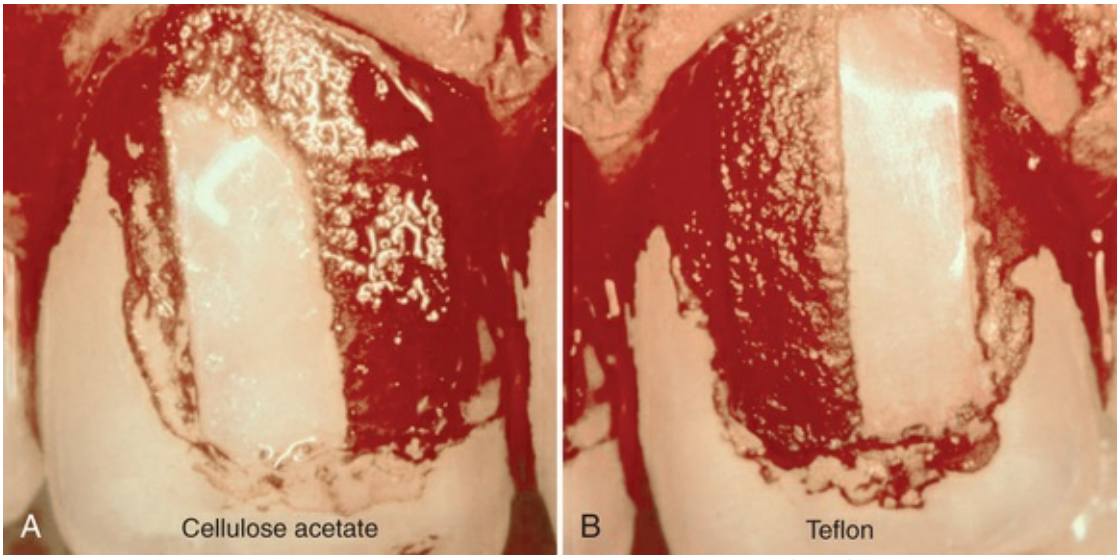

FIG. 8.20 **Photographs showing the clinical impact of surface roughness and surface free energy on de novo plaque formation. (A) and (B) Two small strips were glued to the central upper incisors of a patient who refrained from oral hygiene for 3 days. Each strip was divided in two halves: a rough region (R_a 2.0 µm) located mesially and a smooth region (R_a 0.1 µm) located distally. (A) Cellulose acetate strip (medium surface free energy [sfe]: 58 $ergcm^{-2}$). (B) Teflon strip (low sfe: 20 $ergcm^{-2}$). Plaque was disclosed with 0.5% neutral red solution. The smooth regions show the decrease in biofilm formation because of the low sfe; the rough regions demonstrate the predominance of surface roughness (i.e., more plaque with no difference between the two surfaces), even with different sfe.** (From Quirynen M, Listgarten MA: Distribution of bacterial morphotypes around natural teeth and titanium implants ad modum Brånemark. *Clin Oral Implants Res* 1:8, 1990.)

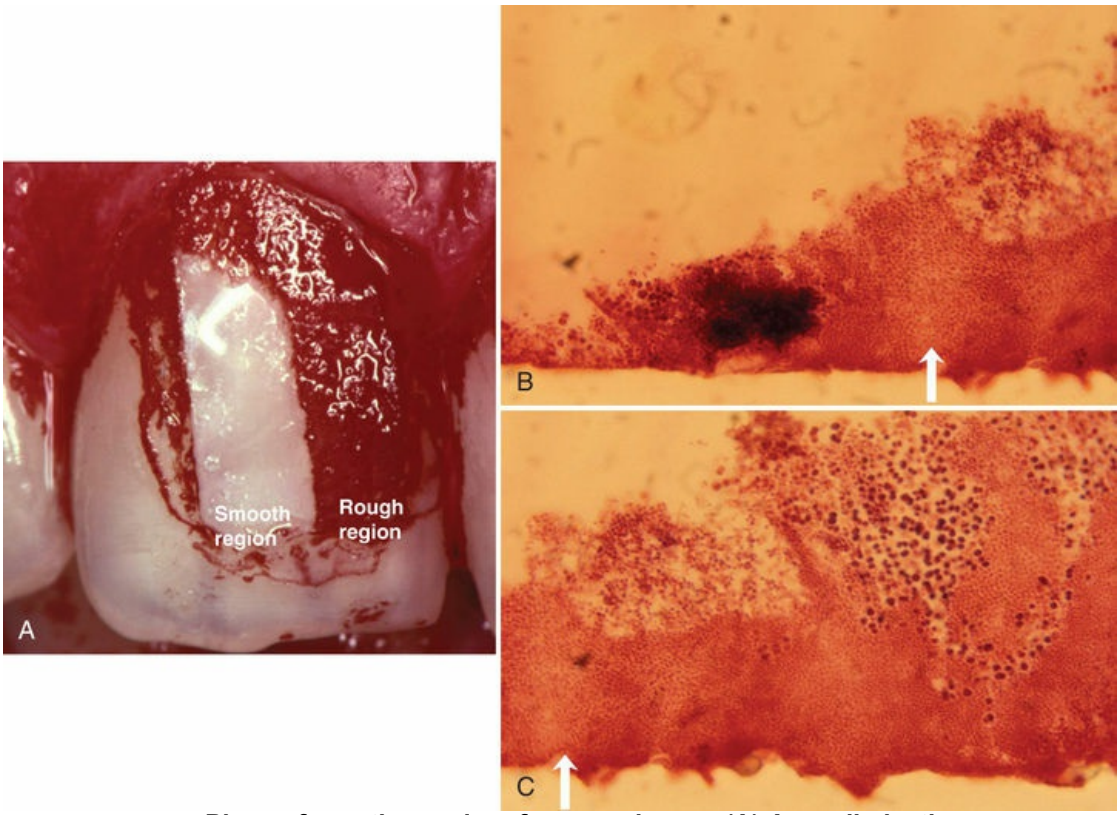

FIG. 8.21 **Plaque formation and surface roughness. (A) A small plastic strip, divided in half (a rough region [R_a 2.0 µm] located mesially and a smooth region [R_a 0.1 µm] located distally), had been glued to the central upper incisors of a patient who refrained from oral hygiene for 3 days. (B) and (C) After removal, the strip had been cut into small slices for microscopic evaluation. It is obvious that the rough part (C) contains a thicker plaque layer than the smooth part (B). The *arrow* shows the border between the rough and smooth surfaces.** (From Quirynen M, Listgarten MA: Distribution of bacterial morphotypes around natural teeth and titanium implants ad modum Brånemark. *Clin Oral Implants Res* 1:8, 1990.)

Individual Variables That Influence Plaque Formation

The rate of plaque formation differs significantly among subjects, and these differences may overrule surface characteristics. A distinction is often made between "heavy" (fast) and "light" (slow) plaque formers (Video 8.3: Difference in plaque growth between heavy and light plaque formers).

A multiple regression analysis showed that the clinical wettability of the tooth surfaces, the saliva-induced aggregation of oral bacteria, and the relative salivary flow conditions around the sampled teeth explained 90% of the variation. Moreover, the saliva from light plaque formers reduced the colloidal stability of bacterial suspensions of, for example, *S. sanguinis*.[364]

Clinician's Corner

Do some patients form plaque faster than others?

Yes, so-called heavy and light plaque formers exist. However, in both cases it takes days before the plaque is clinically visible. Patients cannot justify poor oral hygiene by being heavy plaque formers.

In a study by Zee and colleagues,[459] de novo plaque formation was followed on small enamel blocks that were bonded onto the teeth of slow and heavy plaque formers. After 1 day, the heavy plaque formers showed more plaque with a more complex supragingival structure. However, from days 3 to 14, no discernible differences were noted between both groups, except for a more prominent intermicrobial matrix in the group of fast growers. In another study by the same group of investigators, qualitative differences in the composition of the plaque between slow and rapid plaque formers were detected.[458] Rapid plaque formers demonstrated higher proportions of gram-negative rods (35% versus 17%) in 14-day-old plaque. The intersubject variation in plaque formation can also be explained by factors such as diet, chewing fibrous food, smoking, the presence of copper amalgam, tongue and palate brushing, the colloid stability of bacteria in the saliva, antimicrobial factors present in the saliva, the chemical composition of the pellicle, and the retention depth of the dentogingival area.*

Variation Within the Dentition

Within a dental arch, large differences in plaque growth rate can be detected. In general, early plaque formation occurs faster: in the lower jaw (as compared with the upper jaw); in molar areas; on the buccal tooth surfaces (as compared with palatal sites, especially in the upper jaw); and in the interdental regions (as compared with the buccal or lingual surfaces).[109,207,304]

Impact of Gingival Inflammation and Saliva

Several studies clearly indicate that early in vivo plaque formation is more rapid on tooth surfaces facing inflamed gingival margins than on those adjacent to healthy gingivae.[309,322,323] These studies suggest that the increase in crevicular fluid production enhances plaque formation. Probably some substances from this exudate (e.g., minerals, proteins, carbohydrates) favor both the initial adhesion and/or the growth of the early colonizing bacteria. In addition, it is known that, during the night, the plaque growth rate is reduced by some 50%.[317] This seems surprising because one would expect that reduced plaque removal and the decreased salivary flow at night would enhance plaque growth. The fact that the supragingival plaque obtains its nutrients mainly from the saliva appears to be of greater significance than the antibacterial activity of saliva.[47]

Impact of Patient's Age

Although older studies were contradictory, more recent reports clearly indicate that a subject's age does not influence de novo plaque formation. In a study by Fransson and colleagues,[105] no differences could be detected in de novo plaque formation between a group of young (20 to 25 years old) patients and a group of older (65 to 80 years old) subjects who abolished mechanical tooth cleaning measures for 21 days, neither in amount nor in composition.[105] This observation largely confirms data by Holm-Pedersen and colleagues[154] and data by Winkel and coworkers.[446] However, the developed plaque in the older patient group resulted in more severe gingival inflammation, which seems to indicate an increased susceptibility to gingivitis with aging.

Clinician's Corner

Do older people form more plaque?

No, the rate of de novo plaque formation is similar in young and old patients. However, older patients may have less dexterity, which could explain larger amounts of plaque.

Spontaneous Tooth Cleaning

Many clinicians still think that plaque is removed spontaneously from the teeth, such as during eating. However, on the basis of the firm attachment between the bacteria and the surface, this seems unlikely. Even in the occlusal surfaces of the molars, plaque remains, even after chewing fibrous food (e.g., carrots, apples, chips). The inefficiency of the spontaneous plaque removal is neatly illustrated by the clinical pictures in Fig. 8.22, which were taken before and after dinner starting from 4 days of undisturbed plaque formation. Only negligible differences in plaque extent could be observed.

FIG. 8.22 Lower premolars and molars from a dental student who refrained from oral hygiene for 100 hours to evaluate undisturbed plaque formation. (A) Before dinner. (B) After dinner, which included fibrous foods. Nearly no reduction in plaque extension could be observed, thereby illustrating the absence of spontaneous plaque removal.

De Novo Subgingival Plaque Formation

It is technically impossible to record the dynamics of subgingival plaque formation in an established dentition for the simple reason that one cannot sterilize a periodontal pocket. Some early studies involving the use of culturing techniques examined the changes within the subgingival microbiota during the first week after mechanical debridement and reported an only partial reduction of around 3 logs (from 10^8 bacterial cells to 10^5 cells), followed by rapid regrowth toward nearly pretreatment levels (−0.5 log) within 7 days.[118,145,242] The fast recolonization was explained by several factors. A critical review of the effectiveness of subgingival

debridement, for instance, revealed that a high proportion of treated tooth surfaces (5% to 80%) still harbored plaque and/or calculus after scaling. These remaining bacteria were considered the primary source for the subgingival recolonization.[294] Some pathogens penetrate the soft tissues or the dentinal tubules and eventually escape instrumentation (see Fig. 8.14).[5,115,338] In a beagle dog study, Leknes and colleagues[214] studied the extent of subgingival colonization in 6-mm pockets with smooth or rough root surfaces. These investigators also observed that smooth surfaces harbored significantly less plaque and concluded that subgingival irregularities shelter submerged microorganisms. Moreover, biopsies of the soft tissues showed an elevated proportion of inflammatory cells in the junctional epithelium (and the underlying connective tissue) facing the rough surfaces.[215] Finally, the same group reported higher rates of attachment loss around teeth with grooves in the root surface.[213]

The introduction of oral implants, especially of the two-stage type, provided a new experimental setup. When the transmucosal part of the implant (the abutment) is inserted on top of the osseointegrated endosseous part, a new "pristine" surface is created on which the intraoral translocation of bacteria can be investigated.[306] It has been demonstrated that a complex subgingival microbiota, including most periodontopathogens, is established within 1 week after abutment insertion. This is followed by a slow increase in the number of periodontopathogens.[108,319,320] Oral implants have also been used as a model to study the impact of surface roughness on subgingival plaque formation.[28,43,125,306,316,333] Smooth abutments ($R_a < 0.2$ μm) were found to harbor 25 times fewer bacteria than rough ones, with a slightly higher density of coccoid (i.e., nonpathogenic) cells. The subgingival microbiota was also largely dependent on the remaining presence of teeth and the degree of periodontitis in the remaining natural dentition (for a review, see reference 293). These observations highlight the importance of intraoral bacterial translocation for subgingival biofilms.

Characteristics of Biofilm Bacteria

(Life in "Slime City")

Metabolism of Dental Plaque Bacteria

Most nutrients for dental plaque bacteria originate from saliva or gingival crevicular fluid, although the host diet provides an occasional but nevertheless important food supply. The transition from gram-positive to gram-negative microorganisms observed in the structural development of dental plaque is paralleled by a physiologic transition in the developing plaque.

The early colonizers (e.g., *Streptococcus* and *Actinomyces* spp.) use oxygen and lower the redox potential of the environment, which then favors the growth of anaerobic species.[80,428] Many of the gram-positive early colonizers use sugars as an energy source. The bacteria that predominate in mature plaque are anaerobic and asaccharolytic (i.e., they do not break down sugars), and they use amino acids and small peptides as energy sources.[231]

Laboratory studies have demonstrated many metabolic interactions among the different bacteria found in dental plaque (Fig. 8.23). For example, lactate and formate are byproducts of the metabolism of streptococci and *Actinomyces* spp.; they may be used in the metabolism of other plaque microorganisms, including *Veillonella* spp. and *A. actinomycetemcomitans*.[42,91] Interestingly, the commensal bacterium *S. gordonii* have also been shown to provide electron acceptors that promote respiratory growth of *A. actinomycetemcomitans* in vivo during abscess formation.[392] The importance of this cross-respiration in dental plaque biofilms is not yet clear.

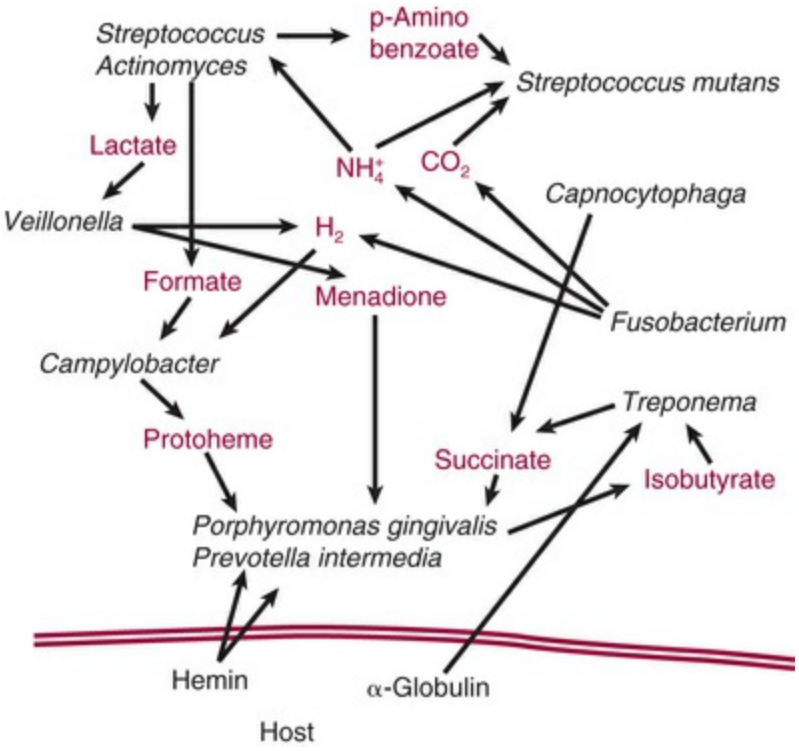

FIG. 8.23 Schematic illustration of metabolic interactions among different bacterial species found in plaque and between the host and the plaque bacteria. These interactions are likely to be important to the survival of bacteria in the periodontal environment. CO_2, Carbon dioxide; H_2, hydrogen; NH^+_4, ammonium. (Data from Carlsson J: Microbiology of plaque associated periodontal disease. In Lindhe J, editor: *Textbook of clinical periodontology,* Munksgaard, 1983, Munksgaard International Publishers; Grenier D: Nutritional interactions between two suspected periodontopathogens, *Treponema denticola* and *Porphyromonas gingivalis. Infect Immun* 60:5298, 1992; Loesche WJ: Importance of nutrition in gingival crevice microbial ecology. *Periodontics* 6:245, 1968; and Walden WC, Hentges DJ: Differential effects of oxygen and oxidation-reduction potential on the multiplication of three species of anaerobic intestinal bacteria. *Appl Microbiol* 30:781, 1975.)

The growth of *P. gingivalis* is also enhanced by metabolic byproducts produced by other microorganisms, such as succinate from *C. ochracea* or *T. denticola* and protoheme from *Campylobacter rectus* (see Fig. 8.2R).[121,122,248] In turn, *P. gingivalis* provides isobutyric acid that stimulates growth of *T. denticola.*[121] Overall, the total plaque population is more efficient than any one constituent organism at releasing energy from the available substrates.[443]

Metabolic interactions also occur between the host and the plaque microorganisms. The bacterial enzymes that degrade host proteins mediate the release of ammonia, which may be used by bacteria as a nitrogen source.[48] Hemin iron from the breakdown of host hemoglobin may be important in the metabolism of *P. gingivalis.*[34] Increases in steroid hormones are associated with significant increases in the proportions of *P. intermedia* found in

subgingival plaque.[191] These nutritional interdependencies are probably critical to the growth and survival of microorganisms in dental plaque, and they may partly explain the evolution of the highly specific structural interactions observed among bacteria in plaque.

Communication Between Biofilm Bacteria

Bacterial cells do not exist in isolation. In a biofilm, bacteria have the capacity to communicate with each other. One example of this is quorum sensing, in which bacteria secrete a signaling molecule that accumulates in the local environment and triggers a response such as a change in the expression of specific genes once they reach a critical threshold concentration. The threshold concentration is reached only at a high cell density, and therefore bacteria sense that the population has reached a critical mass or quorum. Some evidence indicates that intercellular communication can occur after cell–cell contact and that, in this case, communication may not involve secreted signaling molecules.[165] Two types of signaling molecules have been detected from dental plaque bacteria: peptides released by gram-positive organisms during growth and a "universal" signal molecule called *autoinducer 2* (AI-2).[182] Peptide signals are produced by oral streptococci; they are recognized by cells of the same strain that produced them and possibly also by different species of streptococci.[103] Responses are induced only when a threshold concentration of the peptide is attained, and thus the peptides act as cell density or quorum sensors. Local concentrations of signaling molecules may be enhanced in biofilms if the signals become trapped in the biofilm matrix. The streptococcal peptides are known as *competence-stimulating peptides* because the major response to these signals is the induction of competence, a physiologic state during which cells are primed for DNA uptake and incorporation.

In some species, such as *S. mutans,* a few of the cells in a population respond to competence-stimulating peptides by lysing.[292] Lysis is considered to be an altruistic behavior that helps to disseminate genetic information throughout the population of *S. mutans* cells.

In contrast to the strain-specific competence-stimulating peptides, AI-2 is produced and detected by many different bacteria. The detection of AI-2 produces wide-ranging changes in gene expression, in some cases affecting up to one-third of the entire genome.[399]

Little is known about the specific functions of AI-2 in oral biofilms. However, this molecule has been demonstrated to play a role in mutualistic interactions between *S. oralis* and *A. oris (A. naeslundii)*.[332] Thus, in an in vitro model system, neither *S. oralis* nor *A. oris* formed biofilms in monoculture. When cultured together, these organisms grew abundantly on surfaces to form thick, confluent biofilms. This mutualistic behavior was observed only when AI-2 was present: disrupting the gene for AI-2 in *S. oralis* abrogated mutualistic growth. These data demonstrate that AI-2 is produced and sensed by oral bacteria and suggest that interbacterial communication is important for the development of dental plaque.

Quorum sensing therefore appears to play diverse roles in, for example, modulating the expression of genes for antibiotic resistance, encouraging the growth of beneficial species in the biofilm, and discouraging the growth of competitors.

Interactions Among Dental Plaque Bacteria

Several clinical studies followed the detection frequency and relative proportion of cariogenic species after periodontal therapy. They all suggest a relative increase in the number, as well as the detection frequency of *S. mutans* up to 8 months after mechanical debridement.[78,311] In a cross-sectional study, subgingival plaque samples from chronic periodontitis patients were tested for the presence and levels of *S. mutans* and putative periodontal pathogens.[415] The patients were divided into four groups on the basis of the stage of periodontal treatment: untreated, after initial periodontal therapy, maintenance phase without periodontal surgery, and after periodontal surgery. The prevalence of mutans streptococci in the four study groups was equivalent. The shift toward a more cariogenic flora observed after initial and surgical periodontal therapy could be explained by a subgingival outgrowth

by *S. mutans* occupying spots that became available after periodontal therapy (e.g., increased number of free adhesion/receptor sites), the creation of a new ecosystem in the subgingival area (i.e., a more anaerobic environment, changes in redox potential, pH, and nutrition) that allows or facilitates the growth of *S. mutans* species, and/or a downgrowth of *S. mutans* from the supragingival area in which the species could survive in the saliva. In addition, Socransky and coworkers[128a] showed that the total numbers of *P. gingivalis, T. forsythia,* and *T. denticola* are reduced 2 weeks after scaling and root planing and that concomitantly several orange complex organisms are also reduced in number at this point. However, the proportion of *S. sanguinis* in the population increased 2 weeks after treatment by scaling and root planing in conjunction with azithromycin or metronidazole and 3 months after treatment with doxycycline. Although these observations may result from an antagonistic relationship between *S. sanguinis* and periodontal pathogens, they may also reflect the relatively high intrinsic antibiotic resistance of oral streptococci.

Some evidence indicates from laboratory studies that nonpathogenic organisms in subgingival dental plaque can modify the behavior of periodontal pathogens. For example, long and short fimbriae of *P. gingivalis* are required for adhesion and biofilm formation. The expression of long fimbriae is down-regulated in the presence of *Streptococcus cristatus,* and short fimbriae are down-regulated by *S. gordonii, S. mitis,* or *S. sanguinis.*[221,284] Changes in bacterial physiology after transitions from monoculture to mixed-species communities may be quite wide ranging.

With the use of a proteomics approach to probe the phenotype of *P. gingivalis*, it has been shown that the expression of almost 500 *P. gingivalis* proteins is changed in model oral microbial communities that contain *S. gordonii* and *F. nucleatum*.[197] At present, it is not clear how these changes affect the interaction between *P. gingivalis* and the host.

In multispecies biofilms in which many bacteria are juxtaposed to cells of different species, interactions among genetically distinct microorganisms can be mutually beneficial (see Fig. 8.5A). However, many examples of competitive interactions between different bacteria exist (Fig. 8.24). For example, *S. mutans* produces

antimicrobial peptides that have broad activity against bacteria in vitro.[195] Other oral streptococci compete with *S. mutans* by excreting the strongly oxidizing molecule H_2O_2.[195] In fact, *Streptococcus oligofermentans* can convert lactic acid produced by *S. mutans* into H_2O_2, which then kills the *S. mutans* cells.[411]

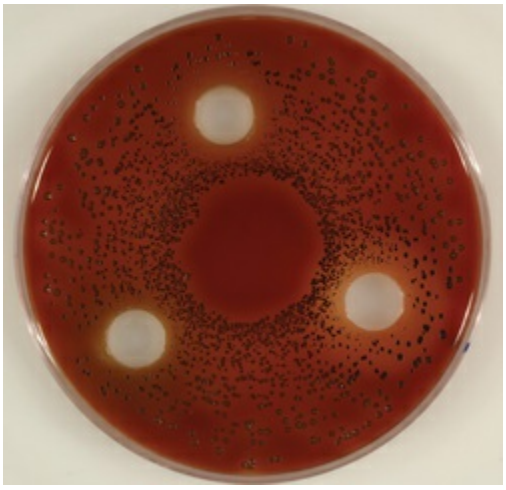

FIG. 8.24 Growth inhibition induced by streptococci. The growth of *Prevotella intermedia* (black colonies) is inhibited by the presence of *Streptococcus mitis*, *Streptococcus salivarius*, and *Streptococcus sanguinis* (in the white holes). This is represented by a zone of no growth (halo) around the white holes. This is a typical example of growth inhibition induced by streptococci.

In subgingival biofilms, oxygen is scarce, and therefore H_2O_2 production by bacteria is lower. Oxidizing agents may be more important in the interaction between the host and the pathogen because reactive oxygen species are a major component of the neutrophil response to bacteria.

Another example of competitive interaction exists between streptococci and periodontopathogens. *S. sanguinis*, *S. salivarius*, and *S. mitis* have been shown to inhibit hard and soft tissue colonization of *A. actinomycetemcomitans* (Video 8.4: Colonization inhibition), *P. gingivalis*, and *P. intermedia* in vitro.[370,405,422]

Studies have shown that these interactions can also influence the host. Although in a study by Teughels and coworkers[406] no clinical effect was expected, a reduction in bleeding on probing was noted in pockets that received the streptococci. At that time, this observation was explained by the establishment of a more host-

compatible microbiota. However, an interaction with the host via the immune system seems to be an additional interesting hypothesis. Oral streptococci have been shown to modulate bacteria–host interactions that involve both *F. nucleatum* and *A. actinomycetemcomitans*. Thus, *S. cristatus* and other oral streptococci attenuate the ability of *F. nucleatum* to stimulate interleukin-8 production by host oral epithelial cells.[460] Sliepen and coworkers[371] demonstrated similar results for the streptococci that were used in the study by Teughels and coworkers.

Another interesting example is the *S. gordonii*–induced increased expression of a complement resistance protein, ApiA, in *A. actinomycetemcomitans,* thereby resulting in a higher resistance to killing by host serum.[326]

Biofilms and Antimicrobial Resistance

Bacteria growing in microbial communities adherent to a surface do not "behave" the same way as bacteria growing suspended in a liquid environment (i.e., in a planktonic or unattached state). For example, the resistance of bacteria to antimicrobial agents is dramatically increased in the biofilm.[9,65,147,302] Almost without exception, organisms in a biofilm are 1000 to 1500 times more resistant as compared with antibiotics in their planktonic state. The mechanisms of this increased resistance differ from species to species, from antibiotic to antibiotic, and for biofilms growing in different habitats.

It is generally accepted that the resistance of bacteria to antibiotics is affected by their nutritional status, growth rate, temperature, pH, and prior exposure to subeffective concentrations of antimicrobial agents.[40,41,444] Variations in any of these parameters will lead to a varied response to antibiotics within a biofilm. An important mechanism of resistance appears to be the slower rate of growth of bacterial species in a biofilm, which makes them less susceptible to many but not all antibiotics.[18,38,65,452] The biofilm matrix, although not a significant physical barrier to the diffusion of antibiotics, does have certain properties that can retard antibiotic penetration. For example, strongly charged or chemically highly reactive agents can fail to reach the deeper zones of the biofilm

because the biofilm acts as an ion-exchange resin that removes such molecules from solution.[113,400]

Key Fact

The bacteria within biofilms are often up to 1000 times more resistant to antimicrobial agents than their planktonic counterparts.

In addition, extracellular enzymes such as β-lactamases, formaldehyde lyase, and formaldehyde dehydrogenase may become trapped and concentrated in the extracellular matrix, and as such inactivate some antibiotics (especially positively charged hydrophilic antibiotics).

Some antibiotics, such as the macrolides, which are positively charged but hydrophobic, are unaffected by this process.

"Superresistant" bacteria were identified within a biofilm. These cells have multidrug resistance pumps that can extrude antimicrobial agents from the cell.[38] Because these pumps place the antibiotics outside of the outer membrane, the process offers protection against antibiotics that target, for example, cell wall synthesis. The penetration and efficacy of antimicrobials against biofilm bacteria are critical issues for the treatment of periodontal infections.

Antibiotic resistance may be spread through a biofilm via the intercellular exchange of DNA. The high density of bacterial cells in a biofilm facilitates the exchange of genetic information among cells of the same species and across species and even across genera. Conjugation (i.e., the exchange of genes through a direct interbacteria connection formed by a sex pilus), transformation (i.e., the movement of small pieces of DNA from the environment into the bacterial chromosome), plasmid transfer, and transposon transfer have all been shown to occur in biofilms.

Bacterial Transmission and Translocation

The transmission of pathogens from one *locus* to another is an

important aspect of infectious diseases. In theory, such transmission may jeopardize the outcome of periodontal therapy; in addition, the transmission of pathogens from one person to another may be important in terms of disease transmission. The significance of such an intraoral transmission or of a vertical or horizontal transmission is, however, difficult to prove or to quantify.

One of the first questions in this regard is, "Are oral bacteria transmissible between humans?" Molecular fingerprinting techniques have clearly illustrated that periodontal pathogens are transmissible within members of a family[455] (Fig. 8.25).

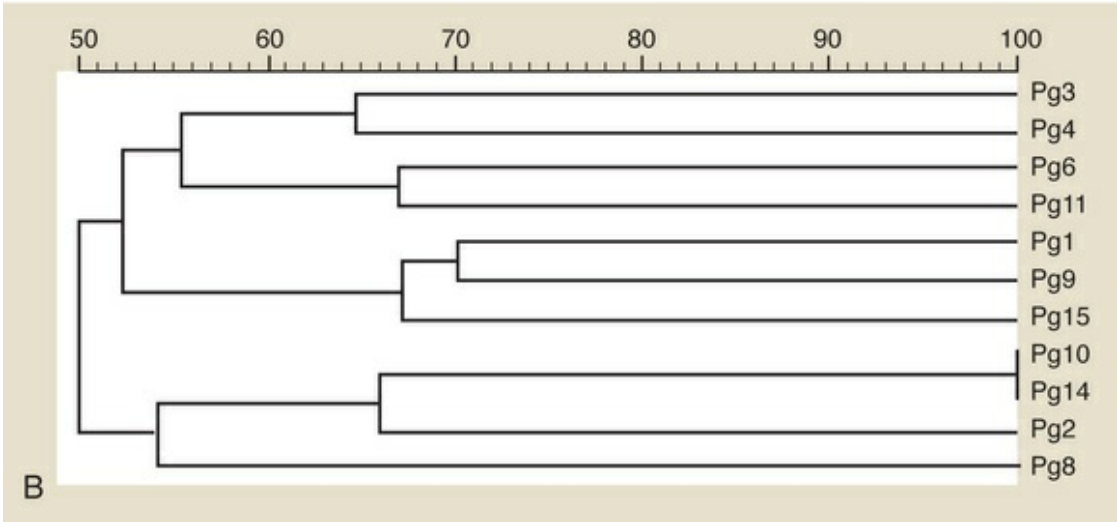

FIG. 8.25 ***Porphyromonas gingivalis*** **strains. (A) Band pattern of DNA isolated from multiple *Porphyromonas gingivalis* strains after pulsed-field gel electrophoresis. Lanes 1, 8, and 15 contain a reference strain of DNA (*Staphylococcus aureus*) cut with SmaI (a restriction endonuclease) in lanes 2 through 7 and 9 through 14; 12 different *P. gingivalis* strains are compared for their genetic similarity. (B) The**

genetic similarity is expressed in a dendrogram. Bacteria are considered genetically similar when their band patterns are 80% similar.

This bacterial transmission between subjects (and even between animals and human beings) should not be confused with contagion (with the term *contagious* referring to the likelihood that a microorganism will be transmitted from an infected to an uninfected host to create disease). Asikainen and coworkers[19] used a genetic fingerprinting method called *arbitrarily primed-polymerase chain reaction* to genotype *A. actinomycetemcomitans* isolates from family members. In 11 of 12 families, these investigators found identical *A. actinomycetemcomitans* genotypes among family members. This finding suggests the transmission of this microorganism among family members. However, it was more often encountered that children carried a genotype identical to one of their parents than that spouses carried an identical genotype. This indicates that, in terms of *A. actinomycetemcomitans* transmission, vertical transmission is more important than horizontal transmission. Similar observations were made for the transmission of cariogenic species from mother to child.[177] The vertical or horizontal transmission of *P. gingivalis* has rarely been observed.[418]

The existence of an "intraoral" translocation of bacteria (i.e., from one niche to another) has been investigated more thoroughly. Intraoral transmission of bacteria was first examined in cariology. Loesche and coworkers[233] showed that streptomycin-resistant strains of *S. mutans* grown on a dental inlay were spontaneously transmitted to the neighboring teeth (probably via saliva) and could even reach the contralateral quadrant after transmission with a dental explorer. Previously, Edman and coworkers[89] had successfully implanted the previously mentioned species in two volunteers by means of inoculated dental flosses. Comparable observations have been made for periodontopathogens.

Christersson and coworkers[57] demonstrated a translocation of *A. actinomycetemcomitans* via periodontal probes in localized juvenile periodontitis patients. These investigators were able successfully to colonize previously noninfected pockets with *A. actinomycetemcomitans* via a single course of probing with a probe

that had been previously inserted in an infected pocket of the same patient. Although the colonization was only temporary, the question remained whether the colonization could not have become permanent if the site had offered more suitable growth conditions (e.g., a deep bleeding pocket, as frequently encountered immediately after initial periodontal therapy). It is well established that colonization of an already established microbial niche by a new species is difficult because it is hampered by a variety of microbial interactions. Therefore, intraoral translocation to and the colonization of sterile surfaces may be different from the translocation and colonization of already colonized surfaces. Within the oral cavity, such sterile surfaces are not naturally occurring. However, at the moment of abutment placement on a dental implant, a sterile subgingival pocket is created. A large series of articles compared the microbiota in pockets around teeth with that found in peri-implant pockets in partially edentulous patients and reported a striking similarity.* Several studies have investigated the subgingival colonization of such "sterile" peri-implant pockets in partially edentulous patients. Investigators have shown that translocation to and the colonization of these pockets is extremely fast. Periodontopathogens could already be detected in this niche 30 minutes after abutment placement.[108] The initial colonization of these pockets with periodontopathogens is completed within 1 week. After 2 weeks, only minor additional changes occur in this newly developed microbiota.[108,319,320] These additional changes mainly reflect changes in the numbers of species. On the basis of the previously mentioned similarities between the microbial populations associated with teeth and implants, it has been suggested that, at least in partially edentulous patients, teeth may act as a reservoir for the (re)colonization of the subgingival area around implants. This hypothesis was supported by Sumida and coworkers,[397] who detected similar intrasubject pulsed field gel electrophoresis patterns for *P. gingivalis* from teeth and implants (indicating that these locations contained precisely the same *P. gingivalis* strains) as compared with large intersubject variations.

The clinical significance of intraoral translocation can be derived from several studies.

Nowzari and coworkers[272] evaluated the amount of guided tissue

regeneration and membrane contamination after the treatment of mandibular bony defects in either a group of patients with a healthy periodontium in the remaining dentition or a group of patients with multiple deep pockets and numerous pathogens. The healthy group showed significantly less membrane contamination both immediately after insertion and at their removal after 6 weeks. The healthy group also showed significantly more clinical gain in attachment (3.4 mm versus 1.4 mm).

Mombelli and coworkers[259] compared clinical and microbial changes when tetracycline fibers (local applications of antibiotics) were applied only to the two deepest pockets in the mouth (without further treatment to the remaining pockets) with the changes obtained when all teeth were cleaned and every pocket with a depth of more than 3 mm was treated. After 6 months, significant "additional" improvements (clinical as well as microbiologic) were recorded in the group of patients with the more global approach. Their pockets showed a probing depth reduction (1.7 mm) and attachment gain (0.7 mm) that was significantly higher than that found in the pockets of patients with some remaining pockets (0.9 and 0.3 mm, respectively). The investigators concluded that, most likely, pathogens were transferred via saliva from infected untreated periodontal lesions or other niches to the treated sites.

Quirynen and coworkers[307] used a treatment strategy called "one-stage, full-mouth disinfection" to investigate the impact of intraoral translocation on the outcome of nonsurgical periodontal therapy. This strategy attempted to suppress the translocation of periodontopathogens from all of their intraoral habitats (i.e., mucous membranes, tongue, and saliva) to root-planed periodontal pockets. Several comparative studies between the one-stage, full-mouth approach and the standard therapy from the Leuven group (i.e., root planing per quadrant with 2-week intervals that allow for translocation) illustrated the impact of bacterial translocation in relation to the obtained gain in attachment, pocket depth reduction, and changes in the microbiota.[308]

Nonbacterial Inhabitants of the Oral Cavity

Oral microbiology is often reduced to "oral bacteriology." However, the oral cavity comprises a much more diverse microbiota than merely a bacterial one. Viruses, fungi, archaea, and protozoa can be encountered in the oral cavity of humans. Many of these species can reside in the oral cavity in harmony with the host as commensals, similar to oral bacteria, but they can also cause several oral diseases.

Key Fact

In addition to bacteria, viruses can be present in the mouth. Herpesviruses, human papillomaviruses, picornaviruses, and retroviruses can all contribute to the development of oral ulcers, tumors, mononucleosis, Sjögren syndrome, osteomyelitis, osteonecrosis, oral leukoplakia, and oral lichen planus.

Viruses

Viral diseases of the oral mucosa and the perioral region are often encountered in dental practice. Viruses are important ulcerogenic and tumorigenic agents of the human mouth. The finding of an abundance of mammalian viruses in periodontitis lesions may suggest a role for viruses in more oral diseases than previously recognized.[360] A more in-depth review can be found in two articles by Slots.[375,376]

In contrast to most bacteria, viruses replicate only when they are present within eukaryotic (animals, plants, protists, and fungi) or prokaryotic (bacteria and archaea) cells and not on their own. The extracellular virion particle ranges in size from 20 to 300 nm and consists of either DNA or ribonucleic acid (RNA) contained within a protective protein coat or capsid (Fig. 8.26).

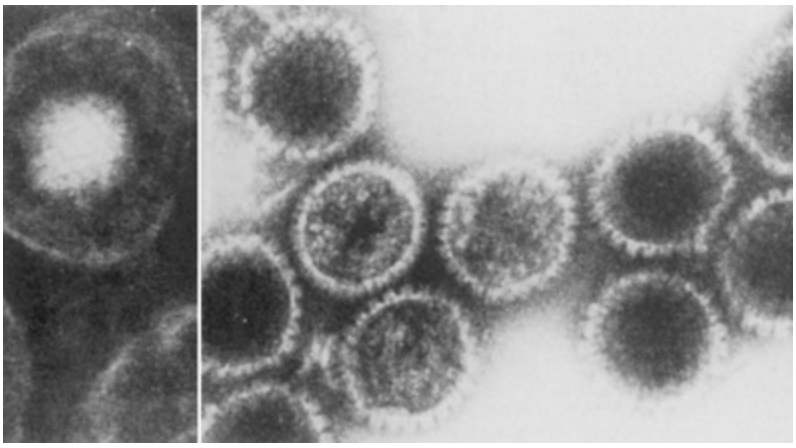

FIG. 8.26 Herpes simplex virus type 1. Electron micrographic picture of herpes simplex virus type 1, enveloped *(left)* and naked capsids *(right)*. ×198,000. (From Fields BN, Knipe DM: In Fields BN, editors: *Virology*, New York, 1985, Raven Press.)

Some viruses have an additional envelope that comprises a lipid bilayer derived from the outer cellular membrane, the internal nuclear membrane, or the endoplasmic reticulum membrane of the infected cell. In healthy individuals, most viruses in the oral cavity are bacteriophages.[10] Four major viral families are associated with the main viral oral diseases of adults:

1. The group of herpesviruses contains eight different members that are all enveloped double-stranded DNA viruses (Table 8.4). In the oral cavity, they are related to different ulcers, tumors, and other oral pathoses.

TABLE 8.4

Herpesviruses That Can Be Recovered in the Oral Cavity

Virus	Characteristics	Disease Association	Oral Pathoses
Herpes simplex virus-1	Latency in sensory ganglia Causes orolabial disease	Herpetic gingivostomatitis, recurrent orolabial lesions, herpetic whitlow, keratoconjunctivitis, eczema herpeticum, pharyngitis, mononucleosis-like syndrome, encephalitis, neonatal infections	Adult herpetic gingivostomatitis HIV/AIDS-related oral ulcers Recurrent oral aphthous stomatitis Behçet syndrome Oral pemphigus vulgaris Erythema multiforme Dry socket after tooth extraction

Herpes simplex virus-2	Latency in sensory ganglia Causes genital and newborn infections	Genital infection, aseptic meningitis, sacral autonomic nervous system dysfunction.	—
Varicella-zoster virus	Latency in sensory ganglia Only three major genotypes of the wild-type virus are known More than 90% are infected before adolescence in an unvaccinated population	Varicella (chickenpox), herpes zoster (shingles), central nervous system involvement, pneumonia, secondary bacterial infections, and death Available varicella vaccines (about 90% effectiveness) include a single-antigen vaccine and a combination vaccine against MMRV	Recurrent oral aphthous stomatitis Osteomyelitis Herpes zoster (Hunt syndrome)
EBV	Identified initially in 1964 from African Burkitt lymphoma Infects epithelial cells with a cytolytic infection and B lymphocytes with a latent infection	Infectious mononucleosis, hairy leukoplakia of the tongue, Burkitt lymphoma, B lymphoproliferative disease, Hodgkin lymphoma, X-linked lymphoproliferative disease, nasal T-cell lymphoma, nasopharyngeal carcinoma, gastric carcinoma, parotid carcinoma, and leiomyosarcoma	Recurrent oral aphthous stomatitis Erythema multiforme Various epithelial type tumors, such as lymphoepithelioma-like carcinoma, salivary gland lymphoepithelial carcinoma, Warthin tumor (cystadenolymphoma) of the parotid gland, oral squamous cell carcinoma, tonsillar carcinoma, oral undifferentiated carcinomas, and oral hairy leukoplakia Various lymphoid type tumors, such as Hodgkin lymphoma, T-cell/natural killer cell

			lymphoma, Burkitt lymphoma, cyclosporine-related posttransplant lymphoproliferative disorder, oral post-transplant lymphoproliferative disorder/B-cell lymphoma, follicular lymphoid hyperplasia, and plasmablastic lymphoma Infectious mononucleosis
hCMV	Infects mainly T lymphocytes and macrophages The gB protein in the virion envelope participates in the virus–cell interaction and is a major target of the immune response	Preterm birth, preeclampsia, transplant rejection, immunosenescence, hemorrhagic retinal necrosis (patients with HIV), encephalitis, infectious mononucleosis, atherosclerosis, gastrointestinal disease, pneumonia, and encephalitis	HIV/AIDS-related oral ulcers Recurrent oral aphthous stomatitis Behçet syndrome Oral pemphigus vulgaris Erythema multiforme Cyclosporine-steroid associated lymphoproliferative disorder Benign infantile hemangioendothelioma Kaposi sarcoma Occasionally infectious mononucleosis Sialadenitis Osteomyelitis
Human herpesvirus-6	Cell tropism for T lymphocytes and neural cells Frequently shed in the saliva of healthy donors	Roseola infantum (sixth disease), meningitis, encephalitis, and possibly multiple sclerosis	Uvulopalatoglossal junctional ulcers Oral squamous cell carcinoma Oral leukoplakia Oral lichen planus
Human herpesvirus-7	Latency in macrophages and T lymphocytes	Exanthema subitum, macular–papular rashes, and transplant–recipient	

	Frequently shed in the saliva of healthy donors	pathogens	
Human herpesvirus-8	Six genetic subtypes with marked clustering to geographic areas B lymphocytes and monocytes serve as reservoirs	Kaposi sarcoma, multicentric Castleman disease, primary effusion lymphoma, mononucleosis-like illness, and aplastic anemia (Unlike EBV, herpesvirus-8 is not involved in epithelial tumors)	Recurrent oral aphthous stomatitis Kaposi sarcoma

EBV, Epstein-Barr virus; *hCMV,* human cytomegalovirus; *HIV,* human immunodeficiency virus; *AIDS,* acquired immunodeficiency syndrome; *MMRV,* measles, mumps, rubella, and varicella.

2. Human papillomaviruses are grouped within five genera and are nonenveloped double-stranded DNA viruses (Table 8.5). In the oral cavity, they are related to ulcers, tumors, and oral pathoses.

TABLE 8.5

Papillomaviruses That Can Be Recovered in the Oral Cavity

Virus	Characteristics	Disease Association	Oral Pathoses
Papillomavirus (types 6, 11, 16, 18, 31, 36, and 42)	Epithelial cell proliferation with specificity principally in the anogenital area, the urethra, the skin, the larynx, tracheobronchial region, and the oral mucosa	Genital and cutaneous warts, cervical and anogenital cancers, condylomata acuminate (sexually transmitted disease), and recurrent respiratory papillomatosis	Unspecified oral ulcers Recurrent oral aphthous stomatitis Focal epithelial hyperplasia Oral squamous cell carcinoma/verrucous carcinoma Oral leukoplakia Oral lichen planus

Adapted from Slots J: Oral viral infections of adults. *Periodontol 2000* 49:60, 2009.

3. Picornaviruses are all nonenveloped, single-stranded RNA

viruses (Table 8.6). In the oral cavity, they are related to ulcers and different oral pathoses.

TABLE 8.6

Picornaviruses That Can Be Recovered in the Oral Cavity

Virus	Characteristics	Disease Association	Oral Pathoses
Coxsackievirus	Coxsackievirus A16 is closely related to enterovirus-71, and both belong to a discrete subgroup of type A enteroviruses that are prominently associated with hand, foot, and mouth disease	Uncomplicated hand, foot, and mouth disease (coxsackievirus A serotypes 10 and 16); herpangina (mostly coxsackievirus A); myocarditis; infectious type 1 diabetes (coxsackievirus B); and atherosclerosis	Herpangina Hand, foot, and mouth disease
Echovirus	Some echovirus replication occurs in the nasopharynx	Meningitis; pericarditis; myocarditis; herpangina; and Guillain-Barré syndrome	Herpangina
Enterovirus	Enterovirus-71 was first isolated in 1969 from a child with encephalitis Can cause large epidemics of acute disease Mutates readily	Hand, foot, and mouth disease (enterovirus-71); herpangina (enterovirus-71); poliomyelitis-like illness; meningoencephalitis (enterovirus-71); acute pulmonary edema (enterovirus-71); and hemorrhagic conjunctivitis	Herpangina Hand, foot, and mouth disease

4. Retroviruses are divided into seven genera of which two are human pathogens. All retroviruses are enveloped single-stranded RNA viruses (Table 8.7). In the oral cavity, they are related to different tumors and oral pathoses.

TABLE 8.7

Retroviruses That Can Be Recovered in the Oral Cavity

Virus	Characteristics	Disease Association	Oral Pathoses
HIV-1	Global infection Infects cells that contain CD4 receptors, such as T-	Rank order of AIDS-defining pathoses is as follows:	Plasmablastic lymphoma

	helper lymphocytes and cells of the macrophage lineage		
		Pneumocystis pneumonia (43%)	Kaposi sarcoma
		Esophageal candidiasis (15%)	Xerostomia (Sjögren syndrome)
		Wasting (11%)	Sialadenitis
		Kaposi sarcoma (11%)	Osteomyelitis
		Disseminated *Mycobacterium avium* infection (5%)	
		Mycobacterium tuberculosis infection (5%), cytomegalovirus disease (4%)	
		HIV-associated dementia (4%)	
		Recurrent bacterial pneumonia (3%)	
		Toxoplasmosis (3%)	
		Oral hairy leukoplakia	
HIV-2	Infection occurring mainly in West Central Africa (Guinea-Bissau)	HIV-2 is associated with similar types of diseases as HIV-1 but is generally less virulent	Oral hairy leukoplakia Plasmablastic lymphoma Kaposi sarcoma Xerostomia (Sjögren syndrome) Sialadenitis Osteomyelitis

AIDS, acquired immunodeficiency syndrome; *HIV,* Human immunodeficiency virus.

Herpesviruses

Herpesvirus virions vary in size from 120 to 250 nm. They consist of a double-stranded linear DNA molecule surrounded by an icosahedral capsid, a proteinaceous tegument, and a lipid-containing envelope with embedded viral glycoproteins.[290] Eight human herpesvirus species with distinct biologic and clinical characteristics have been described: herpes simplex virus-1, herpes

simplex virus-2, varicella-zoster virus, Epstein-Barr virus (EBV), human cytomegalovirus (hCMV), human herpesvirus-6, human herpesvirus-7, and human herpesvirus-8 (see Table 8.4). Typically, after a primary infection, each herpesvirus subfamily maintains latent infection in specific cell populations. In the oral cavity, an infection with herpesviruses can present itself as a primary herpetic stomatitis, herpes labialis (cold sores), chickenpox (varicella), or shingles (zoster). In contrast to a chronic infection, this latency is not associated with the production of infectious virions. In addition, a single individual can simultaneously exhibit herpesvirus latent infection in some cells and active viral infection in other cells. Herpesviruses express proteins during the normal lytic and latent viral life cycle that can interfere with activities of the innate and adaptive immune systems and alter the cellular environment. The alteration of the host defense ensures a lifelong persistence of the viruses in the infected host, and it can contribute to disease development. Herpesvirus active infections can remain asymptomatic but still give rise to viral shedding, or they can cause illness that ranges from classic infectious diseases to benign and malignant tumors, especially in immunocompromised hosts (e.g., patients with acquired immunodeficiency syndrome [AIDS], organ transplant recipients).

Papillomaviruses

The papillomaviruses comprise a group of small, epitheliotropic, nonenveloped, icosahedral, double-stranded, and circular DNA viruses (see Table 8.5). Human papillomaviruses are grouped within five genera, and they comprise more than 100 types. They can induce benign lesions of the skin (warts) and mucous membranes (condylomas), but they can also cause epithelial malignancies such as cancer of the uterine cervix, certain types of anal cancer, vulvar cancer, penile cancer, laryngeal cancer, and oral cancer. Type 16 papillomaviruses have been implicated in one-third of oropharyngeal squamous cell carcinomas, and they show a particularly strong relationship with cancer of the tonsils.[137,152] Head and neck cancers related to papillomaviruses exhibit relatively high mortality rates despite early diagnosis and treatment.

Picornaviruses/Enteroviruses

Picornaviruses are nonenveloped, single-stranded, positive-sense RNA viruses with a virion diameter of approximately 30 nm.[280] This family of viruses consists of nine genera, and it contains several serious pathogens, including poliovirus, hepatitis A virus, rhinovirus, and the hand, foot, and mouth disease virus (see Table 8.6).

The enteroviruses form a specific genus in the picornavirus family. They include coxsackievirus, echovirus, poliovirus, and human enterovirus. Enteroviruses are common human pathogens that are associated with a broad spectrum of clinical presentations, including asymptomatic infections, various enanthems and exanthems, respiratory diseases, aseptic meningitis, severe illness in newborns and immunocompromised hosts, and fatal outcomes. They replicate in the alimentary tract.[275]

Retroviruses

Retroviral virions are composed of one or two copies (e.g., human immunodeficiency virus [HIV] has two copies) of single-stranded, positive-sense RNA enclosed by a conical capsid and a phospholipid envelope. A total of seven retrovirus genera have been established. HIV and T-lymphotropic virus are human pathogens. HIV belongs to the *Lentivirus* genus and includes two subspecies, HIV-1 and HIV-2. Lentiviruses are characterized by long incubation periods between the infection of the host and the manifestation of clinical disease. The course of HIV infection can be divided into primary (or acute) infection, chronic (asymptomatic) infection, and AIDS.[201] Early-stage secondary infections include oral and vulvovaginal candidiasis, pneumococcal infections, tuberculosis, and the reactivation of herpes simplex virus and varicella-zoster virus. Later-stage infections include *Pneumocystis jiroveci* (previously *Pneumocystis carinii*) pneumonia, *Candida* esophagitis, disseminated histoplasmosis, toxoplasma encephalitis, and cryptococcal meningitis. Late-stage diseases include disseminated *Mycobacterium avium* complex infection, recurrent or disseminated CMV infection, cryptosporidiosis, and microsporidiosis. CMV viremia predicts lower survival rates of AIDS patients who are receiving antiretroviral therapy.[447]

Malignant diseases in patients with AIDS are generally virally related and include EBV lymphomas, human herpesvirus-8, Kaposi sarcoma, and papillomavirus cervical and anal carcinomas.

Clinical Manifestations of Oral Viral Diseases

Oral Ulcers

Ulcers or erosions are relatively common in the oropharyngeal mucosa.[356] Although oral ulcers can have a variety of causes, a viral cause of oral ulcers has been established for primary and recurrent herpetic gingivostomatitis (primarily herpes simplex virus-1 but also herpes simplex virus-2), varicella/herpes zoster outbreak (varicella-zoster virus), herpangina (coxsackievirus), and hand, foot, and mouth disease (enteroviruses). Viruses may also play a role in some cases of recurrent aphthous stomatitis (varicella-zoster virus, cytomegalovirus [CMV], other herpesviruses, adenoviruses, and measles virus) and in systemic diseases with an oral ulcerogenic component, such as erythema multiforme (herpes simplex virus), Behçet syndrome (herpes simplex virus and CMV), pemphigus vulgaris (herpes simples virus and CMV), and systemic lupus erythematosus (Epstein-Barr virus [EBV]).

Oral Tumors

Viruses can be connected to a single or a limited number of tumor types (e.g., hepatitis B virus) or to multiple tumor types (e.g., EBV), a difference that probably reflects the extent of tissue tropism of the viruses. Viruses may cause cell transformation and proliferation by directly expressing oncogenic genes in infected cells or by acting as a necessary or noncompulsory cofactor in the development of malignancy. However, even though most individuals harbor oncogenic viruses in the oral cavity, cancer that occurs as a result of infection with such viruses is relatively rare. Risk factors apart from the viral infection are obviously important for cancer development, including family history, age, tobacco smoking, and alcohol consumption. The most important oncoviruses of the human mouth are EBV, herpesvirus-8, and papillomaviruses; the most common virally related malignant diseases in the oral cavity are epithelial neoplasms, lymphomas, and Kaposi sarcoma.[348]

Other Oral Pathologies

In addition to oral ulcers and tumors, viruses have also been implicated in infectious mononucleosis (primary EBV infection and occasionally a primary CMV infection), Sjögren syndrome (hepatitis C virus, human T-lymphotropic virus type I, human immunodeficiency virus [HIV], and herpesviruses), osteomyelitis (herpes zoster virus and CMV), osteonecrosis (herpes zoster), oral leukoplakia (papillomaviruses, mainly types 16 and 18), and oral lichen planus (papillomaviruses and hepatitis C virus).

Periodontitis

Bacteria are recognized as indispensable for the development of periodontitis, and the current hypotheses regarding the pathogenic mechanisms of periodontitis emphasize the importance of assessing bacterial and host factors collectively. Sole bacterial–host interactions appear insufficient to explain the clinical characteristics of the disease.[374] The localized distribution and intermittent exacerbations of periodontal breakdown and other issues remain a riddle. In response, the involvement of herpesviruses in the etiology of periodontitis has been suggested on the basis of their increased presence in inflamed gingival tissue, crevicular fluid, and subgingival plaque in periodontally diseased sites and their potential to induce proinflammatory cytokines.[374,376] However, it remains unclear whether herpesvirus activation occurs spontaneously or as a result of concurrent infection, stress, or other immunosuppressive factors.[46] Several risk factors for periodontitis also have the potential to reactivate herpesviruses.[66] Bacterioviral synergism may play an important role in the onset and progression of periodontitis.[376] However, the hypothesis that herpesviruses are involved in the etiology of periodontitis is still controversial.[46] No doubt exists that herpesviruses are present in the periodontal pocket. Next to herpesviruses, many other viruses have been detected in periodontal pockets. Papillomaviruses, HIV, human T-lymphotropic virus type I, hepatitis B and C viruses, and torque teno virus can all inhabit periodontitis lesions.[375] In addition, the inflamed periodontium may constitute the major oral reservoir for EBV, CMV, papillomaviruses, and hepatitis C virus.[375]

Fungi

Many fungal species have been isolated from the oral cavity. Most isolates are *Candida*, and the most prevalent species is *Candida albicans* (Fig. 8.27). Together with *C. albicans*, some of the most common opportunistic fungal candidal pathogens in humans are *C. tropicalis*, *C. glabrata*, *C. krusei*, *C parapsilosis*, *C. guilliermondii*, and *C. dubliniensis*. *Candida* spp. thrive in low-pH environments, and high *Candida* loads are associated with the presence of relatively low-diversity dental plaque that contains aciduric and acidogenic species such as *Streptococcus* spp. and *Lactobacillus* spp.[193] In addition to *C. albicans, C. glabrata* is now emerging as an important agent in both mucosal and bloodstream infections.[219,295]

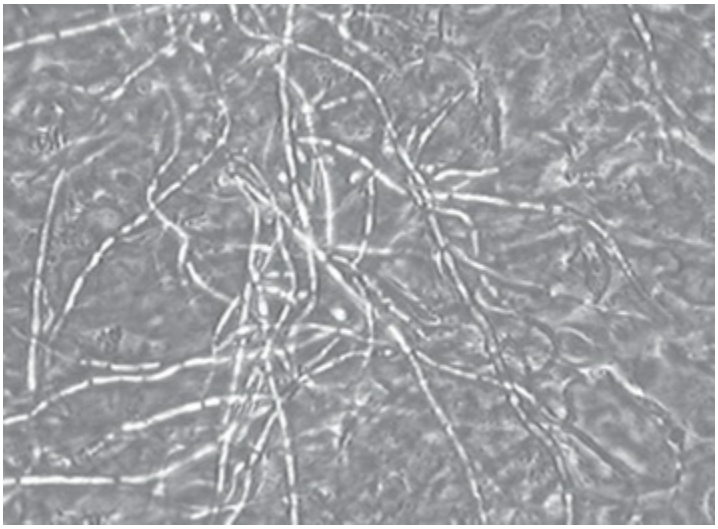

FIG. 8.27 Sample from the palate of a patient with denture stomatitis with clear candidal mycelia visualized under a phase-contrast microscope.

Yeasts such as *Rhodotorula glutinis* and *Saccharomyces cerevisiae* are rarely found in the oral cavity and are not known to cause oral infections. *Cryptococcus neoformans* is occasionally isolated from the mouth but usually from patients with pulmonary cryptococcosis.[393]

C. albicans is the species that is most frequently encountered in infected tissues, including the oral mucosal layers. It is also the predominant species found during vaginal and invasive bloodstream infections. Superficial *C. albicans* infections are increasing in prevalence, especially among denture wearers and aging people; they may lead to invasive disease, which has a high

mortality rate.[351]

In contrast to most other *Candida* spp., *C. albicans* is a pleomorphic fungus that exhibits different modes of growth. It can proliferate as unicellular budding yeast, and it may undergo morphologic switching when triggered by specific environmental conditions, thereby leading to elongated growth forms called *pseudohyphae* and *hypha* and collectively named *filamentous forms*.[398] Hyphae are characterized as unconstricted filaments with parallel-sided walls. In contrast, pseudohyphae seem to represent a growth form between those of yeast and hyphae in which the cells remain attached to each other but can vary in shape from elongated ellipsoidal cells to forms that superficially closely resemble hyphae. The various growth forms are important for the establishment of *Candida* infections, with specific roles proposed in the areas of adhesion, biofilm formation, tissue penetration, and organ colonization.[198] In addition, *C. albicans* produces a cytolytic toxin, candidalysin, which damages epithelial barriers and is essential for virulence in animal models of mucosal infection.[266]

Some systemic mycotic diseases that were once considered exotic are now manifesting intraorally with increasing frequency as a result of the high prevalence of immunocompromised individuals in the community[239,347] (Table 8.8).

TABLE 8.8

Etiologic Agents for Different Types of Oral Yeast Infections

Oral Mycoses	Etiologic Agent
Candidiasis	*Candida albicans, Candida glabrata, Candida tropicalis, Candida dubliniensis, Candida krusei,* and so on
Aspergillosis	*Aspergillus fumigatus*
Blastomycosis	*Blastomyces dermatitidis*
Coccidioidomycosis	*Coccidioides immitis*
Cryptococcosis	*Cryptococcus neoformans*
Fusariosis	*Fusarium moniliforme*
Geotrichosis	*Geotrichum candidum*
Histoplasmosis	*Histoplasma capsulatum*
Mucormycosis	*Order* Mucorales
Paracoccidiomycosis	*Paracoccidioides brasiliensis*
Penicilliosis	*Penicillium marneffei*
Sporotrichosis	*Sporothrix schenckii*

From Samaranayake LP, Keung LW, Jin L: Oral mucosal fungal infections. *Periodontol 2000* 49:39, 2009.

Protozoa

The mouth is the entry port for many parasites that have adapted to the human host. Only a few parasites affect the oral cavity, but an increasing body of literature indicates that oral protozoa are more common than previously appreciated.[24] Depending on the type of infection, the parasitic infectious agents can be divided into two categories: those that induce local infections and those that induce systemic infections with indirect effects on the oral cavity. The former group comprises saprophytes (e.g., *Entamoeba gingivalis, Trichomonas tenax*) (Fig. 8.28; Video 8.5: Phase contrast) that have the potential to turn into opportunistic pathogens or free-living amoebas that occasionally become invasive but that are seldom present clinically. Protozoa tend to be seen in cases of poor oral hygiene and poor periodontal health.

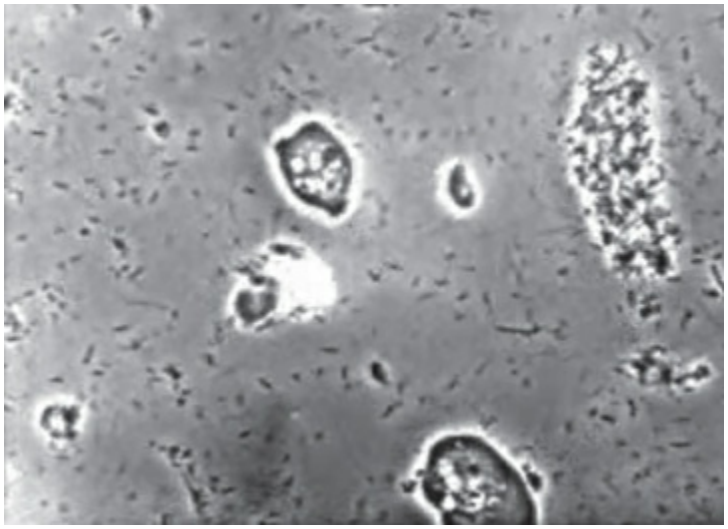

FIG. 8.28 ***Trichomonas*** **in dental plaque visualized under a phase-contrast microscope.**

E. gingivalis is possibly less commonly found in the oral cavity than *T. tenax*. However, there are indications that *E. gingivalis* produces a particular progressive periodontal disease in immunocompromised patients, who often present with a necrotic gingival infection.

This type of painful oral lesion often has an unclear etiology, but, during the late 1990s, a Swedish study not only showed its association with HIV-1 but also reported that this parasite

association seemed to be exclusive for HIV-1 in that no other parasite was ever found with this type of immunodeficiency.[238]

Among systemic parasitic infections, only the protozoan flagellate *Leishmania* can produce clinical symptoms that affect the oral cavity.[24] This effect is indirect, and it is caused by disfigurations produced by infections with the mucocutaneous form of the infection, thereby resulting in granulomatous growth that involves the mouth and nose. Although the distribution of the local oral parasites is worldwide, leishmaniasis exists only in certain areas.

Archaea

Archaea are single-celled organisms that are as distinct from bacteria as they are from eukaryotes. The role of archaea in oral diseases is only beginning to be explored. Methanogenic archaea produce methane from hydrogen gas (H_2)/carbon dioxide (CO_2) and sometimes from formate, acetate, methanol, or methylamine. These organisms have been isolated from patients with periodontal disease via the enrichment of cultures with H_2 and CO_2. They mainly occur in the anaerobic part of the subgingival biofilm and in infected root canals.[22,424,425] In addition, although they were not identified in periodontally healthy subjects, archaea were identified in 37 out of 48 samples from periodontal disease sites with the use of molecular detection methods.[217] Methanogenic archaea were found to thrive better in diseased sites as compared with healthy sites in patients with aggressive periodontitis, and a clear correlation was established with pathogenic microbiota.[98,247] It is postulated that these archaea may favor the growth of periodontopathogens by modulating the subgingival biofilm constitution inherent in their metabolism. However, the precise clinical relevance of archaea remains a matter of conjecture.[246]

Microbiologic Specificity of Periodontal Diseases

Nonspecific Plaque Hypothesis

During the mid-1900s, periodontal diseases were thought to result from an accumulation of plaque over time, eventually in conjunction with a diminished host response and increased host susceptibility with age. This theory, which is called the *nonspecific plaque hypothesis*, was supported by epidemiologic studies that correlated both age and the amount of plaque with evidence of periodontitis.[237,340,355]

According to the nonspecific plaque hypothesis, periodontal disease results from the "elaboration of noxious products by the entire plaque flora."[232] When only small amounts of plaque are present, the noxious products are neutralized by the host. Similarly, large amounts of plaque would cause a higher production of noxious products, which would essentially overwhelm the host's defenses.

Key Fact

Although the nonspecific plaque hypothesis has been discarded in favor of other etiologic hypotheses, most of the therapeutic interventions are still based on the principles of the nonspecific plaque hypothesis.

Several observations contradicted these conclusions. First, some individuals with considerable amounts of plaque and calculus, as well as gingivitis, never developed destructive periodontitis. Furthermore, individuals who did present with periodontitis demonstrated considerable site specificity with regard to the pattern of disease. Some sites were unaffected, whereas advanced disease was found in adjacent sites. In the presence of a uniform host response, these findings were inconsistent with the concept that all plaque was equally pathogenic. Recognition of the differences in plaque at sites of different clinical status (i.e., disease versus health) led to a renewed search for specific pathogens in periodontal diseases and a conceptual transition from the nonspecific to the specific plaque hypothesis.[230,373,380]

Inherent in the nonspecific plaque hypothesis is the concept that the control of periodontal disease depends on the reduction of the total amount of plaque. The current standard treatment of

periodontitis by debridement (nonsurgical or surgical) and oral hygiene measures still focuses on the removal of plaque and its products. Although the nonspecific plaque hypothesis has been discarded in favor of other etiologic hypotheses, most of the therapeutic interventions are still based on the basic principles of the nonspecific plaque hypothesis.

Specific Plaque Hypothesis

The specific plaque hypothesis underlines the importance of the qualitative composition of the resident microbiota. The pathogenicity of dental plaque depends on the presence of or an increase in specific microorganisms.[232] This concept encapsulates that plaque that harbors specific bacterial pathogens may provoke periodontal disease because key organisms produce substances that mediate the destruction of host tissues. The association of specific bacterial species with disease came about during the early 1960s, when the microscopic examination of plaque revealed that different bacterial morphotypes were found in healthy versus periodontally diseased sites (see Video 8.5). At about the same time, major advances were made in the techniques used to isolate and identify periodontal microorganisms. These included improvements in procedures to sample subgingival plaque, in the handling of samples to prevent killing the bacteria, and in the media used to grow the bacteria in the laboratory.[382] The results were a tremendous increase in the ability to isolate periodontal microorganisms and considerable refinement in bacterial taxonomy.[196] Acceptance of the specific plaque hypothesis was spurred by the recognition of *A. actinomycetemcomitans* as a pathogen in localized aggressive periodontitis.[269,373] These advances led to a series of association studies focused on identifying specific periodontal pathogens by examining the microbiota associated with states of health and disease in cross-sectional and longitudinal studies.

The introduction of molecular methods for bacterial identification has greatly increased the power of association studies because we are no longer constrained to analyzing those bacteria that can be cultured (i.e., up to 50% of the total oral microbiota). For example,

specific members of the phylum Synergistetes that have never been cultured in isolation show a clear association with periodontal disease.[423] Molecular identification techniques such as DNA checkerboard hybridization can identify and enumerate many different organisms simultaneously and are thus well suited to high-throughput studies (see eFig. 8.8 online). The association of Socranksy's "red complex" bacteria (*P. gingivalis*, *T. forsythia,* and *T. denticola*) with periodontal disease was based on the analysis of 40 different bacteria in more than 13,000 plaque samples.[384] Nevertheless, disease association studies do not reveal whether the presence of specific bacteria *causes* or *correlates with* the presence of disease. In addition, these studies have shown that periodontal disease can occur even in the absence of defined "pathogens," such as red complex bacteria, and conversely that "pathogens" may be present in the absence of disease.

Ecologic Plaque Hypothesis

During the 1990s, Marsh and coworkers[245a] developed the "ecologic plaque hypothesis" as an attempt to unify the existing theories regarding the role of dental plaque in oral disease (Fig. 8.29). According to the ecologic plaque hypothesis, both the total amount of dental plaque and the specific microbial composition of plaque may contribute to the transition from health to disease. The health-associated dental plaque microbiota is considered to be relatively stable over time and in a state of dynamic equilibrium or "microbial homeostasis." The host controls subgingival plaque to some extent by a tempered immune response and low levels of gingival crevicular fluid flow. Perturbations to the host response may be brought about by an excessive accumulation of nonspecific dental plaque, by plaque-independent host factors (e.g., the onset of an immune disorder, changes in hormonal balance [e.g., during pregnancy]), or by environmental factors (e.g., smoking, diet).

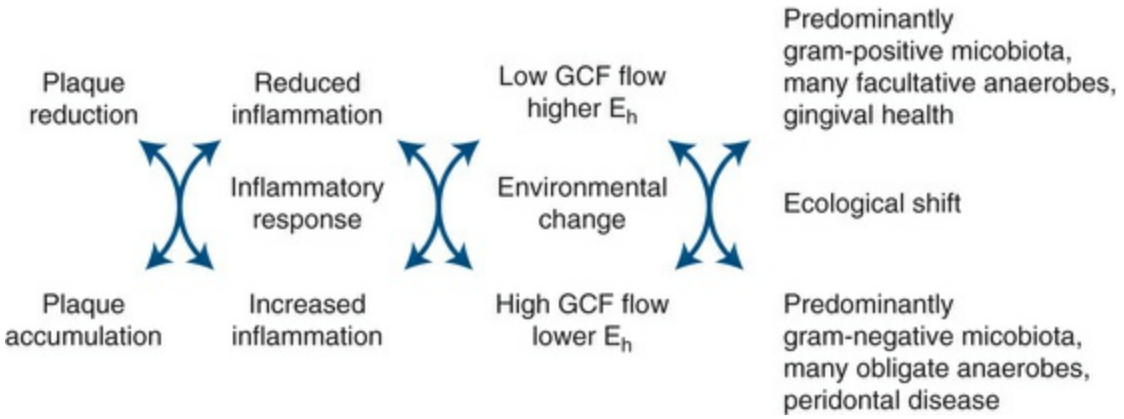

FIG. 8.29 Ecologic plaque hypothesis in relation to periodontal diseases: gingivitis and periodontitis. The accumulation of plaque causes the inflammation of adjacent tissues (gingivitis) and other environmental changes that favor the growth of gram-negative anaerobes and proteolytic species, including periodontopathogens. The increased proportions of such species result in the destruction of periodontal tissues (i.e., periodontitis). *E_h*, Redox potential; *GCF*, gingival crevicular fluid. (Adapted from Marsh PD: Microbial ecology of dental plaque and its significance in health and disease. *Adv Dent Res* 8:263, 1994.)

Changes in the host status, such as inflammation, tissue degradation, and/or high gingival crevicular fluid flow, may lead to a shift in the microbial population in plaque. As a result of microenvironmental changes, the number of beneficial species may decrease, whereas the number of potentially pathogenic species increases. This gradual shift in the entire microbial community, known as *dysbiosis*, may result in a chronic disease state such as periodontitis.[23] The ecologic plaque hypothesis is entirely consistent with observations that disease-associated organisms are minor components of the oral microbiota in health; these organisms are kept in check by interspecies competition during microbial homeostasis. Disease is associated with the overgrowth of specific members of the dental plaque biofilm when the local microenvironment changes, but it is not necessarily the same species in each case. An important consideration of the ecologic plaque hypothesis is that therapeutic intervention can be useful on a number of different levels. Eliminating the etiologic stimulus—whether it is microbial, host, or environmental—will help to restore microbial homeostasis. Targeting specific microorganisms may be less effective because the conditions for disease will remain.

Keystone Pathogen Hypothesis and

Polymicrobial Synergy and Dysbiosis Model

The keystone pathogen hypothesis indicates that certain low-abundance microbial pathogens can orchestrate inflammatory disease by remodeling a normally benign microbiota into a dysbiotic one. It may provide a novel conceptual basis for the development of targeted diagnostic and treatment modalities for complex dysbiotic diseases.[131,133]

Some evidence indicates that certain pathogens may trigger the disruption of microbial homeostasis, thereby leading to the development of periodontal disease, even when they are present only in low numbers. For example, specific pathogen-free mice exposed to *P. gingivalis* developed periodontal bone loss even when the pathogen was present in less than 0.1% of the total microbiota. Disease did not occur in the absence of other bacteria (i.e., in germ-free mice) or in mice lacking the C3a or C5a complement receptors. These data indicated that *P. gingivalis* subverts the host immune system and changes the microbial composition of dental plaque, ultimately leading to periodontal bone loss. On this basis, *P. gingivalis* was labeled a "keystone" pathogen; this means that it is an organism that is central to the disease process, even when it is at a relatively low abundance.

Three "keystone pathogen" mechanisms are proposed for *P. gingivalis*.[336] First, it is suggested that *P. gingivalis* can manipulate the Toll-like receptor 4 (TLR4) response.[75] *P. gingivalis* can act as an agonist of TLR4, activating the immune system, or as an antagonist of TLR4, dampening the immune response. This is dependent on the concentration of iron. In the mouth, the most important source of iron is hemin from the gingival crevicular fluid. So during inflammation, gingival crevicular fluid increases, and *P. gingivalis* acts as antagonist of TLR4, thus inhibiting the immune response.[336] Second, *P. gingivalis* can inhibit the synthesis of interleukin-8 (also in response to other bacteria).[74] This phenomenon is called "local chemokine paralysis" and leads to delayed polymorphonuclear leukocytes transmigration, impairing the host to confront the microbial challenge.[74,240] Third, *P. gingivalis* is able to interfere with the complement system, a component of the innate immune system.[133] On one side, it suppresses its activation by degradation of C3 and capturing of C4b-binding protein and, on the other side, by

paradoxically using the proinflammatory C5a through a crosstalk mechanism between its receptor and TLR2.[434]

The keystone pathogen hypothesis has been extended to include the concept of a disrupted homeostasis in addition to the important roles of keystone pathogens in the polymicrobial synergy and dysbiosis model of disease.[132] In this model, interspecies communication between keystone pathogens and other members of the community (known as *accessory pathogens*) is considered one important factor that leads to overgrowth of the more pathogenic microbiota and to a dysbiotic microbial community. This model is based on a number of observations of microbial synergy among species that are not considered periodontal pathogens such as the oral streptococci and more pathogenic organisms including *P. gingivalis* and *A. actinomycetemcomitans*.[132]

Complicating Factors

The identification of bacterial pathogens in periodontal diseases has been difficult because of a number of factors.[382] The periodontal microbiota is a complex community of microorganisms, many of which are still difficult or impossible to cultivate or identify. The chronic nature of periodontal disease has complicated the search for bacterial pathogens. It was previously thought that periodontal diseases progressed at a slow but steady rate.[228] However, epidemiologic studies established that the disease progresses at different rates, with alternating episodes of rapid tissue destruction and periods of remission (Fig. 8.30).[385] At this moment, by means of multilevel modeling, the linear and burst theories of periodontitis progression are considered to be manifestations of the same phenomenon: some sites improve, whereas others progress, and this occurs in a cyclic manner.[114] Identification of the microorganisms found during the different phases of the disease progression is technically challenging. The interpretation of microbiologic data is further complicated by the clinical classification of the disease status, an area that has undergone revisions.[15,421] Previous and perhaps current classifications involve the grouping of potentially different disease states as a result of difficulties with accurately distinguishing them clinically. It is

important to recognize that groupings such as this may obscure microbiologic associations.

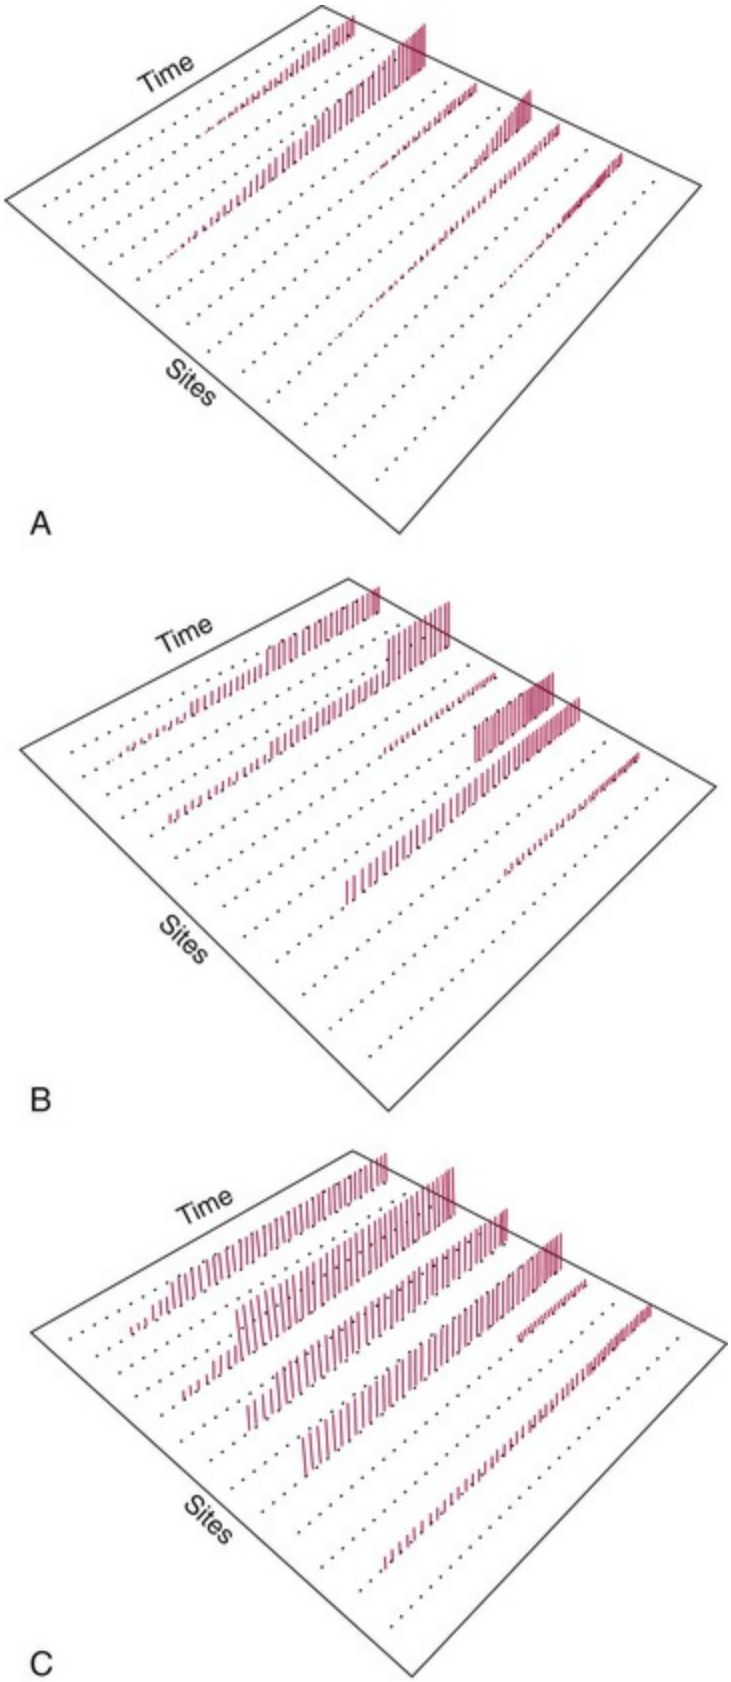

FIG. 8.30 **Diagrammatic representation of possible modes of progression of chronic destructive periodontal diseases. Sites on the x-axis are plotted against time on the y-axis, and activity is shown on the z-axis. (A) Some sites show a progressive loss of attachment over time, whereas others show no destruction. The time of onset and the**

extent of destruction vary among sites. (B) Random burst model. Activity occurs at random in any site. Some sites show no activity, whereas others show one or several bursts of activity. The cumulative extent of destruction varies among sites. (C) Asynchronous multiple burst model. Several sites show bursts of activity over a finite period followed by prolonged periods of inactivity. Occasional bursts may occur infrequently at certain sites at later periods. Other sites show no periodontal disease activity at any time. The difference from the model shown in (B) is that in (C) the majority of destructive disease activity takes place within a few years of the individual's life. (Courtesy Drs. S. Socransky, A. Haffajee, and M. Goodson, [Boston] and J. Lindhe [Göteborg, Sweden].)

Periodontitis is currently considered a mixed infection. This has significant implications for both the diagnosis and the treatment of periodontitis. For the diagnosis, some clinicians evaluate the presence of up to 40 species, but it still is unclear whether some combinations of species are more pathogenic than others. The treatment is directed toward the eradication or reduction of the number of key periodontopathogens. Because several species may be involved, the appropriate use of antimicrobials (especially antibiotics) is extremely difficult to define, given that not all expected periodontopathogens are equally susceptible to the same antibiotic.

Microbiologic diagnostic tests indicated that the presence of periodontopathogens alone is not sufficient for the development of periodontitis. Because of the high sensitivity of these tests, several pathogens have been detected in periodontitis-free patients. Thus, merely the presence of pathogens is not sufficient for disease, and the amount of the pathogens plays a key role in relation to disease.[339] These observations have major clinical implications. First, the specificity of microbial detection is dramatically reduced (specificity in the sense that the presence of a specific pathogen means periodontitis). In other words, even though the result of a microbiologic analysis is positive, the patient can be without disease.[236] In addition, the understanding of the etiology becomes more complicated, because the threshold level for periodontopathogens between health and disease is unknown and obviously subject dependent. Moreover, for several species, large intrastrain variations in genetic information have been detected (i.e., different genotypes), so that, in fact, genotypical information is necessary for pathogenicity assessment.[55,77,124,289] The quality of the host response also plays an essential role, but this cannot yet be

correctly estimated. Finally, it may be questioned whether periodontopathogens are endogenous resident species or exogenous invaders. Indeed, the newer techniques have reported high detection frequencies of all pathogens in healthy subjects.[236,350] This has significant impact on the treatment strategies. For endogenous species, the endpoint of a therapy is the quantitative reduction of the species, whereas for exogenous species, the endpoints are eradication and the prevention of reinfection.

It is currently impossible to alter the susceptibility of the host, so periodontal therapy must be focused on the reduction or elimination of periodontopathogens in combination with the reestablishment, often by surgical pocket elimination, of a more suitable (i.e., less anaerobic) environment for a more beneficial microbiota. Several studies have indicated that the presence of the previously mentioned periodontopathogens (that persist or are reestablished after treatment) is associated with a negative clinical outcome of periodontal treatment.[127,328,329] Because several species may be involved, the use of antimicrobials (especially antibiotics) is extremely difficult because antibiotic susceptibility is very diverse among periodontopathogens and often depends on the geographic region.[315,419]

It is obvious that several key questions still remain unanswered. Some researchers question whether the presence of specific microorganisms in the periodontal pocket is a cause or a consequence of disease.[386] Because most periodontopathogens are fastidious strict anaerobes, they may contribute little to the initiation of disease in shallow gingival pockets and instead be found only in deep periodontal pockets, which is their preferred habitat.

Criteria for the Identification of Periodontopathogens

During the 1870s, Robert Koch developed the classic criteria by which a microorganism can be judged to be a causative agent in human infections. These criteria, known as Koch's postulates, stipulate that the causative agent must do the following:

1. Be routinely isolated from diseased individuals
2. Be grown in pure culture in the laboratory
3. Produce a similar disease when inoculated into susceptible laboratory animals
4. Be recovered from lesions in a diseased laboratory animal

Difficulties exist with regard to the application of these criteria to polymicrobial diseases, and the applicability of Koch's postulates has been increasingly challenged. In the case of periodontitis, three primary problems exist: (1) the inability to culture all of the organisms that have been associated with disease (e.g., many of the oral spirochetes), (2) the difficulties inherent in defining and culturing sites of active disease, and (3) the lack of a good animal model system for the study of periodontitis.[382] In fact, if the ecologic plaque hypothesis proves correct, it must be inherently impossible to fulfill Koch's postulates because no single organism or group of organisms is responsible for all cases of disease.

Sigmund Socransky, a researcher at the Forsyth Dental Center in Boston, proposed criteria by which periodontal microorganisms may be judged to be potential pathogens.[382] According to these criteria, a potential pathogen must do the following:

1. Be associated with disease, as evidenced by increases in the number of organisms at diseased sites
2. Be eliminated or decreased in sites that demonstrate the clinical resolution of disease with treatment
3. Induce a host response in the form of an alteration in the host cellular or humoral immune response
4. Be capable of causing disease in experimental animal models
5. Produce demonstrable virulence factors that are responsible for enabling the microorganism to cause the destruction of the periodontal tissues

On the basis of these criteria, data that support the role of *A. actinomycetemcomitans* and *P. gingivalis* as periodontal pathogens are presented earlier in this chapter. The association and elimination criteria are discussed in the preceding sections. The latter three criteria focus on the host–parasite interaction, which is discussed in

Chapter 9.

The Transition From Health to Disease

The oral microbial ecology is dynamic. The presence and numbers of particular microorganisms, even as a part of a community colonizing a niche in a human being, are controlled by the type and quantity of nutrients present (nutritional determinant), their ability to tolerate the specific physicochemical factors (physicochemical determinants), and their ability to cope with antimicrobial compounds (biologic determinants) or mechanical removal forces (mechanical determinants).[445] Although these determinants are well defined from a theoretical point of view, in practice they overlap each other, especially in more complex environments (i.e., multispecies environments). Inherent to their biologic nature, bacteria interact with each other, with their environment, and vice versa. Therefore, the microbial ecology will change its composition or the composition of the microbial ecology will be changed when transitioning from a healthy status to a diseased status or vice versa. A change in the composition of a bacterial community as the result of external, nonmicrobial factors is termed *allogenic succession.* Smoking is a good example of such interaction. In *autogenic succession* (i.e., a change in the composition of a microbial community that arises from microbial activities), interbacterial and viral–bacterial interactions are involved.

Key Fact

Transition from health to disease results from complex interplay among the host, pathogenic bacteria, and commensal bacteria.

Early microscopic studies clearly demonstrated that the number and proportions of different subgingival bacterial morphotypes differ between healthy and diseased sites (Figs. 8.31 and 8.32; see Video 8.5). [223,373,380] The total number of bacteria, which was determined by microscopic counts per gram of plaque, was twice as high in periodontally diseased sites as compared with healthy

sites.[380] Because considerably more plaque is found at diseased sites, this suggests that, in general, the total bacterial load in diseased sites is greater than that of healthy sites. Fewer coccal cells and more motile rods and spirochetes are found in diseased sites as compared with healthy sites.[223] Although this morphologic criterion can be of diagnostic value, one should remember that nearly all key periodontal pathogens (except *C. rectus* and spirochetes) are immobile rods, which adds to the confusion regarding the bacterial etiology of periodontal diseases. Culturing has shown that the microbiota in periodontally healthy sites consists predominantly of gram-positive facultative rods and cocci (approximately 75%).[373] The recovery of this group of microorganisms is decreased proportionally in gingivitis (44%) and periodontitis (10% to 13%). These decreases are accompanied by increases in the proportions of gram-negative rods, from 13% in health to 40% in gingivitis and 74% in advanced periodontitis.

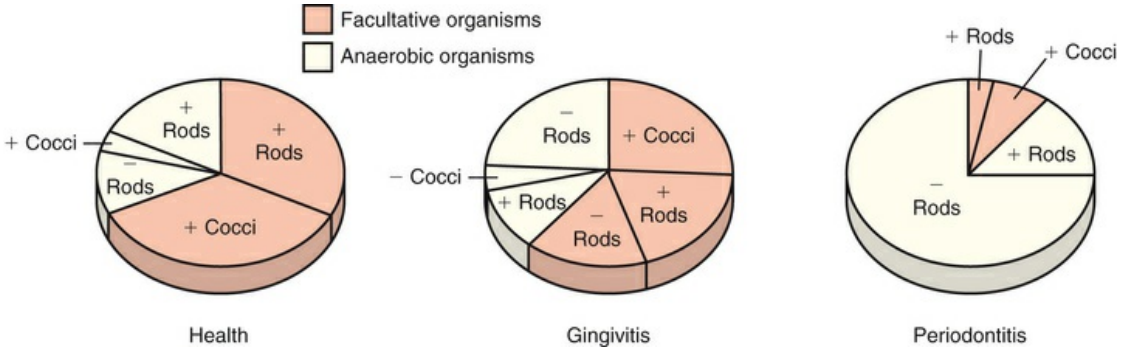

FIG. 8.31 Pie charts based on culturing studies that represent the relative proportion of different morphotypes in subgingival samples in cases of periodontal health, gingivitis, and periodontitis. A clear distinction is made between facultative species and obligate anaerobic species. Spirochetes are not included. +, Gram-positive; −, gram-negative.

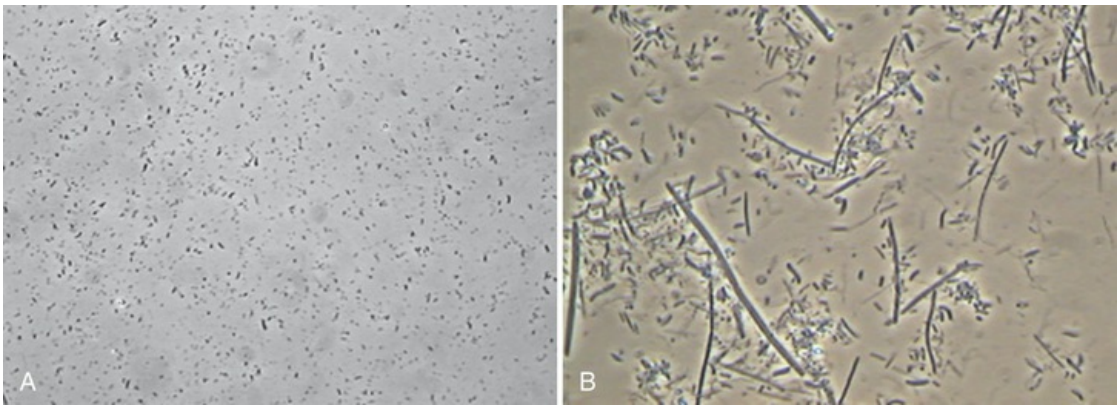

FIG. 8.32 **Phase-contrast micrographs of plaque samples. Phase-contrast micrographs of plaque samples from (A) a healthy patient and (B) a patient with periodontitis. Note the large rods and spirochetes in the periodontitis plaque sample.**

The current concept regarding the etiology of periodontal diseases considers three groups of factors that determine whether active periodontal destruction will occur in a subject: a susceptible host, the presence of pathogenic species, and the absence or small proportion of so-called beneficial bacteria.[12,379,382,389,448] The clinical manifestations of periodontal destruction will result from a complex interplay among these etiologic agents. In general, small amounts of bacterial plaque can be controlled by the body's defense mechanisms without destruction; however, when dysbiosis happens (e.g., as a result of increased susceptibility, high bacterial load, or pathogenic infections), periodontal destruction could occur.[23]

Host Susceptibility

The susceptibility of the host is determined by genetic factors, as well as by environmental and behavioral factors, such as smoking, stress, and viral infections.

Genetic factors seem important for patients with so-called early onset periodontitis, which is now referred to as aggressive periodontitis.[252] Reports regarding the familial nature of chronic forms of periodontitis are less conclusive. The aggregation of aggressive periodontitis within families is consistent with a genetic predisposition, although common environmental factors cannot be excluded (see Chapter 11).

Smoking is considered a behavioral factor and eventually an

environmental factor. It dramatically increases host susceptibility to periodontal breakdown. Nevertheless, the exact nature of the relationship between periodontitis and smoking is unclear (see Chapter 12). Reports are conflicting regarding the effects of smoking on the oral microbiota. Some are in favor of an increased prevalence of *P. gingivalis*, *A. actinomycetemcomitans*, *T. forsythia, E. coli*, and *C. albicans* in smokers, whereas others report no difference.[29,129,303,398,413,417,456]

More recently, pyrosequencing revealed a lower subgingival taxonomic diversity in smokers as compared with nonsmokers.[26] Moreover, investigators showed that in smokers the ability to rebound from a dysbiotic state and reestablish a health-compatible community is impaired.[169] Smoking cessation, in contrast, can alter the subgingival biofilm and suggests a mechanism for improved periodontal health associated with smoking cessation.[107] Some evidence indicates that the epithelial cells of smokers are more prone to colonization by respiratory pathogens. Depending on the bacterial strain, the relative increase in the number of adhering pathogens in smokers versus nonsmokers ranged from 40% up to 150%.[97,342] Cigarette smoke has been shown to modify the expression of *P. gingivalis* genes directly, including several virulence-associated genes.[20] After exposure to cigarette smoke extract, *P. gingivalis* cells induce a lower proinflammatory response than unexposed *P. gingivalis* cells.

Viral infections have been added to the list of factors that modify host susceptibility. HIV and herpesviruses are often associated with periodontal infections.

Several studies show a clear association between HIV infection and some distinct forms of periodontal infection (i.e., necrotizing lesions).[286,297,359] The increased prevalence and severity of chronic periodontitis in HIV-positive subjects suggest that HIV infection predisposes affected individuals to chronic periodontitis.[341] A similar association has been shown for herpesviruses and periodontitis.[374] hCMV was positively associated with severe periodontitis (odds ratio: 4.65; confidence interval: 1.12 to 19.30).[63] Moreover, active hCMV replication in periodontal sites may suggest that hCMV reactivation triggers periodontitis activity.[61] However, caution is warranted in view of concerns regarding

sampling, methods, and interpretation.[46]

It is thought that virus-associated periodontal destruction originates from virus-induced changes in the host response to the local subgingival microbiota.[374]

The influence of viral infections and of the bacterial colonization of cells was investigated by Sanford and coworkers,[349] who first described an increased adhesion of bacteria to virally infected cultured cells. Similar observations have been made since then for a wide variety of viruses, cells, and bacteria.[35] Viral infections relatively increase bacterial adhesion to cells by 20% to 362%.[92,134]

With regard to periodontopathogen adhesion to virally infected cells, Teughels and coworkers[407] showed a 100% increase in *A. actinomycetemcomitans* colonization when epithelial cells were infected with human CMV (hCMV).

Increasing evidence suggests that emotional stress and negative life events can play an important role in the development and progression of periodontitis and that they may also modify the response to periodontal treatment. Stress associated with financial strain is a significant risk indicator for more severe periodontitis in adults (odds ratio: 2.24; confidence interval: 1.15 to 4.38).[111] Emotional and psychological loads can influence the immune system, and they will also alter oral health behaviors.[69] Both factors increase the susceptibility to periodontitis.

Racial factors have also been implicated in the differences in prevalence of early-onset periodontitis and in the frequency of detection of putative periodontopathogens.[21,229]

Pathogenic Bacteria

The second essential factor for disease initiation and progression is the presence of one or more pathogens of the appropriate clonal type and in sufficient numbers. Despite the difficulties inherent in characterizing the microbiology of periodontal diseases, a small group of pathogens is recognized because of their close association with disease. Obvious data support the designation of *A. actinomycetemcomitans, T. forsythia, T. denticola,* and *P. gingivalis* as key pathogens because they are strongly associated with periodontal disease status, disease progression, and unsuccessful

therapy. For the following list of bacteria, moderate evidence for etiology has been reported, at least if their concentration passes a certain threshold level: *P. intermedia, Prevotella nigrescens* (see Fig. 8.2I), *C. rectus, P. micra* (see Fig. 8.2J), *F. nucleatum, Eubacterium nodatum* (see Fig. 8.2N), and various spirochetes.[12,379,382,389,448] The significance of the role of these key pathogens is largely based on epidemiologic data, the ability of these microorganisms to produce disease when inoculated in animals, and their capacity to produce virulence factors. However, the mere presence of putative periodontopathogens in the gingival crevice is not in itself sufficient to initiate or cause periodontal inflammation. An elevation in the relative proportion or number of these pathogens to reach a critical mass seems more crucial to mount an effective tissue-damaging process. Indeed, even in health, periodontopathogens are or can be present in the gingival crevice, albeit in low numbers, as members of the normal resident flora.[236] Table 8.9 gives a general overview of the detection frequency for most key pathogens in different forms of periodontal infections. It is immediately obvious that no black-and-white situation exists; there are no specific types of periodontitis for which any known pathogen is always present. This table also illustrates the difficulties with using the microbial composition to differentiate between different forms of periodontal infections. Table 8.10 further highlights the complexity of the microbiology of periodontitis. Most periodontopathogens can also be detected in healthy subjects, with frequencies that range from 10% to 85%. It is obvious that this automatically reduces the specificity of microbiologic testing in periodontology.

TABLE 8.9

Prevalence of Microbial Species Associated With Various Clinical Forms of Periodontitis

	FORMS OF PERIODONTITIS		
Species	**Chronic Periodontitis (%)**	**Localized Aggressive Periodontitis (%)**	**Aggressive Periodontitis (%)**
Aggregatibacter actinomycetemcomitans	28.2	81.8	40.9
Porphyromonas gingivalis	53.8	13.3	79.6
Prevotella	50.2	53.4	71.4

intermedia/nigrescens			
Tannerella forsythia	50.6	O	50.8
Campylobacter rectus	40.3	12.5	47.8

O, Occasionally isolated.

However, technologic advancements such as next-generation sequencing have lengthened the list of bacterial species associated with periodontitis. Moderate evidence in the literature is suggested to support the association of 17 species of phylotypes from the phyla Bacteroidetes, Candidatus Saccharibacteria, Firmicutes, Proteobacteria, Spirochaetes, and Synergistetes.[287] The phylum Candidatus Saccharibacteria and the Archaea domain also seem to be associated with disease.[287] For more information, see Table 8.11.

TABLE 8.11

Newly Identified Pathogens in the Etiology of Periodontitis for Which Three or More Studies Are Available

Phylum	Species	Gram	Culture Characteristics	No. of Studies
Bacteroidetes	*Bacteroidales* sp. oral taxon 274 HOT 274	−	a	3

Beneficial Species

The role of "beneficial" species is less obvious in the development of periodontal diseases.[334,382] These bacteria can affect the pathogenic species in different ways and thus modify the disease process as follows: (1) by passively occupying a niche that may otherwise be colonized by pathogens, (2) by actively limiting a pathogen's ability to adhere to appropriate tissue surfaces, (3) by

adversely affecting the vitality or growth of a pathogen, (4) by affecting the ability of a pathogen to produce virulence factors, or (5) by degrading the virulence factors produced by the pathogen. The often-used textbook example of such a beneficial action is the effect of *S. sanguinis* (formerly known as *S. sanguis*) on *A. actinomycetemcomitans*.[412] *S. sanguinis* produces H_2O_2, which either directly or by host enzyme amplification can kill *A. actinomycetemcomitans*.[151] However, interactions between oral streptococci and *A. actinomycetemcomitans* are not so simple and streptococci may actually promote the growth of *A. actinomycetemcomitans* by providing nutrients in the form of lactic acid and electron acceptors that enhance respiratory growth.[325,392] To obtain the benefits of oral streptococcal products without succumbing to H_2O_2, *A. actinomycetemcomitans* regulates the exopolysaccharide-degrading enzyme dispersin B to position itself at an optimal distance from streptococcal cells.[391] Although the so-called beneficial bacteria may be of importance for maintaining a healthy subgingival ecosystem, evidence is limited.[334] Despite rapidly increasing knowledge of periodontopathogen–host interactions, the role of beneficial microbiota in this crosstalk remains obscure. In periodontal microbiology, a bacterial strain is considered beneficial when its prevalence is high in periodontal health and low in diseased situations. It has been shown for other fields in microbiology that direct and indirect microbial interactions can suppress the emergence of pathogens.[36] The importance of the latter is evidenced within the oral cavity by the development of *Candida* infections when the normal oral flora is reduced, such as after a period of systemic antibiotic usage.[430]

Because it has so far been impossible to alter the susceptibility of the host, periodontal therapy is necessarily focused on the reduction or elimination of periodontopathogens in combination with the reestablishment, often by surgical pocket elimination, of a more suitable (e.g., less anaerobic) environment for a more beneficial microbiota. Several studies have indeed indicated that the presence of the previously mentioned periodontopathogens (that have persisted or been reestablished after treatment) is associated with a negative clinical outcome of periodontal treatment.[67,128,328,329,384]

Taking all of this together, it is clear that the periodontal microbiota will shift when going from a periodontally healthy situation toward a periodontally diseased situation (Fig. 8.33).

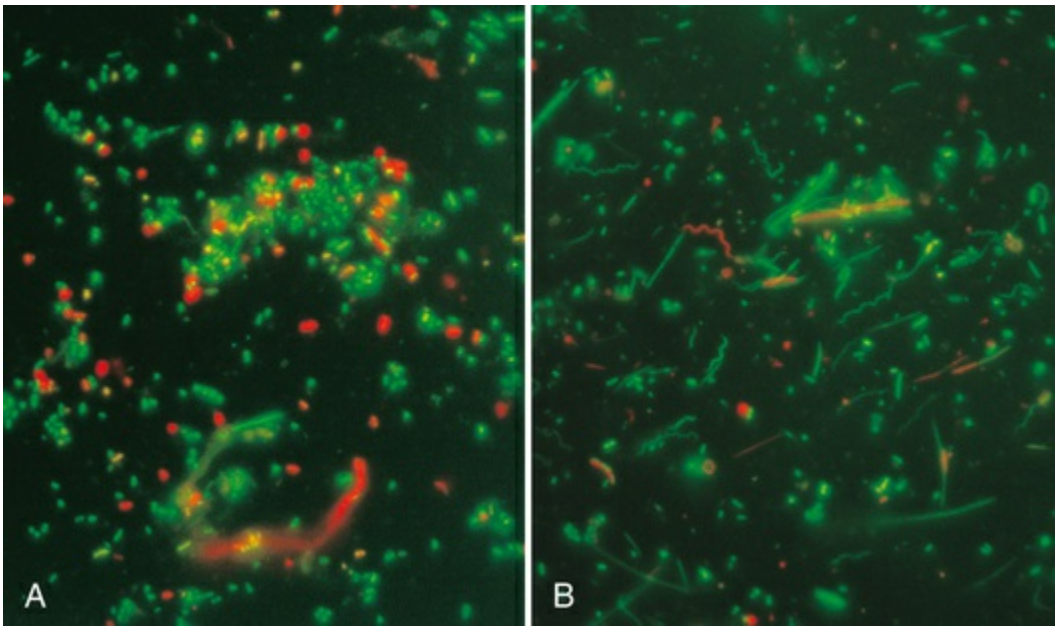

FIG. 8.33 **Vitality stain of subgingival plaque. (A) Plaque derived from a healthy patient that primarily consists of cocci. (B) Plaque derived from a patient with periodontitis. Note the important morphologic differences from (A). Green bacteria are alive; red bacteria are dead.**

When comparing the microbiota among conditions of health, gingivitis, and periodontitis, the following microbial shifts can be identified as health progresses to periodontitis:

- From gram-positive to gram-negative
- From cocci to rods (and, at a later stage, to spirochetes)
- From nonmotile to motile organisms
- From facultative anaerobes to obligate anaerobes
- From fermenting to proteolytic species

Periodontal Health

The recovery of microorganisms from periodontally healthy sites is lower as compared with diseased sites (Table 8.12). The bacteria

associated with periodontal health are primarily gram-positive facultative species and members of the genera *Streptococcus* and *Actinomyces* (e.g., *S. sanguinis, S. mitis, A. oris, Actinomyces israelii, Actinomyces gerencseriae, Actinomyces viscosus* [see Fig. 8.2C], *A. naeslundii*). Small proportions of gram-negative species are also found, most frequently *P. intermedia, F. nucleatum, F. nucleatum* spp. polymorphum, *F. periodonticum, Capnocytophaga* spp. *(C. gingivalis, C. ochracea,* and *C. sputigena*), *Neisseria* spp., and *Veillonella* spp. Microscopic analyses indicate that a few spirochetes and motile rods may also be present. On the basis of checkerboard DNA–DNA hybridization data, *Eubacterium saburreum, Propionibacterium acnes, S. anginosus, S. gordonii,* and *S. oralis* can also be considered as health-associated bacteria.[98,404,450,451]

TABLE 8.12

Summary of Bacterial Species Significantly Associated With Different Clinical Conditions Based on Culture, Polymerase Chain Reaction, and Checkerboard Data

Bacterial Species	Health	Gingivitis	Chronic Periodontitis	Localized Aggressive Periodontitis	Aggressive Periodontitis	Nec Peri Dis
Actinomyces gerencseriae	X

Treponema spp.		X	X	X	X	X
Veillonella parvula	X	X				

Certain bacterial species have been proposed to be protective or beneficial to the host, including *S. sanguinis, Veillonella parvula* (see Fig. 8.2B), and *C. ochracea.* They are typically found in high numbers at periodontal sites that do not demonstrate attachment loss

(inactive sites) but in low numbers at sites where active periodontal destruction occurs.[88,382] These species probably function to prevent the colonization or proliferation of pathogenic microorganisms. Clinical studies have shown that sites with high levels of *C. ochracea* and *S. sanguinis* are associated with a greater gain in attachment after therapy, thereby further supporting this concept.[382] A better understanding of plaque ecology and the interactions between bacteria and their products in plaque will undoubtedly reveal many other examples.

Gingivitis

The development of gingivitis has been extensively studied in a model system referred to as *experimental gingivitis* and initially described by Löe and coworkers.[230,409] Periodontal health is first established in human subjects via cleaning and rigorous oral hygiene measures that are followed by abstinence from oral hygiene for 21 days. After 8 hours without oral hygiene, bacteria may be found at concentrations of 10^3 to 10^4 per square millimeter of tooth surface, and they will increase in number by a factor of 100 to 1000 during the next 24-hour period.[387] After 36 hours, the plaque becomes clinically visible (see Video 8.2). The initial microbiota of experimental gingivitis (see Fig. 8.17) consists of gram-positive rods, gram-positive cocci, and gram-negative cocci. The transition to gingivitis is evidenced by inflammatory changes; it is accompanied first by the appearance of gram-negative rods and filaments and then by spirochetal and motile microorganisms.[409]

The subgingival microbiota of dental-plaque–induced gingivitis (chronic gingivitis) differs from that of both health and chronic periodontitis (see Table 8.11).[174] It consists of roughly equal proportions of gram-positive (56%) and gram-negative (44%) species as well as facultative (59%) and anaerobic (41%) microorganisms.[373] It should be noted that the majority of predominant species in chronic periodontitis are already present in the gingivitis state, but mostly in small numbers.

Predominant gram-positive species include Streptococcus spp. *(S. sanguinis, S. mitis, S. intermedius, S. oralis, S. anginosus), Actinomyces* spp. *(A. oris, A. naeslundii), E. nodatum,* and *P. micra.* The gram-

negative microorganisms are predominantly *Capnocytophaga* spp., *Fusobacterium* spp., *Prevotella* spp., *Campylobacter gracilis, Campylobacter concisus, V. parvula, Haemophilus* spp., and *Eikenella corrodens.* Both groups are commonly associated with gingivitis. The following gram-negative species are commonly found in periodontitis, and they are also associated with gingivitis but in fewer numbers: *P. gingivalis, T. forsythia, P. intermedia, C. rectus, Treponema* spp., and *A. actinomycetemcomitans* serotype a.[258,264,373] Pyrosequencing has identified additional taxa that are associated with gingivitis, including *Leptotrichia* spp. and *Selenomonas* spp.[157] In this study, *Streptococcus* spp. were more strongly associated with health than with gingivitis.

Pregnancy-associated gingivitis is an acute inflammation of the gingival tissues that is associated with pregnancy. This condition is accompanied by increases in steroid hormones in the crevicular fluid and dramatic increases in the levels of *P. intermedia* and *C. rectus*, which use the steroids as growth factors.[191,454]

Studies of gingivitis support the conclusion that disease development is associated with selected alterations in the microbial composition of dental plaque and not just the result of an accumulation of plaque. Gingivitis was generally thought to precede the development of chronic periodontitis; however, many individuals demonstrate long-standing gingivitis that never advances to the destruction of the periodontal attachment.[39,227]

Chronic Periodontitis

Numerous forms of periodontal disease are found in adult populations, and they are characterized by different rates of progression (see Fig. 8.30) and different responses to therapy.[15] Studies in which untreated populations were examined over long time intervals indicate disease progression at mean rates that range from 0.05 mm to 0.3 mm of attachment loss per year (i.e., the gradual model).[39] When populations are examined over short time intervals, individual sites demonstrated short phases of attachment destruction interposed by periods of no disease activity (i.e., the burst model).[119] At this moment, by means of multilevel modeling, the linear and burst theories of periodontitis progression are

considered to be manifestations of the same phenomenon: some sites improve whereas others progress, and this occurs in a cyclic manner.[114]

Microbiologic examinations of chronic periodontitis have been carried out in both cross-sectional and longitudinal studies; the latter have been conducted with and without treatment. These studies support the concept that chronic periodontitis is associated with specific bacterial agents. The microscopic examination of plaque from sites with chronic periodontitis has consistently revealed elevated proportions of spirochetes (see Video 8.5).[223,234] The cultivation of plaque microorganisms from sites of chronic periodontitis reveals high percentages of anaerobic (90%) gram-negative (75%) bacterial species[372,373] (see Fig. 8.23 and Table 8.12).

In patients with chronic periodontitis, the bacteria that are most often detected at high levels include *P. gingivalis, T. forsythia, P. intermedia, P. nigrescens, C. rectus, E.a corrodens* (see Fig. 8.2S), *F. nucleatum, A. actinomycetemcomitans* (often serotype b), *P. micra, E. nodatum, Leptotrichia buccalis, Treponema (T. denticola), Selenomonas* spp. (*S. noxia),* and *Enterobacter* spp.* The introduction of pyrosequencing techniques for microbial community analysis has provided additional sensitivity for detecting periodontal pathogens, although the broad picture has not changed. Unculturable organisms such as Synergistetes appear to correlate with periodontal disease, whereas high proportions of *Actinomyces* spp., *Rothia* spp., and *Streptococcus* spp. are correlated with health.[2,123] When periodontally active sites (i.e., with recent attachment loss) were examined in comparison with inactive sites (i.e., with no recent attachment loss), concentrations of *C. rectus, P. gingivalis, P. intermedia, F. nucleatum,* and *T. forsythia* were found to be elevated in the active sites.[87] Furthermore, detectable levels of *P. gingivalis, P. intermedia, T. forsythia, C. rectus,* and *A. actinomycetemcomitans* are associated with disease progression, and their elimination via therapy is associated with an improved clinical response.[59,87,127,378,440] Both *P. gingivalis* and *A. actinomycetemcomitans* are known to invade host tissue cells, which may be significant in aggressive forms of periodontitis.[52,56,345]

Studies have documented an association between chronic periodontitis and viral microorganisms of the herpesviruses group,

most notably EBV-1 and hCMV.[62] Furthermore, the presence of subgingival EBV-1 and hCMV are associated with high levels of putative bacterial pathogens, including *P. gingivalis, T. forsythia, P. intermedia,* and *T. denticola.* These data support the hypothesis that viral infection may contribute to periodontal pathogenesis, but the potential role of viral agents remains to be determined.

Localized Aggressive Periodontitis

Several forms of periodontitis are characterized by rapid and severe attachment loss that occurs in individuals during or before puberty. Localized aggressive periodontitis, which was previously referred to as localized juvenile periodontitis, develops around the time of puberty. It is observed in females more often than in males, and it typically affects the permanent first molars and incisors (Fig. 8.34). This condition is almost uniformly seen in individuals who demonstrate some systemic defect in immune regulation, and often affected individuals demonstrate defective neutrophil function. Without treatment, the local form often extends to a more generalized form that involves severe attachment loss around many teeth. The first symptoms of localized juvenile periodontitis are already detectable in the deciduous dentition, especially via periodontal destruction around the canines and the second molars.[48]

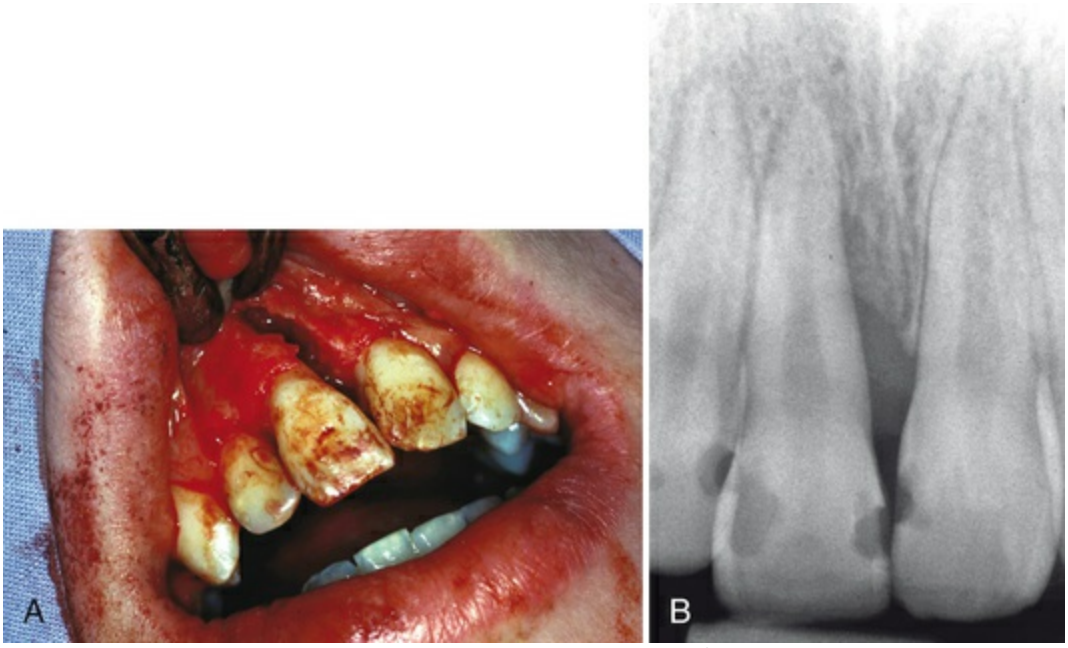

FIG. 8.34 **Localized aggressive periodontitis. (A) Clinical photograph and (B) intraoral radiograph of dramatic bone destruction in an adolescent patient with localized aggressive periodontitis.**

The microbiota associated with localized aggressive periodontitis is predominantly composed of gram-negative, capnophilic (i.e., CO_2-requiring), anaerobic rods[269,270,373] (see Table 8.12). Microbiologic studies indicate that almost all localized juvenile periodontitis sites harbor *A. actinomycetemcomitans,* which may comprise as much as 90% of the total cultivable microbiota.[192,261] Other organisms found in significant levels include *P. gingivalis, E. corrodens, C. rectus, F. nucleatum, B. capillus, Eubacterium brachy,* and *Capnocytophaga* spp. and spirochetes.[192,253,261,263] Checkerboard DNA–DNA hybridization studies have also shown high proportions of *E. nodatum, P. intermedia, Treponema* spp. *(T. denticola), L. buccalis,* and *T. forsythia.*[98,450] In addition, herpesviruses, including EBV-1 and hCMV, have also been associated with localized aggressive periodontitis.[62,253,410]

A. actinomycetemcomitans is generally accepted as the primary etiologic agent in most but not all cases of localized aggressive periodontitis.[190,382] A high leukotoxic clone, known as JP2, is uniquely associated with aggressive forms of periodontitis. However, the finding that not all patients with aggressive periodontitis show this feature points to the possibility that several other factors may provoke this disease.[257] Studies of therapy indicate that mechanical debridement in combination with systemic

antibiotic treatment is necessary to control the levels of *A. actinomycetemcomitans* associated with this disease.[192,330,331] The failure of mechanical therapy alone may relate to the ability of this organism to invade host tissues.[52,56,345]

Aggressive Periodontitis

Aggressive periodontitis, which is also known as generalized aggressive periodontitis, early-onset periodontitis, and rapidly progressive periodontitis, is a severe form of periodontitis that occurs at a relatively young age (i.e., between 20 and 40 years). It is characterized by severe gingivitis, a large number of deepened pockets, and a high tendency for bleeding on probing. In relation to the patient's age, bone destruction is extensive. It is sometimes considered a generalized form of localized aggressive periodontitis. From a microbiologic point of view, it has many similarities with localized aggressive periodontitis (see Table 8.12). However, aggressive periodontitis is clearly dominated more by *P. gingivalis, P. intermedia, T. forsythia,* and *Treponema* spp. *(T. denticola)* and less by *A. actinomycetemcomitans*. Checkerboard DNA–DNA hybridization studies also indicate high proportions of *E. nodatum, Campylobacter gracilis, Campylobacter showae,* and *P. nigrescens*.[98,450]

Necrotizing Periodontal Diseases

Necrotizing periodontal diseases (Fig. 8.35) manifest as acute inflammation of the gingival and periodontal tissues that is characterized by the necrosis of the marginal gingival tissue and the interdental papillae. Clinically, these conditions are often associated with stress or HIV infection. They may be accompanied by malodor and pain and possibly systemic symptoms, including lymphadenopathy, fever, and malaise. Microbiologic studies indicate that high levels of *P. intermedia* and especially of spirochetes and *F. nucleatum* are present in necrotizing ulcerative gingivitis lesions. Spirochetes are found to penetrate necrotic tissue and apparently unaffected connective tissue.[224,225]

FIG. 8.35 Clinical picture of lower front teeth with necrotizing gingivitis.

Abscesses of the Periodontium

Periodontal abscesses (Fig. 8.36) are acute lesions that may result in the very rapid destruction of the periodontal tissues. They often occur in patients with untreated periodontitis, but they also may be found in patients during maintenance or after the scaling and root planing of deep pockets. Periodontal abscesses may also occur in the absence of periodontitis; for example, they may be associated with the impaction of a foreign object (e.g., a popcorn kernel, dental floss) or with endodontic problems.[150] Typical clinical symptoms of periodontal abscesses include pain, swelling, suppuration, bleeding on probing, and mobility of the involved tooth. Signs of systemic involvement may be present, including cervical lymphadenopathy and an elevated white blood cell count.[149] Investigations reveal that bacteria that are recognized as periodontal pathogens are commonly found in significant numbers in periodontal abscesses. These microorganisms include *F. nucleatum, P. intermedia, P. gingivalis, P. micra,* and *T. forsythia.*[130,149,269] Periradicular lesions, which arise as a consequence of endodontic infections, appear to have a similar microbial composition, with a microbiota that is dominated by anaerobes. In addition, *Streptococcus* spp. can also be detected.[343]

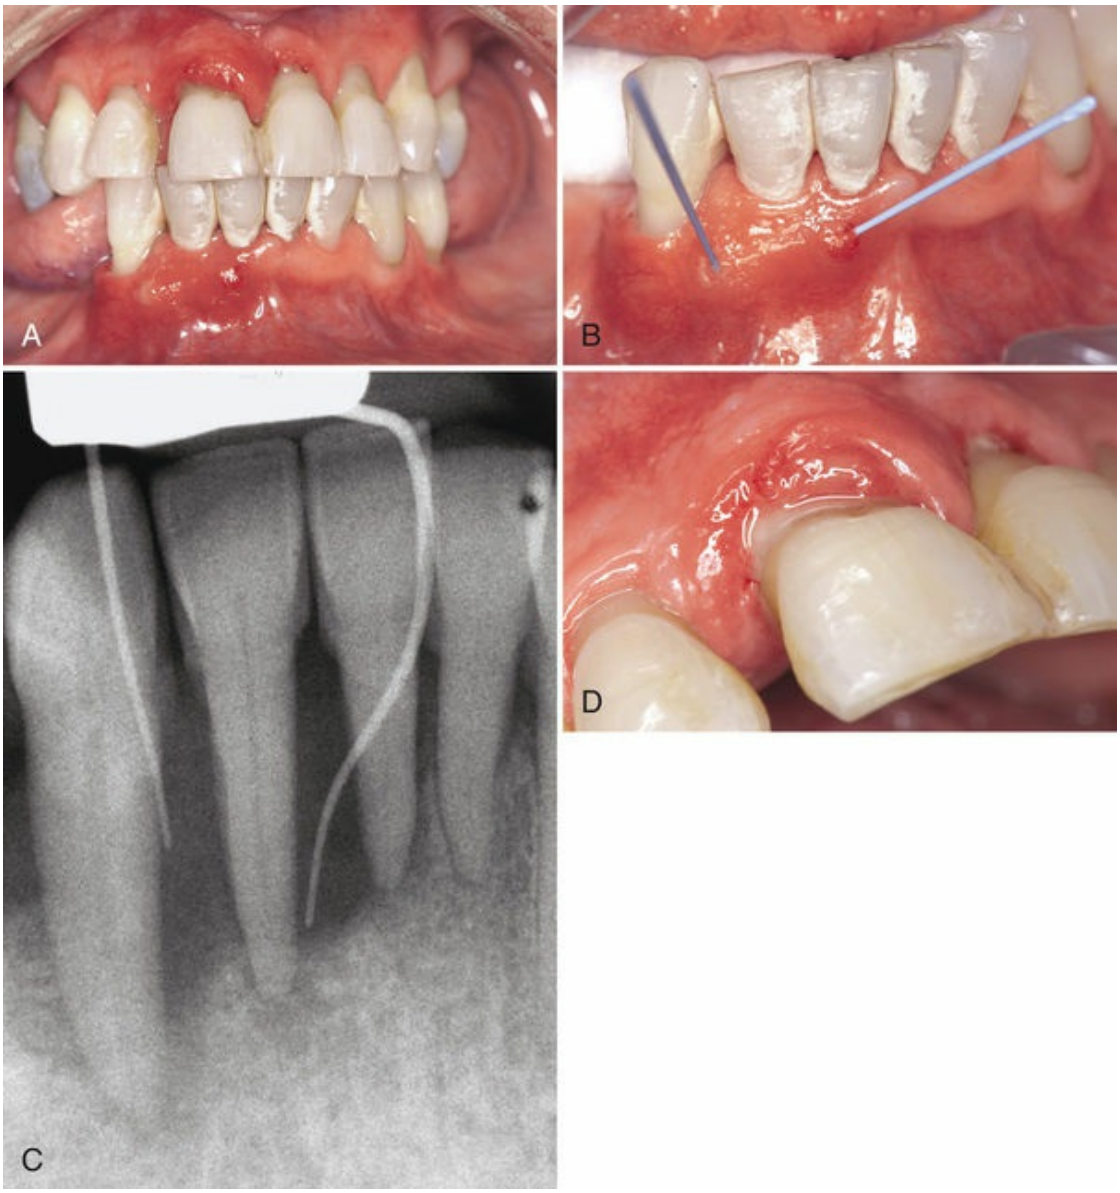

FIG. 8.36 **Periodontal abscesses. (A) to (D) Periodontal abscesses. (A), (B), and (D), Clinical photographs of a patient with several periodontal abscesses. (C) An intraoral radiograph showing the severity of the periodontal destruction. Gutta-percha points (B) and (C) are inserted in the fistulas to show their course.**

Peri-implantitis

The term *peri-implantitis* refers to an inflammatory process that affects the tissues around an already osseointegrated implant and that results in the loss of supporting bone.[15] Originally this inflammatory process was thought to be associated (e.g., in animal studies, in cross-sectional and longitudinal observations in man) with a microbiota comparable to that of periodontitis (i.e., a high

proportion of anaerobic gram-negative rods, motile organisms, and spirochetes), but this association does not necessarily prove a causal relationship.[310] Evidence suggests a lower degree of bacterial complexity in the peri-implant crevice.[199] Healthy peri-implant pockets are characterized by high proportions of coccoid cells, a low ratio of anaerobic-to-aerobic species, a low number of gram-negative anaerobic species, and low detection frequencies for periodontopathogens.[4,31,212,278] Implants with peri-implantitis reveal a microbiota that encompasses conventional periodontal pathogens (see Table 8.12), as well as the cariogenic bacterium *S. mutans*.[199,293] Species such as *A. actinomycetemcomitans, P. gingivalis, T. forsythia, P. micra, C. rectus, F. nucleatum, P. intermedia, T. denticola,* and *Capnocytophaga* are often isolated from failing sites, but they can also be detected around healthy peri-implant sites.[363] Other species, such as *Pseudomonas aeruginosa*, *Enterobacter* spp., *C. albicans,* and staphylococci, are also frequently detected around implants.[8] These organisms are uncommon in the subgingival area, but they have been associated with refractory periodontitis.[379] High proportions of *Staphylococcus aureus* and *S. epidermidis* on oral implants have been reported.[324] The relative resistance of these organisms to commonly used antibiotics suggests that their presence may represent an opportunistic colonization that is caused by systemic antibiotic therapy.[378]

However, some studies using open-ended microbial techniques suggest that the microbiota associated with peri-implantitis is not as similar as thought to that associated with periodontitis.[68,70,99,200,390,461] Some large-scale clinical follow-up studies seem to indicate that implant failures cluster within patients, with increased odd ratios for a second implant failure in patients who have already lost one implant.[416,441] These observations indicate that, within patients, systemic factors are important for the characterization of implant losses.

Virulence Factors of Periodontopathogens

It is clear that some organisms, such as *P. gingivalis, A.*

actinomycetemcomitans, spirochetes, and *P. intermedia,* are strongly associated with a number of periodontal diseases. However, periodontal disease never occurs in the absence of a complex microbiota, and it is often difficult (if not impossible) to determine precisely how different organisms contribute to an individual case of disease. In fact, the contributions of specific bacteria to disease may be unimportant according to the ecologic plaque hypothesis.

Key Fact

The best-known virulence factors of periodontopathogens are adhesive surface proteins and fibrils, tissue destruction–promoting factors, and host immunity–evading strategies.

Targeting one or more "pathogens" will not necessarily cure disease because other organisms with similar activities may take their place. Therefore, it may make sense to focus on the specific molecules that contribute to disease (virulence factors), rather than on the microorganisms that produce them. In fact, it is often difficult to separate the virulence determinants from the organisms that produce them. For example, adhesins are produced by commensal organisms, as well as by pathogens, yet only those adhesins that promote the attachment of a pathogenic organism could be considered virulence determinants. With this in mind, some of the known or putative virulence factors for periodontal disease are described in the following sections. The following are important:

1. Only a proportion of periodontal bacteria has ever been isolated, and almost certainly many other virulence factors are currently unknown.
2. Most of our understanding of virulence factors has come from studies of a very limited number of bacterial species and strains. It is far from clear that the molecules that have been studied in the greatest detail are truly representative of their classes.

Virulence factors of periodontal microorganisms can be subdivided as follows: (1) factors that promote colonization (adhesins), (2) toxins and enzymes that degrade host tissues, and (3) mechanisms that protect pathogenic bacteria from the host.

Adhesive Surface Proteins and Fibrils

To colonize the periodontal pocket, bacteria must adhere to cells or tissues in the region, such as teeth, the existing microbial biofilm, or the pocket epithelium. Bacterial cell surface structures provide the points of contact. Often these structures extend some distance from the cell surface. Fimbriae or pili are polymeric fibrils that are composed of repeating subunits that can extend several micrometers from the cell membrane. Pili were once thought to be unique to gram-negative bacteria, but they have now been identified in several gram-positive organisms, including streptococci and actinomyces.[243] Strains of *P. gingivalis* produce two types of fimbriae, which are known as the major fimbriae and the minor fimbriae.[135]

The major fimbriae are single-stranded filaments approximately 5 nm in diameter and up to 3 μm in length. The backbone of major fimbriae is a chain of repeating subunits of the 43-kDa FimA protein. Minor fimbriae are composed of a 67-kDa protein, Mfa1, and they extend approximately 0.1 to 0.5 μm from the cell surface.[14] Major and minor fimbriae interact with oral streptococci such as *S. gordonii*. *P. gingivalis* FimA binds to glyceraldehyde-3-phosphate dehydrogenase, whereas Mfa1 interacts with the *S. gordonii* cell surface adhesin B.[241,285] Major fimbriae have also been shown to bind host extracellular matrix proteins fibronectin and type I collagen, salivary proline-rich proteins and statherin, and epithelial cells.[11,136,271] Extensive variation in the *fimA* gene that encodes the FimA fimbrial subunit has been observed, and six different genotypes have been designated (i.e., genotypes I, Ib, II, III, IV, and V).[95] Of these, genotypes II and IV are associated with periodontitis.[10,94] However, at present, no evidence indicates that fimbriae of genotypes II and IV are functionally distinct from other major fimbriae.

Adhesion is a fundamental process in the lifestyle of *A.*

actinomycetemcomitans. On solid media, fresh isolates of *A. actinomycetemcomitans* generally form roughly star-shaped colonies that are embedded in the agar. In broth, these strains form clumps (autoaggregate) and grow firmly attached to the sides of the culture vessel, thus leaving the bulk fluid almost completely clear. After several laboratory subcultures, rough strains often revert to "smooth" colony variants. The conversion from a rough form to a smooth form is associated with the loss of pili. *A. actinomycetemcomitans* pili are encoded by a region of the chromosome that contains 14 genes, including the structural pilus subunit gene *flp-1* and an associated system for the secretion and modification of the fibrils. Twelve of these genes have been shown in gene disruption studies to be essential for biofilm formation.[291,296] In a rat model of periodontitis, genes in the *A. actinomycetemcomitans* pilus locus (*flp-1* and *tadA*) were essential for pathogenesis.[357] Despite these seemingly convincing data, some debate still exists regarding the exact role of pili in *A. actinomycetemcomitans* adhesion. Carbohydrates appear to be more important for the attachment of *A. actinomycetemcomitans* than proteins. Treatment with periodate (which disrupts carbohydrate structures) detaches cells from surfaces, whereas the degradation of cell surface proteins by trypsin does not.[101] During growth, *A. actinomycetemcomitans* produces a glycosidase enzyme, dispersin B, that degrades poly-N-acetylglucosamine and that releases even tightly adherent cells from surfaces.[171] In *A. actinomycetemcomitans*, poly-N-acetylglucosamine remains tightly bound to cells, and it co-purifies with lipopolysaccharides.[163] Some evidence indicates that the production of extracellular polysaccharides may be linked to pilus biosynthesis because knocking out almost any gene in the pilus locus reduces extracellular polysaccharide production.[435]

Several nonpilus proteins from periodontopathogens have been shown to interact with host or bacterial receptors, as well as, in some cases, with both. A relatively well-studied example is the major sheath protein (Msp) of *T. denticola*. Msp is a 53- to 64-kDa protein that was originally thought to assemble into a hexagonal array in the outer sheath. However, careful analysis by electron microscopy indicated that Msp is predominantly a periplasmic protein and that some regions are exposed on the cell surface.[45]

Purified Msp interacts with the host extracellular matrix proteins fibrinogen, fibronectin, and laminin.[90,100,126] In addition, Msp recognizes receptors on *P. gingivalis* and *F. nucleatum* and mediates coaggregation.[335] Therefore, Msp is a multifunctional adhesin that promotes binding to host and bacterial receptors.

Tissue Destruction–Promoting Factors

Many bacterial proteins that interact with host cells are recognized by the immune system, and they may trigger immune responses. Fimbriae of *P. gingivalis* and *A. actinomycetemcomitans* are highly antigenic. Inflammation is a major contributor to tissue destruction in periodontal disease; this is considered separately in Chapter 7. However, some bacterial products directly promote tissue destruction in addition to modulating host immunity, with extracellular proteolytic enzymes being the most notable. Most of the tissue destruction in periodontal pockets is actually caused by host matrix metalloproteinases (MMPs), but bacterial proteases play important roles in activating the host enzymes.[120]

Bacterial proteolytic activity in dental plaque—and, in particular, trypsin-like protease activity—is closely correlated with clinical markers of periodontal disease.[276]

Trypsin-like proteases are produced by *P. gingivalis*, *T. denticola,* and *T. forsythia,* and these molecules have been the subject of a comprehensive review.[298] Proteases supply nutrition in the form of peptides or amino acids to the bacteria that produce them. During this process, they may cause the extensive degradation of host extracellular proteins. Periodontopathogens frequently produce complex proteolytic systems that consist of multiple peptide-degrading enzymes; at least 13 peptidases of *P. gingivalis* have been characterized, and a further 29 peptidases are predicted from the genome sequence of strain W83, for example.[267,298]

However, the bulk of the host tissue–degrading activity is restricted to a small number of these enzymes. In the case of *P. gingivalis*, three enzymes known as gingipains are responsible for at least 85% of the total proteolytic activity of the bacterium.[299]

The gingipains belong to the cysteine protease family, and they use an active-site cysteine residue for catalysis. Gingipains are

classed as "Arg-gingipains" (RgpA and RgpB) or "Lys-gingipains" (Kgp) on the basis of their ability to cleave Arg-Xaa or Lys-Xaa peptide bonds (Xaa represents any amino acid). Gingipains are multifunctional proteins that play important roles in adhesion, tissue degradation, and the evasion of host responses.

Protein domains involved in adhesion are located in the C-terminus of pro-RgpA and pro-Kgp, and they are subsequently removed by posttranslational proteolytic processing. The cleaved protease and adhesin domains sometimes reassociate noncovalently. By contrast, the gene that encodes RgpB does not contain the sequences for adhesin domains. The combination of adhesin functions and protease activity together in the same molecule provides an efficient mechanism for targeting substrates. Thus, the catalytic/adhesion domain complex of RgpA is more efficient than RgpB at binding and degrading fibrinogen.[161]

Proteases are produced by *A. actinomycetemcomitans,* but these appear to be less important for the virulence of this organism than the leukotoxin (LtxA). LtxA is a member of the repeats-in-toxin family of proteins. These toxins act by delivering an adenylate cyclase domain into cells, which catalyzes the uncontrolled conversion of adenosine triphosphate to cyclic adenosine monophosphate.

Most strains of *A. actinomycetemcomitans* produce low levels of LtxA. However, some strains are regarded as hyperleukotoxic because they express high levels of the transcript from the *ltxA* gene, thereby encoding LtxA. Hyperleukotoxic strains include the JP2 clone of *A. actinomycetemcomitans,* which is uniquely associated with localized aggressive periodontitis.[146,257] Two distinct mechanisms that give rise to high levels of *ltxA* expression have been described.[354] The JP2 clone contains a deletion in a regulatory gene, designated *orfA*, that is upstream of the *ltxCABD* gene locus. Hyperleukotoxic *A. actinomycetemcomitans* strains isolated in Japan were not found to contain deletions in *orfA* but instead harbored a mobile genetic element (transposon), IS*1301,* that was upstream of the *orfA* gene. The sequence of IS*1301* contains elements that direct the enhanced transcription of the *orfA-ltxCABD* operon. From a diagnostic point of view, it is important to consider that simply detecting *A. actinomycetemcomitans,* LtxA, or both in the periodontal

biofilm is by no means indicative of disease. However, the detection of a hyperleukotoxic strain of *A. actinomycetemcomitans* may be significant.

Strategies for Evading Host Immunity

Pathogenic bacteria have many and varied strategies for evading or subverting the host immune system, including the following: (1) the production of an extracellular capsule, (2) the proteolytic degradation of host innate or acquired immunity components, (3) the modulation of host responses by binding serum components on the bacterial cell surface, and (4) the invasion of gingival epithelial cells. A detailed description of bacteria–host interactions is given in Chapter 9. Selected examples of factors that mediate these processes are given in the following paragraphs.

Strains of *P. gingivalis* produce polysaccharide capsules (Fig. 8.37) that surround the outer membrane. Six different antigenic capsule types have been described on the basis of the differences in the polysaccharide K antigen.[204] In a mouse model, capsular strains of *P. gingivalis* produced a spreading type of infection, whereas acapsular strains tended to form more localized abscesses.[205] Most *P. gingivalis* isolates from periodontitis patients are encapsulated.[203] It is hypothesized that the capsule protects cells from the host immune system. However, protection against the complement system appears to be mediated primarily by a branched phosphomannan polysaccharide that is independent of the K antigen.[369]

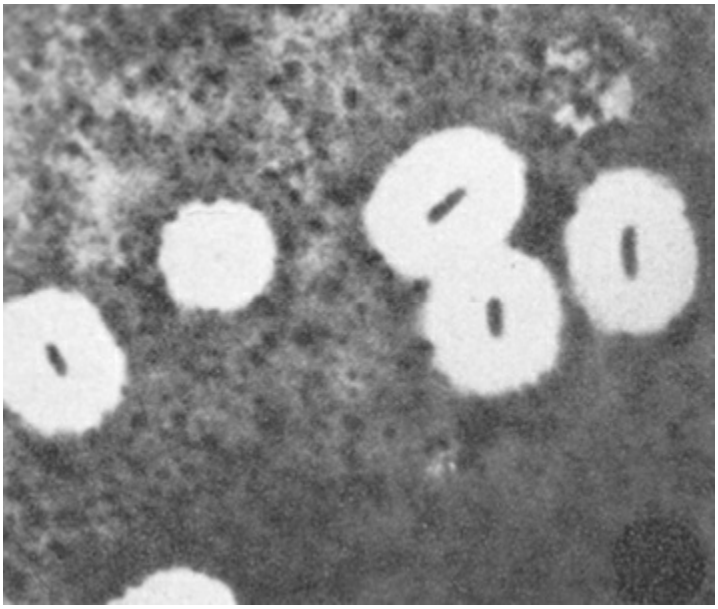

FIG. 8.37 Glycocalyx or polysaccharide capsule of *Porphyromonas gingivalis* visualized with East Indian ink staining (clear halo).

Several periodontopathogens are resistant to complement-mediated phagocytosis, and it is thought that the proteolysis of complement components contributes to resistance to some extent. *P. gingivalis* gingipains have been shown to degrade complement components C3, C4, C5, and factor B.[298] More recently, a cysteine protease of *P. intermedia* called interpain A has also been shown to degrade C3.[300] In vitro, interpain A acts synergistically with gingipains to decrease the deposition of complement C3b.[300] These data fit with the hypothesis that periodontal disease processes are mediated by polymicrobial consortia rather than by individual periodontopathogens.

A novel mechanism for complement evasion has been identified in *A. actinomycetemcomitans*. This organism produces a 100-kDa protein on the outer membrane, Omp100 or ApiA, which mediates adhesion to and the invasion of host cells.[17,218] Mutants lacking ApiA were sensitized to killing by human serum: wild-type cells were almost completely resistant to 30% or 50% normal human serum, whereas 90% of ApiA mutant cells were killed. ApiA was shown to bind factor H, which is an inhibitor of the complement cascade. H_2O_2 produced by *S. gordonii* induces the expression of ApiA and enhances the serum resistance of *A. actinomycetemcomitans*.[326] It has been proposed that H_2O_2 derived from oral streptococci may stimulate the immune response and that

the early detection of H_2O_2 by *A. actinomycetemcomitans* may provide an ecologic advantage under these conditions.[327] Alternatively, the ability of *A. actinomycetemcomitans* to detect streptococcal H_2O_2 may be a fortuitous consequence of a system that has evolved primarily to detect and respond to the neutrophil oxidative burst.

Periodontal pathogens are notoriously difficult to eradicate completely. Despite aggressive antibacterial attacks from the host defenses and from clinical treatments, it is often impossible to prevent reinfection. One potential reservoir for periodontopathogens is inside gingival epithelial cells. *P. gingivalis* and *A. actinomycetemcomitans*, for example, can invade epithelial cells in vitro.[206,251] In vivo, *P. gingivalis*, *T. forsythia*, *P. intermedia*, *T. denticola*, and *A. actinomycetemcomitans* can be detected within the gingival epithelial cells of patients with periodontitis before and after periodontal therapy.[168] Adhesion to host cells is critical for invasion. However, it has been suggested that some factors may specifically control the ability of bacteria to invade cells. In *A. actinomycetemcomitans*, a screen for invasion-associated genes identified two loci, encoding ApiA (see previous paragraph) and ApiBC, which are related to known bacterial invasion proteins (invasins).[218] The ability of bacteria to invade cells may be influenced by their interactions with other organisms in the gingival sulcus. Thus, the coinfection of an epithelial cell line with *P. gingivalis* and a coaggregating strain of *F. nucleatum* resulted in increased invasion by *P. gingivalis* as compared with a monoculture control.[346] Coaggregation with *F. nucleatum* is mediated by the *P. gingivalis* capsular polysaccharide and lipopolysaccharide; therefore, these molecules may indirectly contribute to invasion.[335]

Future Advances in Periodontal Microbiology

Scientific progress at the end of the 20th century, particularly in the field of molecular biology, has led to significant advances in our understanding of periodontal microbiology. DNA-based methodologies for the identification and detection of specific

bacteria and viruses offer remarkable time and cost advantages as compared with culturing techniques. A dramatic increase in the number of samples that can be examined and the number of microorganisms enumerated is now possible. Perhaps even more relevant is the present ability to detect microorganisms that cannot be cultivated so far, which has underscored the limitations of our knowledge of this complex ecologic niche. Greater awareness of the role of the host response in periodontal disease will further improve the understanding of the severity and therapy of periodontal infections. Finally, the recognition of the beneficial activity of several groups of commensal species may open new strategies for the treatment of periodontal disease, such as the use of probiotics or microbial replacement therapy.[408]

Case Scenario 8.1

Patient:
32-year-old female patient

Chief Complaint:
Heavy pain at the gums for the last 3 days. The pain does not allow the patient to sleep or to brush.

Background Information:
The patient is systemically healthy. Her last professional dental cleaning was 4 years ago. The patient smokes currently 20 cigarettes a day. She was recently fired and has financial problems.

Current Findings:
Yellow-grayish matter on top of the gingival margin. Punched-out appearance. Spontaneous bleeding. Too painful to probe.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the yellow-grayish matter? A. Dental plaque B. Materia alba C. Necrotic tissue D. Food remnants	**Answer: C** **Explanation:** This patient has necrotizing periodontal disease. Please refer to Chapter 29.
2. What would a plaque sample look like under a phase contrast microscope? A. All coccoid bacteria B. All filamentous bacteria C. Combination of motile rods and coccoid bacteria D. Combination of filamentous and motile spiral bacteria	**Answer: D** **Explanation:** Necrotizing periodontal diseases typically show filamentous and motile spiral bacteria under a microscope. This relates to the specific microbiology of these diseases.
3. Which specific bacteria could you primarily expect in a plaque sample of affected lesions? A. *P. gingivalis* and *P. intermedia* B. *P. gingivalis*, *T. denticola*, and *T. forsythia* C. *F. nucleatum* and *T. denticola* D. *F. nucleatum* and *P. gingivalis*	**Answer: C** **Explanation:** Although all mentioned bacteria will be present in the sample, the sample will be dominated by *F. nucleatum* (filamentous) and treponemes (motile spiral). This combination is a microbiologic hallmark of necrotizing periodontal diseases.

Case Scenario 8.2

Patient:
68-year-old male patient who is edentulous and wears a removable prosthesis in the upper and lower jaw

Chief Complaint:
No complaint

Background Information:
The patient is systemically healthy. The patient currently smokes 10 cigarettes a day. The patient has no pain. He wears his prosthesis day and night.

Current Findings:
Primarily white-yellowish matter on top of a red, inflamed surface. The matter covers the whole base of the prosthesis. It can be removed by a swab.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Which is the most plausible origin of the white-yellow	**Answer: A** **Explanation:** The matter can be removed by a swab.

matter? A. Microbial infection B. Allergic reaction C. Cancer D. Smokers palate	
2. How would a smear look like under a phase contrast microscope? A. Primarily epithelial cells B. Primarily filamentous organisms C. Primarily motile bacteria D. Primarily nonmotile bacteria	**Answer: B** **Explanation:** This is typically a case of denture stomatitis. One would expect large, filamentous-like organisms.
3. Which specific microorganisms would you expect in a sample of affected lesions? A. *F. nucleatum* and *T. denticola* B. *C. albicans* C. *T. tenax* D. *F. nucleatum* and *P. gingivalis*	**Answer: B** **Explanation:** Although bacteria and epithelial cells will be present in the sample, the sample will show elongated ellipsoidal cells and hyphae forms.

Case Scenario 8.3

Patient:
23-year-old male patient

Chief Complaint:
Painful swelling at the lip since 1 day ago

Background Information:
The patient is systemically healthy. The patient does not smoke but is tired because of school exams. His oral health and oral hygiene are optimal

Current Findings:
Vesicular swelling at the border of the lip that is painful

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Which is the most plausible origin of the vesicular lesion? A. Bacterial infection B. Cancer C. Viral infection D. Fungal infection	**Answer: C** **Explanation:** All other options typically do not result in vesicular lesions.
2. What would an aspiration biopsy sample look like under a phase contrast microscope? A. Viral particles B. Inflammatory cells C. Bacteria D. Clear fluid	**Answer: B** **Explanation:** Viruses cannot be seen under a phase-contrast microscope due to their small dimensions. The fluid will contain inflammatory cells. Normally superinfection with bacteria will occur if the vesicle has not erupted.
3. Which specific virus would you expect? A. Picornavirus B. EBV C. HPV D. HSV-1	**Answer: D** **Explanation:** HSV-1 is the most common cause of herpes labialis.

CHAPTER 9

Practical Molecular Biology of Host–Microbe Interactions

Chad M. Novince, Carlos Rossa Jr., Keith L. Kirkwood

CHAPTER OUTLINE

Microbe-Associated Molecular Patterns
Toll-Like Receptors
NOD-Like Receptors
Complement System
Antimicrobial Peptides
Immunomodulatory Therapies

The periodontium is a dynamic remodeling tissue that is continuously challenged by bacterial biofilms colonizing proximal odontogenic and mucosal surfaces. Periodontal disease pathogenesis has classically been associated with specific "periopathogenic" bacteria, initially identified as the prominent

culturable bacteria isolated from periodontal pocket disease sites.[154,155] Although early empiric thought dictated that periopathogenic bacteria had direct catabolic actions on periodontal tissue matrices, extensive molecular research has elucidated that the host immune response is the primary mediator of periodontal tissue destruction.[8,37,91,169] Experimental periodontitis investigations in animal models deficient in specific immune cell subsets,[9,82] receptors,[20,26,72,86,126] and cytokines[4,42,145,192] have begun to delineate the immunopathophysiology of periodontal disease. Clinical observations and studies in immunocompromised persons demonstrating increased susceptibility and greater severity of periodontal disease further underscore the significance of the host immune response to the oral bacterial challenge.[39,104]

This chapter focuses on molecular aspects of host–microbe interactions in periodontal disease. To avoid redundancy with other chapters addressing the pathophysiology of periodontitis, we emphasize the direct recognition of microbe-associated molecular patterns (MAMPs) at pattern-recognition receptors (PRRs). PRRs that predominantly recognize bacteria, including Toll-like receptors (TLRs) and nucleotide-binding oligomerization domain–like receptors (NLRs), are discussed in detail, along with their associated signal transduction pathways. Complement and antimicrobial peptides are covered briefly, highlighting their influence on PRR signaling. Finally, immunomodulatory therapeutic interventions targeting host–microbe molecular interactions in periodontitis are examined mechanistically.

Microbe-Associated Molecular Patterns

Considering the oral microbiome as a diverse microbial community consisting of more than 600 known bacterial species[33] and knowing that classically defined periopathogenic bacteria are present in both health and disease[170,178] implies that the vigilance and the tolerance mechanisms are used by the host to mount an appropriate immune defense response. Tolerance mechanisms modulate the host response to commensal (nonpathogenic) bacteria to establish a

balanced or homeostatic relationship, whereas vigilance mechanisms protect against periopathogenic bacteria–associated opportunistic infections. The host is capable of discerning among commensal and pathogenic bacteria, and appropriately modulating the immune response, by the direct recognition of MAMPs at PRRs.[21,81,165]

MAMPs, which are evolutionary-conserved molecular motifs present in microorganisms, are not found in higher eukaryotes. MAMPs include microbial cell wall macromolecules, nucleic acids, and flagellin, which function as ligands having specificity for corresponding PRRs, expressed by host cells.[21,81,165] The host immune system discriminates between self and the resident oral flora by direct recognition of MAMPs at PRRs (Table 9.1). MAMP recognition by the corresponding PRR induces host cell signaling, leading to the expression of cytokines and enzymes (Table 9.2) that drives the immune response. MAMP signaling immunomodulation plays a critical role in the homeostatic regulation of colonizing commensal microbes in health, and it also contributes to pathophysiologic tissue destruction in chronic inflammatory disease states such as periodontitis.

TABLE 9.2

Periopathogenic Bacteria Microbe-Associated Molecular Pattern Induction of Biologic Mediators in Host Periodontal Tissue Cells

Host Cells	MAMPs	Biologic Mediators	References
Epithelial cells	LPS, fimbriae, bacteria cell wall extracts, gingipains	IL-8, G-CSF, GM-CSF, β-defensin-2, MMPs-3/9/13, MIP-1α, IL-1β	27, 32, 49, 57, 63–65, 112, 120, 141, 144, 159, 163, 183
Dendritic cells	LPS, CpG-DNA, fimbriae	IFN-α, IL-6, IL-8, IL-10, IL-12, TNF-α, GM-CSF	68, 77, 78, 128, 158
Endothelial cells	LPS	IL-6, GM-CSF, ICAM-1	31, 40, 63, 75, 98
Gingival fibroblasts	LPS, CpG-DNA, gingipains, peptidoglycan	IL-1β, IL-6, IL-8, TNF-α, PGE_2, MCP-1, MMP-2	5, 15, 35, 62, 63, 110, 112, 116, 118, 131, 164, 171, 183, 184
PDL fibroblasts	LPS	IL-6, IL-8, MMP-13, RANKL	62, 63, 138, 139, 189
Cementoblasts	LPS	OPN, OCN, RANKL, IL-6	107, 109
Macrophages	LPS, CpG-DNA, leukotoxin	IL-1α/1β, IL-6, IL-12, TNF-α, MMP-1, NO	63, 83, 87, 103, 110, 116, 168, 187
Osteoblasts	LPS	IL-1β, IL-6, TNF-α, RANKL, PGE_2, NO, MMP-2, MMP-9	63, 85, 124, 161, 185–188, 196
Neutrophils	LPS, CpG-DNA	IL-8, MIP-1α	141, 172, 173
Monocytes	LPS, CpG-DNA, fimbriae	IFN-γ, IL-1α/1β, IL-6, IL-8, IL-12, TNF-α, LIF, RANKL, PGE_2	10, 11, 16, 31, 34, 40, 51, 59, 63, 71, 94, 97, 106, 131, 134
B lymphocytes	CpG-DNA, cell sonicate extracts	IL-6, IL-10, IL-12, TNF-α	23, 114, 181, 193
T lymphocytes	LPS, CpG-DNA, peptidoglycan	IFN-γ, IL-4, IL-10, IL-13	43, 99, 100, 128, 166, 193

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *ICAM,* intercellular adhesion molecule; *IFN,* interferon; *IL,* interleukin; *LIF,* leukocyte inhibitory factor; *LPS,* lipopolysaccharide; *MAMP,* microbe-associated molecular pattern; *MCP,* monocyte chemoattractant protein; *MMP,* matrix metalloproteinase; *NO,* nitric oxide; *OCN,* osteocalcin; *OPN,* osteopontin; *PDL,* periodontal ligament; *PGE_2,* prostaglandin E_2; *RANKL,* receptor activator of nuclear factor-κB ligand; *TNF,* tumor necrosis factor.

Key Fact

In periodontal health, pattern-recognition receptor (PRR) signaling is effectively modulated to regulate the oral commensal microbiota (tolerance) and protect against periopathogenic bacteria (vigilance), thus supporting periodontal tissues homeostasis. Conversely, failed tolerance and vigilance mechanisms in periodontal disease states lead to shifts in the oral microbiota that drive supraphysiologic PRR signaling–induced proinflammatory periodontal tissue destruction.

The periodontal innate immune response functions as the first line of defense against the colonizing oral microbiota. Although the innate immune response was formerly perceived as nondiscriminate and crude, the discovery of PRRs led to the realization that the innate immune response is specific and calculated. Recognition of MAMPs by innate immune cells stimulates the secretion of proinflammatory cytokines (e.g., interleukin-1 beta [IL-1β], IL-6, and tumor necrosis factor [TNF]) and type I interferons (IFN-α, IFN-β), critical for mounting an appropriate innate immune response to colonizing or invading microorganisms (see Table 9.2). Furthermore, MAMP signaling at innate immune cells up-regulates the production of co-stimulatory molecules that are critical for the activation of adaptive immunity. For this reason, PRRs are considered the bridge between the innate and adaptive immune systems.[69,113]

In addition to innate immune cells (neutrophils, monocytes, macrophages, dendritic cells, natural killer cells), investigators have realized that PRRs are also expressed by epithelial cells, extracellular matrix cells (fibroblasts, cementoblasts, osteoblasts), and adaptive immune cells (T lymphocytes, B lymphocytes) (see Table 9.1). Although innate immune cells were formerly perceived to derive solely from the hematopoietic lineage, MAMP-PRR recognition at epithelial cells and tissue extracellular matrix cells revealed that both hematopoietic and mesenchymal cells are central to innate immune defense mechanisms regulating colonizing or invading microorganisms. The realizations that MAMPs are directly recognized by adaptive immune cells and do not require

innate immune cell processing or priming provided insight demonstrating that the innate and adaptive immune systems act more as a continuum than as separate entities. Notably, the identification of PRRs has significantly advanced our understanding of innate and adaptive immunity.

The two major families of PRRs that have been most extensively studied in the periodontium are the TLRs and the NLRs.[21,81,165] TLRs are transmembrane receptors, and NLRs are cytosolic receptors, which recognize a broad range of MAMPs derived from the oral microbiota (see Table 9.1). In addition to recognizing MAMPs, more recently it has been realized that PRRs also recognize immunostimulatory by-products derived from damaged host tissues, known as *damage-associated molecular patterns* (DAMPs).[21,81,165] Although PRR recognition of MAMPs and DAMPs is essential for the host immune defense and normal tissue remodeling, the chapter focuses on MAMPs studied in the context of periodontal bacteria (see Table 9.1).

Toll-Like Receptors

The TLR family currently consists of 10 known functional TLRs in humans, of which TLR-10 is the only member having an unclear biologic role.[80,113] TLR-1 through TLR-9 have been reported to be expressed in the periodontium, in both health and disease.[12] TLR family members are generally subdivided into two groups according to their localization at the plasma membrane (TLR-1, TLR-2, TLR-4, TLR-5, TLR-6, TLR-10) or endolysosomal membrane (TLR-3, TLR-7, TLR-8, TLR-9).[80] Notably, TLR-4 is unique in that it has the ability to localize to both the plasma membrane and the endolysosomal membrane.[80,113] Plasma membrane TLR signaling induces the expression of proinflammatory cytokines, whereas endosomal TLR signaling predominantly induces the expression of type I IFNs.[81,165]

TLRs localized to the plasma membrane recognize extracellular microbial cell wall components (TLR-1, TLR-2, TLR-4, TLR-6) or flagellin (TLR-5), whereas TLRs localized to the endolysosomal membrane recognize microbial nucleic acids (TLR-3, TLR-7, TLR-8, TLR-9).

The chapter focuses on MAMP ligand recognition at TLR-2, TLR-4, and TLR-9 because these TLR family members have been studied most extensively in the context of sensing periopathogenic bacteria (see Table 9.1). TLR-2 and TLR-4 are discussed in the context of recognizing extracellular bacterial cell wall components at the cell surface, and TLR-9 is addressed with regard to recognizing bacterial nucleic acids within endosomes (Fig. 9.1).

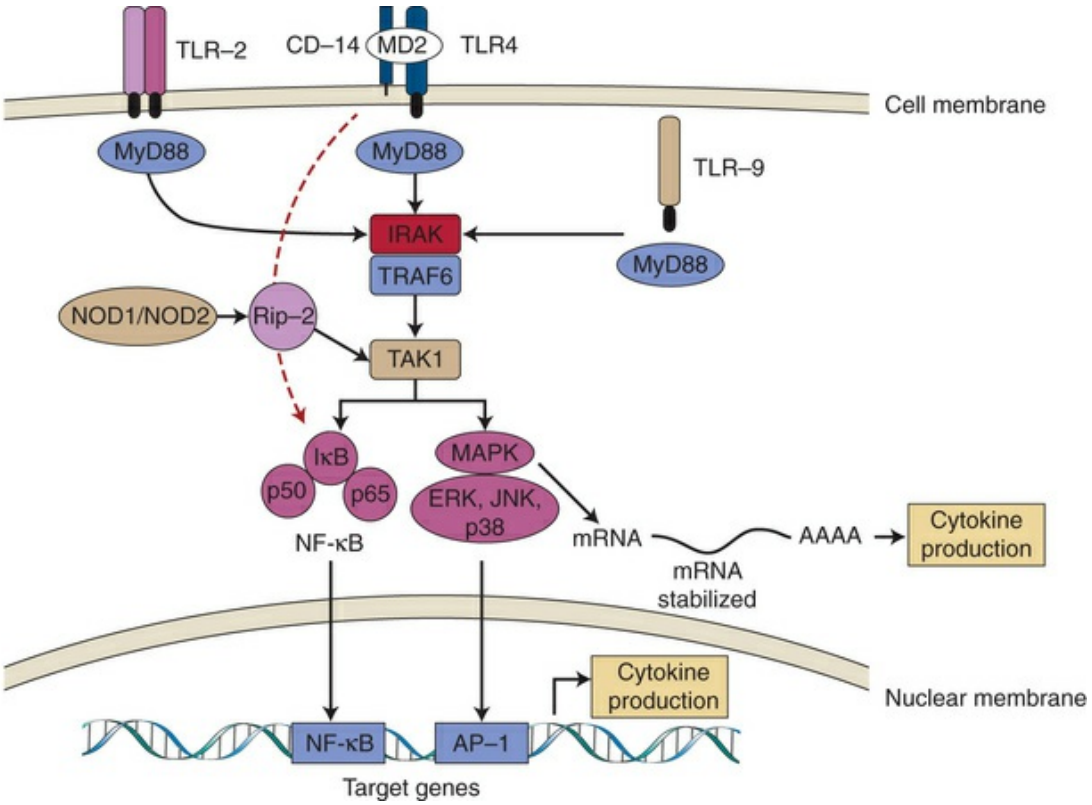

FIG. 9.1 Pattern-recognition receptor (PRR)/microbe-associated molecular pattern (MAMP) signaling. Toll-like receptor 2 (TLR-2), TLR-4, and TLR-9 are depicted as examples of TLRs expressed in cells of the periodontal tissues. After ligand binding, all TLRs (except TLR-3) recruit myeloid differentiation primary response gene 88 (MyD88) adaptor protein and activate the common upstream activator (interleukin-1 receptor-associated kinase [IRAK]/tumor necrosis factor receptor-associated factor-6 [TRAF6] and transforming growth factor-β activated kinase 1 [TAK1]) of nuclear factor-kappa B (NF-κB) and mitogen-activated protein kinases (MAPKs). TLR-4 may also activate NF-κB independently of MyD88, with delayed kinetics *(red dashed arrow)*. Nucleotide-binding oligomerization domain 1 (NOD1) and NOD2 are cytosolic PRRs that recognize peptidoglycan fragments of the bacterial cell wall, and they may amplify the TLR-induced activation of signaling pathways. Activated NF-κB and MAP kinases translocate to the nucleus and bind to their motifs (NF-κB and activator protein 1 [AP-1]) in the promoters of target genes (including early-response and inflammatory genes) and induce their transcription into mRNA, which will ultimately lead to increased cytokine production. p38 MAPK is also

involved after the transcriptional regulation of proinflammatory genes (e.g., interleukin-6 [IL-6], cyclooxygenase-2 [COX-2]) via the modulation of mRNA stability in the cytoplasm. *CD14,* cluster of differentiation 14 molecule; *ERK,* extracellular signal-regulated kinase; *I-κB,* inhibitor of NF-κB; *JNK,* c-Jun N-terminal kinase; *MD2,* myeloid differentiation protein-2, *RIP-2,* serine/threonine kinase adapter protein.

The TLRs are single-pass transmembrane proteins (see Fig. 9.1) characterized by an N-terminal leucine-rich recognition domain and an intracellular C-terminal Toll/IL-1 receptor signaling domain (TIR). On MAMP ligand recognition at the N-terminal domain and subsequent formation of a sustainable homodimer or heterodimer, TIR domains of TLRs act as a scaffold to recruit various TIR domain-containing adaptor proteins: myeloid differentiation primary-response protein 88 (MYD88) and MYD88-adaptor-like protein (MAL), or TIR domain-containing adaptor protein inducing IFN-β (TRIF) and TRIF-related adaptor molecule (TRAM).[81,165] With the exception of TLR-3, all TLRs engage the MyD88 adapter protein. TLR-3 and endosomal TLR-4 uniquely interact with the TRIF adapter protein.[80,113] Engagement of the adapter proteins at the TIR domain of TLRs initiates signal transduction (see Fig. 9.1) that involves interactions between the adaptor molecules, IL-1 receptor–associated kinases (IRAKs) and TNF receptor–associated factors (TRAFs). In the case of TLR-2 and TLR-4 localized to the plasma membrane, MyD88-dependent downstream activation of transforming growth factor-beta (TGF-β)–activated kinase 1 (TAK-1) simultaneously induces mitogen-activated protein kinase (MAPK) and nuclear factor-κB (NF-κB) signaling. NF-κB translocates to the nucleus, and MAPK cascades activate activator protein 1 (AP-1), ultimately resulting in the expression of proinflammatory cytokine genes. When TLR-4 translocates to endosomes, TRIF-dependent signaling leads to the activation of NF-κB and IFN-regulatory factor (IRF)-3, resulting in the expression of proinflammatory cytokine and type I IFN genes. Concerning TLR-9 localized to the endolysosomal membrane, MyD88-dependendent signaling leads to the activation of IRF-7, which up-regulates the expression of type I IFN genes.[81,165] The notable crosstalk of the TLR signaling pathways (see Fig. 9.1) highlights the potential for synergy or amplification effects modulating the host immune response.

Toll-like Receptor-4–Lipopolysaccharide Recognition

Knowledge of the molecular architecture of gram-positive versus gram-negative bacterial cell walls is central to a conceptual understanding of MAMP recognition by the host. Oral bacterial interactions with host TLRs are largely dependent on the exposed macromolecules making up the outer membrane of bacterial cell walls. Whereas lipopolysaccharide (LPS) is unique to the outer membrane of gram-negative bacteria, lipoteichoic acid (LTA) and peptidoglycan are distinct to the outer membrane of gram-positive bacteria. Importantly, lipoproteins are common constituents of the outer membranes of both gram-negative and gram-positive bacteria.[130]

LPS is the major macromolecule composing the outer surface envelope of gram-negative bacteria, critical to the bacterium for maintaining structural integrity, selective permeability, and proper folding and insertion of outer membrane proteins. LPS is typically made up of three domains (lipid A, a short core oligosaccharide, and an O-antigen), and it induces a host immune response through recognition of lipid A.[108,129] Mammalian cells recognize LPS through a TLR-4 homodimer protein complex consisting of TLR-4, the coreceptor myeloid differentiation factor 2 (MD2), and accessory proteins CD14 and lipopolysaccharide-binding protein (LBP) (see Fig. 9.1). LBP processes and delivers LPS to CD14, which sensitizes cells for LPS binding by the MD2-TLR-4 receptor.[80,113]

Toll-like Receptor-2–Lipoprotein/Lipoteichoic Acid/Peptidoglycan Recognition

Different from the TLR-4 homodimer protein complex that is specific for LPS, TLR-2 has the capacity to recognize diverse microbial macromolecules due to forming heterodimer protein complexes with other TLR family members (TLR-1, TLR-6).[80,113] TLR-2 ligands highly relevant to oral flora interactions with host cells include lipoproteins, LTA, and peptidoglycan (see Table 9.1). Lipoproteins, ubiquitously expressed in the outer cell membranes of all bacteria, are anchored to the bacterial cell membrane by lipid

chains covalently attached to conserved N-terminal cysteines.[130] Triacylated lipoproteins commonly expressed by gram-negative bacteria are recognized by TLR-2/TLR-1 heterodimer complexes, whereas diacylated lipoproteins primarily expressed by gram-positive bacteria or mycoplasmas are recognized by TLR-2/TR-6 heterodimer complexes.[80,113] Unique to the outer membranes of gram-positive bacteria, LTA and peptidoglycan are recognized by incompletely characterized TLR-2/TLR-6 heterodimer complexes.[81] Not as well understood as LPS–TLR-4 signaling (reviewed in the previous paragraph), differences in extracellular accessory or coreceptor proteins (CD14, CD36) and intracellular adaptor proteins associated with TLR-2/TLR-1 versus TLR-2/TLR-6 signal transduction appear to regulate TLR-2–mediated host immune response mechanisms critically.[80,113]

Toll-like Receptor-9–CpG-DNA Recognition

Different from TLR-2 and TLR-4 localized to the plasma membrane, which recognize MAMPs at the cell surface, TLR-9 recognizes MAMPs in endosomes (see Fig. 9.1). TLR-9 is the endosomal TLR family member that has been studied most extensively with regard to the recognition of intracellular microbial nucleic acids. During infection, microbe-derived nucleic acids are sensed by endosomal TLRs, and this sensing facilitates mounting a host immune response to clear the invading microorganisms. Although TLR-9 recognizes both viral and bacterial CpG-DNA,[81,165] periodontal research has focused on TLR-9 because CpG motifs are abundant in bacterial DNA (see Table 9.1). CpG-DNA localized within lysosomal compartments induces the trafficking of TLR-9 from the endoplasmic reticulum to the endolysosome, which activates TLR-9 signal transduction.[81,165]

Role of Toll-like Receptors in Periodontitis

TLRs are expressed in the periodontium in health, and they notably have been reported to be expressed at supraphysiologic levels in periodontal tissues afflicted by severe disease states.[12] Both commensal and pathogenic periodontal bacteria stimulate TLR-2 signaling,[84,191] a finding that speaks to the importance of vigilance

and tolerance mechanisms in the host immune defense regulation of the colonizing oral microbiota. The fact that lipoproteins derived from gram-positive versus gram-negative bacteria are differentially recognized by TLR-2/TLR-6 and TLR-2/TLR-1 heterodimer complexes[80,113] highlights the complexity of a single TLR receptor in the modulation of the host immune defense response. Considering that the resident periodontal flora shifts from a predominantly gram-positive microbiota in health to a predominantly gram-negative microbiota in periodontal disease states, gram-negative periopathogenic bacteria–induced periodontal destruction could be mediated through differential TLR-2 signal transduction associated with increased activation of TLR-2/TLR-1 versus TLR-2/TLR-6 heterodimer complexes.

Current knowledge of TLR signaling suggests that gram-negative periopathogenic bacteria–induced catabolic actions are due to differential signaling at the TLR-2 receptor, as well as the concomitant activation of TLR-4 receptor by LPS.[84,115] *Porphyromonas gingivalis* has been most extensively investigated in its ability to stimulate TLR signal transduction through various MAMPs. Early investigations assessing *P. gingivalis* LPS induced up-regulation of proinflammatory cytokine expression in various human and murine cells were controversial in terms of whether the actions of LPS were mediated through TLR-2– versus TL-R4–dependent recognition. Understanding that LPS recognition is specific to the lipid A domain, definitive evidence that *P. gingivalis* LPS activates only TLR-4 was elucidated through chemically synthesized *P. gingivalis* lipid A analogues which activated TLR-4, not TLR-2.[92,147,195] Research demonstrating that a *P. gingivalis*–derived lipoprotein that specifically activates TLR-2 can be co-isolated with LPS[115] implies that early contradictory reports concerning *P. gingivalis* LPS recognition at TLR-2 versus TLR-4 were due to lipoprotein contamination. Highlighting the importance of periopathogenic bacteria–induced activation of concomitant TLR receptors in periodontal tissue destruction, studies using TLR-2 or TLR-4 knockout mice have shown that *P. gingivalis* coactivation of TLR-2 and TLR-4 is critical in stimulating host immune response mechanisms driving alveolar bone loss.[20]

Relative to TLR-2 and TLR-4, investigations delineating the role

of TLR-9 in the pathogenesis of periodontal disease have been scarce. Similar to TLR-2 and TLR-4, TLR-9 expression has been reported to be up-regulated in clinical periodontitis tissues when compared with gingivitis tissues[79] and healthy gingival biopsy samples.[136] Notably, an experimental periodontitis investigation assessing *P. gingivalis*–challenged TLR-9–deficient mice provides evidence indicating that TLR-9 contributes to periodontal bone loss.[86] TLR-9 knockout versus wild-type mice were resistant to *P. gingivalis*–induced alveolar bone loss, which correlated with lower levels of IL-6, TNF, and receptor activator of NF-κB ligand (RANKL) in the gingival tissues of knockout mice. Ex vivo studies performed in the aforementioned report, demonstrating that TLR-2 or TLR-4 agonist challenge resulted in significantly lower cytokine production in TLR-9 knockout versus wild-type cells, highlight the possibility of TLR-9 crosstalk with TLR-2 and TLR-4 signaling in periodontal pathogenesis.[86]

Nucleotide-Binding Oligomerization Domain–Like Receptors

Currently, 22 family members comprise the intracellularly expressed NLRs in humans.[21,81,165] NLRs are localized to the cytosol, and they play a critical role in sensing invading microorganisms and prompting the immune response. NLRs are characterized by C-terminal leucine-rich repeats that act as a sensing domain, a central nucleotide-binding and oligomerization domain (i.e., a NOD), and an N-terminal effector domain that mediates downstream signaling.[21,81,165] This discussion is limited to NOD1 and NOD2, which are specialized NLRs that recognize bacterial peptidoglycan structures of invading pathogens in the cytoplasm, and NLRP3, which is an example of how NLRs function as a component of inflammasome complexes.

NOD1/NOD2–Peptidoglycan Recognition

NOD1 recognizes gamma-D-glutamyl-mesodiaminopimelic acid (iE-DAP), a component of peptidoglycan present in most gram-

negative and some gram-positive bacteria, whereas NOD2 recognizes muramyl dipeptide (MDP), which is found in peptidoglycan from all gram-negative and gram-positive bacteria.[3,165] Peptidoglycan binding at NOD1 and NOD2 receptors causes their oligomerization, which results in recruitment of a serine/threonine kinase adapter protein, RIP-2/RICK, to a caspase activation and recruitment domain (CARD) at the N-terminus. RIP-2/RICK recruitment at the N-terminus activates NF-κB and MAPK-dependent up-regulation of proinflammatory cytokine genes (see Fig. 9.1).[3,165]

NLRP3–Inflammasome Complex

Inflammasomes are multiprotein complexes that recognize diverse inflammation-inducing stimuli, including exogenous MAMPs and endogenous DAMPs, to control the production of proinflammatory cytokines and regulate pyroptosis (an inflammatory form of cell death).[48,160] Several PRR families act as components in the inflammasome complex, including the cytosolic NLRs. The NLR proteins represent the "core" of the multiprotein inflammasome complex and are reflected in the name of the inflammasome. NLRP3, the most extensively investigated inflammasome complex and the focus of this chapter, plays a critical role in the terminal processing and secretion of the proinflammatory cytokines IL-1β and IL-18.[48,160]

Recognition of cytosolic MAMPs and DAMPs induces NLRP3 to acts as a recruiting scaffold for the inactive zymogen pro-caspase-1. Pro-caspase-1 (which has a CARD) is recruited to the inflammasome complex through homotypic binding of CARD via a pyrin domain (PYD) and the adaptor apoptosis-associated specklike protein containing a CARD (ASC). Oligomerization of pro-caspase-1 proteins in the inflammasome leads to their autoproteolytic cleavage into active caspase-1. Activated caspase-1 subsequently functions to cleave pro–IL-1β and pro–IL-18 into their biologically active forms.[48,160]

Pattern-Recognition Receptor–Microbe-

Associated Molecular Pattern Ligand Recognition in Periodontitis

PRRs	Localization	MAMP Ligand	Ligand Origin
TLR-2/TLR-1	Plasma membrane	Triacylated lipoproteins	G− bacteria
TLR-2/TLR-6	Plasma membrane	Diacylated lipoproteins	G+ bacteria
		Lipoteichoic acid (LTA)	G+ bacteria
		Peptidoglycan	G+ bacteria

Role of NOD-like Receptors in Periodontitis

Clinical investigations of NOD1 and NOD2 receptor expression in oral tissues biopsies and isolated cultured cells have demonstrated that both NOD1 and NOD2 are expressed in human oral epithelium,[162] gingival fibroblast cells,[95,177] and periodontal ligament fibroblast cells.[95,167] Interestingly, no reports show that periodontal disease states alter NOD1 or NOD2 expression levels in the human periodontium.

Experimental periodontitis investigations in NLR-deficient mice have provided limited insight into the critical role of NOD1 and NOD2 in periodontal pathogenesis. Although study methodologies were not consistent across investigations, intriguingly no consistency has been found in reported study outcomes. The initial experimental periodontitis investigation using the NOD1 and NOD2 knockout mouse models, which induced periodontitis via applying ligatures, found that mice deficient in NOD2 showed comparable levels of alveolar bone resorption, whereas mice deficient in NOD1 demonstrated reduced levels of alveolar bone loss when compared with wild-type control mice.[72] Corresponding

with the blunted alveolar bone loss findings, NOD1 knockout mice had fewer osteoclasts and lower proinflammatory cytokine expression levels in gingival tissue isolates.[72] A subsequent experimental periodontitis investigation in the NOD1 knockout mouse model, which induced periodontitis via intragingival injection of heat killed gram-negative or gram-positive bacteria, reported contradictory findings.[26] NOD1 knockout mice had exacerbated alveolar bone loss, increased osteoclast numbers, and up-regulated proinflammatory cytokine expression levels in cultured bone marrow macrophages.[26] In light of the aforementioned conflicting study outcomes concerning NOD1, and an additional experimental periodontitis report showing that *P. gingivalis* inoculation induced less alveolar bone loss in NOD2 knockout versus wild-type mice,[126] it is unclear whether NOD1 or NOD2 critically regulates periodontal bone loss.

Although ongoing research is indicated to delineate whether NOD1 and NOD2 receptor signaling is required for periodontitis-associated tissue destruction, investigations highlighting that NOD1and NOD2 and TLR receptor signaling have crosstalk provide novel insight into the role of NOD1 and NOD2 in the pathogenesis of periodontitis. MAMPs that are present in the biofilm can simultaneously activate TLRs and NOD1/2 signaling, which converge at the MAPK and NF-κB signaling pathways. Downstream synergistic signaling effects may enhance the host immune response to the colonizing oral biofilm. A seminal report demonstrating that NOD1 and NOD2 activation has synergistic effects with TLR signaling to enhance the production of proinflammatory cytokines in cultured human periodontal ligament fibroblast (IL-1β, IL-6, IL-8)[167] provides early evidence that periopathogenic biofilms may induce a destructive host immune response via concomitant activation of diverse PRRs.

With regard to NLR family inflammasome complexes, periodontitis investigations have predominantly focused on NLRP3. The expressions of NLRP3 and its endogenous antagonist NLRP2 were found to be increased in human gingival tissues afflicted by various forms of periodontal disease versus gingival biopsy samples from periodontally healthy sites.[17] The aforementioned clinical study also demonstrated that IL-1β and IL-

18 mRNA expression levels were increased in gingival tissues affected by periodontal disease states,[17] a finding consistent with prior periodontitis gene expression studies assessing IL-1β and IL-18 levels.[38,76,121] The realization that NLRP3 levels were positively correlated with the IL-1β and IL-18 expression levels in periodontal disease–affected versus healthy gingival biopsy samples[17] provides indirect evidence implying a role for the NLRP3 inflammasome in the pathogenesis of periodontal diseases states. In vitro studies showing that microorganisms from the dental biofilm modulated the expression of the NLRP3 inflammasome, which correlated with the production of IL-1β and IL-18, provide additional support for the NLRP3 inflammasome in periodontitis-associated catabolic effects.[18]

Key Fact

Diverse pattern-recognition receptor (PRR) signaling pathways commonly converge downstream, resulting in crosstalk that has the potential for synergy or amplification effects modulating the periodontal immune response. Considering that individual periopathogenic bacteria express a multitude of heterogeneous microbe-associated molecular patterns recognized at several distinct Toll-like receptors and nucleotide-binding oligomerization domain–like receptors, which commonly activate nuclear factor-κB and mitogen-activated protein kinase signal transduction pathways, downstream signaling synergy or amplification likely contributes to the supraphysiologic expression of proinflammatory cytokines driving periodontal tissue destruction. Although current research has focused on elucidating the biologic actions of individual PRRs in the periodontium, future research is necessary to delineate the role of PRR signaling crosstalk in orchestrating immune responses supporting periodontal health versus causing disease.

Complement System

Complement is addressed briefly in the current chapter due to its

role in PRR signaling and the periodontal host immune defense. The periodontal host immune response is dependent on a functional complement system, which notably coordinates the recruitment and activation of immune cells, bacterial opsonization, phagocytosis, and lysis.[55,132]

Complement–Pattern-Recognition Receptor Signaling

In addition to PRR localization in plasma membranes (TLRs) and the cytoplasmic compartment (NLRs), some soluble PRR families are also secreted into the plasma as humoral proteins. Soluble PRRs include pentraxins, mannose-binding lectin (MBL), ficolins, and properdin, which represent the functional ancestors of antibodies. Soluble PRRs interact with circulating MAMPs and DAMPS to activate the complement system, ultimately resulting in the opsonization, phagocytosis, and lysis of microbes.[132,133] Notably, complement interactions can amplify the host immune response through synergy with TLRs, another example of crosstalk among diverse PRR signaling pathways.[53]

Classical/Lectin/Alternative Pathways

The activation of the complement cascade involves the sequential activation and proteolytic cleavage of a series of serum proteins by three distinct mechanisms, namely, the classical, lectin, and alternative pathways (Fig. 9.2).[132,133] Classical pathway activation occurs in response to antigen–antibody complexes that are recognized by the C1q subunit of C1. C1q activates complement by functioning as a PRR to recognize distinct MAMPs and DAMPs, or alternatively through other soluble PRRs such as pentraxins (i.e., C-reactive protein). The lectin pathway is similarly triggered through soluble PRRs, including MBL and ficolins, which predominantly recognize carbohydrate groups. Both the classical and the lectin pathways then proceed through C4 and C2 cleavage for the generation of the classical/lectin C3 convertase (C4bC2b) (see Fig. 9.2). The alternative pathway is initiated by the hydrolysis of C3 to C3(H_2O), which is a C3b analogue that forms the initial alternative

pathway for C3 convertase. The alternative pathway also possesses a PRR-based initiation mechanism via properdin, which recognizes MAMPs and DAMPs. The alternative pathway also serves as a positive feedback loop for the classical and lectin pathways. All three pathways converge at the third component of complement (C3), which on activation by pathway-specific C3 convertases leads to the generation of key effector molecules. These include the C3a and C5a anaphylatoxins, which activate specific G-protein–coupled receptors and mediate the mobilization and activation of leukocytes. Also important are the C3b opsonins, which promote phagocytosis through complement receptors, and the C5b-9 membrane attack complex, which can lyse targeted pathogens (see Fig. 9.2).[132,133]

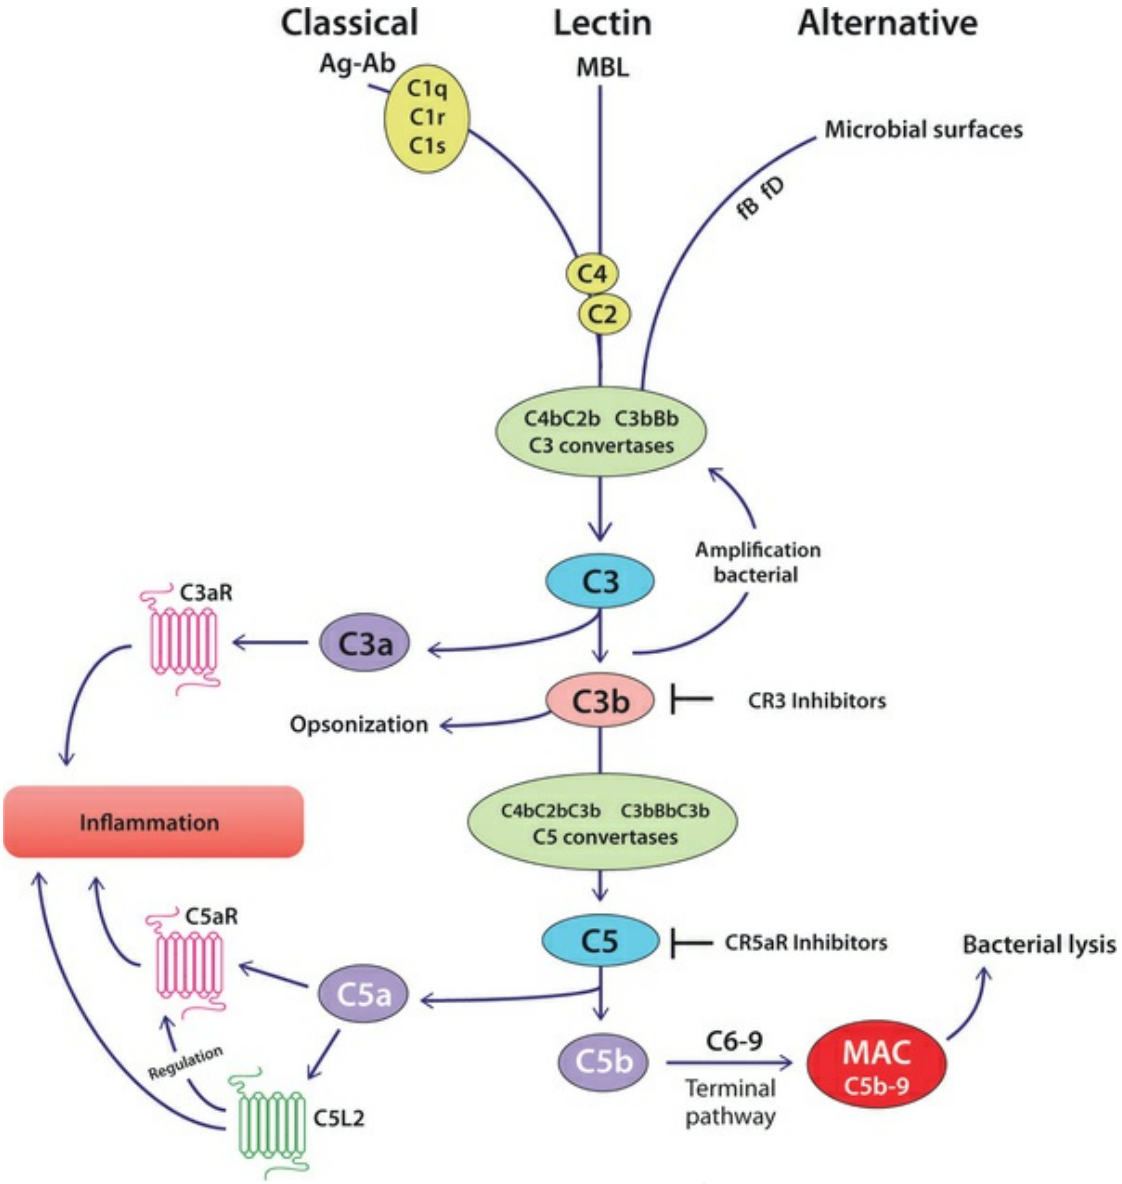

FIG. 9.2 **Activation and therapeutic blockade of the complement system. All three pathways converge at the third component of complement (C3). The classical pathway is activated by antigen–antibody (Ag–Ab) complexes, and it requires C1, C2, and C4 components. Mannose-binding lectin (MBL) activates the lectin pathway through MBL-associated serine proteases (MASPs) and C2 and C4 cleavage. The alternative pathway is propagated through hydrolyzed C3 by complexing with factor B (fB) and via the fB cleavage of factor D (fD). The alternative pathway can also be activated via bacterial lipopolysaccharide in a properdin-dependent manner. Downstream from C3, proteolytic cleavage generates C3a and C5a anaphylatoxins, which activate the receptors C3aR and C5aR. C5aR can also be activated via C5L2. C5b initiates the assembly of C5b-9 membrane attack complex (MAC), which can induce bacterial lysis. Therapeutic blockage is depicted with the C3 and C5 components. *C5L2,* C5a receptor-like-2.**

Role of Complement in Periodontitis

In the context of periodontal inflammation, complement subversion appears to play a major role in periodontal pathogenesis.[54,96] The dysregulation of complement activities may lead to a failure to protect the host against pathogens and amplify inflammatory tissue damage.[55,132] Activated complement components are found at higher levels in the gingival crevicular fluid of periodontitis patients as compared with healthy subjects.[7,123,148] Furthermore, virtually all of the complement components have been detected in chronically inflamed gingiva, whereas complement is nondetectable or not present at lower levels in healthy gingival biopsy specimens.[50,55] Local complement activation may promote periodontal inflammation predominantly via C5a-induced vasodilation, increased vascular permeability and flow of inflammatory exudate, and chemotactic recruitment of inflammatory cells, especially neutrophils.[50,55]

Antimicrobial Peptides

Antimicrobial peptides are components of the innate immune response in eukaryotes, thus providing defense against a wide spectrum of gram-positive and gram-negative bacteria, viruses, and fungi.[58,185,194] In the oral cavity, at least 45 different antimicrobial peptides belonging to different biochemical classes are found in the saliva and the gingival crevicular fluid.[45,46] The discussion of antimicrobial peptides in this chapter focuses on defensins and the cathelicidin LL-37, to highlight another molecular variable that affects PRR signaling and the periodontal host immune response.

Defensins and Cathelicidin LL-37

Defensins and cathelicidin LL-37, the most thoroughly studied antimicrobial peptides,[47,74] are cationic peptides that bind to negatively charged molecules on the microbial cell surface (e.g., LPS in gram-negative bacteria and lipoteichoic acid in gram-positive bacteria) that ultimately depolarize the cell membrane and render it permeable, with resulting bacterial cell death. In addition to their primary antimicrobial function, defensins are modulated by immune response mediators and also have immunomodulatory

functions of their own.[90,151]

Defensins can be classified into α-defensins and β-defensins, based on structural distinctions in the connecting patterns of three disulfide bonds and in the spacing of cysteine residues.[74] Six human α-defensins and four human β-defensins have been extensively characterized. α-Defensins 1 to 4, known as human neutrophil peptides due to their expression in neutrophils, are present in the oral cavity, whereas α-defensins 5 and 6 are localized to the mucosal Paneth cells of the small intestine. β-Defensins 1 to 4, which are produced by a variety of epithelial cells throughout the body,[29,30] are abundantly produced by epithelial tissues within the oral cavity and are found in the gingival crevicular fluid and saliva.[30,36,47,142,149] Cathelicidin LL-37 is another important human defense peptide residing in neutrophils, and it can be found in the gingival epithelium.[47]

Role of Antimicrobial Peptides in Periodontitis

In the periodontium, the expression of β-defensins 1, 2, and 3 is observed at the mRNA level, in both clinically healthy and diseased tissues; the expression of these epithelium-derived peptides appears to be correlated with periodontal health, thereby suggesting a protective role.[14,19,180] Specific β-defensins are located in different anatomic regions of the periodontal epithelium: β-defensins 1 and 2 are observed in the upper layers of the gingival and sulcular epithelium, adjacent to the microbial biofilm and external environment, consistent with the innate immune "barrier" function of the epithelium. Interestingly, neither β-defensin 1 nor β-defensin 2 is found in the junctional epithelium. Protection in the junctional epithelium may be provided by the higher concentration of α-defensins and LL-37 produced by granulocytes migrating toward the gingival sulcus.[29,30,102]

Although the role of defensins and LL-37 in periodontal disease is currently not well understood, the expression of neutrophil derived α-defensins 1 to 3 and LL-37 has been reported to be significantly elevated in the gingival crevicular fluid of patients with chronic periodontitis.[127,174] The expression of defensins induced

by whole periopathogenic bacteria such as *Fusobacterium nucleatum*, *P. gingivalis*, *A. actinomycetemcomitans*, and *T. denticola* is largely dependent on TLR signaling,[70,125,153,179] a property that reinforces the complexity of host–microbe interactions and the periodontal immune defense.

Antimicrobial Peptides in the Periodontium

Antimicrobial Peptides	Cellular Expression	Periodontitis Presentation
α-defensins 1, 2, 3, 4	Neutrophils	Elevated in GCF
β-defensins 1, 2, 3, 4	Epithelial cells	Elevated in gingival / crevicular epithelium
Cathelicidin LL-37	Neutrophils	Elevated in GCF

GCF, Gingival crevicular fluid.

Immunomodulatory Therapies

Various treatment strategies have been developed to target the host response to LPS-mediated tissue destruction.[88] Matrix metalloproteinase (MMP) inhibitors (e.g., low-dose formulations of doxycycline) have been used in combination with scaling and root planing[22] or surgical therapy.[41] In addition, high-risk patient populations (e.g., diabetic patients, patients with refractory periodontal disease) have benefited from the systemic administration of MMP inhibitors.[25,111,140] Encouraging results have been shown with the use of soluble antagonists of TNF-α and IL-1β delivered locally to periodontal tissues in nonhuman primates.[6] Other therapeutic strategies that are being explored are aimed at inhibiting the signal transduction pathways involved in inflammation. Pharmacologic inhibitors of NF-κB and p38 MAPK pathways are actively being developed to manage rheumatoid arthritis and inflammatory bone diseases,[2,73,93] and they have been applied in periodontal disease models with noteworthy accomplishments.[89,135] With the use of this novel strategy, inflammatory mediators including proinflammatory cytokines (e.g., IL-1, TNF, IL-6), MMPs, and others would be inhibited at the level of the cell-signaling pathways required for the transcription factor activation necessary for inflammatory gene expression or mRNA

stability. Indeed, the targeting of RNA-binding proteins that mediate the effects of inflammatory cytokines does have therapeutic value in small animal models of periodontal disease progression.[122] These therapies may provide the next wave of adjuvant chemotherapeutics that may be used to manage chronic periodontitis.

Regarding the complement system, therapeutic strategies are evolving that target either CR3 or CR5 (see Fig. 9.2). Because C3 is a central component of all three activation pathways, blockade at this level is a reasonable approach to treating complement-associated diseases, including periodontitis. CR3 antagonism through topical small molecule inhibitors has been shown to reduce *P. gingivalis*–induced alveolar bone loss.[52,56] The complement-generated fragment C5a functions as a potent mediator of complement signaling and neutrophil recruitment that may protect but also mediate excessive neutrophil activation, and it has the potential to augment tissue damage during periodontal disease progression. As such, C5aR inhibitor use in preclinical models indicate that the potential to inhibit C5aR may be a viable option for the treatment and management of periodontal diseases.[1]

The antimicrobial and immunomodulatory roles of defensins also have obvious attractiveness for therapeutic applications. However, the biochemical purification process is cost inefficient, and the synthesis process is complicated by the size and tridimensional structure of the peptides. Novel analogues of defensins have shown even higher antibacterial activity than the endogenous β-defensins 1 and 3, without any cytotoxic effects on host cells,[150] thus indicating the promise of this approach.

CHAPTER 10

Resolution of Inflammation

Marcelo Freire

CHAPTER OUTLINE

Inflammation
Acute Inflammation Is Self-Limited
Unresolved Chronic Inflammation in Periodontal Diseases
Systemic Link *(Online Only)*
Therapeutic Actions of Resolution Mediators
Final Remarks

Inflammation has protective functions that are regulated by multiple endogenous interactions with the host cells and microbiome. Acute inflammation is temporally and spatially controlled to maintain homeostasis. Four specialized lipid mediator families activate resolution signals (lipoxins, resolvins, protectins, and maresins). Understanding the crosstalk of resolution signals in tissue response to injury has the potential to prevent and treat

chronic diseases. The therapeutic applications of inflammation resolution include prevention, maintenance, and regeneration of periodontal tissues. This chapter presents fundamental concepts of resolution as an active biochemical mechanism regulated by endogenous/therapeutic lipid mediators. Novel concepts of resolution mediators in tissue regeneration and potential therapeutic applications are also discussed.

Inflammation

Inflammation is an essential biologic response observed across species with particular importance to human health and disease. The first description of a localized response to injury and infection that resembled signs of inflammation was recorded by the ancient Egyptian and Greek cultures. Four cardinal signs describing inflammation were identified: *rubor et tumor cum calore et dolore* (redness and swelling with heat and pain).[93] In 1958 Virchow's investigations led to the understanding of the cellular basis of inflammation as a pathologic condition, and his observations led to the addition of a new cardinal sign, functio laesa (loss of organ/tissue function).[93]

More recently, advanced cellular and molecular mechanisms governing the fate of inflammation have been identified. The initiation of acute response is accepted to be a physiologic response occurring in vascularized tissues to defend the host and maintain homeostasis. Inflammation, or “set on fire,” response is an active cellular and molecular response that aims to control challenge.[61] When activated, inflammation is protective to host tissues against stimuli, such as pathobions, foreign bodies, toxic chemicals, and trauma.

Innate immunity, characterized by the local inflammatory response, is the early response to identifying and eliminating infectious agents or damaged tissues. As an initial and protective response to challenges presented by host tissues, inflammation is characterized by increased blood flow, vascular dilation, increased vascular permeability, and cellular recruitment. This response requires four biologic components: inflammation inducers, detecting sensors, downstream mediators, and target tissues. The

type and degree of an inflammatory response are dependent on the nature of the trigger (e.g., bacterial, viral, parasitic, or chemical) and its duration.[60] With specific cellular and molecular cues, inducers will be detected by antigen first line of response and activate a cascade of events that are tightly regulated.

The major sensors for the inflammatory response are epithelial cells and innate immune cells that migrate to the injured site and resident stromal cells. Polymorphonuclear leukocytes (PMNs) or neutrophils (named for their staining characteristics with hematoxylin and eosin) constitute the cellular arm of the first line of defense of the innate immune system. PMNs are phagocytes with potent oxidative and nonoxidative killing mechanisms that combat bacteria.[10] PMN infiltration is followed by the entry of mononuclear cells, monocytes, and activated macrophages into the inflammatory site that clears cellular debris, bacteria, and apoptotic PMNs by phagocytosis without prolonging inflammation. Together, innate cells trigger production of mediators that modulate the fate of inflammation. Neutrophils, macrophages, dendritic cells, and mast cells produce low-molecular-weight proteins called cytokines that control initiation, maintenance, and regulation of the amplitude and duration of the inflammatory response.

In response to bacteria conserved receptors, expressed in innate immune cells, Toll-like receptors (TLRs) sense molecules expressed on pathogens, such as pathogen-associated molecular patterns (PAMPs). Binding of TLRs to specific pathogen molecules induces a signal that activates downstream events. In consequence, the production of communicating molecules such as inflammatory cytokines, interleukins (ILs), chemokines (CXCs), and inflammatory lipid mediators (LMs) is key to signal an effective response.[13,14] The inflammatory mediators are communicators establishing the "language" responsible to signal bacterial clearance. A didactical, and hopefully functional, classification of mediators categorized the inflammatory molecules according to their functions in the context of activation (pro-) or inhibition (anti-) of inflammation. It is important to note the binary terminologies of pro- and anti-inflammatory are more dynamic than first described. This complex relationship is controlled by the molecule concentration, the interaction with its receptors and other interactants, and finally the

time of production and activity. The binary view of a molecule's activity is still the convention and the accepted terminology, but it is crucial to contextualize these concepts. Pro-inflammatory mediators, for example, are produced locally in the tissues or systemically in the bloodstream (e.g., IL-1β, IL-6, tumor necrosis factor alpha [TNF-α], and PGE2). In response to the direct challenge or to the production of pro-inflammatory molecules, anti-inflammatory cytokines control the response and maintain the reaction in check (e.g., IL-10, IL13, TGF-β, IL1RA).[82]

The regulation leading to transcription of pro-inflammatory cytokine genes, their translation, and secretion from a variety of cells is dependent on nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). NF-κB gene clusters and proteins function as dimeric transcription factors that regulate a broad range of biologic processes, including innate and adaptive immunity, inflammation, stress responses, B-cell development, lymphoid organogenesis, and cytokine production. Cytokines are low-molecular-weight proteins that modulate inflammation positively or negatively. Cytokines are released by local cells, such as epithelial cells and fibroblasts, and phagocytes in the acute inflammation phase, and by immune cells in adaptive immunity (please refer to Chapters 7 and 9 for more details on inflammation).

Although the inflammatory response is protective, unresolved inflammation is detrimental to tissue function, promoting dysbiosis. Failure to resolve inflammation leads to chronic diseases including inflammatory bowel syndrome, type 2 diabetes, cardiovascular diseases, Alzheimer disease, cancer, and periodontal diseases. Resolution of inflammation is an active biochemical mechanism regulated by mediators that switch gene expression, protein functions, and cells to return to homeostasis. Among the mediators that regulate this process, specialized lipid mediators (SPMs) activate cells to start resolution. Thus, beneficial acute inflammation is spatially and temporally regulated by SPMs.[9,20,67,74,86]

Key Facts

Pro-resolution Versus Anti-inflammation

Pro-resolution lipid mediators are fatty acids that are expressed endogenously to activate cells and tissues to control inflammation. Initiation of inflammation requires external and internal cellular signals, which in turn activates pro-resolution enzymes to produce lipid ligand signals. Upon interaction with a cellular receptor with lipid ligands, cells are activated to produce pro-resolution or anti-inflammation. The stereospecificity guides the cell function to either suppress and/or pro-resolve. In anti-inflammation, blocking and suppressing pathways that activate inflammation are the usual mechanism. In pro-resolution, specific lipids are able to activate cell switching from pro-inflammation to pro-resolution. For example, the endogenous mediators are able to enhance deficient phagocytosis seen in type 2 diabetes, increase chemotaxis in localized aggressive periodontitis, and prevent gingivitis. Thus, stimulating resolution either endogenously or therapeutically activates protective signals that prevent collateral damage and limit acute or continuous inflammation.

Acute Inflammation Is Self-Limited

To maintain homeostasis, a class switch activity of enzymes from pro-inflammation to pro-resolution controls temporal regulation of acute inflammation.[26,31] For many years, our understanding of inflammation was mostly on initiation as an active process, whereas termination (a.k.a. resolution) was thought to be a passive process with decay of inflammation (Fig. 10.1) until basic and translational studies from Drs. Charles Serhan and Thomas Van Dyke came to light that proved otherwise. Contrary to old belief, they showed that resolution is an active process and can only be initiated when enzymes produce bioactive pro-resolution lipids.[31,77,88]

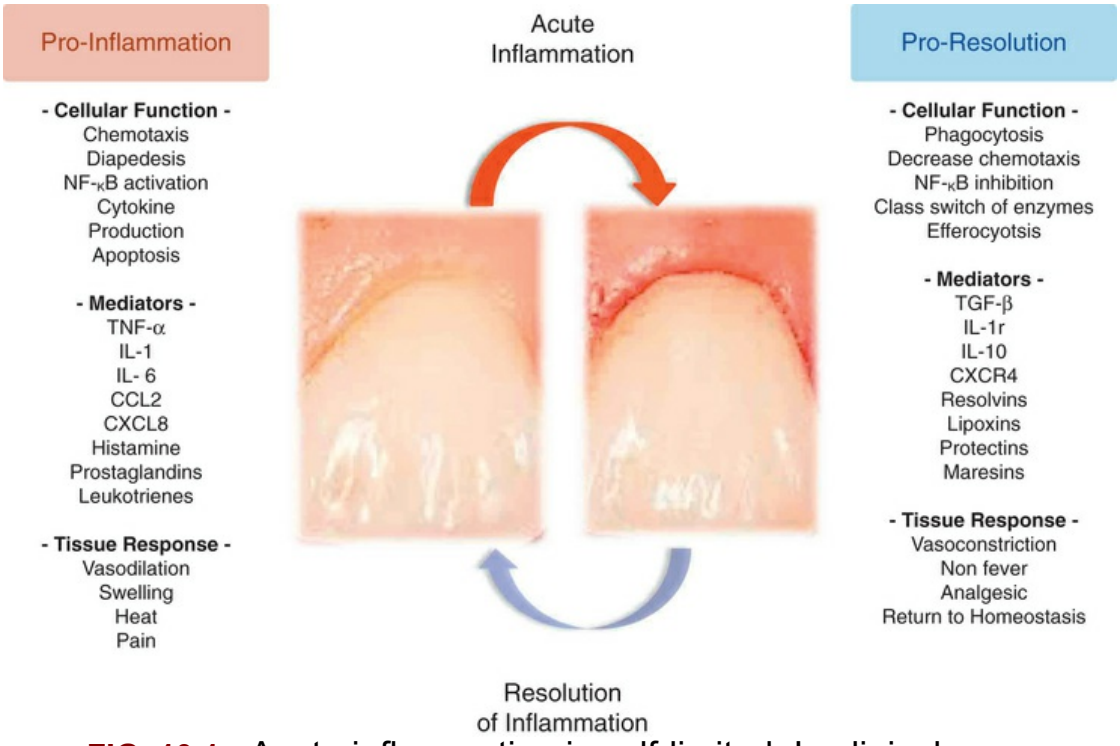

FIG. 10.1 Acute inflammation is self-limited. In clinical scenarios of health, resident cells, molecular mediators, and tissues respond to injure effectively and return to homeostasis. If acute inflammation is unresolved, chronic inflammation and disease will establish. Tissue healing is effective when a class switch from pro-inflammation to pro-resolution is activated. *CXC motif,* Chemokine; *IL,* interleukin; *NF-κB,* nuclear factor kappa-B; *TNF-α,* tumor necrosis factor-α.

In the context of acute inflammation initiation, locally produced lipid mediators, such as prostaglandins, prostacyclin, leukotrienes, and thromboxanes, regulate major processes and act as autacoids (short-lived molecules that act at the site of synthesis). These lipid mediators are synthesized in a sequence of enzymatic activation when arachidonic acid (AA) is released from the cell membrane due to trauma or via cell-cell communication. Structurally, most of the lipids of inflammation are eicosanoids (20-carbon chains) and act as endogenous precursors for biosynthesis of a chain of several molecules. In fact, the enzyme phospholipase A2 releases AA from the phospholipid membrane. This release constitutes the rate-determining step in the generation of eicosanoids produced by most phagocytic and immune cells.[54] AA is rapidly converted into

various potent lipid mediators with specific functions in a cell-specific manner by cyclooxygenases (COXs), lipoxygenases (LOs), or epoxygenases to yield prostaglandins, leukotrienes, and endoperoxides, respectively.

Arachidonic acids are metabolized mostly by two major enzyme pathways: COXs and LOs. Whereas COX-1 (constitutively expressed COX) is responsible for basal levels of prostaglandin synthesis, COX-2 (inducible COX) catalyzes the conversion of AA to lipid mediators during inflammation. Prostaglandins have ten subclasses, of which, D, E, F G, H, and I are the most important in inflammation. Specifically, PGE2 is generated via PGE synthase in leukocytes, whereas PGI2 is generated by prostacyclin synthase in endothelial cells and thromboxanes (TXA) are generated via TXA synthase in platelets.[16,32]

Lipoxygenases catalyze the formation of hydroxyeicosatetraenoic acids (HETEs) from AA leading to the formation of leukotrienes (LTs) and other biologically active compounds.[94] LTs are predominantly produced by inflammatory cells, including polymorphonuclear leukocytes, macrophages, and mast cells. There are three distinct lipoxygenases (LOs) that are cell specific; 5-LO in myeloid cells, 12-LO in platelets, and 15-LO in epithelial/endothelial cells. Cellular activation by pathogens and immune complexes results in activation of a sequential enzymatic reaction that includes cPLA2 and 5-LO. 5-LO converts released AA to the epoxide LTA4, which undergoes transformation by distinct pathways—one to generate LTB4, which is a potent regulator of neutrophil chemotaxis and leukocyte adhesion to endothelial cells.[32] The end products of 12- and 15-LO are 12- and 15-HETE, which are further metabolized. Excessive production of inflammatory mediators such as prostaglandins and leukotrienes with an exacerbated sensing response to inflammatory triggers is correlated with progression from acute inflammation to chronic inflammation in many diseases. Favorable inflammatory processes are self-limiting, which implies the existence of termination signals that regulate acute inflammation. Endogenous pro-resolution lipids are produced by enzymatic pathways that switch inflammation to resolution.[75] In addition to pro-inflammatory mediators that turn on inflammation, there is a separate set of lipid mediators that act as

endogenous agonists to activate termination of inflammation by stimulating resolution.[72] The following sections provide a more detailed look at specific lipid mediators (SLMs) in the resolution of acute inflammation.

Specialized Lipid Mediators

Pro-resolution signals are activated mostly by resolvins, lipoxins, maresins, and protectins. Lipid mediator class-switches biosynthesize pro-resolution lipid mediators, such as lipoxin A4, eicosapentaenoic acid (EPA)–derived resolvins (i.e., RvE1, RvE2), and docosahexaenoic acid (DHA)–derived lipid mediators including D-series resolvins, protectins, and maresins (Fig. 10.2).[92] More details on the key pro-resolution mediators are given next.

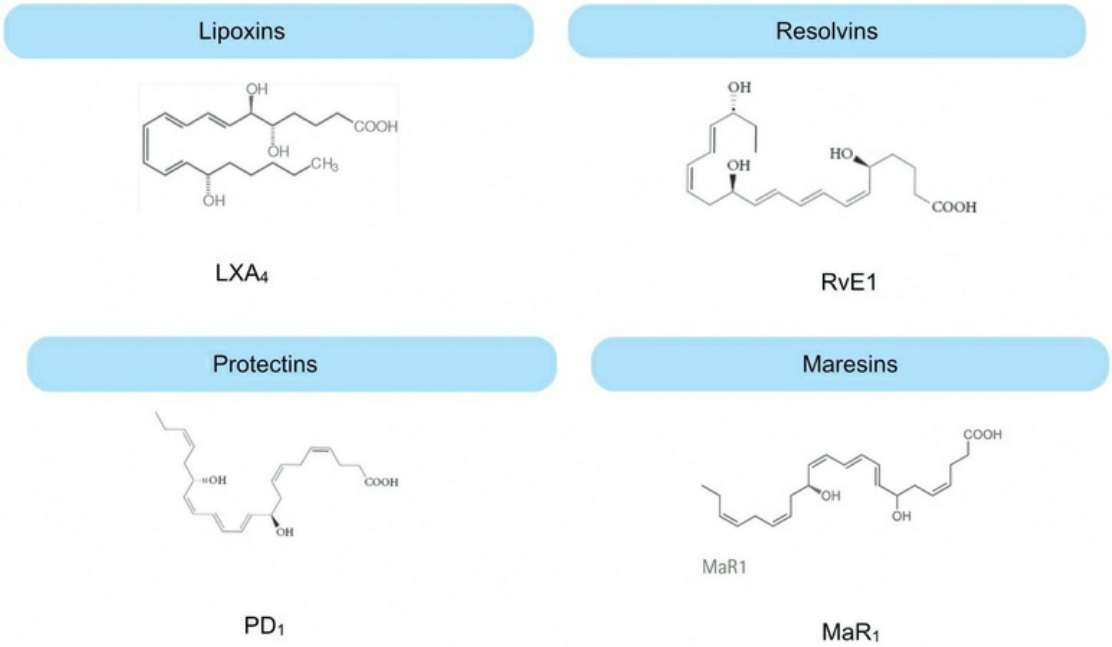

FIG. 10.2 Chemical structure of pro-resolution lipid mediators. Lipid mediator class switches yield lipoxins, eicosapentaenoic acid–derived E-series resolvins, and docosahexaenoic-acid derived D series resolvins, protectins, and maresins. *LXA_4*, Lipoxin A4; *MaR_1*, maresin 1; *PD_1*, protectin D1; *RvE_1*, resolvin E1.

Lipoxins

Derived from AA, lipoxins are natural pro-resolving molecules produced from endogenous fatty acids. Lipoxins have strong dual anti-inflammatory and pro-resolution actions. Lipoxins A4 and B4 were first isolated and identified as inhibitors of PMN infiltration and stimulators of nonphlogistic (non fever) recruitment of macrophages.[27,35,71] Three main pathways of lipoxin synthesis have been identified. In humans, sequential oxygenation of AA-derived lipids by 15-lipoxygenase and 5-lipoxygenase, followed by enzymatic hydrolysis, leads to LXA4, and LXB4 occurs in the mucosal tissues including the oral cavity, gastrointestinal tract, and airways. While in blood vessels, 5-lipoxygenase biosynthesizes LXA4 and 12-lipoxygenase in platelets produce LXB4. Lipoxin receptors are ubiquitously expressed by many cells, including neutrophils and monocytes. Aspirin triggers a third synthetic pathway. Aspirin promotes acetylation of COX-2 leading to a change in COX-2 activity and the chirality of the products, which are termed *aspirin triggered lipoxins* (ATLs).[34] Cells that express COX-2 include vascular endothelial cells, epithelial cells, macrophages, and neutrophils.[81] In addition to the synthesis of lipoxin, aspirin also blocks prostaglandin synthesis by acetylation of COX-2 inhibiting inflammation.[66]

Resolvins

Resolvins are endogenous lipid mediators induced during the resolution phase of inflammation. These lipid mediators are biosynthesized from the essential ω-3 polyunsaturated fatty acids (EPA and DHA) derived from the diet. The two primary groups of the resolvin family have distinct chemical structures: E-series, obtained from EPA, and D-series, derived from DHA. Vascular endothelium produces E-series resolvins via aspirin-modified COX-2 that converts EPA to 18R-hydroperoxyeicoapentaenoic acid (18R-HPEPE) and 18S-hydroperoxyeicoapentaenoic acid (18S-HPEPE). Neutrophils are rapidly taken up by human monocytes and metabolized to RvE1 and RvE2 by 5-lipoxygenase. Resolvin E1 production increases in plasma of individuals taking aspirin or EPA, resulting in amelioration of clinical signs of inflammation.[58] Similarly, DHA-derived D-series resolvins have been shown to

reduce inflammation by decreasing platelet–leukocyte adhesion, and aspirin-triggered DHA conversion produces molecules with dual anti-inflammatory and pro-resolution function.[79]

The interaction between resolvins and specific receptors modulates the fate of innate immune cells and counterregulates active inflammation. Selective target sites for resolvins are G-protein coupled receptors (GPCRs).[80] ERV1 receptor (also known as ChemR23 or CMKLR1) is a GPCR expressed on monocytes and dendritic cells. BLT1, a leukotriene receptor, is the resolvin E1 receptor on neutrophils. Upon selective binding to the receptors, RvE1 attenuates NF-κB signaling and production of pro-inflammatory cytokines including TNF-α.[12,65] D-series resolvins target GPR32 and ALX receptors[97] expressed on platelets and PMN. Activation of CB2 leads to inhibition of P-selectin expression, decreasing PMN chemotaxis. Resolvins induce hallmark functions of resolution of inflammation, including decreasing neutrophil migration, phagocytosis of apoptotic cells, and increasing clearance of infection to activate tissue healing.[80]

Protectins

Protectins are also biosynthesized via a lipoxygenase-mediated pathway. The pathway converts DHA into a 17S-hydroxyperoxide-containing intermediate that is taken up by leukocytes and converted into 10,17-diHDHA, known as protectin D1 or neuroprotectin.[11] The name accounts for the protective actions observed in neural tissues and within the immune system. Human peripheral blood lymphocytes produce protectin D1 with a Th2 phenotype, thereby reducing TNF-α and interferon-γ secretion, blocking T-cell migration, and promoting T-cell apoptosis.[59] A novel protectin synthesis pathway was found that utilizes aspirin-triggered COX-2 to synthesize epimeric 17R-hydroxyperoxide from DHA, called AT-PD1, and has shown a positive interaction with CB2 and peroxisome proliferator-activated receptor (PPAR) family receptors. Protectins reduce PMN transmigration through endothelial cells and enhance clearance (efferocytosis) of apoptotic PMN by human macrophages.[84]

Maresins

Macrophage mediators in resolving inflammation (maresins, or MaR) have been identified as primordial molecules produced by macrophages with homeostatic functions. Metabololipidomic approaches in peritonitis models led to the identification of a novel pathway of DHA metabolism.[1] Macrophage phagocytosis of apoptotic cells triggers biosynthesis of RvE1, PD1, LXA4, and MaR1. Conversion of DHA into 14-hydroxy diHA was identified via the 14-lipoxygenase cascade. MaR1 effectively stimulates efferocytosis of human cells and also has regenerative functions.[21]

In sum, the local lipid mediators constitute a new genus of pro-resolving endogenous compounds with potent actions in treating immune-metabolic human diseases. Lipoxin A4/ATL and resolvin E1 have been shown to inhibit neutrophil recruitment, attenuate pro-inflammatory gene expression, and reduce the severity of colitis in a murine model. PMN infiltration and lymphatic removal of phagocytes were observed when resolvin E1, D2, protectin D1, lipoxin, and maresin were used to ameliorate colitis.[3,44]

Key Facts

- Resolution of inflammation is an active biochemical process regulated by a class switch of enzymes and lipid mediators.
- A novel class of lipid mediators is known to modulate the resolution of inflammation; it consists of lipoxins, resolvins, maresins, and protectins.

Unresolved Chronic Inflammation in Periodontal Diseases

The oral microbiome modulates oral and systemic immune development, and a physiologic interaction maintains the homeostatic response. Periodontal diseases are chronic inflammatory diseases initiated by dybiosis and microbial biofilms.[17] In the case of gingivitis, acute inflammation is self-

limited and reversible. When the etiologic factor and modifiers are "removed," the host returns to health. When stimuli persist, unresolved inflammation causes chronic lesions, loss of attachment, disease progression, and tissue loss. The host immune response functions as a protective mechanism, but continuous or exacerbated response risks the tissue integrity.[64]

The presence of plaque bacteria is highly prevalent in humans; in fact, 90% of the adult dentate population presents with some form of gingivitis.[22] Through co-evolution host-microbiota interactions results in host benefits including, nutrient utilization, colonization resistance and immune development. Altered balance either from the microbiota or the host response (or both) allows the disease initiation and progression.[17,36]

Although plaque is an evident etiologic factor in gingivitis, in periodontitis the specificity or number of the pathogens has not explained the variability in individual host response. Despite abundant microbial deposits in most people, the prevalence of moderate periodontitis is only around 40% of the population.[51] It is therefore possible that bacteria are not the primary factor of gingivitis-periodontitis transition. Whereas "plaque" is a traditional concept in etiology, the host presents multiple variations that provide increased susceptibility changing taxonomic composition of the plaque and metabolomic functions.[90] Resolution failure is a plausible explanation of this pathologic transition.

Host modifiers, including genetic, behavioral, anatomic, metabolic, and environmental, modulate the magnitude of the disease. These factors influence the disease severity, progression, and response to therapy. Classic studies in the 1980s showed that intake of antiinflammatory medications prevented the progression of periodontal disease.[43a] Although this was promising, it is now clear that inflammation is an important biologic process, and complete suppression of its cascade influences the host entirely. Instead of suppressing the system, resolution aims to enhance "good" inflammation to terminate the disease process.[52,68] In fact, deficient phagocytosis is seen in aggressive forms of periodontitis and is reversed by resolution mediators.[29,37] Thus, host-derived etiology is now well accepted and is a target for future therapies.

In a clinical trial of patients with moderate to severe

periodontitis, the actions of dietary supplementation of ω-3 polyunsaturated fatty acid (PUFA) and aspirin were evaluated. In patients taking the preceding supplements, in addition to scaling and root planing, significant improvements were noted in pocket depth reduction and clinical attachment level gain, with lower levels of inflammatory mediators in saliva compared to patients who underwent scaling and root planing alone.[23] Lipid mediators are considered excellent candidates for the prevention and treatment of periodontal diseases.

« Flash Back

Bacteria have been recognized for years as the main etiologic factor for periodontal diseases. With advances in molecular immunology and genetics, inflammation and resolution pathways have shown to play an integral part in the multifactorial pathogenesis of periodontal diseases.

Systemic Link

Several biologic pathways have been identified linking periodontal disease and systemic inflammatory diseases. The establishment of cause and effect relationships in the complex interactions between the microbiome, host immunity, pathologies, and environmental factors is a key step in the development of successful targeted therapies for periodontal diseases. In healthy gingival sulcus, a number of microbes, mostly facultative anaerobes, are present in the gingival crevice. However, in periodontal diseases, inflammatory tissues are vulnerable to bacterial invasion, providing communication channels with the bloodstream.

After microbial recognition by the host, mediators of the innate response, including TNF-α, IL-1β, and IL-6, are the first to activate the pathways. TNF-α up-regulates the production of IL-1β and IL-6. Cytokines such as TNF-α are associated with degradation and bone resorption through actions promoting secretion of matrix metalloproteinases (MMPs) and receptor activator or NFκB ligand (RANKL) and uncoupling of bone remodeling.[30,31,42,89] In addition,

chemokines, cytokines with chemoattractant functions, induce cell migration to the site of infection or injury.

Microorganisms that enter the bloodstream are usually phagocytosed and cleared within minutes (transient bacteremia) with no clinical symptoms. Local bacterial antigens, such as lipopolysaccharide (LPS), that are systemically dispersed trigger significant systemic inflammation. Leukocytes, endothelial cells, and hepatocytes respond to bacteria and their virulence factors with the secretion of pro-inflammatory immune mediators called acute phase proteins, like C-reactive protein (CRP). Persistence of infection, with continuous exposure of the host to new antigens, results in the activation of humoral immunity and antibody production. In addition to the bacterial challenge, viral infections induce the production of interferon (IFN-α, IFN-β) and cytotoxic activation of lymphocytes, whereas parasites lead to the production of IL-4, IL-5, and IL-13 by mast cells and basophils. Pro-inflammatory cytokines in systemic circulation induce leukocytosis and increase acute phase proteins production by the liver. With continued exposure to the inducers, the response becomes more accurate and adapts to the challenge.

Pro-inflammatory mediators, such as IL-1β, IL-6, TNF-α, and PGE2, produced locally can "spill" into the systemic circulation and can impact the general health, such as the induction of endothelial cells.[25,49] If the inflammation response resolves in a temporal manner, then tissue homeostasis is reestablished.

Inflammatory mechanisms link chronic diseases such as periodontal diseases with systemic conditions. Loss of resolution and continuous destruction leads to chronic inflammation and disease formation.

Type 2 Diabetes

Among many diseases that impact the population globally, type 2 diabetes is a major public health problem. Worldwide, 347 million adults currently suffer from type 2 diabetes.[38] According to the World Health Organization, this epidemic is predicted to double by the year 2040, and diabetes-related health care expenditures will increase significantly.[2]

Inflammatory and metabolic diseases share common etiologic factors modulating host response against antigenic challenge. For example, inflammatory processes are shown to be exacerbated in type 2 diabetes. Patients with diabetes are at two to three times greater risk for developing chronic periodontitis; high HbA1c levels have a significantly higher prevalence of periodontitis and more tooth loss when compared to controlled individuals. Acute and chronic infections may adversely influence glycemic control. In this context, a biologically plausible link between metabolic control and periodontitis has been established. If effective treatment of periodontitis can modify glycemic control, as suggested in some studies, then periodontal therapy may play an important part in the patient management program that incorporates lifestyle changes and medications.

As more studies are published, the question of periodontal therapy actions on diabetic control becomes clearer. Meta-analyses have investigated the effect of periodontal therapy on type 2 diabetes outcomes, 3 months following therapy. An average of 0.36% HbA1c reduction (95% CI 0.66, 0.19) following therapy is consistent in the literature.[50,95,96]

The clinical relevance of periodontal treatment on metabolic control has shown beneficial actions, along with pharmacotherapy and lifestyle changes.[5] Among all type 2 diabetes patients, 50% of patients are treated with one or more additional drugs to achieve metabolic control. In combination with metformin, other drugs that have shown beneficial effects in the reduction of HbA1C include sulphonylureas (0.85%), α-glucosidase inhibitors (0.61%), and thiazolidinediones (0.42%). Periodontal therapy can decrease HbA1c levels by 0.4% to 0.5% and definitely has a place in the management of diabetes due to control of inflammation.

Cardiovascular Diseases

Common risk factors for cardiovascular diseases (CVDs) and periodontitis are thought to be related to increased systemic inflammation.[7,18,48,96] Diet, genetics, medications, and environmental factors influence the course of periodontal disease, and when combined they influence cardiovascular health status. In

cardiovascular diseases, active periodontal pathology was shown to be a contributing factor.[7] This is partially influenced by lipid of low-density lipoproteins (LDL), which is known to initiate and propagate an inflammatory response.[70] Cytokines, such as INF-γ, are involved in the destabilization of the plaques because they lead to a decrease in matrix synthesis as well as matrix degradation. In addition to cytokines, matrix metalloproteinase (MMP) enzymes are involved in controlling degradation; macrophages express MMPs, further contributing to degradation.[70]

Periodontal inflammation causes a local and systemic cytokine response. The notion that periodontal disease can be local has been due to anatomic and didactic reasons, but one can argue that it has direct systemic effect because the head, and thus the mouth, are parts of the systemic apparatus. Pro-inflammatory effector molecules produced from the periodontal compartment are not only expressed locally, but they also disseminate to distant organs as noted by the increase in acute phase response (C-reactive protein and fibrinogen production) in the liver, which in turn promotes atherogenesis. Gingival ulceration in periodontitis allows the migration of bacteria into the blood (bacteremia), which could provide a second inflammatory stimulus leading to atheroma formation.[41] Thus, direct actions from the pathobions and indirect actions from inflammation aggravate the disease manifestation.

A positive association between cardiovascular diseases and chronic inflammatory diseases, in particular periodontal diseases, has been found. Given the wide range of etiologic and risk factors involved in CVD, many of which are common risk factors for periodontitis and CVD, it has been difficult to demonstrate causation. To that end, the relationship between CVD and periodontitis was investigated longitudinally in an animal model. Rabbits were fed with a 0.5% cholesterol diet for 13 weeks. This is known to cause atheromatous changes in the large arteries of the animals.[47] Periodontitis induced by a ligature model was compared with normal periodontium; all animals were on the atherogenic diet. When the areas of the atheromatous lesion were evaluated, the animals that had periodontitis exhibited twice the atheroma formation of the controls. The findings suggest the impact of infection as direct stimulation of arterial endothelium.[19]

Patients with periodontitis who have two or more known risk factors for atherosclerosis should be referred to the medical team for evaluation of atherosclerotic risk, which should include a physical examination and annual measurement of blood pressure and blood lipid profile. Animal studies demonstrated that TLR receptor signaling influences the course of progression of the disease.[8] Patients with periodontitis and abnormal serum lipid values, elevated levels of plasma CRP by the high-sensitivity CRP, or both are recommended to follow a multifaceted lifestyle modification program to reduce CVD risk. Furthermore, patients with periodontitis who have elevated blood pressure (>140/90 mm Hg)[69] should be treated according to standard hypertension management protocols and should undertake lifestyle changes, including reduction of weight and dietary sodium intake. Moreover, when periodontitis is newly diagnosed in patients with CVD, dentists and physicians should closely collaborate to optimize CVD risk reduction and periodontal care.

When the periodontal disease is treated/maintained, it is also notable that levels of inflammatory markers decrease, which in turn decreases vascular disease.[15,33] After adjusting for risk factors, such as smoking, diabetes, alcohol intake, obesity, and blood pressure, subjects with periodontal disease had a 1.14- to 1.59-fold greater risk of developing cardiovascular disease compared to those without periodontal disease.

Although inflammatory responses to injury and infection are essential to health, the chronic exacerbated response leads to increased severity of diseases. Innovative research is needed to elucidate the intricate pathways by which chronic local inflammation can impact large vessels and, consequently, the cardiovascular system.

Cancer

A higher incidence of cancer development is found in individuals with chronic inflammatory conditions. Recent evidence demonstrated the role of microbiome-derived signals in the pathogenesis of several chronic inflammatory diseases. Oral pathobions such as *Fusobacterium nucleatum* colonize epithelium

barrier surfaces of gut, promoting adenomas and colon cancer via TLR4/MYD88-dependent signaling.[64] Associations between periodontal disease and the risk for precancerous lesions, tumors, and oral neoplasms have been shown. The third National Health and Nutrition Examination Survey (NHANES III) found periodontitis to be significantly related to the presence of tumors,[85] but stratified analysis found this association was only present in current smokers. A stronger association was found between periodontitis and human papilloma virus (HPV) status in patients with oropharyngeal cancer.[62]

The risk of death from cancer increases when patients are diagnosed with periodontitis. According to NHANES I,[45] patients diagnosed with periodontitis had a 55% (95% CI 25%–92%) risk of death when diagnosed with cancer. There was a significantly increased risk of lung cancer; however, this risk was not evident in nonsmokers.

The incidence of cancer had consistently increased in patients with periodontitis. A larger study with a 17.7-year follow-up identified 5720 incident cancers in 48,375 men enrolled. For men who reported periodontal disease, a slight increase in total cancer incidence of 14% (95% CI 7%–22%) was observed, which remained significant when the analysis was limited to never smokers.[63] There was a significantly increased risk of lung, kidney, pancreatic, and hematologic cancers, after the adjustment of confounders. Notably, the risk for lung cancer showed a positive association when the number of teeth was used as the exposure.[63]

Similar genetic risk factors for periodontal disease and cancers were found in a prospective study in Sweden. The study identified more than 4000 incident cancers after a median follow-up of 27 years.[4] Periodontal disease was associated with a 15% (95% CI 1%–32%) increased risk of all cancers. Colorectal cancer has shown positive association with periodontal diseases; similar relationships were found with pancreatic and prostate cancers. In co-twin analyses, monozygotic twins with baseline periodontal disease showed a 50% increase in total cancer risk, but in dizygotic twins this association was markedly attenuated. Similar patterns emerged for digestive tract cancers, suggesting that shared genetic risk factors may partially explain associations between periodontal

disease and cancers.[4]

Pregnancy Outcomes

When introduced in the early 1900s, the theory of "focal infection" revolutionized thinking regarding the relationship of an apparent local infection and its systemic actions. Not surprisingly, a local inflammation can interfere with the homeostasis of normal pregnancy and labor. Although a large number of epidemiologic studies showed a positive association between periodontal disease and pathologic pregnancy outcomes, the results presented so far have not always been confirmatory.[55]

In healthy pregnancy, there is an exchange of nutrients and waste between the mother and the fetus via the umbilical cord. Amniotic fluid levels of inflammatory mediators including prostaglandin E2 (PGE2), TNF-α, and IL-1β increase incrementally through pregnancy and reach a specific threshold that promotes uterine contraction, cervical dilation, and delivery.[40] It is extremely important that levels of inflammatory mediators along with hormones are tightly regulated to maintain a normal course of pregnancy.[55]

Evidence suggests that periodontal pathogens interfere with homeostatic control of pregnancy. Through DNA identification and immunodetection, both P. *gingivalis* and A*ggregatibacter actinomycetemcomitans* have been detected in the biopsies of placenta diagnosed with preeclampsia.[99] Most commonly, in amniotic fluids, *F. nucleatum* was identified in patients suffering from premature labor or low birth weight.[39] The presence of bacteria in diverse tissues during the establishment of pathologies during pregnancy is evident, yet the exact mechanism by which pathogens reach these distant sites is yet to be investigated.[55] Studies suggest that pathogens can gain access to the amniotic cavity by ascending from the vagina and the cervix, by hematogenous dissemination through the placenta, by the accidental inoculation at the time of invasive procedures (amniocentesis), and by retrograde spread through the fallopian tubes. Besides the pathogens themselves, their virulent factors, including LPS, have been associated with triggering the same type of pathologic actions to the maternal placenta and fetus.

Localized elevated levels of maternal IL-1β, IL-6, PGE2, and TNF-α in the amniotic fluid have been associated with pregnancy alterations, including premature birth.[43,69] Other biomarkers such as MMPs, estriol, elastase, protease, phospholipase, prolactin myeloperoxidase, and tissue inhibitor of MMP (TIMP)-1 have been evaluated, but with inconclusive results.[43] An acute phase molecule synthesized by the liver, C-reactive protein (CRP), activates systemic inflammation and pro-inflammatory cytokines; it is also associated with premature birth in African American woman.[43] Other pregnancy complications have been associated with elevated levels of CRP including intrauterine growth restriction and preeclampsia.[55]

Finally, a combination of local complications places the host at risk for adverse pregnancy outcomes. For example, women with gestational diabetes have a high risk of presenting with elevated serum CRP, IL-6, and TNF-α.[53] Through inflammatory pathways, these cytokines interfere with insulin signaling homeostasis. Therefore carbohydrate metabolism, hormonal control, and inflammatory mediators together influence the fate of pregnancy and labor.

Therapeutic Actions of Resolution Mediators

Periodontal diseases, including gingivitis and periodontitis, are leukocyte-driven inflammatory conditions characterized by soft-tissue and osteoclasts-mediated bone loss.[51,64,83] Resolution mediators are needed to control and treat periodontal diseases. In animal models, restoration of tissue health by resolution lipids is initiated after acute response generates classic eicosanoids, prostanoids, and prostacyclins and leukotrienes. The synthesis of immune-resolvents by key enzymes that induce a class switch is partially known.[73] Thus, return to homoeostasis is highly regulated by resolution pathways (Table 10.1).

TABLE 10.1

Therapeutic Actions of Pro-resolution Lipid Mediators

Disease Models	Lipid Mediator Therapeutic Actions	References
Periodontitis	**Lipoxin A4/ATL**	
	Rescues attachment loss	Van Dyke et al. (2008)
	Enhances tissue healing	Serhan et al. (2003)
	Promotes periodontal regeneration	Van Dyke et al. (2015)
	Ceases infiltration of neutrophils	Van Dyke et al. (2015)
	Resolvin E1	
	Decreases bone loss	Hasturk et al. (2005)
	Lowers number of osteoclasts	Hasturk et al. (2007)
Type 2 diabetes	**Resolvin E1**	
	Increases cell counts	Herrera et al. (2015)
	Increases chemotaxis	Tang et al. (2013)
	Rescues phagocytosis	Freire et al. (2016)
	Resolvin D1	
	Increases monocyte recruitment	Spite et al. (2014)
	Decreases inflammation in adipocytes	Spite et al. (2014)
Colitis	**Lipoxin A4/ATL**	
	Decreases severe colitis	Aliberti et al. (2002)
	Pro-inflammatory gene expression is	Gewirtz et al. (2002)
	down expressed	Gewirtz et al. (2002)
	Reduces immune dysregulation	Wallace et al. (2003)
	Resolvin E1	
	Improves animal survival rate	Arita et al. (2005)
	Reduces weight loss	Arita et al. (2005)
	Activates LPS detoxification	Campbell et al. (2010)
	Inhibits neutrophil recruitment	Ishida et al. (2010)
	AT-Resolvin D1	
	Reduces diseases activity index	Bento et al. (2011)
	Attenuates pro-inflammatory mediators' gene expression	Bento et al. (2011)
	Attenuates neutrophil recruitment	Bento et al. (2011)
	Resolvin D-2	
	Ameliorates disease activity index	Bento et al. (2011)
	Reduces colonic PMN infiltration	Bento et al. (2011)
Retinopathy	**Protectin D1**	
	Protects against neovascularization	Connor et al. (2007)
Calvaria defects	**Resolvin E1**	
	Promotes bone regeneration in calvaria defects	Gao et al. (2012)

Evidence from animal studies demonstrated that overexpression of 15-lipoxygenase type I in rabbits increased endogenous levels of LXA4 protecting the host from developing periodontal disease. While no animal model is a perfect fit for humans, as proof-of principle, these concepts could be translated. Also, RvE1 when topically applied to the tissues ameliorates signs of disease activity, decreasing bone loss by 95% and significantly reducing the number

of tissue neutrophils. Leukocyte infiltration was also reduced when RvE1 was applied in a murine dorsal air pouch model.[46] Similarly, in human cells obtained from localized aggressive periodontitis (LAP), RvE1 and LXA4 treatment decreased neutrophil superoxide production in response to TNFα and the bacterial surrogate peptide marker N-formyl-methionyl-leucyl-phenylalanine by 80%.[29,87,98]

The potential for treatment of periodontal diseases with one or a combination of specialized lipid mediators is clear and requires further investigation clinically. In one trial, scaling and root planing (SRP) with dietary supplementation of ω-3 PUFA and lower dose of aspirin reduced pocket depths and increased clinical attachment levels significantly when compared to SRP alone.[24] The clinical benefits were accompanied by lower levels of inflammatory mediators in saliva compared to scaling and root planing alone.[23]

Failure to remove pathobions and inefficient clearance of the innate immune cells (mainly dead neutrophils) characterize the progression to chronic pathologic lesion. In susceptible individuals, periodontal inflammation fails to resolve, and chronic inflammation becomes periodontal pathology. In periodontitis, primed neutrophils can mediate destruction and feed forward destruction of the extracellular matrix, bone, scarring, and loss of periodontal tissue function.[17] In an inflammatory model, resolvin D1 has been associated with the regulation of miRNAs and target genes and the reduction of LTB4, PGD2, TXA2, PGF2α, and TXA2 in peritoneal exudates.

Clinical Implications

- Inflammation is a biologic protective mechanism against injury.
- Acute inflammation seen in gingivitis is reversible and self-limited.
- Chronic inflammation in periodontitis has a failure of signals that activate resolution and return to homeostasis.
- Inflammation and resolution are connecting links with systemic disease (e.g., type 2 diabetes, cancer, and

cardiovascular diseases) and periodontal diseases.

Tissue regeneration has also being a target of specialized resolution mediators. Treatment with maresin 1 has been demonstrated to stimulate tissue regeneration in system models, including planaria models.[78] Consistently in periodontal disease models, lipoxin A4/ATL prevented connective tissue and bone loss. Treatment of experimental periodontitis with lipid mediators completely resolved inflammation and rescued tissue loss with the regeneration of periodontal tissues.[89,91] It has been suggested that defective endogenous resolution of inflammation underlies the inflammatory phenotype presented in chronic diseases and that exogenous therapeutic molecules rescue this phenotype. Pro-resolution lipid mediators play a role as natural molecules in the maintenance of homeostasis with promising potential as therapeutic agents in human diseases.[28,31]

Final Remarks

The role of acute inflammation is protection of the host and development of tissue integrity. The fate of this process is determined by the balance and magnitude of mediators and sensors that amplify the inflammatory process or control the restoration to normal health. It is now evident that the resolution of inflammation is modulated by protective mediators, such as AA-derived lipoxins and ATLs, ω3- EPA-derived resolvins of the E-series, DHA-derived resolvins of the D series, protectins, and maresins. The selective interaction of the lipid mediators with GPCR receptors of innate immune cells induces the cessation of leukocyte infiltration; the return to normal levels of vascular permeability/edema; PMN death (mostly via apoptosis); and nonphlogistic infiltration of monocyte/macrophages and macrophage removal of apoptotic PMN, foreign agents (bacteria), and necrotic debris from the site. These cellular events lead to resolution with a return to predisease homeostasis. Unresolved inflammation is a hallmark of various human diseases including diabetes, ulcerative colitis, rheumatoid arthritis, cancer, cardiovascular diseases, and periodontitis. The fate of acute inflammation determines the restoration to homeostasis

versus disease establishment. Diseases associated with uncontrolled acute inflammation are characterized by a continuous release of histotoxic substances that results in local tissue damage, prolonged inflammatory response, and loss of function. In contrast, in health, the fate of inflammation is influenced by endogenous mediators, cells, tissue, and scaffolds to resolve the acute process and reestablish homeostasis, thereby promoting tissue healing and regeneration (Fig. 10.3).[6]

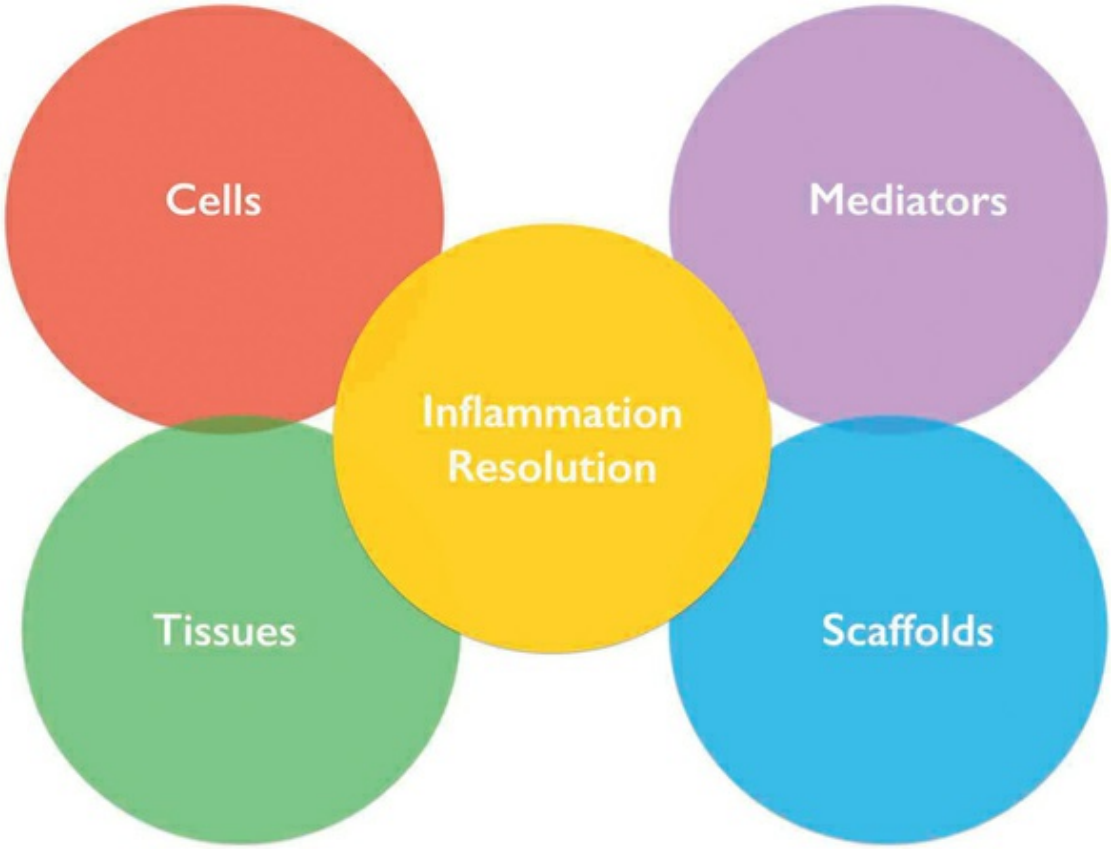

FIG. 10.3 Inflammation resolution is a key component of tissue healing and regeneration. Upon antigenic challenge, cells, tissue, vasculature, and mediators have to synchronize the host response to adequately remove triggers and protect the host prior to regeneration. Resolution of inflammation has main functions in the activation of cells to promote clearance, return to homeostasis, and together with the factors described promote tissue regeneration..

A localized inflammatory response to an injury or infection is a

spatially defined and temporally regulated process that ideally should be self-limited as previously described. If the lesion does not resolve and becomes chronic, the acquired immune system is stimulated, including broad activation of lymphocytic pathways as well as cell-mediated and humoral immunity. The local infection or injury, if sustained, becomes systemic, defined as an extended response that goes beyond the confined localization of one tissue. The chronicity of the lesion alters molecular, cellular, and overall tissue responses in remote regions of the body having a transient or permanent impact on overall health.

Case Scenario 10.1

Patient:
30-year-old male

Chief Complaint:
"My gums are inflamed."

Background Information
A healthy patient with crowding presents with localized plaque and generalized inflammation. Patient is a graduate student and has reported stress affecting his sleep.

Patient Oral Hygiene Index (OHI) is average. Patient avoids brushing where inflammation and bleeding persists. He would like his gums to be "healthy" prior to orthodontic treatment.

Current Findings:
Probing depths were in the range of 2 to 3 mm, BOP was 42%. Recession noted in the mandibular left canine, lateral incisor, and central incisors.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the most probable etiology for the erythematous gingival margin of mandibular left canine (#22)? A. Plaque-induced inflammation B. Puberty C. Plaque only D. Stress E. Orthodontic treatment	**Answer: A** **Explanation:** The buccal gingival margin of the mandibular left canine (#22) has plaque-induced gingivitis. Redness, swelling, and bleeding upon probing are all signs of inflammation. The region has been more prone to plaque accumulation due to adjacent recession, tooth and tooth anatomy, and crowding. Stress and hormonal influences impact the magnitude of gingivitis but are not primary etiologic factors.
2. All of the following conditions modulate gingivitis EXCEPT: A. Diet B. Inflammation C. Biofilm D. Bone loss E. Medications	**Answer: D** **Explanation:** Bone loss is not characteristic of gingivitis. Gingivitis is a reversible inflammatory mechanism that is modulated by hormones, genetic factors, medications, and environmental factors. Upon removal of the etiologic challenge, resolution of inflammation ensues, which returns the tissue to a healthy state.
3. All of the following are resolution of inflammation mediators, EXCEPT: A. Resolvins B. Protectins C. Lipoxins D. Maresins E. Prostaglandins	**Answer: E** **Explanation:** Prostaglandins are pro-inflammatory mediators derived from COX-2 responsible for increasing inflammation. Pro-resolution lipid mediators are active lipids responsible for activating cells to return to homeostasis. Upon binding to cells, resolution lipids are capable of increasing phagocytosis and activating the clearance of dead cells and microbes.

This table contains 15 columns, which are described in detail below. Each row represents the association test result from testing DNA polymorphisms of a gene against a specific disease definition among individuals from a specific population. Therefore, a study may have multiple rows in this table when it includes multiple disease definitions, multiple ethnic groups, and multiple candidate genes.	
Header Description	
A	Gene Symbol
	National Center for Biotechnology Information (NCBI) official gene symbol (i.e., a clickable hyperlink to more information about the gene) or the study's reported gene symbol if the NCBI symbol is not available. When the genotype combinations of multiple genes are tested, the gene symbols are concatenated by a period (e.g., "IL1A.IL1B").
B	Disease Type
	Types of periodontal disease being tested:
	• AgP: Aggressive periodontitis • AgP&T1DM: Aggressive periodontitis and type 1 diabetes mellitus • AgP+CP: Test population includes aggressive periodontitis individual and chronic periodontal disease individual • CP: Chronic periodontitis • CP&AMI: Chronic periodontitis and acute myocardial infarction • CP&CHD: Chronic periodontitis and coronary heart disease • CP&CKD: Chronic periodontitis and chronic kidney disease • CP&HIV: Chronic periodontitis and human immunodeficiency virus infection • CP&RA: Chronic periodontitis and rheumatoid arthritis • CP&SLE: Chronic periodontitis and systemic lupus erythematosus • CP&T1DM: Chronic periodontitis and type 1 diabetes mellitus • CP&T2DM: Chronic periodontitis and type 2 diabetes mellitus • PPP: Prepubertal periodontitis
C	Cases
	• Number of cases included in the tests
D	Total
	• Total number of individuals included in the tests (cases and controls)
E	Best *P* Value
	• The most significant reported *P* value; may also be reported as *sig* (significant but *P* value not available) or *ns* (not significant)
F	Level of Support
	• Level of support of association according to the combination of study size and the reported best *P* value: *S,* strong; *M,* moderate; *W,* weak; and *None*
e Sample size (no. of cases)	

P Value				
<50	51–100	101–250	> 250	
<0.05	W	W	W	W
<0.001	W	M	M	M
<0.0001	W	M	M	S
G	Population			

	• Reported ethnic group in the tests
H	Study Design
	• *CC:* Case–control study; *Fam,* family study; *Longitudinal,* longitudinal study; *Quan:* quantitative measures study
I	Stratified or Covariate Adj
J	Gene Name
	• NCBI official full name of gene; *n/a,* not available
K	Gene Aliases
	• NCBI reported gene alias; *n/a,* not available
L	# SNPs Assayed
	• The number of molecular assays run for the gene *GWAS,* genome-wide association study; *n/a,* not available
M	SNP Name
	• SNP name reported in the study *Multiple Genes,* when combined genotype from different genes is tested; *Multiple SNPs,* when combined genotype from multiple SNPs of the gene is tested or none of SNPs tested are associated; *n/a,* not available
N	PubMed ID
	• PubMed ID of the study article, given as a clickable hyperlink to bring up the PubMed abstract page
O	Journal
	• Publication information from PubMed

It is now widely accepted that differences among individuals who are at risk for the development of most diseases have a substantial

inherited component. Factors in the environment (e.g., diet, smoking, preventive care, exposure to pathogens) interact with each person's genetic predisposition to determine his or her health outcomes. This complex combination of variables determines if and when a disease affects the person, how fast and how severely symptoms of the disease progress, and how the person responds to different treatments in terms of both side effects and the success of alternative therapies. Sometimes—and particularly with diseases such as cystic fibrosis and muscular dystrophy—the genetic component of risk predominates, and differences in environment play only a minor role. With other diseases, factors in the environment are most important, and variation inherited in the person's deoxyribonucleic acid (DNA) has only an infrequent or minor influence on disease susceptibility or progression. Examples of the latter include infectious diseases such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) as well as cancers such as mesothelioma, which is strongly associated with asbestos exposure. The majority of human diseases fall about halfway between these two extremes, with genes and the environment both playing important roles.

Most cases of periodontitis appear to fit this complex gene and environment model. With the exception of a handful of rare syndromes caused by mutations of single genes, evidence indicates that inherited variation in DNA has a role roughly equal to that of the environment in determining who remains periodontally healthy versus who is affected by this disease. Beyond this broad generalization, however, and despite more than 800 association studies of periodontitis and genetic polymorphisms reported to date, knowledge of which specific genes are most important remains extremely limited. We know virtually nothing about the role that inherited genetic differences are likely to have in determining how patients respond to alternative treatments. This knowledge is necessary for the development of “personalized” or “individualized” periodontal treatment strategies, an approach that is playing an increasingly important role in improving virtually all other areas of health care today.

This chapter reviews the challenges and barriers that have thus far limited progress in advancing our knowledge of the complex

genetics of periodontitis. This requires a basic understanding of not only the architecture of the human genome and the complexity of genetic susceptibility but also of the critical roles that statistical power and sample size play in the process of discovery. These latter issues are important for all areas of research but especially for situations in which a large number of variables need to be evaluated. In genetic studies, about 20,000 genes need to be considered as potential hypotheses or "candidates" for influencing disease risk. Depending on the gene's size and the frequency of genetic recombination in the gene's chromosomal region, scientists need to evaluate a handful or up to several hundred inherited DNA variants in each gene as potential "biomarkers" of disease risk. Each one of these variants essentially amounts to a test of the hypothesis as to whether the variant is associated with disease risk. Furthermore, many complex diseases have been found to be strongly associated with DNA variation in parts of the human genome where no genes are known to exist but where the genetic material may have important functional effects nonetheless. Therefore to fully evaluate the entire human genome, the number of hypotheses that needs to be tested is truly enormous and involves roughly the equivalent of 1 million independent statistical tests. Only since the early 2000s have laboratory and computational tools been available that make this scale of work technically feasible at an affordable cost, and thus far only a few studies have reported results for a whole genome analysis for periodontitis genetic risk.

Opportunities for advanced study designs and next-generation DNA sequencing and other genomic technologies to improve the understanding of the inherited basis of periodontitis make it likely (although by no means certain) that genetic variation will become an important variable to be routinely considered by practicing dentists within the careers of dental students today, and this is already starting to occur. Therefore it is essential that dentists learn how to access and interpret the information coded in the human genome so they can use this wisely to improve periodontal disease prevention, diagnosis, and treatment for their patients. Alternatively, new interdisciplinary teams will need to be established with dentists as key members working closely with experts in bioinformatics, genomics, and genetic counseling so that

patients will be able to reap the potentially significant benefits of these scientific advances. However the process evolves, the genomics revolution will surely lead to major changes in both dental education and dental practice in the not-so-distant future.[8,30]

Genomic Advances in the 21st Century

Most health care professionals are aware of the many major advances in genetics accomplished during the decades since the Human Genome Project officially began in 1990.[51] Headlines and announcements of "breakthroughs" continue to appear regularly in print and television media. All too often, many of these stories seem to promise rapid and significant improvements in health care that are totally unrealistic.[11] Cautious assessments are usually not deemed newsworthy by the media, and understatement is not in the interest of private companies or of grant-awarding government agencies supporting basic research and clinical trials. Consequently, the public has too often received overly optimistic pictures of what the future of medical care based on genomic medicine really holds in store for them. Despite this all-too-common overstatement about rapid translation to clinical practice, the actual advances in technical capabilities for genomic data acquisition and the accumulation of knowledge in the field of genetics have been truly enormous. The eventual impact of this explosion of biologic knowledge on all areas of human health, including those concerning the field of dentistry, is certain to be substantial over the longer term.

Unfortunately, for reasons explored further in the next section, genomic advances have thus far contributed little to advance our understanding of the molecular–pathologic causes of periodontitis nor pointed toward ways to improve treatment through individualized approaches based on patients' inherited genetic variation. Genome-wide association studies (GWAS, pronounced "gee-wahs") and next-generation DNA sequencing techniques are now being used in periodontology research. For these strategies to be successful, however, they must be combined with further improvement in research definitions of periodontal disease and

much larger sample sizes than have been used in the majority of previous genetic studies. To provide a refresher on basic concepts and to help improve understanding, some of the commonly used terms in genetics are explained in Table 11.1.

TABLE 11.1

Glossary of Terms Relevant to the Genetics of Periodontal Disease

Allele	One of several possible alternative forms of a gene caused by small or large differences in the DNA sequence within or near the gene. These differences arise by mutation, and some may affect the function of the gene product (i.e., a protein) or its abundance in different kinds of cells.
Autosomal dominant	DNA variation in a gene located on an autosome that has a dominant effect over other forms of variation at this location within the gene. When the dominant DNA sequence is present in combination with some other sequence, the gene's function is entirely or nearly entirely determined by the dominant sequence, whereas the alternative sequence that occurs on the person's other chromosome is essentially silent.
Autosomal recessive	DNA variation in a gene located on an autosome that has an effect on the gene's function only when the person has inherited two copies: one from the mother and the other from the father. For example, if an individual has two copies of an abnormal gene that is autosomal recessive, he or she will be subject to the effects of that gene.
Autosome	A chromosome that is not a sex chromosome.
Chromosome	A nuclear structure that contains genetic information. Humans have 46 chromosomes that are arranged in 23 pairs. There are 22 pairs of autosomes and one pair of sex chromosomes (either XX or XY).
Concordance	The probability that a pair of individuals (e.g., twins) both have a certain characteristic (e.g., periodontal disease), given that one of the pair has the characteristic. Presented as a number from 0 to 1 or as a percentage.
Dizygotic twins	Twins that have resulted from the fertilization of two separate eggs. They are no more similar to each other (from a genetic perspective) than are nontwin siblings. Nonidentical twins.
Epigenetics	Term used to describe the changes in phenotype or gene expression that result from mechanisms other than changes in the underlying DNA sequences (i.e., changes in which the gene is expressed rather than a change in the DNA sequence itself). Nongenetic factors cause the organism's genes to be expressed differently.
Exon	Protein coding regions of DNA.
Frameshift mutation	A mutation that results from the insertion or deletion of one or more nucleotides into a gene, thereby causing the coding regions to be read in the wrong frame and usually causing the protein produced to be defective in function.
Gene	The basic unit of heredity that occupies a specific position (locus) on a chromosome and that has specific effect(s) on the phenotype of the organism. A piece of DNA that is transcribed into a molecule of RNA and then translated into a protein.
Gene expression	The process by which the information in a gene is used via transcription and translation, thereby leading to the production of protein. Differences in gene expression can affect the phenotype of the organism, including the risk of disease.
Genetic code	In RNA and DNA, the consecutive nucleotide triplets (codons) that specify the

	sequence of amino acids for protein synthesis (translation).
Genome	The entire hereditary information of an organism. This term refers to all of the genes and other nongene portions of DNA carried by an individual cell.
Genotype	The genetic makeup of an organism or cell as distinct from its expressed features or phenotype.
Haplotype	A contraction of the term *haploid genotype.* This word refers to a combination of alleles at multiple loci, which are usually transmitted together on the same region of a chromosome.
Heredity	The passing of traits to offspring from parents or ancestors. In biology, the study of heredity is referred to as *genetics.* As a result of heredity, variation among individuals allows species to evolve by natural selection in response to changes in their environment or by random change over long periods of time.
Heterozygous	The presence of two different alleles at a specific position in a gene.
Homozygous	The presence of identical alleles at a specific position in a gene.
Intron	A DNA region within a gene that is not translated into protein. These intervening (noncoding) portions of DNA or RNA are removed during RNA processing.
Isoform	Any of several different forms of the same protein. Isoforms may be produced from related genes, or they may arise from the same gene via alternative splicing. Many isoforms are caused by single nucleotide polymorphisms.
Ligand	A molecule that binds to another molecule (usually a cellular receptor molecule).
Linkage	The tendency for certain genes to be transmitted from parent to child together because they are located close to each other on the same chromosome.
Linkage disequilibrium	The occurrence of specific alleles at different locations in the DNA that are relatively close to each other (linked) more often than would be expected by chance alone (disequilibrium).
Locus	The physical location that a gene occupies within a chromosome. (Plural: loci.)
Monozygotic twins	Twins with identical genetic makeup (i.e., identical twins) as a result of the fertilization of a single egg that then splits into two embryos.
Mutation	Changes in the DNA sequence of the genome can result from errors that occur during DNA replication or meiosis and can be caused by radiation, viruses, and mutagenic chemicals. Most mutations have little or no measurable effect on the gene's function; some are harmful, and a rare few may be advantageous.
Nucleotide	Molecules that, when linked, make up the structural units of RNA and DNA. They are composed of a phosphate group; the bases adenine, cytosine, guanine, and thymine; and a pentose sugar. In RNA, the thymine base is replaced by uracil.
Penetrance	The proportion of individuals who have a particular allele/genotype who express an associated trait (phenotype). Genotypes with a high penetrance result in a larger number of individuals in the population with the associated phenotype as compared with genotypes with a low penetrance.
Phenotype	The observable characteristics displayed by an organism (e.g., morphology, development, gender, eye color, physiologic properties, behavior). Phenotype results from the expression of the organism's genes as well as from the influence of environmental factors and interactions between the two.
Polymorphism	Polymorphism exists when two or more different phenotypes exist within different individuals of the same population. In the context of genetics, it refers to a region of the genome that varies between individual members of the population in such proportions that the rarest of them cannot be maintained just by recurrent mutation. Polymorphism may be actively maintained in populations by natural selection and also by random drift.
Sequencing	Determining in the laboratory the linear arrangement of nucleotides (in RNA or DNA) or amino acids (in proteins).
Signal transduction	A cascade of intracellular events that occurs after the binding of an extracellular signal (e.g., a hormone, a cytokine) to a receptor on the cell

	surface. The intracellular cascade can result in changes in gene expression in the nucleus and hence an altered phenotype of the cell (e.g., as a result of different protein production).
Single nucleotide polymorphism (SNP)	A polymorphism in a gene caused by a change in a single nucleotide in the DNA sequence. A large number of protein isoforms result from SNPs. SNPs occur frequently; approximately every 100 to 1000 base pairs occur as a result of deletions, insertions, and substitutions. There are estimated to be more than 10 million SNPs in the human genome. Many SNPs that occur in genes have no effect on the encoded protein, but some SNPs do influence the function of the protein that the gene produces. An SNP initially arises as a rare mutation, but it is considered to be an SNP if it occurs in at least 1% of the population.
Splicing	The removal of introns from transcribed RNA. The process of removal can vary, and some exons are skipped or excluded from splicing. This causes the production of "splice variants" or "alternatively spliced" protein isoforms, thereby resulting in the formation of different proteins from the same initial RNA.
Transcription	RNA synthesis. The process of creating an RNA copy of an equivalent section of DNA is the first step of gene expression, and it occurs in the nucleus. The RNA copy that is produced is called *messenger RNA* (mRNA).
Translation	The first stage of protein synthesis. mRNA produced during transcription is decoded to produce an amino acid chain that will later fold into an active protein. Translation occurs in the cytoplasm: ribosomes bind to the mRNA and then facilitate decoding via the binding of transfer RNAs (tRNAs) that have complementary anticodon sequences to those of mRNA. The tRNAs carry specific amino acids that are joined to form a polypeptide as the mRNA passes through the ribosome.

DNA, Deoxyribonucleic acid; *RNA*, ribonucleic acid.

Patterns in Populations and Pedigrees

With all of the attention focused on silicon arrays, laser scanners, and the other "glamorous" gadgets of advanced genomic technologies, it is important to consider how much can be learned about the genetic basis of a disease before stepping into a DNA laboratory. In fact, a strong foundation of knowledge about a disease's frequency in different populations and its occurrence among closely and distantly related family members (i.e., pedigrees) is absolutely essential. Without this foundation, endless gigabytes of DNA sequence data will not enable scientist–clinicians to develop a solid understanding of the causes of a disease. The human genome has not evolved in a test tube nor inside a supercomputer; rather, it has existed for millennia in natural populations and been transmitted from generation to generation, from parents to children. Only by carefully studying the genetics of a disease in populations and pedigrees can we hope to begin to unearth the complex interactions between genes and the

environment that underlie individual differences in disease susceptibility. This field of research is known as *genetic epidemiology*.

Genetic epidemiologists often first look at whether a disease occurs more often in some human populations than others. These comparisons can include both populations in different geographic areas as well as racial or ethnic groups living in the same region. Does the disease have more severe symptoms, more rapid rates of progression, or an earlier age of onset in some populations? Such findings suggest (but do not prove) that genetic differences that are important for the disease may exist among the populations.

Before the massive human migrations in recent centuries, most human populations existed in semi-isolation from other populations around the globe. As a consequence of natural selection (i.e., differential survival and reproduction), populations sometimes adapted genetically to their local environments. The most famous example of adaptation is the sickle cell hemoglobin variant that protects an individual against the infectious disease malaria. This variant is common among populations who live in areas where this mosquito-borne parasite has long been endemic, because it provides strong protection against the severe symptoms of this disease. The variant persists at high frequency in these populations, although persons who inherit two copies of the mutation (i.e., one from mother and one from father) are severely affected by the disease sickle cell anemia. A balance between the benefit of malaria resistance in persons who inherit only one copy of the variant versus the disadvantage of sickle cell disease keeps the variant at relatively high frequencies among populations where malaria is present. Another example of population differentiation by natural selection is the ability to digest the milk sugar lactose as an adult that evolved in Europeans in conjunction with the domestication of dairy cattle more than 8000 years ago. In addition to differentiation driven by natural selection, as is seen in these examples, a random process called *genetic drift* also causes populations with little or no migration between them to differentiate genetically over time. Thus one cannot assume that every population difference observed has a functional biologic basis.

Regrettably, the comparison of periodontitis in different

populations across the globe is extremely challenging because of the lack of calibrated examiners and standardized disease definitions.[6] One of the most dramatic population differences in which data quality is not an issue is the observation that both localized and generalized forms of early-onset aggressive periodontitis occur about ten times more frequently among African Americans as compared with Caucasians.[38] Human racial and ethnic groups often differ dramatically with regard to the frequency of mutations at genes that have major effects on disease risk. For example, cystic fibrosis is caused exclusively by recessive mutations in the CFTR gene, and it varies in frequency from 1 in 3000 Caucasians to 1 in 15,000 African Americans in the United States, whereas only 1 in 350,000 Japanese individuals are affected.[57] It is possible that the tenfold higher prevalence of early-onset aggressive periodontitis in African Americans is caused by the elevated frequency of high-risk gene variants in this population. However, additional evidence is needed before such a conclusion can be drawn. Although comparative studies of different populations may provide clues as to possible genetic mechanisms underlying a disease, the environments of the populations may also be dissimilar in important ways. It is possible that variations in diet, exposure to pathogenic oral bacteria, or some unknown and unmeasured environmental factors could entirely explain the observed differences in the frequency of aggressive periodontitis among population groups. Until solid data confirm a genetic basis for population differences, we need to wait before drawing firm conclusions.

The comparison of disease occurrence or severity in identical (monozygotic) versus nonidentical (dizygotic) twins is a powerful method for distinguishing between effects caused by variation in genes versus factors in the environment. This requires us to make what is usually a reasonable assumption that the environments of pairs of identical twins are no more or less similar than the environments shared by pairs of nonidentical twins. If variation among individuals in disease susceptibility or severity is caused entirely by factors in the environment, then we expect pairs of identical twins to be no more similar to each other in terms of disease risk than pairs of nonidentical twins. All twins (whether

identical or nonidentical) are expected to be more similar to their co-twins, on average, than to unrelated members of their local population because they were raised in the same family environment, with similar diets, microbial exposures, and so on. However, if genetic variation plays an important role in determining a certain trait, then genetically identical twin pairs will be more similar to each other than nonidentical twin pairs. This is because identical twins share 100% of the same genes, whereas nonidentical twin pairs share only 50% of their parents' genes on average. Genetic epidemiologists calculate a measure called *heritability* that is based on these correlations and that estimates the portion of all variation in the trait attributable to inherited genetic variation. Traits with variation that is determined entirely by differences in environmental exposures have heritabilities of 0.0, whereas traits with variation attributable solely to inherited genetic differences without any environmental influence have heritabilities of 1.0. Heritabilities are sometimes reported as a percentage that ranges from 0% to 100%.

Most human diseases and nondisease traits fall in the middle of this range, with heritability ranging between 0.25 and 0.75. For example, in one study, type 2 diabetes was estimated to have a heritability of 0.26, and abnormal glucose tolerance had a heritability of 0.61.[58] For it to be feasible to use the twin method with adequate statistical power, the disease has to be fairly common so that the researcher can recruit enough twin pairs in which at least one of the twins is affected by the disease. Not surprisingly, with regard to periodontal disease, only chronic periodontitis occurs frequently enough to have been studied using the twin design. Two twin studies of modest size (i.e., 110 and 117 pairs) have been reported, and these estimate the heritability of measures of chronic periodontitis range between 40% and 80%, thereby clearly implicating genetic variation in disease risk.[48,49] Interestingly, a study of bacteria associated with periodontitis found no difference between identical versus nonidentical twins.[50] This suggests (at least for these twins, most of whom did not have severe periodontitis) that inherited variation in risk is not mediated by genes that influence the presence of specific bacteria in subgingival plaque. Another review also failed to find an

association between single nucleotide polymorphisms (SNPs; pronounced “snips”) at interleukin-1 or other host genes and the presence or counts of subgingival bacteria.[52] These studies were performed before today's high-throughput DNA sequencing technologies were fully available to study the microbiome in depth, however, and it remains to be seen whether sharing specific strains of the hundreds of oral microbial species may be related to host genetics.

Another method used by genetic epidemiologists to understand and distinguish different mechanisms of transmission of diseases through families is called *segregation analysis.* This is relatively straightforward for traits in which mutation in a single gene causes the disease to develop with nearly 100% certainty in carriers, whereas persons who do not inherit the mutation are at little or no risk. For example, carriers of a single copy of the Huntington disease gene mutation or carriers of two copies of a cystic fibrosis gene mutation always develop these diseases if they reach the ages at which symptoms of these conditions normally emerge. By tracking the transmission of these diseases in families, it is obvious, for example, that Huntington disease is a dominant single-gene disorder: it is transmitted with 50% probability to offspring of affected individuals, and thus it is often found occurring across many generations of large pedigrees. By contrast, parents of children with cystic fibrosis are rarely affected themselves, and 25% of siblings are affected by cystic fibrosis when the disease is present in a nuclear family. This pattern of transmission is expected if a disease is recessive (i.e., it requires the inheritance of a mutated gene copy from both parents, who themselves have one normal and one mutated copy and so are not affected). For most common “complex” diseases, however, having a high-risk gene does not automatically lead to development of the disease; this phenomenon is called *reduced penetrance.* Furthermore, several genes or even dozens or more different genes may influence disease susceptibility; this is known as *oligogenic inheritance* and *genetic heterogeneity.* Environmental exposures are also important modifiers of disease risk. Such highly complex combinations of multiple genetic and environmental risk factors make the challenge of deciphering genetic mechanisms by merely observing transmission patterns in

families using the segregation analysis approach unfeasible. The limitations of this approach were humorously illustrated in an analysis that facetiously presented evidence of a recessive gene controlling the trait of attending medical school.[44] "Risk" for this outcome among first-degree relatives of a doctor was elevated 61 times above that of the general population. More recently, a robust quantitative analysis of the family histories of characters in the Harry Potter series suggested that a dominant gene controls the inheritance of magic abilities.[62] Because the etiology of periodontitis is likely to be highly complex, segregation analyses of this disease that have been reported in the literature should be viewed with considerable skepticism. Unfortunately, the simplifying assumptions required for this method make the results unreliable and potentially misleading. For highly complex diseases, such as most cases of periodontitis, assays at the DNA level need to be combined with careful evaluations of clinical measures among related individuals to derive robust conclusions about a disease's genetic architecture. Some of the key features of the different techniques for studying the genetics of periodontal disease are explained in Table 11.2.

TABLE 11.2

Techniques for Studying the Genetics of Periodontal Disease

Candidate gene approach	A gene-mapping approach that tests whether one allele of a gene occurs more often in patients with the disease than in subjects without the disease. These methods are also referred to as *association analyses,* and they aim to identify which genes are associated with the disease. Candidate genes are chosen on the basis of their known or presumed function (i.e., they have some plausible role in the disease process, such as producing a protein that is important in the disease pathogenesis). Conceptually this makes sense, but it requires some knowledge of the candidate gene to look for it.
Case–control studies	Studies in which the genetic makeup is compared between cases (who have the disease in question) and controls (who do not). The populations need to be carefully matched, otherwise apparent observed differences between cases and controls could arise because of ethnic or geographic variation, for example.
Twin studies	Comparisons of traits—including diseases in monozygotic, dizygotic, or usually both types of twins—aimed at determining whether variation in the trait among members of a population is caused by genetic variation in inherited DNA sequences, environmental exposures in the subjects' lives, or some combination of both of these processes. Twin studies often measure the *concordance rates* of twins with regard to a particular trait or disease of interest. Monozygotic (identical) twins are nearly identical in their DNA, whereas dizygotic (nonidentical) twins share an average of half of their DNA as identical sequences inherited from their parents. If a disease has high heritability, identical twins will be more likely to be

	either both affected or both unaffected (concordant). However, this assumption is complicated in many diseases. A genetic mutation may not have complete *penetrance,* and environmental conditions may contribute to the development of the disease (e.g., one twin may smoke and the other may not). Furthermore, many diseases are polygenic (i.e., caused by alterations in multiple genes).
Familial aggregation and relative risk	Many diseases run in families, and the degree of clustering within the family can be estimated by comparing the number of disease cases in relatives of patients to the risk of disease in the general population. Difficulties with this approach relate to the fact that, in addition to having many genes in common, family members also share many aspects of a common environment (e.g., diet, nutrition, smoking, infectious organisms, shared socioeconomic factors).
Segregation analyses	Statistical analyses of the patterns of transmission of a disease in families in an attempt to determine the relative likelihood that the disease is caused by a single gene with dominant or recessive inheritance, by multiple genes, or entirely by variation in exposure to risk factors. The observed proportions of offspring who have the trait or disease being evaluated (i.e., the phenotype) are compared with the proportions expected to be found in the general population.
Linkage analysis	A technique used to map a gene responsible for a trait to a specific location on a chromosome. These studies are based on the fact that genes that are located close to each other on the chromosome tend to be inherited together as a unit. As such, these genes are said to be "linked." Because linkage analysis initially requires the use of expensive DNA markers, this was originally only considered justified after finding strong evidence of a genetic basis for a trait with the use of segregation analyses or family aggregation studies. One difficulty with linkage analyses is that many diseases are not caused by a single gene of "major" effect but rather by multiple genes of "minor" effect. In the latter situation, multiple genes each contribute a small amount to the phenotype, disease, or trait. The linkage study approach has little power for detection, whereas association analysis methods may still be quite powerful.
Genome-wide analyses	A genome-wide association study (GWAS) investigates genetic variation across the entire genome simultaneously, with the aim of identifying genetic associations related to a trait or disease of interest. The completion of the Human Genome Project in 2003 and the development of microarray technologies capable of assaying more than half a million single nucleotide polymorphisms have made GWASs possible. This method has the potential to identify the genetic contributions to common diseases. Because the entire genome is analyzed, an important advantage of this approach is that the technique permits the genetics of a disease to be investigated in a nonhypothesis-driven way. In other words, it is not necessary to correctly guess which candidate genes are most interesting to evaluate. A GWAS requires that well-characterized cases and controls be identified. A disadvantage of GWASs is that large clinical sample sizes are required to reduce the likelihood of differences between the cases and controls being observed simply by chance as a result of the hundreds of thousands of multiple statistical tests required to search the entire human genome.

Searching for Answers in the DNA

In theory, a *genetic marker* can be any type of biomolecule or assay that allows us to read inherited differences among individuals in their DNA sequences. Blood groups, protein isozymes, and human leukocyte antigens (HLAs) were among the first developed markers, but even simple traits that are controlled by single genes

(e.g., eye color) can also serve this purpose. Genomic methods have made these methods obsolete, because researchers can now determine a person's inherited variation directly at the DNA level for a much lower cost and with greater speed and accuracy. So-called next-generation DNA sequencing methods are projected to enable researchers and clinicians to obtain nearly the entire 3 billion–DNA base human genetic blueprint for less than $1000.[20,76] At present, most genetic studies use a combination of whole genome arrays that can evaluate up to 1 million variable DNA sites in a single assay in combination with lower-throughput methods that are used for the fine mapping of chromosome regions of special interest.[61] These regions are said to contain *candidate genes* of high priority for further investigation either because of the genes' known biologic functions or because results of previous genome-wide surveys indicate strong statistical chances that disease susceptibility genes are located in certain regions of one or more chromosomes. Types of variation include SNPs in which one DNA base is substituted for another; small insertions and deletions ("in/dels") of one or more DNA bases; and larger structural changes in the DNA, such as inversions (in which a piece of DNA of hundreds or thousands of bases in size is cut out and sewn back into the chromosome in the opposite orientation) and copy number changes (in which a given segment of DNA is either missing or occurs in more than the usual two copies inherited as one copy from each parent).

Equipped with these powerful tools for rapidly measuring DNA variation, the next question to address is what kinds of study designs are most powerful for identifying the dozen or more variants that influence the risk of disease from among the millions of DNA differences that exist between any two individuals in a typical population. One method that has been highly successful for finding molecular defects related to simple genetic diseases caused by the mutation of a single gene, such as cystic fibrosis and Huntington disease, is *linkage analysis*.[1,7] This gene-mapping strategy requires families with one or more members affected by the disease to be recruited and clinically and molecularly evaluated for a relatively small number of genetic markers. Depending on the type of marker used, as few as 500 markers or up to 10,000 markers

distributed evenly across the genome are needed. Investigators usually try to recruit families with two or more close relatives, such as sibling pairs, who are affected by the disease as well as parents and other siblings who may be unaffected. With a *null hypothesis* that suggests that a region of the chromosome does *not* contain genetic variation that influences disease risk, siblings share identical genetic material inherited from their parents an average of 50% of the time. However, if the region of the chromosome being evaluated contains a gene that has a substantial effect on disease risk (i.e., increases the risk by tenfold or more), then pairs of siblings who are both affected by the disease will share the chromosome region that contains the disease gene substantially more often than 50% of the time, and the null hypothesis of 50% sharing will be statistically rejected if the study has an adequately large enough sample of such families. This simple example illustrates how linkage analysis is performed. In practice, both small and large extended families are studied; this will include the simultaneous evaluation of the sharing of genetic material among both affected and unaffected relatives. Sophisticated mathematical algorithms and computer programs are used to carry out the huge number of calculations required for data analyses.

After achieving many successes with the use of linkage analysis for "simple" diseases caused by the mutation of a single gene, this method was extended to complex diseases caused by combinations of multiple susceptibility genes and environmental risk factors. Unfortunately, these conditions proved to be beyond the reach of linkage analysis in most instances. In numerous studies conducted during the 1990s, either researchers failed to find any genes or initially positive findings failed to replicate. Linkage studies of large numbers of carefully diagnosed families for complex diseases (e.g., orofacial clefting, in which twin studies had firmly established heritability of 70%) identified at most a tiny fraction of this genetic variation. Mathematical analyses have subsequently shown that the linkage analysis gene-mapping strategy has extremely low statistical power for complex diseases in which each individual susceptibility gene has a relatively small effect on risk (e.g., twofold or less) and in which there is extensive heterogeneity among different families that have different combinations of susceptibility

genes and environmental exposures.[64] Consequently, it is not surprising that linkage analysis has been successfully applied only to syndromic forms of periodontitis (summarized later in this book).

Disappointment over this setback in human disease mapping caused by the initially unrecognized limitations of linkage analysis was short lived. An alternative approach called *association analysis* was also available, although this had been relegated to studies of HLA and a few other markers of special interest during the prime time of linkage approaches.[1,7] Mathematical analyses indicated that if we make some reasonable assumptions about the nature of genetic factors in human disease, this method could provide adequate statistical power for finding genes of small to modest effect on risk while requiring only moderately large sample sizes that would be feasible to recruit.[64] There was, however, one major catch: to search the entire genome using the GWAS method, the number of genetic markers needed was several orders of magnitude greater (i.e., 500,000 to 1 million assays needed per subject). Fortunately, advances in molecular assay technologies converged at this time period, and several methods of array-based genotyping provided this capability at an acceptable cost.[61]

How association studies are used to find disease susceptibility genes is illustrated for the case–control design in Fig. 11.1. Association analyses are sometimes referred to as *case–control studies,* although this is only one of several sampling methods that can be used (including studies of families). Genotype frequencies of an inherited DNA variant for a group of periodontitis cases are statistically compared with the frequencies of the variant in a matched group of periodontally healthy control subjects. If the genotype frequencies differ so greatly that the results are unlikely to occur by chance, then we conclude that the genotype that is more common in the cases as compared with the controls is "associated with" increased disease risk. In Fig. 11.1, 59% of the cases have the CC genotype (having inherited a C allele from both of their parents), whereas only 17% of the healthy controls inherited the CC genotype. Therefore this DNA variant could be used to predict periodontitis risk (but not until after the finding was validated in additional independent studies). Conversely, we can also say that

the AA genotype is “protective” against disease because it occurs much more often in the healthy controls (50%) as compared with periodontitis cases (8%). Ideally, the cases and healthy controls are matched as closely as possible for race/ethnicity, smoking behavior, age, gender, and so on, so that differences in genotype frequency are likely to be caused by real biologic effects on disease development or progression rather than as artifacts of some kind. For example, it is well known that races and ethnic groups sometimes differ dramatically with regard to genotype frequencies as a result of their historic isolation in different geographic regions. Consider, for example, a study that had mostly Swedish cases and mostly Italian controls. We know that there are thousands of DNA variants that differ substantially among these populations because of their geographic isolation throughout human history. Few if any of these variants have anything to do with differences in disease risk, but they could falsely appear to be associated because of the failure to carefully match ethnicity in cases and controls. In practice, this is usually not a problem, provided that investigators take reasonable precautions with regard to how cases and controls are selected. It is also now routine practice to use several statistical methods to check for mismatching and then adjust for this during data analysis if it occurs.

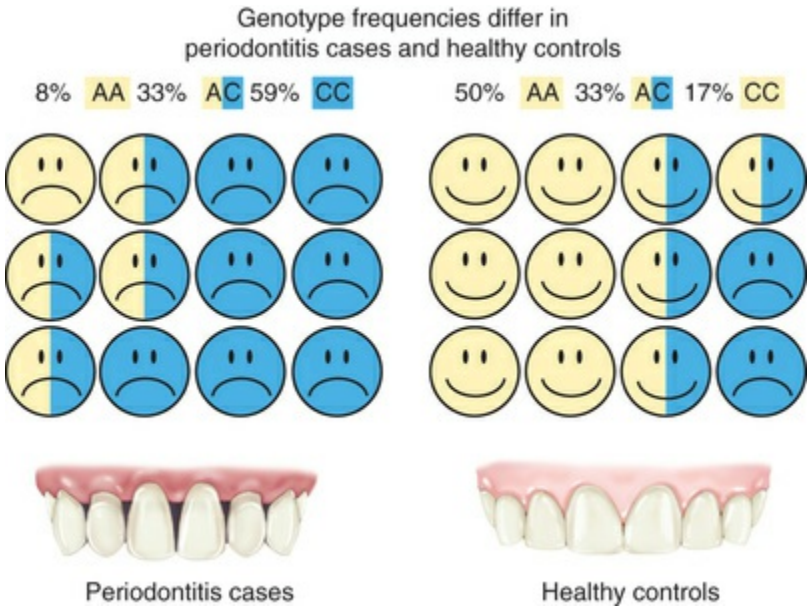

FIG. 11.1 Case–control design for a genetic association study. Periodontitis cases shown on the

left have frequencies for a hypothetic genetic marker of 8% AA, 33% AC, and 59% CC, which are substantially different from genotype frequencies found in healthy periodontal controls of 50% AA, 33% AC, and 17% CC. In this example, the CC genotype is associated with increased risk, because it occurs at a much higher frequency in the disease cases; alternatively, the AA allele is protective, because this variant is much more common in the healthy controls.

The good news is now clearly in: association studies have been a boon for the discovery of inherited genetic variation important for a wide range of complex diseases, including diabetes, cardiovascular disease, metabolic disorders, obesity, and mental illnesses. Reviews show that dozens of genes have been identified with unquestionable statistical confidence for type 2 diabetes alone, and the list continues to grow.[18,73] Most of these genetic polymorphisms with elevated risk are common in the population (i.e., from 5% up to >50%). Although each variant only increases risk slightly (i.e., twofold or less), because the risk alleles are so common they can account for a nontrivial proportion of the occurrence of disease in the population; this is a measure that epidemiologists call *attributable risk.*

An especially attractive aspect of the GWAS approach is that because the entire human genome is searched, we no longer have to depend on prior hypotheses about the disease's molecular pathology. In most GWAS studies, about half of the statistically definitive findings point to genes that experts in the field had no suspicion whatsoever were involved in the disease's etiology. This allows researchers to open up entirely new pathways for investigation that may lead to insights about the disease's biologic mechanism and suggest novel molecular strategies for pharmaceutical or other therapeutic interventions. In more than a few cases, robust GWAS findings implicate regions of the human genome in which no genes appear to be present, thereby highlighting the limitations of our current knowledge of basic genome functions.

Although great progress has been made toward understanding the etiology of many complex human diseases by using GWAS

methods, the approach has nevertheless usually failed to account for most of the heritability known to exist for these conditions.[12,43] One study found that well-established nongenetic diabetes risk factors (e.g., gender, smoking, family history, body mass index, blood lipid and glucose levels) were better predictors of risk than a combination of the top 20 genetic markers for this disease.[74] To improve gene-based risk estimates, the missing heritability needs to be found. The emergence of next-generation DNA-sequencing tools may help advance this search. In theory, data from the entire human genome of more than 3 billion bases may enable researchers to identify the less common (i.e., 1% to 5%) genetic variants that are predicted to have individual gene effects of greater magnitude on disease risk (i.e., greater than twofold but less than tenfold) that cannot readily be found with the use of either GWAS or linkage analysis methods.

Genetic Basis for Individual Differences in Disease Risk

As a result of the appropriate focus on the role of bacterial infections in the disease pathogenesis of periodontitis, inherited human genetic variation is often referred to as *host defense* or, somewhat more broadly, *host response.* However, these terms cover only a small portion of the range of gene functions that may be important for periodontitis risk. Many additional biologic processes that are not directly related to defenses against or responses to infection by microbial pathogens are also likely to play important roles in determining an individual's susceptibility to this disease.

Periodontitis in Genetic Syndromes and Other Diseases

A number of extremely rare conditions consistently include periodontitis among the array of clinical manifestations that define a syndrome. Many genetic syndromes involve mutations of single genes or larger chromosomal regions. However, a number of syndromes, such as fetal alcohol syndrome, are purely

environmental in origin. Some of the syndromes that include periodontitis are caused by mutations in specific genes. For example, mutations in the cathepsin C gene have been shown to cause both Papillon–Lefèvre syndrome and Haim–Munk syndrome as well as some forms of nonsyndromic prepubertal periodontitis, and they may also be associated with a risk of aggressive periodontitis.[55] Periodontitis frequently occurs with some subtypes of Ehlers–Danlos syndrome, Kindler syndrome, Down syndrome (trisomy 21), leukocyte adhesion deficiencies (Fig. 11.2), hypophosphatasia, two types of neutropenia, and aplasia of the lacrimal and salivary glands. A large triracial extended family demonstrated evidence of a single gene that caused both early-onset aggressive periodontitis and dentinogenesis imperfecta.

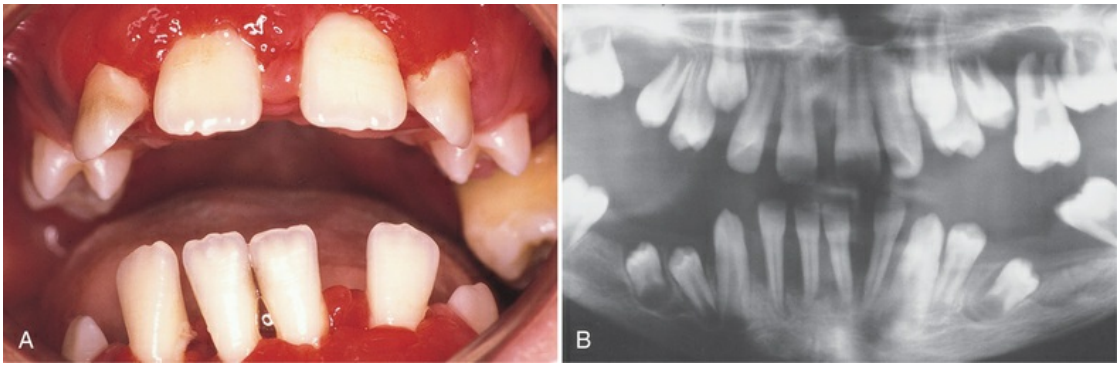

FIG. 11.2 Oral (A) and radiographic (B) appearance of a patient with leukocyte adhesion deficiency. The child was deficient in CD18 (i.e., leukocyte adhesion deficiency type I), which results in absent or severely reduced levels of the β2 integrin molecule. The patient suffered from recurrent infections of the middle ear, the tongue, and the perirectal areas as well as of the periodontium. (B, From Majorana A, Notarangelo LD, Savoldi E, et al: Leukocyte adhesion deficiency in a child with severe oral involvement. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 87:691–694, 1999.)

The gene has been mapped with the use of linkage to a chromosomal region that contains a dentin matrix protein gene.[42] Many of these conditions are so rare that few periodontists see even a single case during a lifetime of practice. However, dentists should be aware that these single-gene conditions exist; they need to be prepared to extend clinical evaluations to close relatives and to seek

the assistance of or to refer to appropriately trained genetic counselors or specialists if a patient's medical history or the presentation of multiple symptoms raises the possibility that he or she may be affected. Clinicians can obtain updated information about these conditions by accessing the publicly available Online Mendelian Inheritance in Man database and typing in "periodontitis OR periodontal disease" as the query term.[2] Further research is necessary to determine whether inherited variation in the genes that cause these rare syndromes may also influence the risk of nonsyndromic forms of aggressive or chronic periodontitis.

Genetic Disorders Associated With Periodontitis

Genetic Syndrome With Periodontitis as an Oral Manifestation	Mutated Gene/Genes	Functions of Affected Genes
Chédiak–Higashi syndrome	LYST	LYST encodes for lysosomal trafficking regulator that aids in intracellular transport of materials into lysosomes.
Ehlers–Danlos syndrome, Periodontal types, 1 and 2; EDSPD1 and EDSPD2 (formerly type VIII)	C1R and C1S	Genes C1r and C1s encode serine proteases that are major constituents of human complement subcomponent C1. Complement is part of the innate immune system and is involved in inflammation.
Papillon–Lefèvre syndrome	CTSC	CTSC encodes for cathepsin C, which is a key activator of serine proteases in immune cells, regulating their function.

Nonsyndromic Aggressive and Chronic Periodontitis

In this section, evidence for the association of inherited genetic variation with aggressive and chronic periodontitis will be considered for cases that present without the co-occurrence of anomalies or disorders of other parts of the body or of the affected individual's behavior. Such cases are appropriately classified as *nonsyndromic periodontitis.* This terminology is similar to the way that other human diseases, such as orofacial clefting, have long been recognized as occurring in both syndromic and nonsyndromic

forms. The elevated risk of periodontitis that is associated with metabolic conditions (e.g., diabetes, which is addressed elsewhere in this book) is more appropriately considered a comorbidity rather than cause for the designation of a syndrome.

"A finding of no statistical significance in a well designed, conceptually sound, adequately powered study testing an important hypothesis is likely to provide more useful information than significance in a study that does not meet these criteria."[5]

As described previously, twin studies have shown that chronic periodontitis has substantial heritability, and we know that aggressive periodontitis aggregates strongly in families. Because aggressive periodontitis occurs so rarely, it is not feasible to perform a twin study to confirm the heritability of this condition. Neither segregation analyses nor gene-mapping linkage studies are capable of providing reliable information about the genetic etiology of a highly complex disease such as periodontitis. However, large numbers of susceptibility genes have been identified for complex disorders, such as diabetes and cardiovascular disease, using association analysis. It seems reasonable to expect that similar successes could be achieved for periodontitis using this approach. In fact, since the early 2000s several hundred papers have reported associations of nonsyndromic aggressive and chronic periodontitis with polymorphisms in a number of candidate genes. Certain classes of genes (e.g., cytokines) that have long been a focus of attention by immunologists and cell biologists studying pathogenic mechanisms associated with periodontitis have received the most attention. Early reports of relatively weak associations with variation in interleukin-1 (IL-1) genes led to a large number of attempts to replicate and extend these findings. Unfortunately, with few exceptions, association studies of periodontitis have been inadequately powered to detect genetic variation with modest effects on disease risk or progression (i.e., sample sizes that are much too small). In addition, inconsistency with regard to the methods used to classify subjects as periodontal cases versus controls or to quantitatively measure disease severity and extent greatly limit our ability to draw sound conclusions by comparing

results reported in different studies.

Key Fact

Oral Manifestations of Chédiak–Higashi Syndrome

This autosomal recessive condition occurs due to a mutation of the LYST gene that encodes for a lysosomal trafficking regulator protein. The phagocytosis function of immune cells is drastically affected in these patients, making them significantly prone to infections. As a result, severe forms of periodontitis and early exfoliation of both deciduous and permanent teeth are common findings in these patients.

The reason why association studies of periodontitis have largely failed will be challenging to fully address. The first issue is straightforward and simply a matter of numbers. It is noteworthy that the successes achieved for many complex diseases (e.g., diabetes) with the use of the GWAS mapping approach were based on sample sizes involving thousands of cases and controls, with multiple replications by *independent* teams of investigators. Statistical theory shows that to detect genes of modest effect, these large sample sizes are absolutely essential. With the use of a statistical power calculator developed for case–control studies,[60] sample sizes required for 80% power are shown in Fig. 11.3 for a study that involves only a single genetic marker as well as for studies that evaluate 5, 50, or 500 independent genetic markers in which the effects of multiple comparisons need to be accommodated. In this example, we assume that the risk gene acts in a dominant manner, with the high-risk allele occurring at a frequency of 25% in the population, and that this allele causes risk among carriers to increase twofold (i.e., a greater effect on risk than observed for many susceptibility alleles found in GWAS studies of other complex diseases).

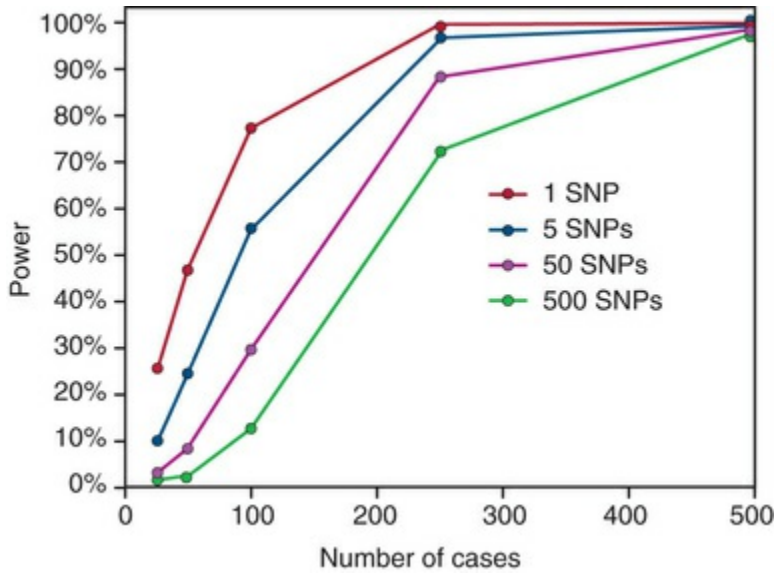

FIG. 11.3 Statistical power estimates are shown for a situation in which we hypothesize that a dominantly transmitted disease susceptibility gene that increases risk twofold and that has an allele frequency in the population of 25% is being mapped by a case–control association study. The lines illustrate the loss of statistical power caused by the requirement to adjust for multiple comparisons when a research study involves the evaluation of not just a single genetic marker but as many as 5, 50, or 500 independent genetic polymorphisms. Although only 100 cases (and 100 controls) may provide sufficient power if only a single marker is being tested, 250 cases and 250 controls are needed if 5 or 50 single nucleotide polymorphisms are assayed; a minimum of 500 cases and 500 controls will be necessary if a study investigates 500 independent genetic markers.

Many periodontitis association studies reported in the literature involved multiple markers in each publication, and often the same research team reported positive findings for other genes in subsequent papers. Furthermore, because of the difficulties of publishing negative findings (i.e., when no association is found), many research teams working in this area may assay 50 or more genetic markers over the course of their work over several years. Results shown in Fig. 11.3 demonstrate that to obtain 80% power, a study of 50 markers would require more than 200 cases and 200 controls. Even if a research team assays only five SNPs, its study

would still require 100 cases and 100 controls to achieve adequate power.

Our search of PubMed in early 2010 using the search term "(periodontal disease OR periodontitis) AND (SNP OR SNPs OR polymorphism OR polymorphisms OR linkage)" identified 311 periodontitis gene association tests with a *P* value of 0.05 or less for at least one statistical test reported. These results are summarized in Fig. 11.4, in which the x-axis indicates the number of cases included in the study; the *P* value for the strongest finding is plotted on the y-axis. When more than one statistical test was reported, only the one with the smallest *P* value is shown in this figure. In some cases, this inflated the actual statistical significance, because investigators rarely adjust their findings for these multiple tests when the findings are reported in a publication. This analysis shows clearly that most association findings have been drastically underpowered if periodontitis is assumed to be a complex disease. The majority (66%) of these association reports for chronic and aggressive periodontitis are based on samples of 100 cases or fewer, and 41% are based on fewer than 60 cases. As shown in Fig. 11.3, studies of such small sample size have little power to detect a susceptibility gene that increases risk twofold. Given the added concern about publication bias (i.e., that positive findings are more likely to be accepted for publication), we can have little confidence that even the more statistically significant findings are valid and likely to be independently replicated if they are based on such inadequate samples sizes. With only a few exceptions from GWAS, which are noted later in this chapter, publications since 2010 have continued to involve small numbers of cases and to provide marginal statistical support for association.

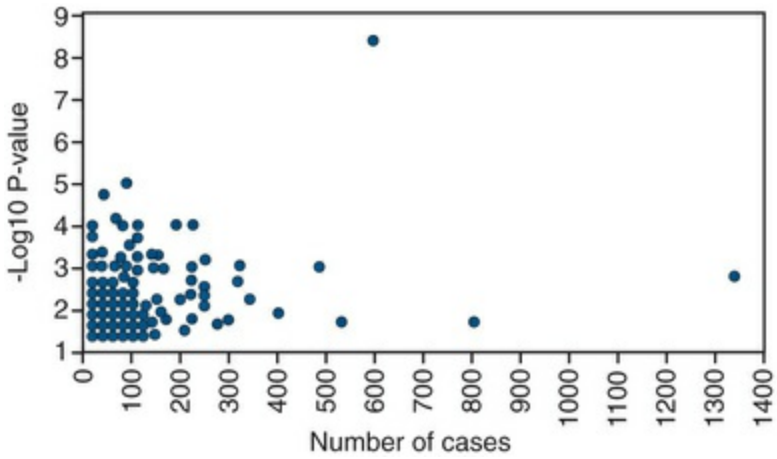

FIG. 11.4 Number of cases and the *P* values reported for 307 gene association tests for aggressive or chronic periodontitis reported in the literature. Only findings with *P* values of 0.05 or less are included. When multiple tests were performed, the strongest association (i.e., the smallest *P* value) is the one used for this presentation.

Aside from important lessons about how *not* to carry out association studies of a complex disease, there are some tentative conclusions that can be drawn from the data available thus far. Detailed results of our review and manual curation of 298 publications reporting association findings for periodontitis are presented in eTable 11.1 (www.expertconsult.com), and key findings are condensed in Table 11.3.

TABLE 11.3

Number of Independent Gene Association Reports for Aggressive Periodontitis and Chronic Periodontitis[a]

	AGGRESSIVE PERIODONTITIS				CHRONIC PERIODONTITIS		
Gene Symbol[b]	**None[c]**	**Weak**	**Moderate**	**Strong**	**None**	**Weak**	**Moderate**
CD14	3				7	5	
CDKN2BAS		1	1

VDR	3	6			7	12	

[a]Only genes with two or more reports of association are included.

[b]Full gene names and a summary of knowledge about the gene's function can be found by typing the gene symbol into the search box at http://www.ncbi.nlm.nih.gov/gene.

[c]Strength of association is defined as follows: weak (*P* value of <0.05 but ≥0.001; if <50 cases are in the study, then the finding is considered weak, regardless of the *P* value); moderate (*P* value of <0.001 but ≥0.0001 or if <101 cases are in the study regardless of *P* value); strong (*P* value <0.0001 and >250 cases in the study).

This summary includes a total of 41 genes plus a combination of the IL-1A and IL-1B genes analyzed jointly. Only genes that had at least two findings classified as “weak” or one finding of association with a “moderate” or “strong” level of support are included in this summary. The technical criteria for these designations are based on a combination of each study's sample size (assuming larger studies are less likely to produce false positives) and the study's *P* value (statistical significance or type I error) as described in the Table 11.3

footnotes and in online supplementary documentation.

Genes in Table 11.3 have usually been evaluated in multiple independent studies for association with either aggressive or chronic periodontitis or both. Occasionally these subtypes of the disease have been pooled together, so it is not possible to determine from the publication whether the association involves primarily one subtype or both. With the exception of only the one GWAS study that has been published for this disease, all association tests reported to date involve the evaluation of candidate genes that were selected on the basis of known or postulated mechanisms of disease pathogenesis.

Clinical Correlation

Ehlers–Danlos Syndromes

Ehlers–Danlos syndromes (EDSs) are connective tissue disorders characterized by joint laxity and skin hyperextensibility, scarring, and bruising. Periodontal EDS (EDSPD; previously EDS VIII) is a subtype with autosomal dominant inheritance with severe periodontal inflammation. Children exhibit extensive gingivitis followed by early-onset periodontitis in teen years leading to attachment and tooth loss. Serious complications including arterial or gastrointestinal ruptures have also been reported.

For example, when bacteria challenge gingival tissue, CD14 binds lipopolysaccharide, and TLR4 plays a key role in pathogen recognition and the activation of innate immunity.[36] Lactotransferrin (LTF) plays an antimicrobial role as the first line of host defense, and it can also neutralize endotoxin and inhibit the induction of nuclear factor-κβ (NF-κβ) in monocytes in response to lipopolysaccharides.[31,75] Myeloperoxidase (MPO) is an oxidative enzyme expressed in polymorphonuclear leukocytes. It is involved in the defense against periodontal bacteria and is also able to mediate inflammatory tissue destruction in periodontal disease.[45] Glutathione S-transferase mu 1 (GSTM1)[10] and *N*-acetyltransferase 2 (NAT2)[34] genes are responsible for the detoxification of a wide range of chemicals, including tobacco carcinogens. HLA complex

genes[72] play a central role in the immune system by presenting extracellular peptides that are important for either self-recognition or initiating immune responses to foreign pathogens. The Fcγ receptor genes (FcγRS) encode receptors for the Fc portion of immunoglobulin G, and they are involved in the removal of antigen–antibody complexes from the circulation as well as other antibody-dependent responses.[40] Formyl peptide receptor (FPR1) is a G-protein–coupled receptor of phagocytic cells that interacts with bacterial peptides and that mediates chemotaxis, degranulation, and superoxide production involved in inflammation.[22] Cytokines such as the interleukins (IL-1, IL-2, IL-4, IL-6, IL-10), tumor necrosis factor (TNF), and lymphotoxin-alpha (LTA) play a number of important roles in the immunopathology of periodontal disease.[54] Prostaglandin-endoperoxide synthase (PTGS2), which is also known as *cyclooxygenase-2*, is the key enzyme in prostaglandin biosynthesis. It is regulated by specific stimulatory events, which suggests that it is responsible for the prostanoid biosynthesis involved in inflammation.[25] S100 calcium binding protein A8 (S100A8), which is the light subunit of calprotectin, is also associated with inflammatory diseases, including periodontitis.[37] Fibrinogen (FBG) is an acute-phase protein; FBG levels are elevated during inflammation, and the substance has been associated with cardiovascular disease risk.[65] Vitamin D receptor (VDR)[24] and estrogen receptor (ESR1)[77] are hormone receptors involved in skeletal muscle metabolism, including calcium absorption and bone loss. The matrix metalloproteinases (MMPs) are a group of endogenous proteinases that contribute to the degradation of extracellular and basement membrane components.[23] CDKN2B antisense RNA (CDKN2BAS) is a nonprotein coding gene of unknown function that has also been reported to be associated with coronary heart disease.[68] The one GWAS reported for periodontitis, which is described in detail later in this chapter, revealed a strong association of a glycosyltransferase gene (GLT6D1) with aggressive periodontitis,[70] but there is no clear functional relationship of this gene with periodontal disease pathogenesis.

With few exceptions, there are just as many or more reports in Table 11.3 in which no significant association was found for the gene as there were reports with positive findings. For example,

HLA-B has 9 negative reports and 6 weak positive findings. IL-1B has 45 negative reports, 20 weak associations, and 3 moderately supportive findings. The inconsistency among these findings requires a much deeper analysis to understand what may be going on. One possibility is that genetic variation at the candidate gene is *not* associated with periodontitis. When a large number of studies are performed using a multitude of alternative ways of classifying small numbers of cases versus controls, when multiple alternative statistical analyses are run for the same small data sets, and when there may be a bias against the publication of negative results, then a substantial portion of studies should report positive findings, even if no real association exists. Then again, heterogeneity among studies may be real. The negative studies may differ in terms of the racial or ethnic composition of the subjects, and the findings may be valid for some human populations but not others. Different genetic polymorphisms in the candidate gene may be evaluated in the different studies, and only some of these may actually be associated with disease risk. Different clinical definitions or sources of information (e.g., clinical attachment loss versus bone loss measured from radiographs) may be used to define cases or various quantitative measures may be employed, and these sources of variation may also influence the outcome of association tests. With data limited to mostly small studies, it is not currently possible to definitively determine which of these potential explanations applies to most of the findings shown in Table 11.3.

Clinical Correlation

Papillon–Lefèvre Syndrome and Dental Implants

Caused by a mutation in the cathepsin C gene, this syndrome is characterized by advanced periodontitis affecting both deciduous and permanent dentition and palmar plantar hyperkeratosis affecting palms and soles. Patients become edentulous very early in life. Limited scientific evidence in the form of case reports indicates that edentulous patients with this syndrome can be successfully treated with dental implant–supported restorations.

Fig. 11.4 shows that a handful of periodontitis association studies have been reported that approach the sample size needed for complex diseases with more than 400 cases.[17,39,46,47,68,69] This includes the GWAS in which more than 322,825 SNP genetic markers were evaluated for association with the risk of aggressive periodontitis.[70] In the GWAS, statistical testing was performed in sequence for three independent sets of samples with a total of 438 cases and 1320 controls. Interestingly, this relatively powerful analysis failed to yield significant support for the usual suspect candidate genes shown in Table 11.3, after adjusting for the large number of hypotheses tested in the analysis. Instead, several novel chromosomal regions and candidate genes were implicated, with among the strongest being a glycosyltransferase gene (GLT6D1), one of several glycosyltransferases in the human genome. This had an unadjusted *P* value of 0.000000006. However, the *P* value was reduced by three orders of magnitude to 0.000006 after accounting for the effects of gender, smoking, and diabetes. The adjusted *P* value indicates that we should expect to see a difference in genotype frequency of this magnitude by chance alone about 1 out of 166,666 times under the null hypothesis of no association with disease risk. This may seem to be strong evidence for rejection of the null hypothesis, but this adjusted finding is actually only a marginal statistical significance in the context of a GWAS. In fact, this sometimes occurs by chance alone in the absence of a valid association, because this study involved testing more than 300,000 genetic markers. Because there is no obvious functional connection of this gene with what we currently know about the pathogenesis of periodontitis (the protein is thought to play a role in signaling in development), it may be tempting to further downplay the finding's significance. However, experience with GWAS studies of other complex diseases has shown that, quite often, valid gene associations are discovered in pathways that experts in the field did not previously realize were even related to the disease's biology. This makes such discoveries all the more valuable, assuming that they are definitively and independently replicated, because they offer the potential of revealing completely new avenues for further exploration at the cellular and molecular levels and because they potentially may also provide novel targets for therapeutic

interventions.

During the years since the report of a strong association of aggressive periodontitis with GLT6D1, it has been interesting that no replications of this finding have been reported. The first genome-wide study that focused on chronic periodontitis included 4504 European Americans, with 43% having moderate chronic periodontitis and 17% having severe chronic periodontitis.[16] No genome-wide significant associations were found in this large sample, with no support whatsoever for the much-studied periodontitis candidate genes IL-1A, IL-1B, IL-1RN, IL-4, IL-6, IL-10, CD14, FCGR2A, MMP1, TLR4, TNF, and VDR. However, intriguing suggestive evidence was found supporting the role of cellular immune response, nervous system, and cytokine signaling pathways. By broadening the phenotype, a subset of these subjects were also analyzed using genome-wide SNP data for periodontal pathogen colonization, but again only statistically suggestive results were obtained with this smaller sample.[15] A large-scale replication analysis of 23 much-studied candidate genes in 600 aggressive periodontitis cases and 1448 control subjects of German ethnicity found support only for SNPs in IL-10, but this association was not replicated in 1437 chronic periodontitis cases of German ethnicity.[67] Several GWAS of periodontitis have now been completed for moderately large sample sizes, and the results are sobering.[53,66] No statistically strong, replicated associations have been found in any of these studies. Furthermore, in two large cohort studies, DNA sequencing of the coding regions of nearly all genes (exome sequencing) also failed to reveal any rare variants with a statistically significant association with chronic periodontitis.[33]

It is clear from these findings that large-scale association studies, possibly involving family-based designs and searches for rare high-risk variants, will be needed to more fully elucidate the role of genetics in periodontal disease. From what we now know, it appears increasingly likely that the high heritability estimated for chronic periodontitis is likely attributable to a large number of inherited DNA variations in more than 100 or possibly 500 or more different genes. This is the genetic architecture that we know underlies other highly heritable traits such as height, and this

discovery has important implications and places limitations on the use of genetic variation for tests to predict risk, as will be addressed later in this chapter.

Challenges and Opportunities for the Future

The classification of disease used for research studies is an especially difficult challenge to be faced if we are to benefit fully from the opportunities offered by the genomics revolution.[59] If we cannot agree which subjects in a study are affected by disease, by a particular subtype of disease, how severely they are affected, or how quantitative measures related to disease should be obtained and analyzed, then the chances of making progress will be low, regardless of how advanced our molecular or bioinformatics technologies become. This problem is important for all kinds of research, not only genetics, and the issue of diagnosis is addressed elsewhere in this book. However, genetics may have a unique role to contribute toward solving this dilemma. This may best be illustrated by an example from the early 1980s, in which medical geneticists and oncologists could not agree about the classification of the disease neurofibromatosis (NF). "Splitters" argued for up to a dozen different etiologic subtypes, whereas "lumpers" suggested that there may be only a single disease with a lot of variation among individuals as a result of differences in environmental exposures and variation in "genetic background" (a term that encompasses the cumulative influence of all other genes distributed throughout the genome in addition to the "major gene"). It had been discovered in research conducted during earlier decades that NF was transmitted in families as a single dominant gene, but the question remained as to how many different genes were involved (locus heterogeneity). Furthermore, even if only one gene was involved, it was possible that different mutations caused unique patterns of signs and symptoms (allelic heterogeneity). The controversy was largely resolved by the discovery of the NF1[41] and NF2[71] genes. After these genes were identified, DNA testing could distinguish individual patients, and the diagnostic classification controversies were resolved. In hindsight, it became clear that the clustering of signs and symptoms fell into two major categories

among different types of families and depended on which NF1 or NF2 mutation was involved and on what kind of gene mutation was involved. Although such gene-based clarity is unlikely for a complex multigenic condition such as periodontitis, the potential exists that subtypes of patients may eventually be classified more effectively by examining their DNA to see what kinds of susceptibility genes they inherited.

To move toward this desired outcome, however, we need to use the best strategies available today to classify research subjects into categories such as cases versus controls. Alternatively, we can attempt to use quantitative measures of bone loss or attachment loss to classify research subjects along a more continuous gradient that ranges from persons with extremely healthy periodontium with little or no signs of disease to those with tooth loss and high measures of pocket depth and attachment loss in remaining teeth. Family studies have numerous advantages in genetics; for these designs, the use of a quantitative measures approach is especially attractive. When searching for gene associations in unrelated cases and controls, we can decide to select only subjects who are clearly affected as cases and compare them with control subjects who clearly are periodontally healthy. When studying families, however, one has to assign a disease status to all of the family members to fully make use of all of the information in the biologic unit. We may initially recruit the family on the basis of an unambiguous case known as the *proband* (i.e., the subject who makes the family eligible for inclusion in the study), but the handling of parents, siblings, and other close relatives who may be neither clearly periodontally healthy nor clearly diseased is not easy to determine. For example, if we establish a threshold and require that two or more teeth have a minimum of 4 mm of attachment loss for subjects to be classified as affected, then how we handle family members who are borderline becomes the challenge. For example, siblings of the proband may have several teeth with 3 mm of attachment loss in addition to one tooth with 6 mm of loss. Such subjects are close to but not quite over the threshold. They are neither clearly healthy nor clearly diseased, and this makes them problematic for categorical data analyses that require them to be classified as cases versus controls.

One aspect of the diagnosis challenge that is especially poorly understood is how and why different teeth are affected by periodontitis. Dentists have long recognized that incisors and first molars are more likely to be affected during early-onset disease, but it is not straightforward to incorporate this information into threshold disease definitions. One way to begin to address the problem of variation among teeth is to apply multivariate methods, such as principal components analysis, as was done in a study of aggressive periodontitis.[14] This method maximizes the proportion of the total variation in attachment loss among all 28 teeth explained by a limited number of master variables called *principal components.* In this study, three principal components explained 77.8% of the total variance. The results are displayed in Fig. 11.5, with color intensities being used to help visualize the patterns of correlation among different tooth types. Mixtures of red, green, and blue are "painted" onto the teeth, with each color's intensity adjusted according to the tooth's relative "weight" calculated for each of the principal components. This quantitative analysis shows how attachment loss is correlated among different kinds of teeth. First molar teeth are consistently painted yellow by their principal components scores; these teeth are very different from all of the other teeth with regard to their patterns of attachment loss. There is a gradual change in the patterns of attachment loss for the other teeth that extend out from the central incisors (magenta) to the lateral incisors (purple), the cuspids (blue), the premolars (blue green), and the second molars (green). In addition to generally exploring patterns of periodontal disease dispersed in the geography of the mouth, because these are studies conducted in families, we can also use genetic epidemiologic methods to validate and compare alternative measures of disease.

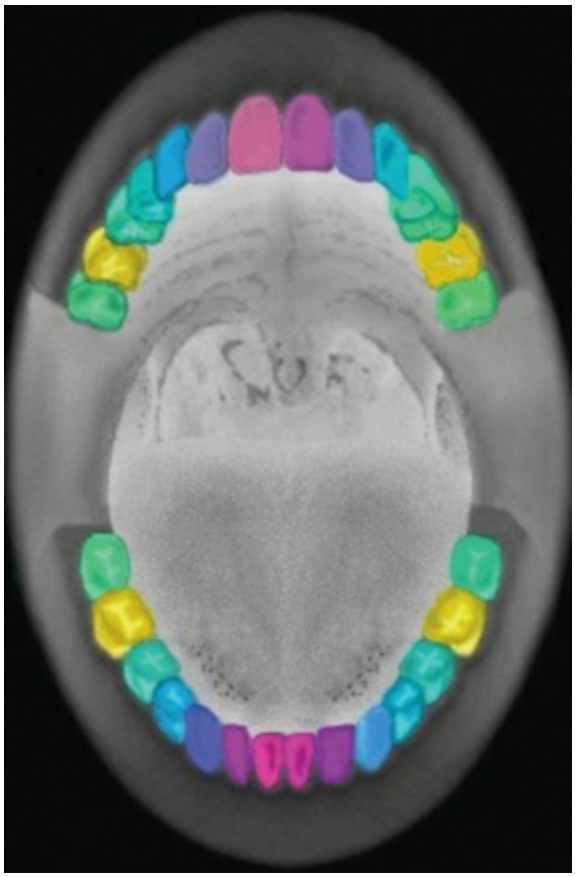

FIG. 11.5 Illustration of the similarities and differences among different kinds of teeth with regard to the frequency and severity of attachment loss observed in early-onset aggressive periodontitis patients and their unaffected family members with the use of the principal components analysis method.[14]

Specifically, we can calculate heritability for different quantitative variables (e.g., simple mean attachment loss averaged across all teeth or averaged for specific groups of teeth) as well as for more complex variables like these principal components. In the study of aggressive periodontitis illustrated in Fig. 11.5, the principal component most heavily weighted on the first molars had a heritability of 30%, which was actually slightly higher than the 26% heritability estimated for a simple mean of attachment loss in the first molars. By using heritability and other genetic measures such as association with specific inherited polymorphisms, it may be possible to refine diagnostic and disease classification systems by aligning these according to subgroups of subjects that share homogeneous etiologies. Another example of moving beyond simply classifying subjects as cases versus controls but using

principal component analysis to combine multiple measures of disease such as levels of pathogens and inflammatory markers was reported using a GWAS design.[56] The results of this more complex approach to the phenotype pointed to several novel genes of potential interest that now require independent replication.

Learning from the experience of other complex diseases, Sir Isaac Newton famously remarked in 1676: "What Descartes did was a good step. You have added much several ways … If I have seen a little further it is by standing on the shoulders of Giants."

Although there remains some enthusiasm for further GWAS studies, as noted previously, even the most successful GWAS results (e.g., those that have been obtained for type 2 diabetes) have failed to identify most of the genetic variation responsible for the disease. The discovery of so many gene associations related to risk of type 2 diabetes accounts for a small fraction of the disease's heritability.[12] To track down the missing genetic variation, a great deal of attention is now turning to whole genome DNA-sequencing methods that will be available at low cost in the coming years. Sequencing methods also expand the ability to measure gene expression in various tissues. These data, in combination with the ever-increasing availability of proteomic assays, will challenge investigators with huge quantities of information. Aside from generating the many gigabytes of data involved in this technology, the greatest challenges of "systems biology" may lie in developing the bioinformatics tools needed to sift through and identify the key bits of information that are important for advancing our knowledge from among the vast rising sea of biologic data pouring out of our laboratories.[4]

Strategies for improving our understanding of the genetics of periodontitis as well as for increasing the possibilities for the translation of this knowledge to benefit patients in the clinic are being mapped out today by teams of geneticists, clinicians, and information scientists who are currently focused on major medical conditions. By continuing to learn from the experiences of these early genomic explorers, it is reasonable to hope that dental researchers will be able to avoid some of their mistakes and follow

the quickest path to advances in knowledge about diseases of interest.

Precision Dentistry: Using Genetics for Personalized Treatment

Pharmacogenomics and Individualized Dentistry

If individuals differ in susceptibility to a disease, especially if underlying the superficial signs and symptoms of a disease there really are etiologically distinct subtypes of disease pathogenesis, then the traditional medical model of "one size fits all" treatment may not be optimal. As shown in Fig. 11.6, cases of disease (as illustrated by circles with unhappy faces) may differ with regard to genotype for a gene that determines which treatment works best for each individual. Some cases inherited G alleles from both their mother and their father and thus have a GG genotype, whereas others have a GT or TT genotype.

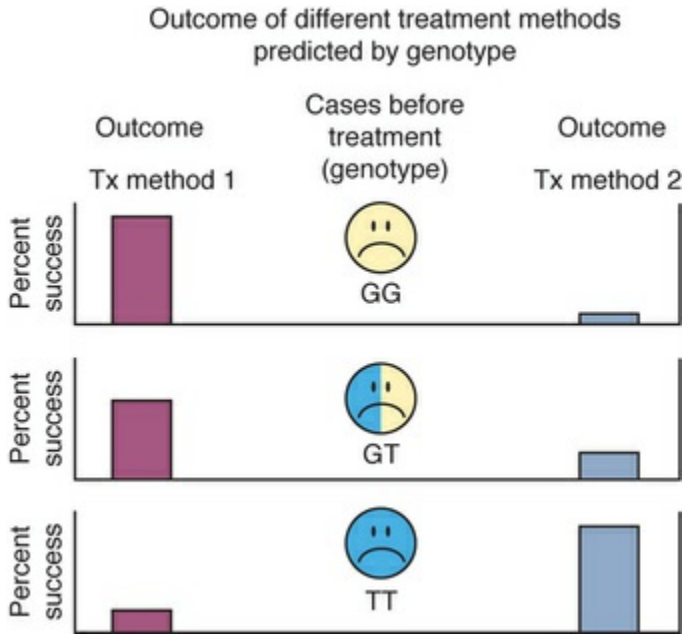

FIG. 11.6 Inherited genetic variation determines treatment success. Individuals who inherited the GG or GT genotypes at a gene involved in a biologic pathway

related to either the underlying disease susceptibility mechanisms or to the body's response to the therapy have very good chances for success with treatment method 1 *(Tx method 1)* but poor prognoses with treatment method 2 *(Tx method 2)*, whereas individuals with the TT genotype respond positively to treatment method 2 only.

The gene may distinguish between different subtypes of disease etiology or pathogenesis, or it might code for an enzyme, transporter, or receptor important for the metabolism of a therapeutic drug and have nothing directly to do with disease susceptibility. In the example illustrated in this figure, treatment method 1 *(Tx method 1)* has a high success rate when it is provided to subjects with the GG or GT genotypes, but it usually fails for cases with the TT genotype. TT genotypes experience much better outcomes when provided with treatment method 2 *(Tx method 2)*, but this method often fails for subjects with the GG and GT genotypes. Sometimes concerns about severe side effects that limit the use of a therapy rather than differences in efficacy and risk of side effects can also be genetically determined. If clinicians are not aware of the relationships between these genotypes and treatment success or side effects, it would appear that neither treatment is consistently effective. Clinicians would be forced to use a trial-and-error approach, first trying one method and then switching to the other if the first method fails. At best, this causes unnecessary expense and does not provide an optimal quality of care. Furthermore—and especially for deadly diseases such as cancer—precious time may be lost in halting the advance of the disease; by the time the clinician discovers an individual's best treatment, it may be too late. This strategy of individualized medicine is already being practiced for an increasing number of diseases.[9,21]

In dentistry, a test based on inherited genetic variation at the interleukin-1 alpha (IL-1α) and IL-1β cytokine genes was proposed as being able to predict the risk, progression, and severity of periodontitis. The test has been commercialized and has gone through multiple versions (PST, PerioPredict, and today's version is called ILUSTRA). Although specific numbers are not available, the test does not appear to be widely used yet. A number of reviews of

the large number of studies of the IL-1 gene polymorphisms (see eTable 11.1 [online] and Table 11.3) indicate that genetic variation at these loci may be associated with, at most, a modest effect on disease risk.[26,54] In 2007 Huynh-Ba and colleagues concluded that "there is insufficient evidence to establish if a positive IL-1 genotype status contributes to progression of periodontitis or treatment outcomes."[26] A similar lack of supporting evidence for the use of IL-1 genetic testing to predict implant success has also been reported.[3,27] A more recent meta-analysis of the available data suggested that these much-studied IL-1 polymorphisms have a small (odds ratio, ≈1.5) but significant effect on periodontitis risk, although only for chronic periodontitis in white populations.[32] However, it is essential to emphasize that because heritability for chronic periodontitis is estimated to be 50%,[49] the small effect of the IL-1 polymorphisms makes up at most a tiny fraction of the genetic component of risk for this disease (which remains missing, as discussed previously).

Candidate Genes Possibly Related to Risk of Chronic or Aggressive Periodontitis

- Interleukin (IL)-1 gene cluster (IL-1A, IL-1B, IL-1 receptor antagonist), IL-4, IL-6, and IL-10.
- TNF-alpha
- Leukocyte receptors for the constant (Fc) part of immunoglobulin (FcγR)
- Vitamin D receptor
- Pattern recognition receptor genes (TLRs, cluster of differentiation [CD]-14)
- Matrix metalloproteinase (MMP)-1

As the benefits of individualized or personalized treatments that are optimally matched to the genome of each patient have been demonstrated for cancer and increasing numbers of other human diseases, interest has grown in applying this approach to

dentistry.[35,63] The first major study that attempted to develop guidelines for individualized treatment has been reported.[19] This study involved 5117 adults between the ages of 34 and 55 years with no prior diagnosis of early periodontitis who were followed retrospectively for 16 years. The aim was to evaluate whether only a subset of high-risk patients really benefits from two versus only one preventive visit per year to avert tooth loss. The risk factors that were tested were smoking, diabetes, and the IL-1 composite genotype. The authors of the study concluded that all three risk factors predict which patients benefit from two preventive visits. They proposed the use of the IL-1 genetic test[28] to detect the IL-1 composite genotype, which along with smoking and diabetic status was looked at as a risk factor for progressive periodontitis. The study claimed that by reducing the preventive dental visits to one per year in so-called low-risk patients, $4.8 billion would be saved annually. However, an independent reanalysis of the findings[13] showed that of the three assessed risk factors, only diabetes and smoking had statistically significant effects on tooth extraction risk. This conclusion was supported by an independent critical commentary by a leading expert in the field of epidemiology.[29] Therefore it is clear that we lack consistent evidence to demonstrate the scientific validity or clinical utility, of the IL-1 genetic test that is commercially available as a periodontitis risk prediction tool.[28] This first major attempt to use a genetic test in mainstream dentistry continues to be an area of great controversy, and dentists will need to remain aware of the scientific consensus regarding such tests as these emerge in the future so that they can accurately advise patients on their use and limitations.

As genetic testing becomes widespread, especially if it is marketed through direct-to-consumer models, increasing responsibility will fall on dentists to fully understand and counsel their patients about the implications of test results for their treatment options and their risk of developing various dental diseases in the future. Tests for diseases of the oral cavity may likely combine inherited polymorphisms with oral microbial profiles, and they might also include assays of gene expression or proteomic data measured in saliva or other oral tissues. Few dentists practicing today have been educated to prepare themselves

for these future challenges. This major shortfall of knowledge urgently needs to be addressed. This can be done by continually educating today's dental professionals about advances in knowledge of human genetics and the uses and potential misuses of genetic testing; by establishing multidisciplinary teams of health practitioners in which dentists work closely with genetics counselors and medical geneticists; or by combining these approaches.

Case Scenario 11.1

Patient:

17-year-old male

Chief Complaint:

“I lost all my primary teeth, and now I am rapidly losing my permanent teeth.”

Background Information:

When presenting to the clinic for periodontal evaluation, patient was partially edentulous and missing many permanent teeth (Fig. A). Patient was a nonsmoker and reported having dermatologic lesions on the palms of the hands and soles of the feet (Fig. B). Patient was not taking any medication. He reported brushing once a day but not flossing. His complete mouth radiographic series, which was taken 1 year before the periodontal evaluation, demonstrated extensive generalized bone loss (Fig. C).

Current Findings:

Probing depths were in the range of 2 to 10 mm; bleeding on

probing % was 39 and exhibited fair oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION

1. Based on oral and dermatologic findings, what is the most likely diagnosis? A. Gardner syndrome B. Papillon–Lefèvre syndrome C. Peutz–Jeghers syndrome	**Answer: B** **Explanation:** The oral and dermatologic findings in this patient are characteristic of Papillon–Lefèvre syndrome. Gardner syndrome is characterized by osteomas, multiple soft tissue tumors, and gastrointestinal (GI) polyps, whereas patients with Peutz–Jeghers syndrome typically presents with GI polyps and hyperpigmented macules on the lips and oral mucosa.
2. Mutations in which gene causes this syndrome? A. COL1 A1 (collagen) B. Adenomatous polyposis coli (APC) C. Osteopontin D. Cathepsin C	**Answer: D** **Explanation:** The cathepsin C gene encodes for a lysosomal cysteine protease. It plays a pivotal role in regulating serine proteinases in immune and inflammatory cells. Activated cathepsin C degrades extracellular matrix components causing tissue damage and chronic inflammation.
3. Is palmar–plantar keratoderma (dermatologic lesions) unique to this syndrome? A. Yes B. No	**Answer: B** **Explanation:** Apart from Papillon–Lefèvre syndrome, palmar–plantar keratoderma also occurs in several other syndromes such as Huriez syndrome and Olmsted syndrome.
4. Which of the following genetic disorders is not associated with periodontal disease? A. Down syndrome B. Cyclic neutropenia C. Hypophosphatasia D. Oral–facial–digital syndrome E. Ehlers–Danlos syndrome	**Answer: D** **Explanation:** Except for oral–facial–digital syndrome, periodontal disease is a common finding in all of the conditions listed.

CHAPTER 12

Smoking and Periodontal Disease

Philip M. Preshaw, Leandro Chambrone, Richard Holliday

CHAPTER OUTLINE

The Smoking Epidemic
Effects of Smoking on the Prevalence and Severity of Periodontal Diseases
Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease
Effects of Smoking on the Response to Periodontal Therapy
Effects of Smoking Cessation on Periodontal Treatment Outcomes

The Smoking Epidemic

Smoking is highly prevalent and can be considered an epidemic in both developed and developing nations. Smoking rates, however, have seen marked declines since the 1980s. Global estimated daily

tobacco smoking prevalence rates (in individuals >15 years old) reduced from 41.2% in 1980 to 31.1% in 2012 for men and from 10.6% (1980) to 6.2% (2012) for women.[96] Despite this development, with population growth, the number of daily smokers worldwide has actually increased to just short of a billion people in 2012, upholding tobacco smoking's position as a major public health threat. Developed countries had their highest prevalence rates in those aged 30 to 34 years, whereas in developing countries the greatest prevalence was among those aged 45 to 49 years. The highest prevalence rates (male) are now often seen in developing countries (e.g., Bangladesh [44.4%], China [40.1%], Indonesia [57%]), although several developed countries also have similarly high rates (e.g., Russia [50.1%], Greece [40.8%], Japan [35.3%]).[96] The overall daily smoking prevalence rates for the United States were 15.5% in 2012 (17.2% for males, 14.3% for females) and for the United Kingdom were 21.6% (23% for males, 20.1% for females).[96] Canada, Iceland, Mexico, and Norway all achieved reductions of greater than 50% in male and female smoking prevalence rates between 1980 and 2012.[96] Interestingly, Sweden is the only country with more female than male smokers (males, 12.3%; females, 14.8%) which can likely be attributed to snus (oral tobacco) use.[96]

A Global Perspective

- As many as 6.25 trillion cigarettes are smoked annually across the globe.[96]
- Tobacco kills 6 million people each year.[147]
- Only 15% of people worldwide have access to smoking cessation services.[147]
- About 18% of people worldwide are protected by smoke-free laws.[147]

Smoking is harmful to almost every organ in the body and is associated with multiple diseases that reduce life expectancy and quality of life. Diseases associated with smoking include lung cancer, heart disease, stroke, emphysema, bronchitis, and cancers of

the oral cavity, bladder, kidney, stomach, liver, and cervix. Approximately half of long-term smokers will die early as a result of smoking, and those who die before the age of 70 years will lose an average of 20 years of life.[37] Most deaths from smoking are due to lung cancer, chronic obstructive pulmonary disease, and coronary heart disease.

Tobacco smoke contains thousands of noxious chemicals, and it comprises a gaseous phase and a solid (particulate) phase. The gas phase contains carbon monoxide, ammonia, formaldehyde, hydrogen cyanide, and many other toxic and irritant compounds, including more than 60 known carcinogens such as benzo(a)pyrene and dimethylnitrosamine. The particulate phase includes nicotine, "tar" (itself made up of many toxic chemicals), benzene, and benzo(a)pyrene. Tar is inhaled with the smoke. In its condensate form, it is the sticky brown substance that stains fingers and teeth yellow and brown. Nicotine, which is an alkaloid, is found within the tobacco leaf and evaporates when the cigarette is lighted. It is quickly absorbed in the lungs, and it reaches the brain within 10 to 19 seconds. Nicotine is highly addictive. It causes a rise in blood pressure, increased heart and respiratory rates, and peripheral vasoconstriction.

Clinician's Corner

Smokeless Tobacco

Smokeless tobacco products are becoming increasingly popular and exist in many different forms. Tobacco can be ground/grated and presented with salt and water as "moist snuff," which is usually delivered as a small tea-bag-like sachet placed under the lip. Alternatively, tobacco can be ground to a powder ("dry snuff") that is inhaled into the nasal cavity. Finally, tobacco can be coarsely cut (chewing tobacco) and placed into the cheek. Numerous smokeless tobacco varieties are popular in South Asian communities. The International Agency for Research on Cancer classifies smokeless tobacco as a cause of mouth, esophageal, and pancreatic cancer.[64]

Snus (or Swedish snuff) is a special type of smokeless tobacco

that is popular in Sweden and increasingly the United States. It is banned across the rest of Europe. The manufacturers claim to use a special process to lower the levels of carcinogens in the product. Studies have shown a link to pancreatic cancer but not to mouth or lung cancer.[81]

All dental patients must be asked about their smoking status or tobacco usage. Current smoking status is the minimal information that must be recorded (e.g., "Patient is currently smoking *X* cigarettes per day"), but the importance of cumulative exposure to cigarette smoke means that it is more appropriate to record pack-years of smoking (Box 12.1). Biochemical tests can also be used to assess smoking status, including exhaled carbon monoxide and the measurement of cotinine (the major metabolite of nicotine) in serum, saliva, or urine. Cotinine is measured in preference to nicotine because the half-life of nicotine is short (≈1 to 2 hours),[104] whereas that of cotinine is approximately 20 hours.[67] Plasma and saliva cotinine concentrations in smokers are approximately 100 ng/mL[11,39] and the urine concentration is approximately 1200 ng/mL.[76] Nonsmokers usually have plasma and saliva cotinine concentrations of less than 2 ng/mL, unless they are passive smokers. Biochemical validation of nonsmoking uses cotinine levels of 1 to 6 ng/mL to confirm nonsmoking status depending on race/ethnicity.[11]

Box 12.1

Challenge of Assessing Smoking Status

Current Smokers

Ask about current smoking and past smoking. Many smokers are trying to quit, and therefore simply asking how many cigarettes they are smoking today may not give an accurate assessment of their lifetime exposure (e.g., a patient who is currently smoking 5 cigarettes per day may have been smoking 40 cigarettes per day until yesterday, when he or she decided to cut down). Try to get an indication of the patient's approximate level of smoking (e.g., the

average number of cigarettes per day for a certain number of years). It can also be useful to calculate the number of pack-years:

$$\text{Pack-years} = \text{Number of packs smoked per day} \times \text{Number of years of smoking}$$

In other words, 1 pack-year is the cumulative exposure that corresponds with the smoking of 1 pack of 20 cigarettes per day for 1 year. For example, a smoker who has smoked 20 cigarettes per day for 15 years has 15 pack-years of smoking.

Former Smokers

Ask patients about their past smoking. Patients with periodontitis may have a significant smoking history that has had an impact on their periodontal status, even if they no longer smoke. Former smokers should always be congratulated for their achievement in quitting, but it is also very important to document the following:

- How much they used to smoke
- How many years they smoked
- When they quit

Is the Patient's Response Accurate?

The inaccurate or false reporting of smoking status is common; patients will tell you what they think you want to hear, or they may be embarrassed because they have not managed to cut down yet. Many patients report smoking 20 cigarettes per day, because this is the number of cigarettes in a pack in most countries, so 20 may be a convenient response rather than an accurate response. Cultural factors may also influence responses.[128]

When Is a Smoker Not a Smoker?

- Smokers have smoked ≥100 cigarettes in their lifetime and currently smoke.
- Former smokers have smoked ≥100 cigarettes in their lifetime and do not currently smoke.

- Nonsmokers have not smoked ≥100 cigarettes in their lifetime and do not currently smoke.

It must be noted that many periodontal research studies have not used these definitions, and this can sometimes make it difficult to interpret the studies, particularly in the context of what constitutes a former smoker. For example, from an exposure point of view, there is a big difference between someone who smoked 5 cigarettes per day for 10 years and who quit 30 years ago as compared with someone who smoked 40 cigarettes per day for 20 years and quit 6 months ago. It is always best in clinical practice to gather full information about each patient's smoking history.

Smoking is a major risk factor for periodontitis, and it affects the prevalence, extent, and severity of disease. In addition, smoking has an adverse impact on the clinical outcome of nonsurgical and surgical therapy as well as the long-term success of implant placement. With 41.9% of periodontitis cases in the United States reported as being *attributable* to smoking (discussed next),[139] it is essential to understand the impact of smoking on the initiation, progression, and management of the disease. This chapter discusses the effects of smoking on the prevalence, severity, etiology, and pathogenesis of periodontal disease as well as its impact on treatment. The reader is referred to several excellent reviews of the topic for detailed results of specific studies.[1,27,54,70,71,97,98,112,140,145]

Effects of Smoking on the Prevalence and Severity of Periodontal Diseases

Gingivitis

Controlled clinical studies have demonstrated that, in human models of experimental gingivitis, the development of inflammation in response to plaque accumulation is reduced in smokers as compared with nonsmokers (Table 12.1).[19,33] In addition, cross-sectional studies have consistently demonstrated that smokers present with less gingival inflammation than nonsmokers.[12,13,17,105,106]

These data suggest that smokers have a decreased expression of clinical inflammation in the presence of plaque accumulation as compared with nonsmokers. The microbiologic, immunologic, and physiologic factors that may account for this observation are discussed later.

TABLE 12.1

Effects of Smoking on Gingivitis and Periodontitis

Periodontal Disease	Effects of Smoking
Gingivitis	↓ Gingival inflammation and bleeding on probing
Periodontitis	↑ Prevalence and severity of periodontal destruction
	↑ Pocket depth, attachment loss, and bone loss
	↑ Rate of periodontal destruction
	↑ Prevalence of severe periodontitis
	↑ Tooth loss
	↑ Prevalence with increased number of cigarettes smoked per day
	↓ Prevalence and severity with smoking cessation

↓, Decreased; ↑, increased.

Periodontitis

Although gingival inflammation in smokers appears to be reduced in response to plaque accumulation as compared with nonsmokers, an overwhelming body of evidence points to smoking as a major risk factor for increasing the prevalence and severity of periodontal destruction. Multiple cross-sectional and longitudinal studies have demonstrated that pocket depth, attachment loss, and alveolar bone loss are more prevalent and severe in patients who smoke as compared with nonsmokers.[70,71,112,140] An assessment of the relationship between cigarette smoking and periodontitis was performed in more than 12,000 dentate individuals who were more than 18 years old as part of the Third National Health and Nutrition Examination Survey.[139] Periodontitis was defined as one or more sites with clinical attachment loss of 4 mm or greater and pocket depth of 4 mm or greater. Smoking status was defined with the use of criteria established by the Centers for Disease Control and Prevention (see Box 12.1). Of the more than 12,000 individuals studied, 9.2% had periodontitis; this represented approximately 15 million cases of periodontitis in the United States. On average,

smokers were four times as likely to have periodontitis as compared with persons who had never smoked after adjusting for age, gender, race/ethnicity, education, and income/poverty ratio. Former smokers were 1.7 times more likely to have periodontitis than persons who had never smoked. This study also demonstrated a dose–response relationship between cigarettes smoked per day and the odds of having periodontitis. In subjects smoking 9 or fewer cigarettes per day, the odds for having periodontitis were 2.8, whereas subjects who smoked 31 or more cigarettes per day were almost six times more likely to have periodontitis. In former smokers, the odds of having periodontitis declined with the number of years since quitting. These data indicated that approximately 42% of periodontitis cases (6.4 million cases) in the U.S. adult population were attributable to current smoking and that approximately 11% (1.7 million cases) were attributable to former smoking. These data highlight the serious threat to dental public health posed by cigarette smoking and raise questions about the best methods for managing periodontitis in patients who smoke (Box 12.2).

Box 12.2

Should We Change How We Manage Periodontal Disease?

Fact 1: Smoking is a major risk factor for periodontal disease.
Fact 2: According to the literature, smoking may be responsible for more than half of periodontitis cases among adults in the United States.[139]
Fact 3: Depending on the study, approximately 10% to 15% of adults in most populations examined have advanced periodontitis.

Questions

- Would there be a benefit at the population level for periodontal health if all smokers in the population quit smoking today?

- Would dental professionals be able to more successfully manage periodontitis in smokers if we focused more on smoking cessation as a primary treatment strategy for managing periodontitis?

These questions are intended to be controversial. It is clear that smoking has a huge deleterious impact on periodontal status, and smoking cessation *must* be a core part of periodontal treatment in patients with periodontitis who smoke. The answer to the first question is almost certainly a resounding yes, but this probably will never be able to be tested. The answer to the second question is more difficult. Certainly smokers with periodontitis must be educated about the harm that they are causing to their periodontal tissues, and they must be encouraged and helped to quit smoking. Treatment outcomes are improved among smokers who quit as compared with those who continue to smoke.[109]

Two Final Points (These Are Contentious and Designed to Stimulate Discussion.)

- If more than half of the cases of periodontitis are attributable to smoking, then patients who smoke may be better served if dental professionals put more than half of their efforts into treating these patients via smoking cessation treatments (as opposed to other forms of periodontal therapy). Discuss!
- It is absurd for smokers in the Western world to worry about anything except stopping smoking.[103]

These data are consistent with the findings of other cross-sectional studies performed in the United States and Europe. The odds ratio for periodontitis in current smokers has been estimated to range from as low as 1.5 to as high as 7.3 compared to nonsmokers, depending on the observed severity of periodontitis.[98] A meta-analysis of data from six such studies involving 2361 subjects indicated that current smokers were almost three times more likely to have severe periodontitis than nonsmokers.[97] The detrimental impact of long-term smoking on the periodontal and dental status of older adults has been clearly demonstrated. Older

adult smokers are approximately three times more likely to have severe periodontal disease,[10,80] and the number of years of tobacco use is a significant factor in tooth loss, coronal root caries, and periodontal disease.[68,69]

Smoking has also been shown to affect periodontal disease severity in younger individuals. Cigarette smoking is associated with increased severity of generalized aggressive periodontitis in young adults,[127] and those who smoke are 3.8 times more likely to have periodontitis as compared with nonsmokers.[48] Longitudinal studies have demonstrated that young individuals who smoke more than 15 cigarettes per day showed the highest risk for tooth loss.[60] In addition, smokers are more than six times as likely as nonsmokers to demonstrate continued attachment loss.[65] Over a 10-year period, bone loss has been reported to be twice as rapid in smokers as in nonsmokers[20] and to proceed more rapidly even in the presence of excellent plaque control.[14] Less information is available about the effects of cigar and pipe smoking, but it appears that effects similar to those of cigarette smoking are observed with these forms of tobacco use.[5,40,41,78] The prevalence of moderate and severe periodontitis and the percentage of teeth with more than 5 mm of attachment loss were most severe in current cigarette smokers, but cigar and pipe smokers showed a severity of disease that was intermediate between that of current cigarette smokers and nonsmokers.[5] Tooth loss is also increased among cigar and pipe smokers as compared with nonsmokers.[78]

Former smokers have less risk for periodontitis than current smokers but more risk than nonsmokers, and the risk for periodontitis decreases with the increasing number of years since quitting smoking.[139] This suggests that the negative effects of smoking on the host are reversible with smoking cessation and therefore that smoking cessation programs must be an integral component of periodontal education and therapy (Box 12.3, Table 12.2). Several tobacco intervention approaches can be used when helping the patient deal with the physiologic factors (i.e., nicotine withdrawal symptoms) and the psychological factors associated with smoking cessation (Box 12.4).[99,116] Electronic cigarettes have also emerged and are being used by many smokers to help them quit (Box 12.5). However, the effects on oral health are yet to be

established.

Box 12.3

Helping Your Patients to Quit Smoking

Smoking cessation is a public health priority for governments around the world. Excellent online resources are available to provide information about the harmful effects of smoking and to help people to quit, including the following:

- http://www.cdc.gov/tobacco
- http://www.ash.org.uk
- http://smokefree.nhs.uk

Smoking cessation must be an integral part of the management of dental patients who smoke, and it is the responsibility of all dental health professionals to address this issue with their patients. The dental team is well placed to provide this treatment, because they see patients on a regular basis as part of ongoing routine dental management. Furthermore, interventions to help patients quit smoking in dental practices are effective, with quit rates of 15% to 20% as compared with approximately 5% in control groups.[119] The whole dental team should therefore be involved in smoking cessation, but this is not always the case. Why? Some of the barriers to providing smoking cessation counseling in the dental practice are shown in Table 12.2.

Various methods for helping patients to quit smoking in the dental environment have been described, and these are typically referred to as *brief intervention programs.* One such program[12] is known as the 5 A's:

ASK Ask the patient about his or her smoking status (see Box 12.1).
This should be part of the medical history.
ADVISE Advise smokers of the associations between oral disease and smoking.
Be informative, honest, and helpful but not judgmental. The

patient's response to this information will reveal his or her interest in quitting.

ASSESS Assess the patient's interest in and readiness to attempt smoking cessation.

Patients may not yet be in an action phase when it comes to quitting smoking, which is why it is always important to make these assessments every time you see the patient.

ASSIST Assist the patient with his or her quit attempt.

If you are trained, there are many techniques that can be used (see Box 12.4). Alternatively, assist the patient with seeking the help that he or she needs.

ARRANGE Arrange for a follow-up visit or a referral to professional smoking cessation services.

The most important aspect of this strategy is to keep in regular contact, particularly around the quit date and during the immediate period after the patient quits.

A simplified version of this is the 3 A's. This is a *very brief intervention* and can be particularly useful for the dental team.[95,111] The intervention is designed to be used at every clinical contact, and its very brief nature may help overcome some of the barriers presented by dental practices (the duration is <30 seconds). The focus is taken away from advising smokers to stop and shifts to offering support. The "advise" step deliberately leaves out the health benefits of stopping smoking or the harms of smoking. This minimizes the duration of the intervention and helps to avoid a defensive reaction or developing anxiety in the patient. The 3 A's technique is as follows:

ASK and record smoking status.

ADVISE how to stop.

ACT on the patient's response (prescribe, monitor, or refer).

Clearly, for the patient undergoing a comprehensive course of periodontal therapy, over several visits, there may be more opportunity to focus on the harms of smoking and the personal benefits of quitting.

TABLE 12.2

Barriers Against and Stimuli for the Provision of Smoking Cessation Advice by the Dental Team in Dental Practice

	Barriers	Stimuli
Professional Characteristics	Perceived lack of efficacy or lack of confidence in giving the advice	Self-efficacy
	Concerns about disturbing the patient–dentist relationship	Positive attitude toward giving advice as part of health care provider role
	Lack of knowledge about how to give the correct advice	Training
	Belief that counseling is unnecessary or perception that advising patients is frustrating and has a low success rate	Self-belief
	Dental team member may be a smoker himself or herself	Dental team member needs to quit!
Practice Organization	Lack of time	Task delegation
	No organizational support in the practice to deliver advice	Focus on helping smokers quit
Health Care System	No reimbursement	Health care system changes to encourage healthier lifestyles
	No referral options for further help	Local availability of smoking cessation services

Adapted from Rosseel JP, Jacobs JE, Hilberink SR, et al: What determines the provision of smoking cessation advice and counselling by dental care teams? *Br Dent J* 206:E13, 2009.[119]

Box 12.4

Methods of Smoking Cessation

Willpower Alone

This is the least effective method of smoking cessation, with only 3% of smokers managing to quit after 12 months.[2]

Self-Help Materials

The provision of self-help materials can increase quit rates compared to no intervention, although only by a small amount.[53] When included with any other intervention, there was no additional benefit.

Brief Intervention Program in Primary Care

A brief advice intervention delivered by a physician or dentist can increase the rate of quitting (12 months) by 40% to 90%.[25,132] Assuming an unassisted quit rate of 3%, a brief intervention by a dentist could increase the quit rates to 4.5% to 6%. Although this cessation rate may seem low, if the dental team gave this brief advice to most of their smoking patients, a significant number of smokers in the whole population would be assisted to quit each year.

Nicotine Replacement Therapy

Nicotine replacement therapy (NRT) can increase the rate of quitting (12 months) by 50% to 70%.[133] For example, in primary care settings in which brief advice is given, 12-month success rates can increase from around 5% to around 8% if NRT is also used. In an intensive setting such as a smoker's clinic, success rates increase from around 10% to up to 16%. NRT is not a magic cure, but it helps with cravings and withdrawal when a person quits smoking. Although NRT products do contain nicotine, they do not contain the toxic products such as tar and carbon monoxide that are found in cigarette smoke. NRT products include the following:

- Patches (available in different doses and worn for 16 to 24 hours per day)
- Lozenges and gum (available in different flavors; should be chewed slowly to allow the nicotine to be absorbed through the mouth)
- Nasal spray (delivers nicotine solution via the nasal passages)
- Inhalator (a plastic mouthpiece with a supply of nicotine cartridges that fit on the end; nicotine is absorbed in the mouth by drawing on the inhalator like a cigarette).

Varenicline

A course of varenicline, at standard dose, can increase the rate of quitting (12 months) by 100% to 150%.[22] Varenicline is a nicotine receptor partial agonist, and it aims to reduce both withdrawal symptoms and the pleasure people usually experience when they smoke.

Bupropion

Bupropion can increase the rate of quitting (12 months) by 50% to 80%.[62] This medication is used as an antidepressant at higher doses, but it is effective for smoking cessation at lower doses. It is usually prescribed to be started 1 to 2 weeks before the quit date. There are serious potential drug interactions and unwanted effects.

Other Methods

Whatever works for the patient is good! In addition to combinations of the methods listed here, techniques for smoking cessation can include intensive counseling, motivational interviewing, cognitive behavioral therapy, hypnosis, and acupuncture. Many smokers are now also using e-cigarettes to help to quit smoking (see Box 12.5).

Box 12.5

Electronic Cigarettes

Electronic cigarettes (e-cigarettes) are electronic devices that produce an aerosol that the user inhales. The e-cigarette contains a solution, often called an "e-liquid," which is drawn through a heating element to produce the aerosol. The process of using an e-cigarette (often referred to as *vaping*) closely resembles tobacco smoking, making e-cigarettes a particularly attractive alternative to smokers. In contrast, this similarity to cigarette smoking has produced much of the controversy and concerns around e-cigarettes.

What Is in the E-liquid?

The e-liquid usually comprises three main components: diluents, nicotine, and flavorings. The diluents account for the majority of the solution and are usually propylene glycol or vegetable glycerin. Nicotine is included at a wide range of concentrations, the most popular strength in Great Britain being 13 to 18 mg/ml.[3] Nicotine-free e-liquids are available and used by approximately 10% of users (Great Britain).[3] Flavorings are often added, as both nicotine and the diluents are largely tasteless. The large range of flavors can

generally be divided into three main groups: tobacco, fruit, and menthol/mint.

Are E-cigarettes a Useful Smoking Cessation Aid?

E-cigarettes are a modern phenomenon introduced to the U.S. and European markets in 2006, with their popularly taking off in around 2011. The evidence base is continually growing with several ongoing clinical trials. A Cochrane Collaboration systematic review concluded that e-cigarettes helped smokers to stop smoking and showed particular promise in reducing cigarette consumption in smokers unwilling to quit (although further studies are needed to confirm this conclusion).[88]

Are E-cigarettes Safe?

This has been the topic of many debates, and controversy still exists. Two substantial reports concluded that the hazard to health from long-term e-cigarette vapor inhalation was unlikely to exceed 5% of the harm from smoking tobacco.[87,120]

What Are the Oral Health Effects?

Very little has been published in this field. A handful of in vitro cell line studies have shown a variety of effects including cytotoxicity and DNA damage.[125,146,148] As with all in vitro studies, the clinical relevance is difficult to interpret, and unfortunately some of these studies are of questionable quality.[59] From a clinical perspective, e-cigarette vapor is likely to have different effects on the oral tissues when compared with the well-known effects of tobacco smoke. Interestingly, nicotine has been shown to be angiogenic[66] with wound-healing properties[85] and with potential intraoral applications.[114,115] Well-conducted clinical studies are required to enable us to appropriately inform patients about e-cigarette use.

How Are E-cigarettes Regulated?

A range of regulatory approaches have been taken across the globe, from e-cigarettes being completely prohibited to being classified under general consumer product regulations.[24]

What Is the Bottom Line?

E-cigarettes are a consumer led bottom-up public health initiative

that has taken the realms of research, public health, regulation, and industry by surprise. They are extremely popular with users (smokers/former smokers), with probably only a fraction of the health hazard of tobacco smoking. From a public health perspective they have the potential to significantly reduce tobacco-related morbidity and mortality. The oral health risks are currently unknown but are likely to be less than those associated with tobacco smoking.

Beyond E-Cigarettes

The popularity of e-cigarettes took most people by surprise. But what's next?

"Heat-Not-Burn" Tobacco Products

These products heat tobacco to ~500°C, producing an inhalable aerosol.[24] Although not a new idea, they have received recent attention. One manufacturer introduced a product into the Japanese market in 2015, which has been popular, with the media reporting sales outstripping demand.

Water Pipes (Hookah, Shisha)

Popular in some communities, these are likely to carry significant negative health risks. A good summary is produced by the National Center for Smoking Cessation and Training (NCSCT).[94]

Nicotine Gels

These gels allow nicotine to be absorbed through the skin. Currently they are not very popular.

Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease

The increased prevalence and severity of periodontal destruction associated with smoking suggests that the host–bacterial interactions normally seen with chronic periodontitis are altered,

resulting in more extensive periodontal breakdown (Table 12.3). This imbalance between bacterial challenge and host response may be caused by changes in the composition of the subgingival biofilm (e.g., increases in the numbers and virulence of pathogenic organisms), changes in the host response to the bacterial challenge, or a combination of both.

TABLE 12.3

Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease

Etiologic Factor	Effects of Smoking
Microbiology	Increased complexity of the microbiome and colonization of periodontal pockets by periodontal pathogens
Immune–inflammatory response	Altered neutrophil chemotaxis, phagocytosis, and oxidative burst
	↑ Tumor necrosis factor-α and prostaglandin E_2 in gingival crevicular fluid
	↑ Neutrophil collagenase and elastase in gingival crevicular fluid
	↑ Production of prostaglandin E_2 by monocytes in response to lipopolysaccharide
Physiology	↓ Gingival blood vessels with ↑ inflammation
	↓ Gingival crevicular fluid flow and bleeding on probing with ↑ inflammation
	↓ Subgingival temperature
	↑ Time needed to recover from local anesthesia

↓, Decreased; ↑, increased.

Microbiology

Several studies have explored the possible changes in the subgingival microbiome caused by smoking. Earlier studies tended to show little difference between smokers and nonsmokers. For example, Preber and colleagues (1992) took plaque samples from deep pockets (i.e., ≥6 mm) in 142 patients and found no differences in the counts of *Aggregatibacter actinomycetemcomitans*, *Porphyromonas gingivalis*, and *Prevotella intermedia*.[108] In a similar study of 615 patients involving the use of immunoassay, the prevalence of *A. actinomycetemcomitans*, *P. gingivalis*, *P. intermedia*, and *Eikenella corrodens* was not found to be significantly different between smokers and nonsmokers.[134]

By contrast, other studies have demonstrated differences in the

microbial composition of subgingival biofilm of smokers and nonsmokers. A study of 798 subjects with different smoking histories found that smokers had significantly higher levels of *Tannerella forsythia* and that smokers were 2.3 times more likely to harbor *T. forsythia* as compared with nonsmokers and former smokers.[149] Of interest were observations that smokers did not respond to mechanical therapy as well as nonsmokers did; this was associated with increased levels of *T. forsythia*, *A. actinomycetemcomitans*, and *P. gingivalis* remaining in the pockets after therapy in the smoking group as compared with nonsmokers.[45,46,49,113]

Many discrepancies between the findings of microbiologic studies are a function of the methodology involved, including bacterial counts versus proportions or prevalence of bacteria, the number of sites sampled and the pocket depths selected, the sampling technique, the disease status of the subject, and the methods of bacterial identification and data analysis. In an attempt to overcome some of these problems, one study sampled subgingival biofilm from all teeth with the exception of third molars in 272 adult subjects, including 50 current smokers, 98 former smokers, and 124 nonsmokers.[51] Using checkerboard DNA–DNA hybridization technology to screen for 29 different subgingival species, it was found that members of the orange and red complex species—including *Eikenella nodatum*, *Fusobacterium nucleatum* ss *vincentii*, *P. intermedia*, *Peptostreptococcus micros*, *Prevotella nigrescens*, *T. forsythia*, *P. gingivalis*, and *Treponema denticola*—were significantly more prevalent in current smokers than in nonsmokers and former smokers. The increased prevalence of these periodontal pathogens was caused by an increased colonization of shallow sites (pocket depth ≤4 mm), with no differences among smokers, former smokers, and nonsmokers in pockets 4 mm or greater. In addition, these pathogenic bacteria were more prevalent in the maxilla than the mandible. These data suggest that smokers have a greater extent of colonization by periodontal pathogens than nonsmokers or former smokers, which may increase the risk of periodontal disease progression. Contemporary studies have drawn similar conclusions, with next generation sequencing analysis of periodontally healthy smokers

demonstrating a highly diverse, pathogen-rich, commensal-poor, anaerobic microbiome that is more similar to the microbiome observed in patients with advanced periodontitis than that observed in periodontally healthy nonsmokers, and which is primed for future development of periodontitis given appropriate ecologic and environmental changes.[86]

Immune–Inflammatory Responses

The immune response of the host to biofilm accumulation is essentially protective. In periodontal health, a balance exists between the bacterial challenge of the biofilm and the immune–inflammatory responses in the gingival tissues, with no resulting loss of periodontal support. By contrast, periodontitis is associated with an alteration in the host–bacterial balance that may be initiated by changes in the bacterial composition of the subgingival biofilm, changes in the host responses, other environmental changes, or a combination of these.

Smoking exerts a major effect on the immune–inflammatory response that results in an increase in the extent and severity of periodontal destruction. The deleterious effects of smoking appear to result from alterations in the immune-inflammatory response to bacterial challenge. The neutrophil is an important component of the host response to the bacterial challenge, and alterations in neutrophil number or function may result in localized and systemic infections. Critical functions of neutrophils include *chemotaxis* (directed locomotion from the bloodstream to the site of infection), *phagocytosis* (internalization of foreign particles such as bacteria), and *killing* via oxidative and nonoxidative mechanisms.

Neutrophils obtained from the peripheral blood, oral cavity, or saliva of smokers or exposed in vitro to whole tobacco smoke or nicotine have demonstrated functional alterations in chemotaxis, phagocytosis, and the oxidative burst.[38,74] In vitro studies of the effects of tobacco products on neutrophils have shown detrimental effects on cell movement as well as on the oxidative burst.[32,73,79,123,129] In addition, levels of antibody to the periodontal pathogens essential for phagocytosis and killing of bacteria, specifically immunoglobulin G_2, have been reported to be reduced in smokers

as compared with nonsmokers with periodontitis,[23,47,49,136] thereby suggesting that smokers may have reduced protection against periodontal bacteria. By contrast, elevated levels of tumor necrosis factor–α have been demonstrated in the gingival crevicular fluid of smokers,[21] and elevated levels of prostaglandin E_2, neutrophil elastase, and matrix metalloproteinase-8 have also been found.[131] In vitro studies have also shown that exposure to nicotine increases the secretion of prostaglandin E_2 by monocytes in response to lipopolysaccharide.[101]

These data suggest that smoking alters the response of neutrophils to the bacterial challenge such that there are increases in the release of tissue-destructive enzymes, causing increased periodontal tissue destruction. However, the exact changes in the immunologic mechanisms involved in the rapid tissue destruction seen in smokers are not yet fully understood, and more research in this area is indicated.

Physiology

Previous studies have shown that certain clinical signs of inflammation (e.g., gingival redness, gingival bleeding) are less pronounced in smokers than in nonsmokers.[13,33] This may result from alterations in the vascular response of the gingival tissues. Although no significant differences in the vascular density of healthy gingiva have been observed between smokers and nonsmokers,[102] the response of the microcirculation to biofilm accumulation appears to be altered in smokers as compared with nonsmokers. With developing inflammation, increases in gingival crevicular fluid flow, bleeding on probing,[19] and gingival blood vessels[18] are lower in smokers than in nonsmokers. In addition, the oxygen concentration in healthy gingival tissues appears to be lower in smokers than in nonsmokers, although this condition is reversed in the presence of moderate inflammation.[52] Subgingival temperatures are lower in smokers than nonsmokers,[35] and recovery from the vasoconstriction caused by local anesthetic administration takes longer in smokers.[75,142] These data suggest that significant alterations are present in the gingival microvasculature of smokers as compared with nonsmokers and that these changes

lead to decreased blood flow and decreased clinical signs of inflammation. This explains the long-observed phenomenon of a transient increase in gingival bleeding when a smoker quits; patients need to be warned about this phenomenon.

Is Nicotine the Bad Guy?

The role of nicotine in the detrimental health effects seen in smokers has never been more relevant with the increasing popularity of novel nicotine delivery devices (e.g., e-cigarettes). Nicotine is not carcinogenic,[55,63] and it is now largely accepted that nicotine has likely been unfairly blamed. A classic quote, with reference to lung cancer, is "smokers smoke for nicotine but are killed by tar."[121] The potential role of nicotine in periodontitis development is less clear. Nicotine has been the subject of many in vitro investigations with oral cells. These studies often present conflicting results with regard to cellular viability and functions. For example, with regard to cellular viability, overall the studies show that the harsher the conditions (e.g., higher concentrations of nicotine and longer durations of exposure), the more significant the detrimental effects of the nicotine on cell culture systems. Cellular viability has generally been shown to be unaffected[44,93,130] by nicotine concentrations in the range found in blood plasma (~36 ng/ml)[122] or the saliva of smokers (906 ng/ml).[42] Much higher nicotine concentrations can be found in the saliva of smokeless tobacco users (70–1560 μg/ml),[58] and studies with these nicotine concentrations demonstrate significant cellular toxicity in vitro.[6,31,138] Interestingly, cells derived from smokers and older donors demonstrated less sensitivity to nicotine.[31]

Clinical studies are required to determine the clinical relevance of these in vitro results.

Effects of Smoking on the Response to Periodontal Therapy

Nonsurgical Therapy

Numerous studies have indicated that current smokers do not respond as well to periodontal therapy as nonsmokers or former smokers do (Table 12.4). Most clinical research supports the observation that probing depth reductions are generally greater in nonsmokers than in smokers after nonsurgical periodontal therapy.[4,45,46,49,72,107,113] In addition, gains in clinical attachment as a result of nonsurgical treatment are less pronounced in smokers than in nonsmokers. In a study of patients with previously untreated advanced periodontal disease, nonsurgical therapy resulted in significantly greater mean reductions in probing depth and bleeding on probing in nonsmokers than in smokers when evaluated 6 months after the completion of therapy.[113] Mean probing depth reductions of 2.5 mm for nonsmokers and 1.9 mm for smokers were observed in pockets that averaged 7 mm or more before treatment. In another study, the nonsurgical management of pockets of 5 mm or greater showed that smokers had less probing depth reduction than nonsmokers after 3 months (1.29 mm versus 1.76 mm) as well as less gain in clinical attachment levels.[45] When a higher level of oral hygiene was achieved as part of nonsurgical care, the differences in the resolution of 4- to 6-mm pockets between nonsmokers and smokers became clinically less significant.[107]

TABLE 12.4
Effects of Smoking on the Response to Periodontal Therapy

Therapy	Effects of Smoking
Nonsurgical	↓ Clinical response to root surface debridement
	↓ Reduction in probing depth
	↓ Gain in clinical attachment levels
	↓ Negative impact of smoking with ↑ level of plaque control
Surgery and implants	↓ Probing depth reduction and ↓ gain in clinical attachment levels after access flap surgery
	↑ Deterioration of furcations after surgery
	↓ Gain in clinical attachment levels, ↓ bone fill, ↑ recession, and ↑ membrane exposure after guided tissue regeneration
	↓ Root coverage after grafting procedures for localized gingival recession
	↓ Probing depth reduction after bone graft procedures
	↑ Risk for implant failure and periimplantitis
Maintenance care	↑ Probing depth and attachment loss during maintenance therapy
	↑ Disease recurrence in smokers
	↑ Need for retreatment in smokers
	↑ Tooth loss in smokers after surgical therapy

↓, Decreased; ↑, increased.

It can be concluded that smokers respond less well to nonsurgical therapy than do nonsmokers. With excellent plaque control, these differences may be minimized, but the emphasis is on truly excellent plaque control. When comparing current smokers with former smokers and nonsmokers, the former and nonsmoking subjects appear to respond equally well to nonsurgical care,[45] thereby reinforcing the need for patients to be informed of the benefits of smoking cessation.

Surgical Therapy and Implants

The less favorable response of the periodontal tissues to nonsurgical therapy that is observed in current smokers is also observed after surgical therapy. In a longitudinal comparative study of the effects of four different treatment modalities (coronal scaling, root planing, modified Widman flap surgery, and osseous resection surgery), smokers (with "heavy" defined as ≥20 cigarettes/day and "light" defined as ≤19 cigarettes/day) consistently showed less pocket reduction and less gain in clinical attachment as compared with nonsmokers or former smokers.[72] These differences were evident immediately after the completion of therapy and continued throughout 7 years of supportive periodontal therapy. During the 7 years, deterioration at furcation areas was greater in heavy and light smokers than in former smokers and nonsmokers. Smoking has also been shown to have a negative impact on the outcomes of guided tissue regeneration[141,143] and the treatment of infrabony defects by bone grafts.[118] By 12 months after guided tissue regeneration therapy at deep infrabony defects, smokers demonstrated less than half the attachment gain that was observed in nonsmokers (2.1 mm versus 5.2 mm).[141] In a second study, 73 smokers also showed less attachment gain than nonsmokers (1.2 mm versus 3.2 mm), more gingival recession, and less bone infill of the defect. Similarly, after the use of bone grafts for the treatment of infrabony defects, smokers showed less reduction in probing depths as compared with nonsmokers.[118]

Open flap access surgery without regenerative or grafting procedures is a common surgical procedure used for accessing the root and bone surfaces. By 6 months after this procedure, smokers

showed significantly less reduction of deep pockets (≥7 mm) than nonsmokers (3 mm for smokers versus 4 mm for nonsmokers) and significantly less gain in clinical attachment (1.8 mm for smokers versus 2.8 mm for nonsmokers), even though all of the patients received supportive periodontal therapy every month for 6 months.[126]

Tobacco smoking also affects the outcomes of periodontal plastic surgery.[27,30] For instance, a systematic review assessed the influence of smoking on the outcomes achieved by root coverage procedures.[27] This review identified that significantly greater root coverage and greater gains in clinical attachment levels were recorded for nonsmokers as compared with smokers after the treatment of gingival recession defects by subepithelial connective-tissue grafts. Furthermore, smokers showed significantly fewer sites with complete root coverage than were seen in the nonsmokers.[30]

Several meta-analyses have investigated the influence of smoking on the short- and long-term outcomes of implant therapy and have identified that smoking increases the risk of implant failure.[28,57,77,90,135] These studies used various definitions to define implant failure, including implant loss, implant bone loss, mobility, pain, and periimplantitis. Overall, the risk for implant failure in smokers appears to be approximately double the risk for failure in nonsmokers, and the risks appear to be higher in maxillary implants and when implants are placed in poor-quality bone. Smoking has also been shown to be a risk factor for periimplantitis, with a majority of studies showing a significant increase in periimplant bone loss as compared with nonsmokers.[56] Collectively, these data indicate that implant failure is more common among smokers than nonsmokers. However, because numerous factors can influence implant success, further controlled clinical trials are needed to address the role of smoking as an independent variable in implant failure. Given the current evidence, all patients who are considering implant therapy should be informed about the benefits of smoking cessation and the risks of smoking for the development of periimplantitis and implant failure.

Maintenance Therapy

The detrimental effect of smoking on treatment outcomes appears to be long lasting and independent of the frequency of maintenance therapy. After four modalities of therapy (scaling, scaling and root planing, modified Widman flap surgery, and osseous surgery), maintenance therapy was performed by a hygienist every 3 months for 7 years.[72] Smokers consistently had deeper pockets than nonsmokers and less gain in attachment when evaluated each year for the 7-year period. Even with more intensive maintenance therapy given every month for 6 months after flap surgery,[126] smokers had deeper and more residual pockets than nonsmokers, although no significant differences in plaque or bleeding on probing scores were found. These data suggest that the effects of smoking on the host response and the healing characteristics of the periodontal tissues may have a long-term effect on pocket resolution in smokers, possibly requiring more intensive management during the maintenance phase. Smokers also tend to experience more periodontal breakdown than nonsmokers after therapy.[82,84] In studies of patients who failed to respond to periodontal therapy, approximately 90% of these poorly responding patients were smokers.[82,83]

A systematic review that assessed the potential predictors of tooth loss during long-term periodontal maintenance care demonstrated that, although oral health and the prevention of tooth loss were achieved in the majority of patients, the long-term outcomes were also influenced by smoking.[26] Tobacco smoking was positively associated with tooth loss even when regular recall maintenance care was performed (overall, smokers had a risk of losing their teeth that was up to 380% higher than that of nonsmokers).[26] Similarly, smoking has a detrimental effect on periimplant tissue status, even when patients are under strict periimplant preventive maintenance care.[34] It has been also demonstrated in a practice-based study that the smoking status may be highly associated with periimplant tissue loss around 10-mm implants restored with single crowns.[34] For instance, when comparing nonsmokers and light smokers (i.e., subjects who smoked <10 cigarettes per day), it was found that the majority of patients who experienced bone loss were smokers (88.9%), with an odds ratio of 39.64 (95% confidence interval, 8.62 to 182.27) for

increased risk of bone loss.[34]

It is clear from these studies that (1) smokers may present with periodontal disease at an early age; (2) they may be difficult to treat effectively with conventional therapeutic strategies; (3) they may continue to have progressive or recurrent periodontitis; and (4) they may be at an increased risk of tooth loss or periimplant bone loss, even when adequate maintenance control is established. For these reasons, smoking cessation counseling must be a cornerstone of periodontal therapy in smokers.

Effects of Smoking Cessation on Periodontal Treatment Outcomes

The effect of smoking cessation on periodontal status has been studied in a large number of cross-sectional and cohort observational studies, in which the periodontal status of smokers, former smokers, and nonsmokers is compared.[8,9,14-16,20,36,48,50,69,100,137,139] Similarly, periodontal treatment outcomes have been assessed in smokers, former smokers, and nonsmokers.[46,61,72,89,110,124] Collectively, these studies have demonstrated that smokers have significantly worse periodontal status (i.e., deeper probing depths, more attachment loss and bone loss) than either former smokers or nonsmokers and usually have poorer treatment outcomes. The periodontal status of former smokers is intermediate to that of current smokers and nonsmokers, and it appears to usually be closer to that of nonsmokers.

There are very few intervention studies of the effect of smoking cessation on periodontal treatment outcomes (i.e., studies in which smokers were helped to quit and in which the effect on periodontal status was then assessed). Two short-term studies have indicated that smoking has a negative impact on the gingival vasculature and that these changes are reversible with smoking cessation.[91,92] Two interventional studies have assessed the impact of smoking cessation on outcomes after nonsurgical periodontal treatment.[109,117] The first study employed dental hygienists who were trained as smoking cessation advisers and who achieved a 20% quit rate at 12 months in a population of smokers who also had periodontitis. The

hygienists used a variety of strategies to assist these smokers, including counseling, nicotine replacement therapy, and bupropion. All of the patients received nonsurgical therapy as treatment for their periodontitis in addition to smoking cessation counseling. Those individuals who successfully quit smoking for the entire 12 months of the study had the best response to the periodontal treatment. The treatment responses in the nonquitters and the failed quitters (i.e., the "oscillators" who initially quit but who then resumed smoking) were significantly poorer than those seen in the quitters, and they did not differ significantly from each other. The second study was a 12-month prospective single-blinded study in which smoking cessation advice, nicotine replacement therapy, and medication were provided at four consecutive appointments, once a week, by a multidisciplinary team that included doctors, psychologists, and a dentist, in addition to nonsurgical treatment of periodontitis.[117] The confirmed continuous quit rate at 12 months was 18.3%. At the end of the 12-month follow-up period, it was identified that the quitters had improved clinical attachment gain as compared with the nonquitters. In addition, a supplementary study that described a set of meta-analyses performed with individual patient data from these two trials reported a highly significant beneficial impact of quitting smoking, with quitters demonstrating 30% more sites with probing depth reductions of 2 mm or more as compared with nonquitters.[29] Equally, quitters had 22% fewer sites with residual probing depths of 4 mm or greater as compared with nonquitters at the end of the 12-month follow-up period.[29]

The benefit of smoking cessation on the periodontium is likely to be mediated through various pathways, such as a shift toward a less pathogenic microbiome, the recovery of the gingival microcirculation, and improvements in certain aspects of the immune–inflammatory responses. In support of this observation, in the interventional study described previously,[109] plaque samples were collected as the study progressed. It became clear that subgingival microbial profiles differed significantly between smokers and quitters at 6 and 12 months after smoking cessation.[43] At 6 and 12 months after treatment, the microbial community in smokers was similar to that observed at baseline (i.e., before

periodontal treatment/smoking cessation counseling), whereas the quitters demonstrated significantly divergent profiles; changes in bacterial levels contributed to this shift. These data suggest a critical role for smoking cessation in the alteration of the subgingival biofilm. Further research is necessary to investigate the impact of quitting smoking on the immune–inflammatory mechanisms that drive tissue destruction in the periodontium.

In conclusion, smoking is a major risk factor for periodontitis, and smoking cessation should be an integral part of periodontal therapy among patients who smoke. Smoking cessation should be considered a priority for the management of periodontitis in smokers.

Case Scenario 12.1

Patient:
62-year-old male

Chief Complaint:
"I have tenderness around dental implants that were placed 1 year ago, and I notice bleeding when I'm brushing them."

Background Information
The patient had a history of hypertension and hypothyroidism. He currently smokes 10 to 15 hand-rolled cigarettes per day, and he has smoked on and off for over 40 years. He managed to quit for a period around the time of implant placement, but he resumed smoking recently.

The patient sees his dentist regularly, has been edentulous for 10 years, and struggled to wear a complete maxillary denture. He uses a powered toothbrush twice per day to brush around the implants.

Current Findings:
(1 year after implant placement): Generalized probing depths of 5 to 6 mm around all the implants. Bleeding on probing score, 80%. Evidence of radiographic bone loss of 2 to 4 mm from baseline records. Generally poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Smokers who receive dental implants are at increased risk for which of the following? A. Failure of osseointegration	**Answer: D** **Explanation:** Smoking has myriad effects that will influence the prognosis of a dental implant in both the short and long term. Similar to the effects seen in periodontitis, smokers with implants will have adverse effects on their vasculature, immune and inflammatory responses, and microbiology.

B. Periimplantitis C. Wound healing complications D. All of the above	
2. If this patient was a current smoker at the time of dental implant placement, would he have been at increased risk of suffering from a dental implant failure? A. No increased risk B. 1.5 times the risk C. 2 times the risk D. 5 times the risk E. None of the above	**Answer: C** **Explanation:** There have been numerous systematic reviews on this topic. Overall, they find that smokers are at approximately double the risk of implant failure compared to nonsmokers. Patients should be made aware of this increased risk and every effort made to support them in their efforts to quit smoking.
3. If a patient successfully quits smoking, how long should you wait until placing dental implants? A. 1 week B. 2 months C. 2 years D. Not known	**Answer: D** **Explanation:** There is insufficient evidence to say with confidence at what time point a former smoker should receive a dental implant. Some early protocols suggested abstinence for 1 week before, and 8 weeks after, dental implant placement, showing significantly improved early outcomes compared to those who continued to smoke.[7] More contemporary studies have suggested a 2-year cutoff is more useful, with those having dental implant placement earlier than 2 years from the time of cessation having a 2.7 times greater risk of implant failure compared to those who had been abstinent for longer than 2 years.[144] Further research is needed on this topic.
4. What should you advise e-cigarette users (former smokers) who are considering dental implant treatment? A. Stop e-cigarettes immediately. B. Consider cutting down. C. Use nicotine free e-liquids. D. Change the e-liquid flavor. E. Use an individualized approach.	**Answer: E** **Explanation:** E-cigarettes are a recent and popular invention (see Box 12.5). Research studies have yet to explore these questions, and no official guidance exists. However, it is highly likely that e-cigarette aerosol (vapor) is likely to be significantly less harmful than tobacco smoke. Given this situation, it would be most suitable to provide individualized advice to the patient. For example, a patient who has recently given up a habit of smoking 20 cigarettes a day and is using an e-cigarette should not be pressured into immediately abstaining from the e-cigarette, for fear of relapse to cigarette smoking. Indeed, long-term e-cigarette use can be a protective factor against relapse back to smoking (relapse rates of 70% can be expected between 4 and 52 weeks). Because patients highly respect the opinions of health care professionals, it is important that we give the most up-to-date, evidence-based advice.

CHAPTER 13

The Role of Dental Calculus and Other Local Predisposing Factors

James E. Hinrichs, Vivek Thumbigere-Math

CHAPTER OUTLINE

Calculus
Other Predisposing Factors

The primary cause of gingival inflammation is bacterial plaque. Other predisposing factors include calculus, faulty restorations, complications associated with orthodontic therapy, self-inflicted injuries, and the use of tobacco. These will be discussed in turn.

Calculus

Calculus consists of mineralized bacterial plaque that forms on the surfaces of natural teeth and dental prostheses.

Supragingival and Subgingival Calculus

Supragingival calculus is located coronal to the gingival margin and therefore is visible in the oral cavity. It is usually white or whitish yellow in color; hard, with a claylike consistency; and easily detached from the tooth surface. After removal, it may rapidly recur, especially in the lingual area of the mandibular incisors. The color is influenced by contact with substances such as tobacco and food pigments. It may be localized on a single tooth or group of teeth, or it may be generalized throughout the mouth.

Key Fact

Mechanical removal of subgingival plaque and calculus is considered the fundamental cornerstone to the treatment of chronic periodontitis.

The two most common locations for the development of supragingival calculus are the buccal surfaces of the maxillary molars (Fig. 13.1) and the lingual surfaces of the mandibular anterior teeth (Fig. 13.2).[37]

FIG. 13.1 Supragingival calculus is depicted on the buccal surfaces of maxillary molars adjacent to the orifice for the parotid duct.

FIG. 13.2 Extensive supragingival calculus is present on the lingual surfaces of the lower anterior teeth.

Saliva from the parotid gland flows over the facial surfaces of the upper molars via the parotid duct, whereas the submandibular duct and the lingual duct empty onto the lingual surfaces of the lower incisors from the submaxillary and sublingual glands, respectively. In extreme cases, calculus may form a bridge-like structure over the interdental papilla of adjacent teeth or cover the occlusal surface of teeth that are lacking functional antagonists.

Subgingival calculus is located below the crest of the marginal gingiva and therefore is not visible on routine clinical examination. The location and the extent of subgingival calculus may be evaluated by careful tactile perception with a delicate dental instrument such as an explorer. Clerehugh and colleagues[34] assessed the validity of the World Health Organization no. 621 probe to detect and score subgingival calculus. Following clinical detection of subgingival calculus, teeth were extracted and microscopically scored for subgingival calculus. An agreement of 80% was found between the two scoring methods. Subgingival calculus is typically hard and dense; it frequently appears to be dark brown or greenish black in color (Fig. 13.3), and it is firmly attached to the tooth surface. Supragingival calculus and subgingival calculus generally occur together, but one may be present without the other. Microscopic studies demonstrate that deposits of subgingival calculus usually extend nearly to the base of periodontal pockets in individuals with chronic periodontitis but do not reach the junctional epithelium.

FIG. 13.3 Dark pigmented deposits of subgingival calculus are shown on the distal root of an extracted lower molar.

When the gingival tissues recede, subgingival calculus becomes exposed and is therefore reclassified as supragingival (Fig. 13.4A). Thus, supragingival calculus can be composed of both the initial supragingival calculus and previous subgingival calculus. A reduction in gingival inflammation and probing depths with a gain in clinical attachment can be observed after the removal of subgingival plaque and calculus (see Fig. 13.4B; see Chapter 50).

FIG. 13.4 (A) A 31-year-old white man with extensive supragingival and subgingival calculus deposits throughout his dentition is shown. (B) One year after receiving thorough scaling and root planing to remove supragingival and subgingival calculus deposits, followed by restorative care. Note the substantial reduction in gingival inflammation.

Clinical Correlation

A reduction in gingival inflammation and probing depths accompanied by a gain in clinical attachment can be expected following thorough removal of subgingival plaque and calculus.

Prevalence

Anerud and colleagues[4] observed the periodontal status of a group of Sri Lankan tea laborers and a group of Norwegian academicians for a 15-year period. The Norwegian population had ready access to preventive dental care throughout their lives, whereas the Sri Lankan tea laborers did not. The formation of supragingival calculus was observed early in life in the Sri Lankan individuals, probably shortly after the teeth erupted. The first areas to exhibit calculus deposits were the facial aspects of maxillary molars and the lingual surfaces of mandibular incisors. The deposition of supragingival calculus continued as individuals aged, and it reached a maximal calculus score when the affected individuals were 25 to 30 years old.

At this time, most of the teeth were covered by calculus, although

the facial surfaces had less calculus than the lingual or palatal surfaces. Calculus accumulation appeared to be symmetric, and by the age of 45 years, these individuals had only a few teeth (typically the premolars) without calculus deposits. Subgingival calculus appeared first either independently or on the interproximal aspects of areas where supragingival calculus already existed.[4] By the age of 30 years, all surfaces of all teeth had subgingival calculus without any pattern of predilection.

In contrast to the Sri Lankan group, the Norwegian academicians who received oral hygiene instructions and frequent preventive dental care throughout their lives exhibited a marked reduction in the accumulation of calculus. Approximately 80% of teenagers formed limited supragingival calculus on the facial surfaces of the upper first molars and the lingual surfaces of lower incisors. However, no additional calculus formation occurred on other teeth, and its presence did not increase with the individual's age.[4]

Both supragingival calculus and subgingival calculus may be seen on radiographs (see Chapter 33). Highly calcified interproximal calculus deposits are readily detectable as radiopaque projections that protrude into the interdental spaces (Fig. 13.5).

FIG. 13.5 A bitewing radiograph illustrating subgingival calculus deposits that are depicted as interproximal spurs *(arrows)*.

However, the sensitivity level of detecting calculus by radiographs is inconsistent.[27] The location of calculus does not indicate the bottom of the periodontal pocket, because the most apical plaque is not sufficiently calcified to be visible on radiographs.

« Flash Back

Whereas the presence of subgingival calculus can be observed on dental radiographs, the sensitivity of such detection is inconsistent.

Composition

Inorganic Content

Dental calculus is primarily composed of inorganic components

(70% to 90%[59]) and the organic components constitute the rest. The major inorganic proportions of calculus are approximately 76% calcium phosphate ($Ca_3[PO_4]_2$), 3% calcium carbonate ($CaCO_3$), 4% magnesium phosphate ($Mg_3[PO_4]_2$), 2% carbon dioxide, and traces of other elements such as sodium, zinc, strontium, bromine, copper, manganese, tungsten, gold, aluminum, silicon, iron, and fluorine.[132,206] The percentage of inorganic constituents in calculus is similar to that of other calcified tissues of the body (Table 13.1).

TABLE 13.1

Calculus versus Other Oral Hard Tissues

Structure	Inorganic Content (%)*
Dental Calculus	70–90
Enamel	96
Dentin	45
Bone	60–70

*Organic components and water constitute the rest.

At least two-thirds of the inorganic component is crystalline in structure.[103] The four main crystal forms and their approximate percentages are as follows: hydroxyapatite, 58%; magnesium whitlockite, 21%; octacalcium phosphate, 12%; and brushite, 9%.

Two or more crystal forms are typically found in a sample of calculus. Hydroxyapatite and octacalcium phosphate are detected most frequently (i.e., in 97% to 100% of all supragingival calculus) and constitute the bulk of the specimen. Brushite is more common in the mandibular anterior region, and magnesium whitlockite is found in the posterior areas. The incidence of the four crystal forms varies with the age of the deposit.[17]

« Flash Back

The four main crystalline inorganic forms of calculus are hydroxyapatite, magnesium whitlockite, octacalcium phosphate, and brushite.

Organic Content

The organic component of calculus consists of a mixture of protein–polysaccharide complexes, desquamated epithelial cells, leukocytes, and various types of microorganisms.[116]

Between 1.9% and 9.1% of the organic component is carbohydrate, which consists of galactose, glucose, rhamnose, mannose, glucuronic acid, galactosamine, and sometimes arabinose, galacturonic acid, and glucosamine.[109,115,186] All of these organic components are present in salivary glycoprotein, with the exception of arabinose and rhamnose. Salivary proteins account for 5.9% to 8.2% of the organic component of calculus and include most amino acids. Lipids account for 0.2% of the organic content in the form of neutral fats, free fatty acids, cholesterol, cholesterol esters, and phospholipids.[110]

The composition of subgingival calculus is similar to that of supragingival calculus, with some differences. It has the same hydroxyapatite content but more magnesium whitlockite and less brushite and octacalcium phosphate.[167,191] The ratio of calcium to phosphate is higher in subgingival calculus, and the sodium content increases with the depth of periodontal pockets.[111] These altered compositions may be attributed to fact that the origin of subgingival calculus is plasma, whereas supragingival calculus is partially composed of salivary constituents. Salivary proteins present in supragingival calculus are not found in subgingival calculus.[12] Dental calculus, salivary duct calculus, and calcified dental tissues are similar in inorganic composition.

Attachment to the Tooth Surface

Differences in the manner in which calculus is attached to the tooth surface affect the relative ease or difficulty encountered during its removal. Four modes of attachment have been described.[94,175,180,214] (1) Attachment by means of an organic pellicle on cementum is depicted in Fig. 13.6, and attachment on enamel is shown in Fig. 13.7. (2) Mechanical locking into surface irregularities, such as caries lesions or resorption lacunae, is illustrated in Fig. 13.8. (3) Close adaptation of the undersurface of calculus to depressions or gently sloping mounds of the unaltered cementum surface[186] is shown in Fig. 13.9. (4) Penetration of bacterial calculus into

cementum is shown in Figs. 13.10 and 13.11.

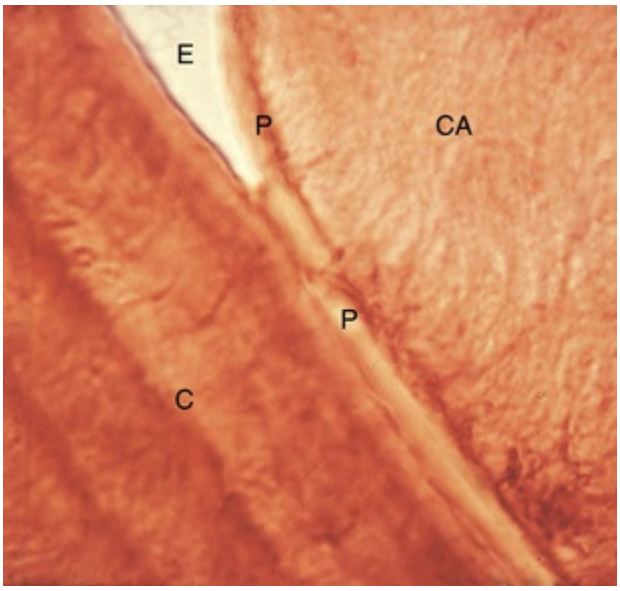

FIG. 13.6 Calculus attached to the pellicle on the enamel surface and the cementum. An enamel void *(E)* has been created during the preparation of the specimen. *C,* Cementum; *CA,* calculus*; P,* pellicle.

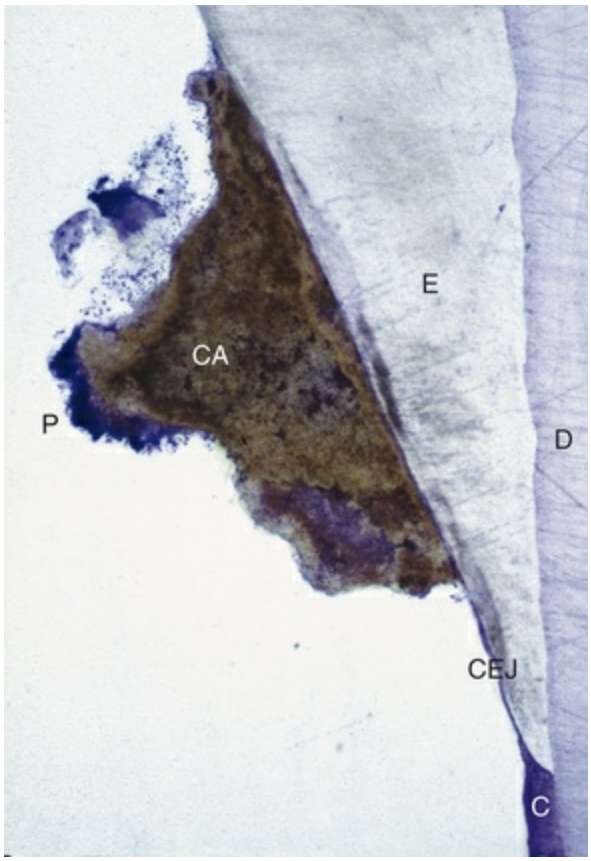

FIG. 13.7 Non-decalcified specimen with calculus *(CA)* attached to enamel *(E)* surface just coronal to the cementoenamel junction *(CEJ).* Note plaque *(P)* on the surface of the calculus; dentin *(D)* and cementum *(C)* are also identified. (Courtesy Dr. Michael Rohrer, Minneapolis, MN.)

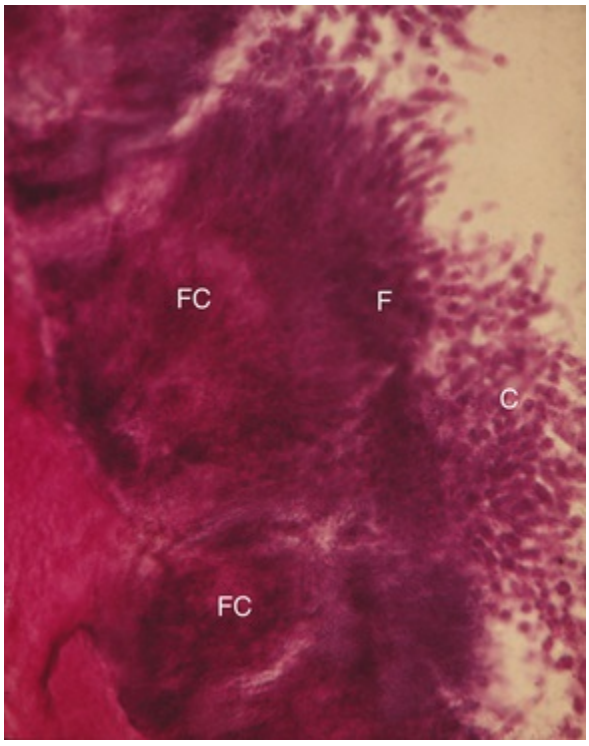

FIG. 13.11 Plaque and calculus on the tooth surface. Note the spherical areas of focal calcification *(FC)* and the perpendicular alignment of the filamentous *(F)* organisms along the inner surface of plaque and cocci *(C)* on the outer surface.

« Flash Back

Four modes by which calculus may attach to cementum are (1) organic pellicle, (2) mechanical locking into surface irregularities, (3) close adaption to gentle depression or sloping mounts of unaltered cementum, and (4) bacterial penetration into cementum surface.

Formation

Calculus is *mineralized dental plaque.* The soft plaque is hardened by the precipitation of mineral salts, which usually starts between the 1st and 14th days of plaque formation. Calcification has been reported to occur within as little as 4 to 8 hours.[192] Calcifying plaques may become 50% mineralized in 2 days and 60% to 90% mineralized in 12 days.[131,170,179] All plaque does not necessarily undergo calcification. Early plaque contains a small amount of inorganic material, which increases as the plaque develops into calculus. Plaque that does not develop into calculus reaches a plateau of maximal mineral content within 2 days.[169] Microorganisms are not always essential in calculus formation, because calculus readily occurs in germ-free rodents.[66]

Key Fact

Calculus by itself does not contribute directly to gingival inflammation. Like other retentive factors such as open crown margin or an overhanging restoration, calculus retains dental plaque, which contributes to gingival inflammation.

Saliva is the primary source of mineralization for supragingival calculus, whereas the serum transudate called *gingival crevicular fluid* furnishes the minerals for subgingival calculus.[80,188] The calcium concentration or content in plaque is 2 to 20 times higher than in saliva.[17] Early plaque of heavy calculus formers contains more calcium, three times more phosphorus, and less potassium

than that of noncalculus formers, suggesting that phosphorus may be more critical than calcium for plaque mineralization.[116] Calcification entails the binding of calcium ions to the carbohydrate–protein complexes of the organic matrix and the precipitation of crystalline calcium phosphate salts.[114] Crystals form initially in the intercellular matrix and on the bacterial surfaces and finally within the bacteria.[60,215]

The calcification of supragingival plaque and the attached component of subgingival plaque begins along the inner surface adjacent to the tooth structure. Separate foci of calcification increase in size and coalesce to form solid masses of calculus (see Fig. 13.11). For the initial mineralization process to occur, calcium phosphate supersaturation, certain membrane-associated components, and regulation of nuclear inhibitors are required.[82] Calcification may be accompanied by alterations in the bacterial content and staining qualities of the plaque. As calcification progresses, the number of filamentous bacteria increases, and the foci of calcification change from basophilic to eosinophilic. There is a reduction in the staining intensity of groups that exhibit a positive periodic acid–Schiff reaction.

Sulfhydryl and amino groups are also reduced and instead stain with toluidine blue, which is initially orthochromatic but becomes metachromatic and disappears.[202] Calculus is formed in layers, which are often separated by a thin cuticle that becomes embedded in the calculus as calcification progresses.[118]

The initiation of calcification and the rate of calculus accumulation vary among individuals, among tooth variety in the same dentition, and at different times in the same person.[132,195] On the basis of these differences, persons may be classified as *heavy, moderate,* or *slight* calculus formers or as noncalculus formers. The average daily increment in calculus formers is from 0.10% to 0.15% of dry weight calculus.[179,195] Calculus formation continues until it reaches a maximum, after which it may be reduced in amount. The time required to reach the maximal level has been reported to be between 10 weeks[35] and 6 months.[200]

The decline from maximal calculus accumulation, which is referred to as the *reversal phenomenon,* may be explained by the vulnerability of bulky calculus to mechanical wear from food and

from the cheeks, lips, and tongue movement.

Theories Regarding the Mineralization of Calculus

The theoretical mechanisms by which plaque becomes mineralized can be stratified into two categories.[133]

1. Mineral precipitation results from a local rise in the degree of saturation of calcium and phosphate ions, which may be brought about in several ways:
    - *A rise in the pH of the saliva causes the precipitation of calcium phosphate salts by lowering the precipitation constant.* The pH may be elevated by the loss of carbon dioxide and the formation of ammonia by dental plaque bacteria or by protein degradation during stagnation.[16,74]
    - *Colloidal proteins in saliva bind calcium and phosphate ions and maintain a supersaturated solution with respect to calcium phosphate salts.* With the stagnation of saliva, colloids settle out, and the supersaturated state is no longer maintained, thereby leading to the precipitation of calcium phosphate salts.[152,171]
    - *Phosphatase liberated from dental plaque, desquamated epithelial cells, or bacteria precipitates calcium phosphate by hydrolyzing organic phosphates in saliva, thereby increasing the concentration of free phosphate ions.*[205] *Esterase* is another enzyme that is present in the cocci and filamentous organisms, leukocytes, macrophages, and desquamated epithelial cells of dental plaque.[10] Esterase may initiate calcification by hydrolyzing fatty esters into free fatty acids. The fatty acids form soaps with calcium and magnesium that are later converted into the less-soluble calcium phosphate salts.
2. Seeding agents induce small foci of calcification that enlarge and coalesce to form a calcified mass.[135] This concept has been referred to as the *epitactic concept* or, more

appropriately, as *heterogeneous nucleation.* The seeding agents in calculus formation are not known, but it is suspected that the intercellular matrix of plaque plays an active role.[117,131,215] The carbohydrate–protein complexes may initiate calcification by removing calcium from the saliva (chelation) and binding with it to form nuclei that induce the subsequent deposition of minerals.[114,201]

Role of Microorganisms in the Mineralization of Calculus

Mineralization of plaque generally starts extracellularly around both gram-positive and gram-negative organisms, but it may also start intracellularly.[99] Filamentous organisms, diphtheroids, and *Bacterionema* and *Veillonella* species have the ability to form intracellular apatite crystals (see Fig. 13.11). Mineralization spreads until the matrix and the bacteria are calcified.[60,216]

Bacterial plaque may actively participate in the mineralization of calculus by forming phosphatases, which change the pH of the plaque and induce mineralization,[43,114] but the prevalent opinion is that these bacteria are only passively involved[60,162,205] and are simply calcified with other plaque components. The occurrence of calculus-like deposits in germ-free animals supports this opinion.[66] However, other experiments suggest that transmissible factors are involved in calculus formation and that penicillin in the diets of some of these animals reduces calculus formation.[11]

Etiologic Significance

Distinguishing between the effects of calculus and plaque on the gingiva is difficult, because calculus is always covered with a nonmineralized layer of plaque.[169] A positive correlation between the presence of calculus and the prevalence of gingivitis exists,[156] but this correlation is not as great as that between plaque and gingivitis.[62] The initiation of periodontal disease in young people is closely related to plaque accumulation, whereas calculus accumulation is more prevalent in chronic periodontitis found in older adults.[62,106]

The incidence of calculus, gingivitis, and periodontal disease

increases with age. It is extremely rare to find periodontal pockets in adults without at least some subgingival calculus being present, although the subgingival calculus may be of microscopic proportions.

Calculus does not contribute directly to gingival inflammation, but it provides a fixed nidus for the continued accumulation of bacterial plaque and its retention in close proximity to the gingiva (Fig. 13.12). Periodontal pathogens such as *Aggregatibacter actinomycetemcomitans, Porphyromonas gingivalis*, and *Treponema denticola* have been found within the structural channels and lacunae of supragingival and subgingival calculus.[136,137]

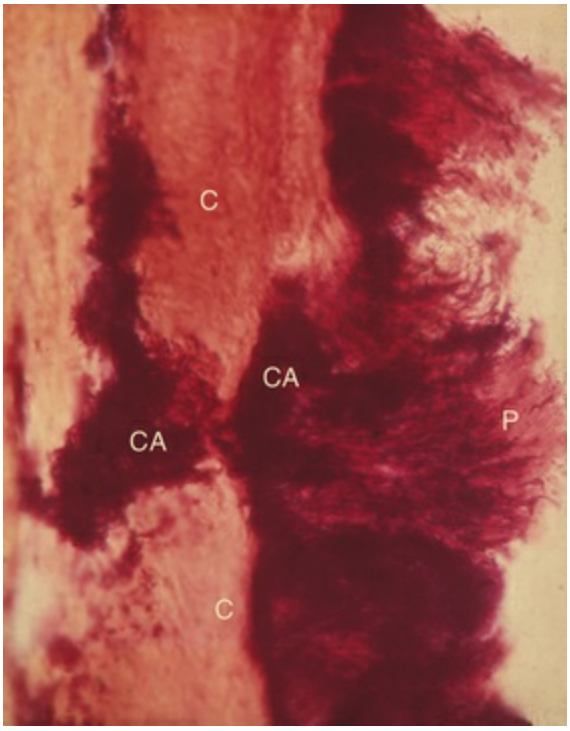

FIG. 13.12 Calculus *(CA)* penetrates the tooth surface and is embedded within the cementum *(C).* Note the plaque *(P)* attached to the calculus.

Subgingival calculus is likely to be the product rather than the cause of periodontal pockets. Plaque initiates gingival inflammation, which leads to pocket formation, and the pocket in turn provides a sheltered area for plaque and bacterial accumulation. The increased flow of gingival crevicular fluid associated with gingival inflammation provides the minerals that

mineralize the continually accumulating plaque, resulting in the formation of subgingival calculus (Fig. 13.13). Over a 6-year period, Albandar and colleagues observed 156 teenagers with aggressive periodontitis.[2] They noted that areas with detectable subgingival calculus at the initiation of the study were much more likely to experience a loss of periodontal attachment than sites that did not initially exhibit subgingival calculus.

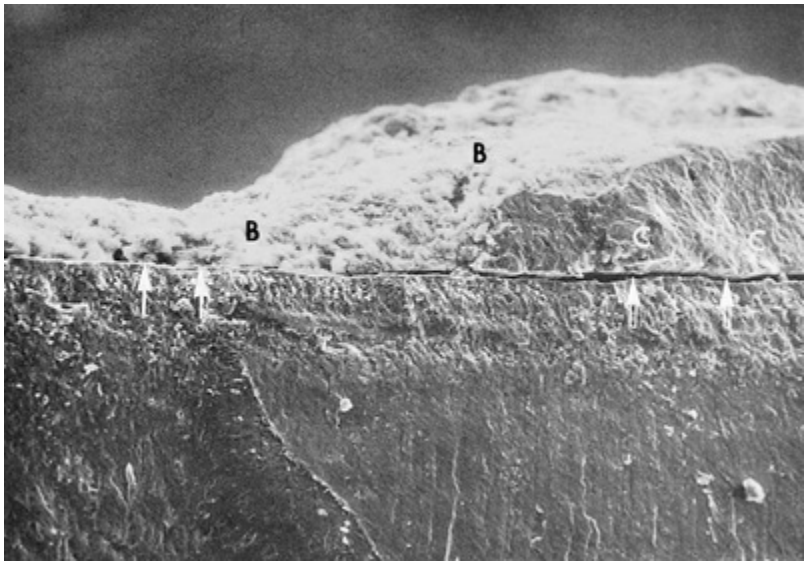

FIG. 13.13 Scanning electron microscope view of an extracted human tooth showing a cross-section of subgingival calculus *(C)* separated *(arrows)* from the cemental surface during processing of the specimen. Note the bacteria *(B)* attached to the calculus and the cemental surfaces. (Courtesy Dr. John Sottosanti, La Jolla, CA.)

Although the bacterial plaque that coats the teeth is the main etiologic factor in the development of periodontal disease, the removal of subgingival plaque and calculus constitutes the cornerstone of periodontal therapy. Calculus plays an important role in maintaining and accentuating periodontal disease by keeping plaque in close contact with the gingival tissue and by creating areas where plaque removal is impossible. Therefore, the clinician must not only possess the clinical skill to remove the plaque and calculus, but he or she must also be very conscientious about performing this task.

Materia Alba, Food Debris, and Dental Stains

Materia alba is an accumulation of microorganisms, desquamated epithelial cells, leukocytes, and a mixture of salivary proteins and lipids, with few or no food particles; it lacks the regular internal pattern observed in plaque.[172] It is a yellow or grayish-white, soft, sticky deposit, and it is somewhat less adherent than dental plaque. The irritating effect of materia alba on the gingiva is caused by bacteria and their products.

Most food debris is rapidly liquefied by bacterial enzymes and cleared from the oral cavity by salivary flow and the mechanical action of the tongue, cheeks, and lips. The rate of clearance from the oral cavity varies with the type of food and the individual. Aqueous solutions are typically cleared within 15 minutes, whereas sticky foods may adhere for more than 1 hour.[101,199] Dental plaque is not a derivative of food debris, and food debris is not an important cause of gingivitis.[42,86]

Pigmented deposits on the tooth surface are called *dental stains.* Stains are primarily an aesthetic problem and do not cause inflammation of the gingiva. The use of tobacco products (Fig. 13.14), coffee, tea, certain mouthrinses, and pigments in foods can contribute to stain formation.[112,187]

FIG. 13.14 Tobacco stains on the apical third of the clinical crown caused by cigarette smoking.

Other Predisposing Factors

Iatrogenic Factors

Deficiencies in the quality of dental restorations or prostheses are contributing factors to gingival inflammation and periodontal destruction. Inadequate dental procedures that contribute to the deterioration of the periodontal tissues are referred to as *iatrogenic factors*. Iatrogenic endodontic complications that can adversely affect the periodontium include root perforations, vertical root fractures, and endodontic failures that may necessitate tooth extraction.[211,214] Immediate implant placement in conjunction with extraction can contribute to an excessive labial and apical position of the implant, whereby the blood supply of surrounding osseous and gingival tissues is compromised, yielding to gingival fenestration or dehiscence[193] (Fig. 13.15). In order to mitigate the risk of dental implant complications, evidence-based clinical guidelines encourage practitioners to consider cone-beam computed tomography (CBCT) for dental implant treatment planning while taking into account the cost, acceptable radiation dose, and risks versus benefits.[196]

FIG. 13.15 (A) A fenestration defect *(arrow)* is noted after placement of a dental implant too far labial and apical, yielding inadequate bone and blood supply to support the surrounding gingiva. (B) Radiograph of the malpositioned dental implant.

Characteristics of dental restorations and removable partial dentures that are important to the maintenance of periodontal health include the location of the gingival margin for the

restoration, the space between the margin of the restoration and the unprepared tooth, the contour of the restorations, the occlusion, the materials used in the restoration, the restorative procedure itself, and the design of the removable partial denture. These characteristics are described in this chapter as they relate to the etiology of periodontal disease. A more comprehensive review with special emphasis on the interrelationship between restorative procedures and the periodontal status is presented in Chapter 70.

Margins of Restorations

Overhanging margins of dental restorations contribute to the development of periodontal disease by (1) changing the ecologic balance of the gingival sulcus to an area that favors the growth of disease-associated organisms (predominantly gram-negative anaerobic species) at the expense of the health-associated organisms (predominantly gram-positive facultative species)[101] and (2) inhibiting the patient's access to remove accumulated plaque.

The frequency of overhanging margins on proximal restorations has varied in different studies from 16.5% to 75%.[19,58,79,142] A highly significant statistical relationship has been reported between marginal defects and reduced bone height.[19,67,79] Gilmore and Sheiham noted that persons with overhanging posterior restorations had an average of 0.22 mm reduced alveolar bone support adjacent to the surfaces with overhangs.[58] The removal of overhangs allows for the more effective control of plaque, thereby resulting in a reduction of gingival inflammation and a small increase in radiographic alveolar bone support[61,71,183] (Fig. 13.16).

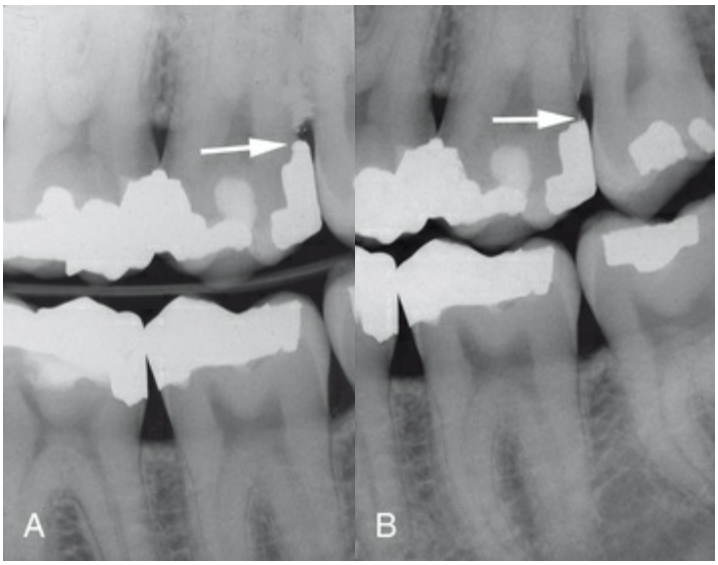

FIG. 13.16 (A) Radiograph of an amalgam overhang on the distal surface of the maxillary second molar that is a source of plaque retention and gingival irritation. (B) Radiograph depicts the removal of excessive amalgam.

The location of the gingival margin of a restoration is directly related to the health status of the adjacent periodontal tissues.[181] Numerous studies have shown a positive correlation between restoration margins located apical to the marginal gingiva and the presence of gingival inflammation.[58,76,85,159,183] Subgingival margins are associated with large amounts of plaque, more severe gingivitis, deeper pockets, and a change in the composition of the subgingival microflora that closely resembles the microflora noted in chronic periodontitis.[98] Even high-quality restorations with clinically perfect margins, if placed subgingivally, will increase plaque accumulation, gingival inflammation,[98,101,129,134,160,182] and the rate of gingival crevicular fluid flow.[13,63] Margins placed at the level of the gingival crest induce less severe inflammation, whereas supragingival margins are associated with a degree of periodontal health similar to that seen with nonrestored interproximal surfaces.[52,181]

Roughness in the subgingival area is considered to be a major contributing factor to plaque buildup and subsequent gingival inflammation.[181] The subgingival zone is composed of the margin of the restoration, the luting material, and the prepared and unprepared tooth surfaces. Sources of marginal roughness include grooves and scratches in the surface of acrylic resin, porcelain, or

gold restorations (Fig. 13.17); separation of the restoration margin and the luting material from the cervical finish line, thereby exposing the rough surface of the prepared tooth (Fig. 13.18); dissolution and disintegration of the luting material between the preparation and the restoration, thereby leaving a space; and inadequate marginal fit of the restoration.[181] Subgingival margins typically have a gap of 20 to 40 μm between the margin of the restoration and the unprepared tooth.[178] Colonization of this gap by bacterial plaque undoubtedly contributes to the detrimental effect of margins placed in a subgingival environment (Fig. 13.19).

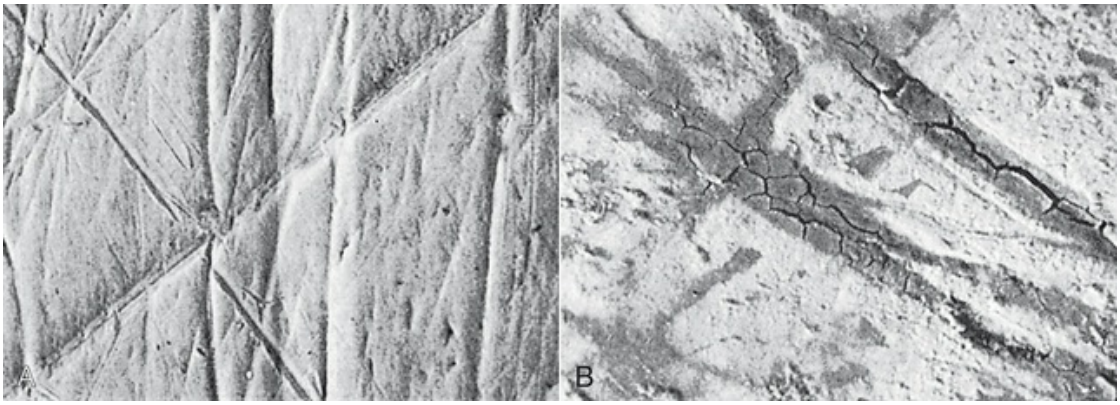

FIG. 13.17 (A) Polished gold alloy crown demonstrating surface scratches. (B) Gold alloy crown that had been in the patient's mouth for several years has scratches filled with deposits. (From Silness J: Fixed prosthodontics and periodontal health. *Dent Clin North Am* 24:317–329, 1980.)

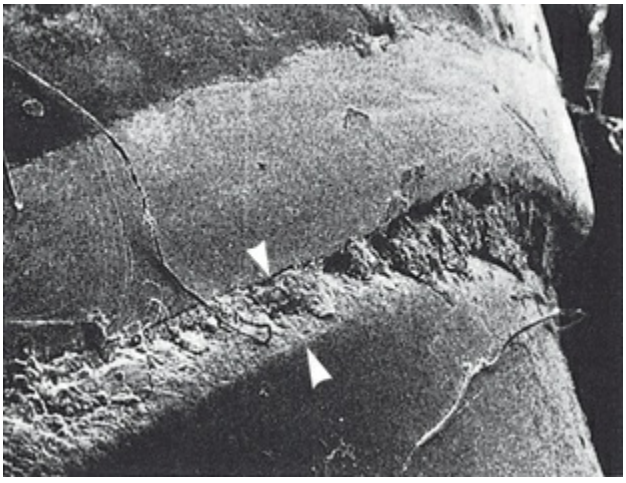

FIG. 13.18 After cementation, luting material prevents the approximation of the crown margin and the finishing line, thereby leaving part of the prepared tooth uncovered *(area between arrowheads)*. Retained Cement and Periimplantitis

Periimplantitis is an inflammatory disease of the tissues around dental implants resulting in progressive bone loss (Fig. 13.20A and B), whereas periimplant mucositis is a reversible inflammatory change of the soft tissues around implants without bone loss.[107] The prevalence of periimplantitis among implant-supported prostheses/restorations ranges from 28% to 56%.[218] The early diagnosis of this condition and its proper management are critical to the longevity of the implant and the supported prosthesis.

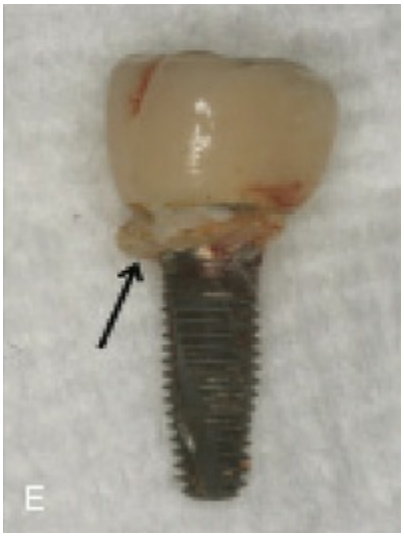
(D) Radiograph of a periimplantitis site shows bone loss associated with retained excessive cement *(arrow)*.



(E) Retrieved implant restoration shows excessive cement remnants *(arrow)* on implant surface.

FIG. 13.20

Complex microbiota colonize pristine periimplant crevices within a week after implant placement, and the microbiota associated with failing implants is significantly different from that of healthy implants.[22,75,102,154,168] Classic studies that explored the composition of the periimplant biofilm in disease have shown that periimplantitis is an infection that is dominated by gram-negative bacteria with many similarities to the microbiota that is responsible for the development of periodontal diseases, including *Aggregatibacter actinomycetemcomitans, Porphyromonas gingivalis, Tannerella forsythia,* and *Fusobacterium* species.[154,161,168] The application of new microbiologic approaches has allowed for a broader characterization of the periimplant microbiome, which has led to the identification of periimplant-specific microbial lineages such as *Streptococcus mutans* and *Butyrivibrio fibrisolvens*.[97,127,168]

« Flash Back

Periimplantitis is frequently associated with crowns exhibiting retained excessive luting cement.

A larger proportion of black-pigmented bacteria are found at periimplantitis sites in dentate patients as compared with edentulous patients. Presumably these periimplantitis infectious organisms arise from the sulcular microbiota of the natural dentition.[7] Consequently, it is critical that practitioners evaluate the patient's periodontal status and provide appropriate periodontal therapy in conjunction with implant rehabilitation.

Local factors such as retained residual cement or inadequate seating of the implant abutment or prosthesis can lead to bone loss around an implant (see Fig. 13.20C–E). In a retrospective study, Wilson found that 81% of the implants diagnosed with periimplantitis had residual cement associated with their cement-retained restorations.[208] The surgical removal of the residual cement resolved the infection and halted the periimplantitis in 74% of the implants. A deeper crown margin makes it more difficult to remove excess cement. The greatest amount of residual cement was noted when the crown margin was 2 or 3 mm below the gingival margin.[108]

Clinical Correlation

The deeper a subgingival crown margin is placed, the higher the likelihood of poorer marginal integrity with accompanying gingival inflammation.

The possible adverse effect of traumatic occlusion on implants has been correlated with early implant failures.[125] However, the relationship between traumatic occlusion and periimplantitis is, to date, a controversial issue. In vivo experiments have shown that, in the absence of periimplant inflammation, the application of excessive occlusal stress leads to only minor alterations in the marginal bone level.[92] Alternatively, the application of excessive occlusal forces in the presence of plaque-induced inflammation can significantly increase the rate of bone loss around implant-supported restorations.[32]

Contours and Open Contacts

Overcontoured crowns and restorations tend to accumulate plaque and handicap oral hygiene measures in addition to possibly preventing the self-cleaning mechanisms of the adjacent cheek, lips, and tongue[6,95,130,209] (Fig. 13.21). Restorations that fail to reestablish adequate interproximal embrasure spaces are associated with papillary inflammation. Undercontoured crowns that lack a protective height of contour do not retain as much plaque as overcontoured crowns and therefore may not be as detrimental during mastication as once thought.[209]

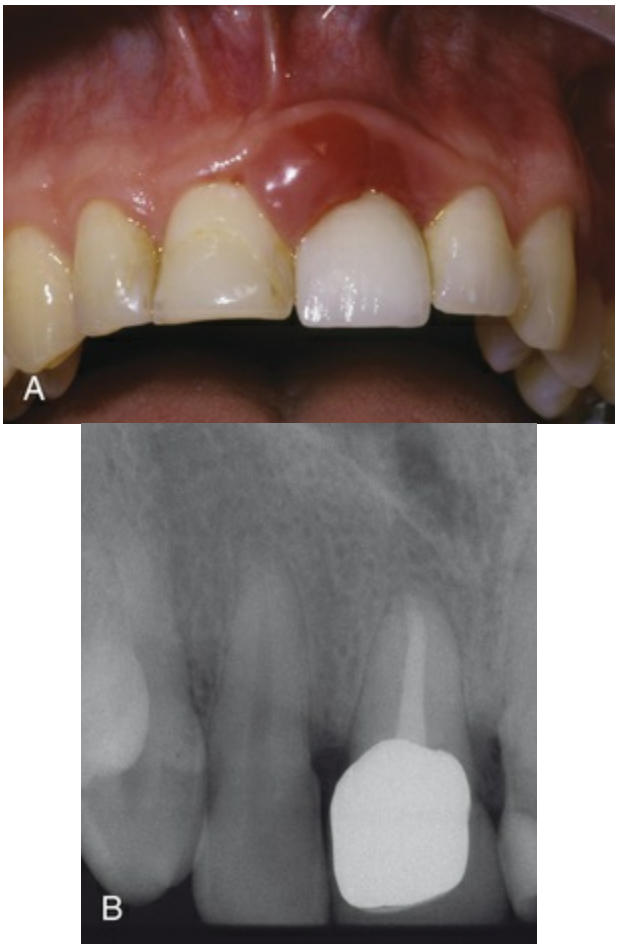


FIG. 13.21 (A) Inflamed marginal and papillary gingiva adjacent to an overcontoured porcelain-fused-to-metal crown on the maxillary left central incisor. (B) Radiograph of an ill-fitting porcelain-fused-to-metal crown.

Clinical Correlation

Overcontoured crowns are more detrimental to periodontal health than undercontoured crowns.

The contour of the occlusal surface as established by the marginal ridges and related developmental grooves normally serves to deflect food away from the interproximal spaces. The optimal cervico-occlusal location for a posterior contact is at the longest mesiodistal diameter of the tooth, which is generally just apical to the crest of the marginal ridge. The integrity and location of the proximal contacts along with the contour of the marginal ridges and developmental grooves typically prevent interproximal food impaction. *Food impaction* is the forceful wedging of food into the periodontium by occlusal forces. As the teeth wear down, their originally convex proximal surfaces become flattened, and the wedging effect of the opposing cusp is exaggerated. Cusps that tend to forcibly wedge food into interproximal embrasures are known as *plunger cusps.* The interproximal plunger cusp effect may also be observed when missing teeth are not replaced and the relationship between the proximal contacts of adjacent teeth is altered. An intact proximal contact precludes the forceful wedging of food into the interproximal embrasure space, whereas a light or open contact is conducive to impaction.

Flash Back

Posterior teeth with open contact and food impaction exhibit greater probing depth and clinical attachment loss than contralateral control sites without food impaction.

The classic analysis of the factors that lead to food impaction was made by Hirschfeld,[73] who recognized the following factors: uneven occlusal wear, opening of the contact point as a result of loss of proximal support or from extrusion, congenital morphologic abnormalities, and improperly constructed restorations.

The presence of the previously mentioned abnormalities does not necessarily lead to food impaction and periodontal disease. A study

of interproximal contacts and marginal ridge relationships[101] in three groups of periodontally healthy males revealed that 4.9% to 62.5% of the proximal contacts were defective and that 33.5% of adjacent marginal ridges were uneven.[140] However, greater probing depth and a loss of clinical attachment have been reported for sites that exhibited both an open contact and food impaction as compared with contralateral control sites without open contacts or food impaction.[81] Excessive anterior overbite is a common cause of food impaction on the lingual surfaces of the maxillary anterior teeth and the facial surfaces of the opposing mandibular teeth. These areas may be exemplified by attachment loss with gingival recession.

Materials

In general, restorative materials are not in themselves injurious to the periodontal tissues.[6,88] One exception to this may be self-curing acrylics[203] (Fig. 13.22).

FIG. 13.22 Inflamed palatal gingiva associated with a maxillary provisional acrylic partial denture. Note the substantial difference in color of the inflamed gingiva adjacent to the premolars and the first molar as compared with the gingiva adjacent to the second molar.

Plaque that forms at the margins of restorations is similar to that found on adjacent nonrestored tooth surfaces. The composition of plaque formed on all types of restorative materials is similar, with the exception of that formed on silicate.[135] Although surface textures of restorative materials differ with regard to their capacity to retain

plaque,[206] all can be adequately cleaned if they are polished and accessible to methods of oral hygiene.[138,184] The undersurface of pontics in fixed bridges should barely touch the mucosa. Access for oral hygiene is inhibited with excessive pontic-to-tissue contact, thereby contributing to plaque accumulation that will cause gingival inflammation and possibly the formation of pseudopockets.[50,181]

Design of Removable Partial Dentures

Several investigations have shown that, after the insertion of partial dentures, mobility of the abutment teeth, gingival inflammation, and periodontal pocket formation all increase.[18,29,174] This is because partial dentures favor the accumulation of plaque, particularly if they cover the gingival tissue. Partial dentures that are worn during both night and day induce more plaque formation than those worn only during the daytime.[18] These observations emphasize the need for careful and personalized oral hygiene instruction to avoid the harmful effects of partial dentures on the remaining teeth and the periodontium.[13] The presence of removable partial dentures induces not only quantitative changes in dental plaque[57] but also qualitative changes, thereby promoting the emergence of spirochetal microorganisms.[56]

Restorative Dentistry Procedures

The use of rubber dam clamps, matrix bands, and burs in such a manner as to lacerate the gingiva results in varying degrees of mechanical trauma and inflammation. Although such transient injuries generally undergo repair, they are needless sources of discomfort to the patient. The forceful packing of a gingival retraction cord into the sulcus to prepare the subgingival margins of a tooth or for the purpose of obtaining an impression may mechanically injure the periodontium and leave behind impacted debris that is capable of causing a foreign body reaction.

Malocclusion

The irregular alignment of teeth as found in cases of malocclusion may facilitate plaque accumulation and make plaque control more

difficult. Several authors have found a positive correlation between crowding and periodontal disease,[28,145,190] whereas other investigators did not find such a correlation.[55] Uneven marginal ridges of contiguous posterior teeth have been found to have a low correlation with pocket depth, loss of attachment, plaque, calculus, and gingival inflammation.[90] Roots of teeth that are prominent in the arch (Fig. 13.23)—such as in a buccal or lingual version or that are associated with a high frenal attachment and small quantities of attached gingiva—frequently exhibit recession.[1,124]

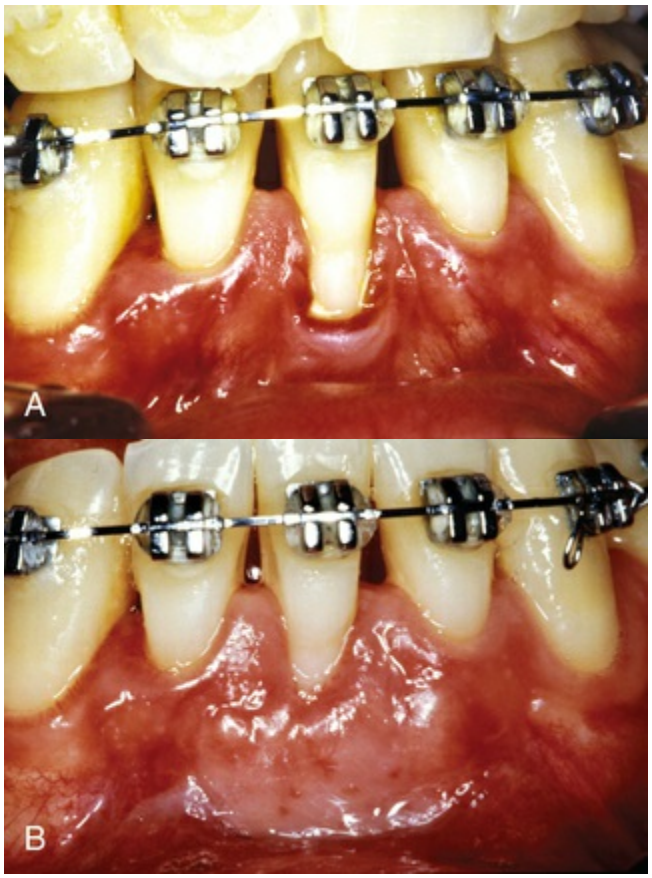

FIG. 13.23 (A) Lower incisor showing a prominent root with gingival recession and a lack of attached gingiva. (B) Appearance 3 months after the placement of a free gingival graft, which resulted in a gain in attached gingiva and a reduction in gingival recession.

The failure to replace missing posterior teeth may have adverse consequences on the periodontal support for the remaining teeth.[31] The following hypothetical scenario illustrates the possible

ramifications of not replacing a missing posterior tooth. When the mandibular first molar is extracted, the initial change is a mesial drifting and tilting of the mandibular second and third molars with extrusion of the maxillary first molar. As the mandibular second molar tips mesially, its distal cusps extrude and act as plungers. The distal cusps of the mandibular second molar wedge between the maxillary first and second molars and open the contact by deflecting the maxillary second molar distally. Subsequently, food impaction may occur and may be accompanied by gingival inflammation with the eventual loss of the interproximal bone between the maxillary first and second molars. This example does not occur in all cases in which mandibular first molars are not replaced. However, the drifting and tilting of the remaining teeth with an accompanying alteration of the proximal contacts is generally a consequence of not replacing posterior teeth that have been extracted.

Tongue thrusting exerts excessive lateral pressure on the anterior teeth, which may result in the spreading and tilting of the anterior teeth (Fig. 13.24). Tongue thrusting is an important contributing factor to tooth migration and the development of an anterior open bite.[30] Mouth breathing may be observed in association with a habit of tongue thrusting and an anterior open bite. Marginal and papillary gingivitis is frequently encountered in the maxillary anterior sextant in cases that involve an anterior open bite with mouth breathing. However, the role of mouth breathing as a local causative factor is unclear, because conflicting evidence has been reported.[3,77,78,190]

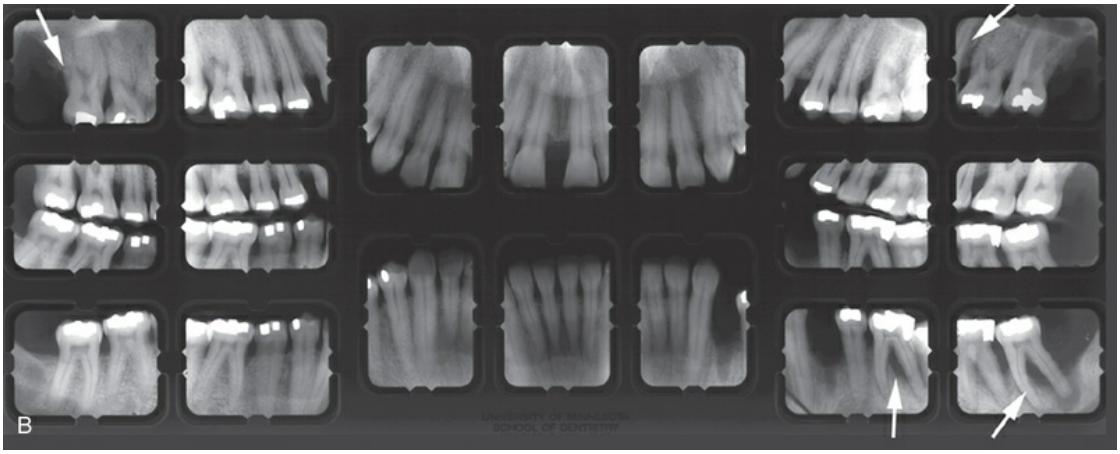

FIG. 13.24 (A) Anterior open bite with flared incisors as observed in association with a habit of tongue thrusting. (B) Radiographs show severe periodontal destruction *(arrows)* in the molar regions.

Restorations that do not conform to the occlusal pattern of the mouth result in occlusal disharmonies that may cause injury to the supporting periodontal tissues. More issues involving deeper initial probing depths, worse prognoses, and greater mobility have been observed for teeth with occlusal discrepancies as compared with teeth without initial occlusal discrepancies.[69,139] Histologic features of the periodontium for a tooth that has been subjected to traumatic occlusion include a widened subcrestal periodontal ligament space, a reduction in the collagen content of the oblique and horizontal fibers, an increase in vascularity and leukocyte infiltration, and an increase in the number of osteoclasts on bordering alveolar bone.[15] However, these observations are generally apical and separate from the bacteria-induced inflammation that occurs at the base of the sulcus. On the basis of current human trials, it is still impossible to definitively answer the question, "Does occlusal trauma modify the progression of periodontal attachment loss that is associated with periodontal inflammation?"[176] (See Chapter 55 for a more detailed explanation of periodontal trauma from occlusion and the periodontal response to external forces.)

Periodontal Complications Associated With Orthodontic Therapy

Orthodontic therapy may affect the periodontium by favoring

plaque retention, by directly injuring the gingiva as a result of overextended bands, and by creating excessive forces, unfavorable forces, or both on the tooth and its supporting structures.

Plaque Retention and Composition

Orthodontic appliances tend to retain bacterial plaque and food debris, thereby resulting in gingivitis (Fig. 13.25), and they are also capable of modifying the gingival ecosystem. Scanning electron microscopic examination of the orthodontic bracket–tooth junction shows that excess bonding composite around the bracket base creates a critical site for plaque accumulation due to its rough surface texture and the presence of a distinct gap at the composite–-enamel interface. A complex community of bacterial plaque may be noted on the excess composite material within 2 to 3 weeks after bonding.[189] An increase in *Prevotella melaninogenica, Prevotella intermedia,* and *Actinomyces odontolyticus* and a decrease in the proportion of facultative microorganisms was detected in the gingival sulcus after the placement of orthodontic bands.[40] More recently, *A. actinomycetemcomitans* was found in at least one site in 85% of children who were wearing orthodontic appliances.[143] By contrast, only 15% of unbanded control subjects were positive for *A. actinomycetemcomitans*.

FIG. 13.25 Gingival inflammation and enlargement associated with an orthodontic appliance and poor oral hygiene.

Key Fact

Orthodontic treatment should not be commenced in the presence of uncontrolled periodontal disease because it will worsen the periodontal condition.

Gingival Trauma and Alveolar Bone Height

Orthodontic treatment is often started soon after the eruption of the permanent teeth, when the junctional epithelium is still adherent to the enamel surface. Orthodontic bands should not be forcefully placed beyond the level of attachment, because this will detach the gingiva from the tooth and result in the apical proliferation of the junctional epithelium with an increased incidence of gingival recession.[146]

Key Fact

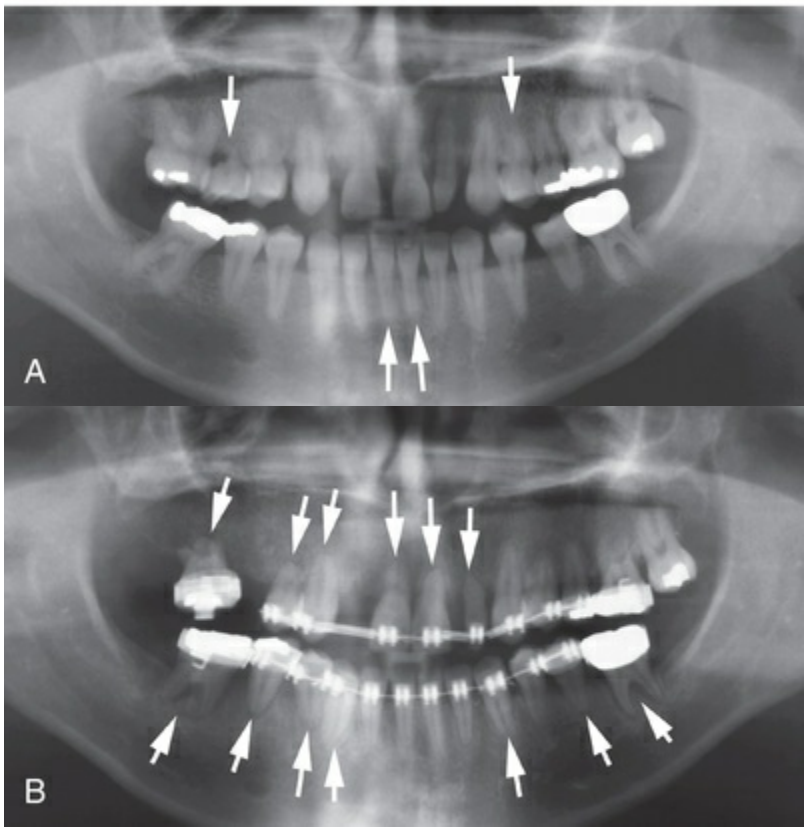
Adult patients planning to undergo orthodontic care should undergo pretreatment assessment for their periodontal status and potential risk for root resorption.

The mean alveolar bone loss per patient for adolescents who underwent 2 years of orthodontic care during a 5-year observation period ranged between 0.1 and 0.5 mm.[21] This small magnitude of alveolar bone loss was also noted in the control group and therefore is considered to be of little clinical significance. However, the degree of bone loss during adult orthodontic care may be higher than that observed in adolescents,[113] especially if the periodontal condition is not treated before the initiation of orthodontic therapy. Orthodontic treatment in adults with active periodontitis (evidenced by deep pockets and bleeding on probing) has been shown to accelerate the periodontal disease process.[8,45,212]

Tissue Response to Orthodontic Forces

Orthodontic tooth movement is possible because the periodontal tissues are responsive to externally applied forces.[158,173] Alveolar

bone is remodeled by osteoclasts that induce bone resorption in areas of pressure and by osteoblasts that form bone in areas of tension. Although moderate orthodontic forces ordinarily result in bone remodeling and repair, excessive force may produce necrosis of the periodontal ligament and the adjacent alveolar bone.[149-151] Excessive orthodontic forces also increase the risk of apical root resorption.[25,26] The prevalence of severe root resorption (i.e., resorption of more than one-third of the root length) during orthodontic therapy in adolescents has been reported to be 3%.[83] The incidence of moderate to severe root resorption for incisors among adults aged 20 to 45 years has been reported to be 2% before treatment and 24.5% after treatment.[113] Risk factors associated with root resorption during orthodontic treatment include the duration of treatment, the magnitude of the force applied, the direction of the tooth movement, and the continuous versus intermittent application of forces[148] (Fig. 13.26).



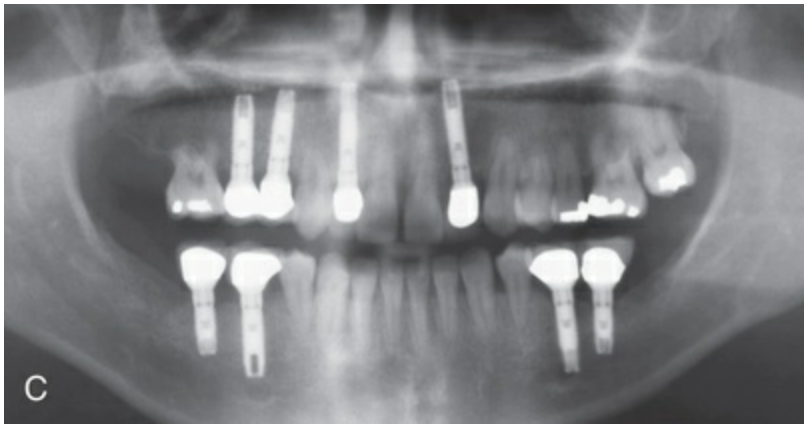


FIG. 13.26 (A) Panoramic radiograph illustrating that a limited degree of pretreatment root resorption *(arrows)* existed before orthodontic care. (B) Note that several roots have undergone severe resorption *(arrows)* during 4 years of intermittent orthodontic treatment. (C) The teeth that developed extensive root resorption with accompanying hypermobility have been extracted and replaced with implant-supported crowns.

Key Fact

It is important to avoid excessive force and too-rapid tooth movement during orthodontic treatment to prevent injury to the periodontium.

The use of elastics to close a diastema may result in severe attachment loss with possible tooth loss as the elastics migrate apically along the root surface (Fig. 13.27). The surgical exposure of impacted teeth and orthodontic-assisted eruption has the potential to compromise periodontal attachment on adjacent teeth (Fig. 13.28). However, the majority of impacted teeth that are surgically exposed and aided in their eruption by orthodontic treatment subsequently exhibited more than 90% of their attachment as being intact.[72]

FIG. 13.27 (A) Maxillary central incisors for which an elastic ligature was used to close a midline diastema. Note the inflamed gingiva and the deep probing depths. (B) Reflection of a full-thickness mucoperiosteal flap reveals elastic ligature *(arrow)* and angular intrabony defects around the central incisors.

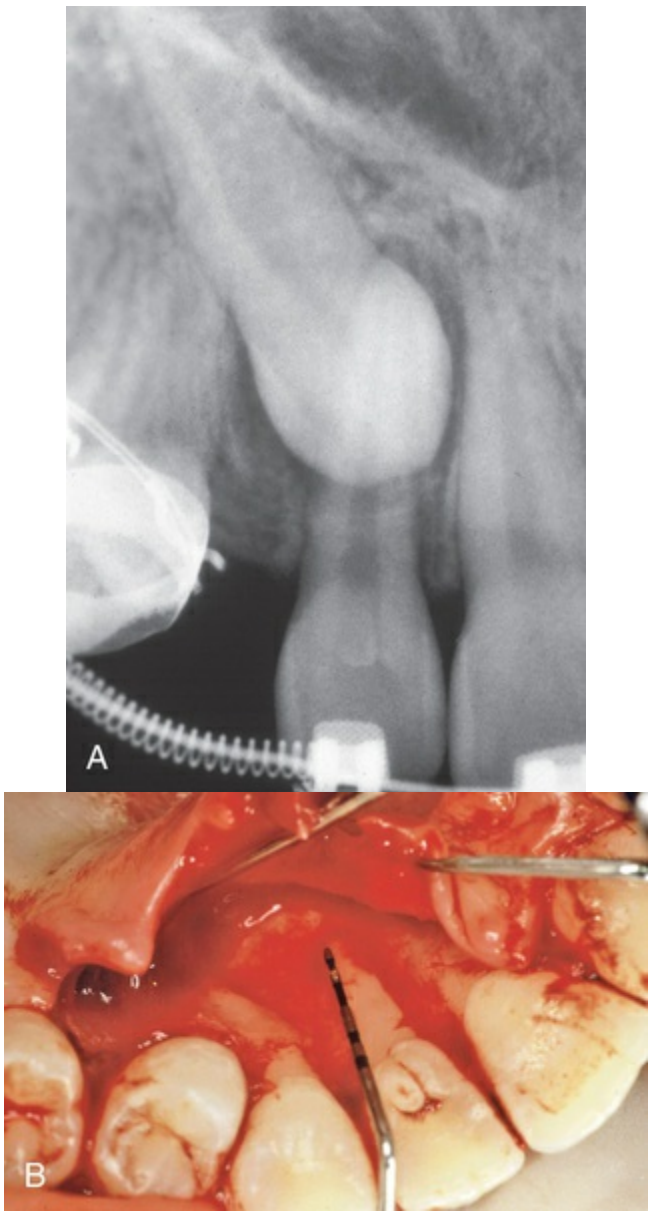

FIG. 13.28 (A) Radiograph of an impacted maxillary canine that required surgical exposure and orthodontic assistance to erupt. (B) A palatal flap is reflected to reveal bony dehiscence on the maxillary lateral incisor after orthodontic therapy.

It has been reported that the dentoalveolar gingival fibers that are located within the marginal and attached gingiva are stretched when teeth are rotated during orthodontic therapy.[41] The surgical severing or removal of these gingival fibers in combination with a brief period of retention may reduce the incidence of relapse after orthodontic treatment that is intended to realign rotated teeth.[24,126]

Extraction of Impacted Third Molars

Numerous clinical studies have reported that the extraction of impacted third molars often results in the creation of vertical defects distal to the second molars.[9,96,121] This iatrogenic effect is unrelated to flap design,[153] and it appears to occur more often when third molars are extracted from individuals who are more than 25 years old.[9,96,121] Other factors that appear to play a role in the development of lesions on the distal surface of second molars—particularly in those who are more than 25 years old—include the presence of visible plaque, bleeding on probing, root resorption in the contact area between the second and third molars, the presence of a pathologically widened follicle, the inclination of the third molar, and the close proximity of the third molar to the second molar (Fig. 13.29).[96] Other potential iatrogenic adverse consequences of the removal of third molars include permanent paresthesia (i.e., numbness of the lip, tongue, and cheek), damage to adjacent teeth, mandibular fracture, maxillary tuberosity fracture, displacement of third molars and root tips, oro-antral communications or fistula, and temporomandibular joint complications.[23] Permanent paresthesia occurs at a frequency of approximately 1 of every 100,000 wisdom teeth removed in the United States.[53] The incidence of damage to second molar as a consequence of third molar extraction has been estimated to be 0.3% to 0.4%.[33] Although the incidence of mandibular fracture during or after third molar removal is low (0.003% to 0.005%),[105] it may pose important medicolegal and patient care implications. Iatrogenic displacement of a maxillary third molar into the maxillary sinus[144,210] and displacement of a mandibular third molar into the sublingual, submandibular, pterygomandibular, and lateral pharyngeal spaces[47,210] have been reported with unknown incidence rates.

FIG. 13.29 Panoramic radiograph illustrating a mesially impacted lower left third molar with a widened follicle and no apparent bone on the distal interproximal surface of the second molar. Alternatively, the lower right third molar is vertically impacted and exhibits interproximal bone distal to the second molar and mesial to the third molar.

« Flash Back

Preoperative use of three-dimensional radiographs in conjunction with extraction of impacted third molars has the potential to minimize the risk of inferior alveolar nerve paresthesia or damage to the adjacent second molar.

For several decades, panoramic radiography has been the standard of choice to assess the state of third molar impaction, including angulation of the tooth, root morphology, root development, related pathology, and, most importantly, the relation between the tooth or roots and the mandibular canal. However, when an overprojection is observed between the impacted third molar and the mandibular canal, or when specific signs suggest a close contact between the third molar and the mandibular canal, CBCT is recommended to be more beneficial in proper treatment planning[123] (Fig. 13.30).

FIG. 13.30 Segmented panoramic images. (A and B) Overprojection between the impacted third molar and the mandibular canal. (C) Signs of close contact between the third molar and the mandibular canal. (D through F) Corresponding core-beam computed tomographic images (axial views) of the impacted third molars reveal the path of the inferior alveolar nerve *(arrow)* (D) lingual to the root, (E) surrounded by three segments of the root, and (F) buccal to the root. (Courtesy Dr. Mansur Ahmad, Minneapolis, MN.)

Habits and Self-Inflicted Injuries

Patients may not be aware of their self-inflicted injurious habits that may be important to the initiation and progression of their periodontal disease. Mechanical forms of trauma can stem from the improper use of a toothbrush, the wedging of toothpicks between the teeth, the application of fingernail pressure against the gingiva (Fig. 13.31), pizza burns, and other causes.[20] Sources of chemical irritation include the topical application of caustic medications such as aspirin or cocaine, allergic reactions to toothpaste or chewing gum, the use of chewing tobacco, and concentrated mouthrinses.[177] Accidental and iatrogenic gingival injuries may be caused by a

variety of chemical, physical, and thermal sources, yet they are generally self-limited. Iatrogenic injuries are often acute, whereas factitious injuries tend to be more chronic in nature.[157]

FIG. 13.31 Gingival recession on a maxillary canine caused by self-inflicted trauma from the patient's fingernail.

« Flash Back

Sources of self-inflicted injuries include improper use of toothbrushes, wedging toothpicks between teeth, application of fingernail pressure against gingiva, and pizza burn. Chemical sources include topical application of caustic medications such as aspirin or cocaine, allergic reaction to toothpaste or chewing gum, use of chewing tobacco, and concentrated mouthrinses.

Trauma Associated With Oral Jewelry

The use of piercing jewelry in the lip or tongue has become more common among teenagers and young adults (Fig. 13.32A). However, piercings are associated with potential complications including gingival injury or recession[70,100,104,213,217]; damage to teeth, restorations, and fixed porcelain prostheses[48,54,70,104]; increased salivary flow[54,197]; interference with speech, mastication, or deglutition[84,198]; scar tissue formation[197]; and development of metal hypersensitivities.[93]

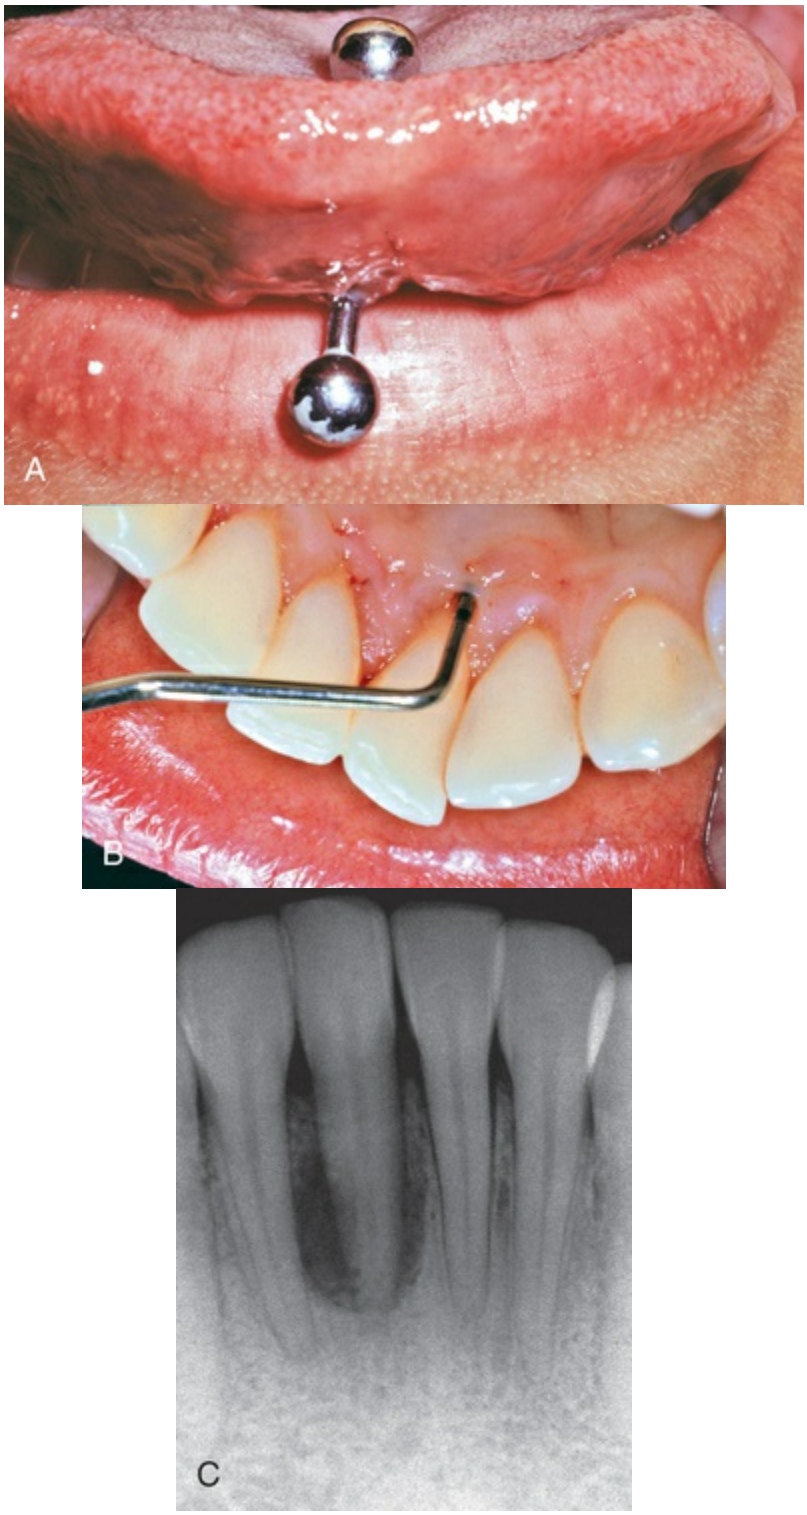

FIG. 13.32 (A) Tongue pierced with oral jewelry. (B) Probing depth of 8 mm with 10 mm of clinical attachment loss on the lingual surface of the lower central incisor adjacent to the oral jewelry in the pierced tongue. The central incisor was found to be vital. (C) Bone loss associated with a tongue pierced by oral jewelry. (B, Courtesy Dr. Leonidas Batas, Thessaloniki, Greece.)

« Flash Back

Use of tongue or lip piercing jewelry is associated with localized gingival recession and periodontitis.

Whittle and Lamden[207] surveyed 62 dentists and found that 97% had seen patients with either lip- or tongue-piercing jewelry within the previous 12 months. The incidence of lingual recession with pocket formation (Fig. 13.32B) and radiographic evidence of bone loss (Fig. 13.32C) was 50% among subjects with a mean age of 22 years who wore lingual "barbells" for 2 years or longer.[38] Chipped lower anterior teeth were noted in 47% of the patients who wore tongue-piercing jewelry for 4 years or longer. Patients need to be informed of the risks of wearing oral jewelry and cautioned against such practices.

Toothbrush Trauma

Abrasions of the gingiva as well as alterations in tooth structure may result from aggressive toothbrushing in a horizontal or rotary fashion. The deleterious effect of excessively forceful brushing is accentuated when highly abrasive dentifrices are used. The gingival changes that are attributable to toothbrush trauma may be acute or chronic. The acute changes vary with regard to their appearance and duration, from scuffing of the epithelial surface to denudation of the underlying connective tissue with the formation of a painful gingival ulcer (Fig. 13.33). Diffuse erythema and denudation of the attached gingiva throughout the mouth may be a striking result of overzealous brushing. Signs of acute gingival abrasions are frequently noted when the patient first uses a new brush. Puncture lesions may be produced when heavy pressure is applied to firm bristles that are aligned perpendicular to the surface of the gingiva. A forcibly embedded toothbrush bristle can be retained in the gingiva and cause an acute gingival abscess.

FIG. 13.33 The overzealous use of a toothbrush resulted in denudation of the gingival epithelial surface and exposure of the underlying connective tissue as a painful ulcer.

Chronic toothbrush trauma results in gingival recession with denudation of the root surface. Interproximal attachment loss is generally a consequence of bacteria-induced periodontitis, whereas buccal and lingual attachment loss is frequently the result of toothbrush abrasion.[185] The improper use of dental floss may result in lacerations of the interdental papilla.

Chemical Irritation

Acute gingival inflammation may be caused by chemical irritation that results from either sensitivity or nonspecific tissue injury. In allergic inflammatory states, the gingival changes range from simple erythema to painful vesicle formation and ulceration. Severe reactions to ordinarily innocuous mouthwashes, dentifrices, and denture materials are often explainable on this basis.

Acute inflammation with ulceration may be produced by the nonspecific injurious effect of chemicals on the gingival tissues. The indiscriminate use of strong mouthwashes, the topical application of corrosive drugs such as aspirin (Fig. 13.34) or cocaine, and accidental contact with drugs such as phenol or silver nitrate are common examples of chemical exposures that cause irritation of the gingiva. A histologic view of an aspirin-induced chemical burn shows vacuoles with serous exudates and an inflammatory infiltrate in the connective tissue (Fig. 13.35).

FIG. 13.34 Chemical burn caused by aspirin; note the sloughing gingival tissue and the resultant recession.

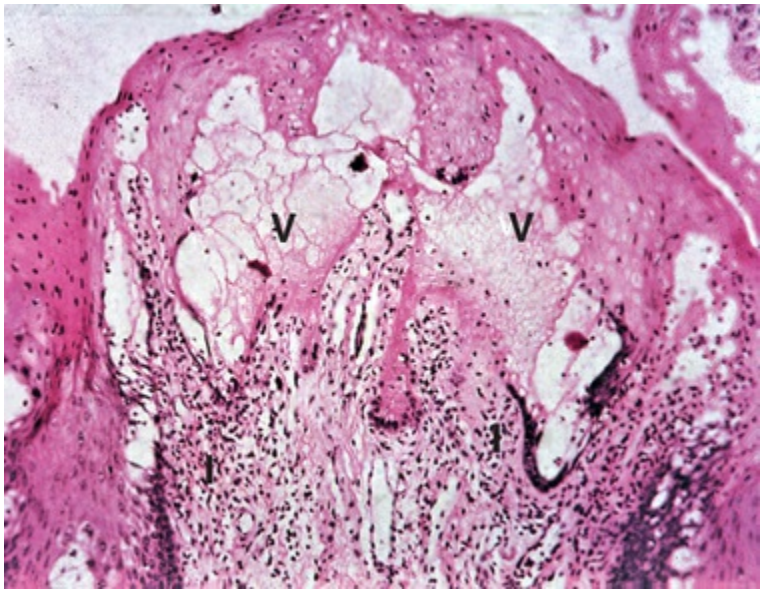

FIG. 13.35 Biopsy of an aspirin-induced chemical burn. Note the intraepithelial vesicles *(V)* and inflammatory infiltrate *(I)* within the underlying connective tissue.

Smokeless Tobacco

Snuff and chewing tobacco constitute the two main forms of smokeless tobacco. Snuff is a fine-cut form of tobacco that is available loosely packed or in small sachets. Chewing tobacco is a more coarse-cut tobacco that is available in the form of loose leaves,

a solid block, a plug, or a twist of dried leaves. Chewing tobacco is typically placed in the mandibular buccal vestibule for several hours, during which time saliva and dilute tobacco are periodically expectorated.[204] The nicotine uptake of smokeless tobacco is similar to that of smoking cigarettes in that the consumption of a 34-gram container of smokeless tobacco is approximately equal to 1.5 packs of cigarettes.[64] Many professional baseball players use chewing tobacco. The perceived benefits of chewing tobacco are those derived from nicotine, including improved mental alertness, diminished reaction time, muscle relaxation, and reduced anxiety and appetite.[65,163] A 1990 survey of 1109 professional baseball players in the United States reported that 39% of the players used smokeless tobacco, with 46% of the users exhibiting leukoplakia within the gingiva or the mucosa (Fig. 13.36).[46] Histologic features of oral leukoplakia associated with smokeless tobacco include (1) a chevron-like pattern of hyperkeratosis with focal areas of inflammation and (2) hyperplasia in the basal cell layer (Fig. 13.37). Increased incidences of gingival recession, cervical root abrasion, and root caries have been reported with the use of smokeless tobacco (Fig. 13.38).[141,164,165,194]

FIG. 13.36 Oral leukoplakia in the vestibule associated with the use of smokeless tobacco.

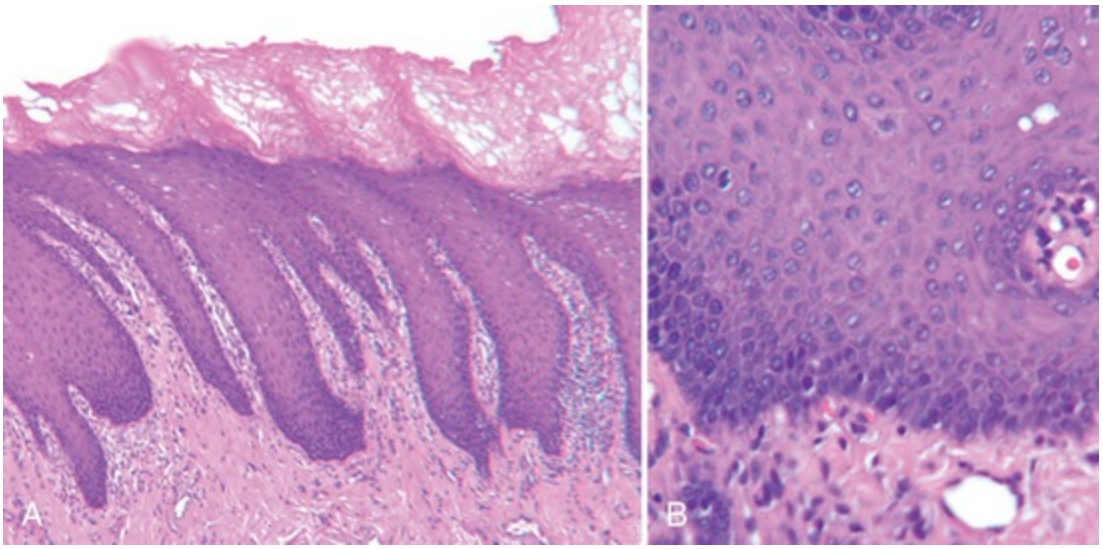

FIG. 13.37 (A) Histologic features of oral leukoplakia associated with smokeless tobacco. Note the chevron-like pattern of hyperkeratosis with focal areas of inflammation. (B) Hyperplasia in the basal cell layer.

FIG. 13.38 Oral leukoplakia, recession, and clinical attachment loss associated with the use of smokeless tobacco.

The incidence of gingival recession among adolescents who use smokeless tobacco has been reported to be 42%, compared with 17% among nonusers.[36,122,124,128] The Third National Health and Nutrition Examination Survey (NHANES III) investigated the adverse effect of smokeless tobacco on the periodontium and found double the incidence of severe periodontitis (odds ratio, 2.1; 95% confidence interval, 1.2 to 3.7) among 12,932 adults who used

smokeless tobacco but who never smoked cigarettes.[49] However, Bergstrom and colleagues found similar incidences of severe periodontitis among both smokeless tobacco users and nonusers.[14] It can be concluded that the use of smokeless tobacco is associated with at least localized gingival recession, clinical attachment loss, leukoplakia, and possibly enhanced susceptibility to severe periodontitis.

Radiation Therapy

Radiation therapy has cytotoxic effects on both normal cells and malignant cells. A typical total dose of radiation for head and neck tumors is in the range of 5000 to 8000 centigray (cGy); 1 cGy is equal to 1 radiation absorbed dose (rad) and equivalent to 50 to 80 Sieverts (Sv).[147] The total dose of radiation is usually given in partial incremental doses, and this is referred to as *fractionation.* Fractionation helps to minimize the adverse effects of radiation while maximizing the death rate for the tumor cells.[51] Fractionated doses are typically administered in the range of 100 to 1000 cGy or 1 to 10 Sv per week.

Radiation treatment induces an obliterative endarteritis that results in soft tissue ischemia and fibrosis; irradiated bone becomes hypovascular and hypoxic.[119] Adverse effects of head and neck radiation therapy include dermatitis and mucositis of the irradiated area as well as muscle fibrosis and trismus, which may restrict access to the oral cavity.[166] The mucositis typically develops 5 to 7 days after radiation therapy is initiated. The severity of the mucositis can be reduced by asking the patient to avoid secondary sources of irritation (e.g., smoking, alcohol, spicy foods) to the mucous membrane. The use of a chlorhexidine digluconate mouthrinse may help to reduce the mucositis.[155] However, most chlorhexidine mouthrinses currently available in the United States have a high alcohol content that may act as an astringent, which dehydrates the mucosa and thus intensifies the pain. Saliva production is permanently impaired when salivary glands that are located within the portal of radiation receive 6000 cGy (60 Sv) or more.[120] Xerostomia results in greater plaque accumulation and a reduced buffering capacity of saliva. Effective oral hygiene,

professional dental prophylactic cleanings, fluoride applications, and frequent dental examinations are essential to control caries and periodontal disease. The use of customized trays appears to be a more effective method for fluoride application compared with the toothbrush.[89]

Among cancer patients who were treated with high-dose unilateral radiation, periodontal attachment loss and tooth loss were reported to be greater on the irradiated site compared with the nonradiated control side of the dentition.[44] Patients who are diagnosed with oral cancer and who require radiation therapy should ideally be assessed for dental needs (i.e., mucositis, xerostomia, faulty restorations, periapical lesion, coronal and cervical decay, and periodontal status) before the initiation of radiation treatment.[68] The treatment and prevention of trismus, oral fungal infections, odontogenic infections, osteoradionecrosis, decay, and periodontal disease are critical to minimize oral morbidity for these patients. Dental and periodontal infections have the potential to be severe risks for patients who have been treated with head and neck radiation. The risk of osteoradionecrosis for oncology patients can be minimized by evaluating their oral status, providing dental care, and allowing time for tissue repair before the commencement of radiotherapy.[91]

Oral conditions that increase the risk of osteoradionecrosis for patients about to undergo radiation therapy for oral malignancies include periodontal probing depths of more than 5 mm, dental plaque score of more than 40%, and alveolar bone loss of more than 60%.[87] Nonrestorable teeth and teeth with significant periodontal problems should be extracted before radiation therapy to reduce the risk of postradiotherapy osteoradionecrosis.[91] (See Chapter 39 for more detail regarding the periodontal management of medically compromised patients.)

The risk of osteoradionecrosis must be evaluated before the performance of atraumatic extractions or limited periodontal surgical procedures in previously irradiated sites. Therefore, the dentist may choose to consult with the patient's oncologist before the initiation of dental therapy. A randomized multicenter clinical trial questioned the merit of using hyperbaric oxygen therapy to treat osteoradionecrosis because, at 1 year after treatment, only 19%

of test subjects had responded to hyperbaric oxygen therapy, compared with 32% of placebo subjects.[5] The administration of the combination of pentoxifylline with vitamin E as antioxidant therapy currently shows the greatest promise for revascularization and treatment of osteoradionecrosis sites.[39]

Case Scenario 13.1

Patient:
42 year old male

Chief Complaint:
'I need dental cleaning and I have bad breath'

Background Information
Patient is a current smoker (smokes a pack of cigarettes a day), did not report any systemic conditions, is not on any medications, and has no known drug allergies. His last dental cleaning was done 10 years ago. Patient denies flossing but reports brushing once a day.

Current Findings:
Probing depths were in the range of 2 to 4 mm; difficulty in probing the mandibular buccal areas due to extensive calculus buildups. Bleeding on probing was 55% with poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Does calculus *per se* cause gingival inflammation? A. Yes B. No	**Answer: B** **Explanation:** Calculus by itself does not cause gingival inflammation, but it acts as a retentive factor (nidus) for dental plaque (as shown in the above image), which in turn causes gingival inflammation.
2. Complete removal of subgingival calculus is feasible with thorough scaling and root planing in pockets deeper than 6 mm. A. True B. False	**Answer: B** **Explanation:** Even with thorough scaling and root planing, leaving some remnants of subgingival calculus on the root surface, especially in deeper pockets, is unavoidable.
3. Which of the following is NOT a tooth-associated retentive factor (like dental calculus) that can retain plaque and cause gingival inflammation? A. Open crown margins B. Overhanging restoration C. Occlusal caries D. Furcation involvement	**Answer: C** **Explanation:** Open cavitation (due to caries) in the occlusal surface of a tooth can accumulate food debris and plaque but is too far from gingiva to induce inflammation. With A, B, or D, the nearness of plaque (that is retained) to gingiva initiates inflammation.

Clinical Correlation

Use of smokeless tobacco has been associated with localized gingival leukoplakia, recession, clinical attachment loss, and increased susceptibility to severe periodontitis.

Hematologic Disorders and Immune Deficiencies
Genetic Disorders
Stress and Psychosomatic Disorders
Nutritional Influences
Medications
Other Systemic Conditions
Conclusion

Many systemic diseases, disorders, and conditions have been implicated as risk indicators or risk factors in periodontal disease. Clinical and basic science research over the past several decades has led to an improved understanding of and appreciation for the complexity and pathogenesis of periodontal diseases.[193] Although

there is clear evidence for a bacterial etiology and there are specific bacteria (periodontal pathogens) associated with destructive periodontal disease, the presence of these pathogens does not invariably cause disease. Their absence, on the other hand, appears to be consistent with periodontal health. The role of bacteria in disease etiology and pathogenesis is discussed in Chapters 7 and 8.

Perhaps the most significant advance in our understanding of the pathogenesis of periodontitis is that the host response varies among individuals and that an altered, deficient, or exaggerated host immune response to bacterial pathogens may lead to more severe forms of the disease. In other words, the individual host immune response to periodontal pathogens is very important and likely explains many of the differences in disease severity observed from one individual to the next. Furthermore, systemic diseases, disorders, and conditions alter host tissues and physiology, which may impair the host's barrier function and immune defense against periodontal pathogens, thereby creating the opportunity for destructive periodontal disease to progress.

Evidence also suggests that periodontal infections can adversely affect systemic health with manifestations such as coronary heart disease, stroke, diabetes, preterm labor, low-birth-weight delivery, and respiratory disease.[171] The role of periodontal infections on these systemic health conditions is discussed in Chapter 15.

The relationships between periodontal infections and host defense are complex. A number of environmental, physical, and psychosocial factors have the potential to alter periodontal tissues and the host immune response, thereby resulting in more severe periodontal disease expression. It is important to recognize that the systemic diseases, disorders, or conditions themselves do not cause periodontitis; rather, they may predispose, accelerate, or otherwise increase the disease's progression. This chapter discusses important systemic diseases, disorders, and conditions that have the potential to influence periodontal health.

Endocrine Disorders and Hormonal Changes

Endocrine diseases such as diabetes and hormonal fluctuations that are associated with puberty and pregnancy are well-known examples of systemic conditions that adversely affect the condition of the periodontium. Endocrine disturbances and hormone fluctuations affect the periodontal tissues directly, modify the tissue response to local factors, and produce anatomic changes in the gingiva that may favor plaque accumulation and disease progression. This section describes the evidence that supports the relationships among endocrine disorders, hormonal changes, and periodontal disease.

Diabetes Mellitus

Diabetes mellitus is an extremely important disease from a periodontal standpoint. It is a complex metabolic disorder characterized by chronic hyperglycemia. Diminished insulin production, impaired insulin action, or a combination of both result in the inability of glucose to be transported from the bloodstream into the tissues, which in turn results in high blood glucose levels and the excretion of sugar in the urine. Lipid and protein metabolism are altered in diabetes as well. Uncontrolled diabetes (chronic hyperglycemia) is associated with several long-term complications, including microvascular diseases (retinopathy, nephropathy, or neuropathy), macrovascular diseases (cardiovascular and cerebrovascular conditions), increased susceptibility to infections, and poor wound healing. An estimated 25.8 million individuals (both children and adults)—8.3% of the US population—have diabetes.[43] Approximately 7 million of these individuals are unaware that they have the disease.

There are two major types of diabetes, type 1 and type 2, with several less common secondary types. *Type 1 diabetes mellitus,* which was formerly known as *insulin-dependent diabetes mellitus,* is caused by a cell-mediated autoimmune destruction of the insulin-producing beta cells of the islets of Langerhans in the pancreas, which results in insulin deficiency. Type 1 diabetes accounts for 5% to 10% of all cases of diabetes and most often occurs in children and young adults. This type of diabetes results from a lack of insulin production, and it is very unstable and difficult to control. It has a

marked tendency toward ketosis and coma, it is not preceded by obesity, and it requires the injection of insulin to be controlled. Patients with type 1 diabetes mellitus present with the symptoms that are traditionally associated with diabetes, including polyphagia, polydipsia, polyuria, and predisposition to infections.

Type 2 diabetes mellitus, which was formerly known as *non–insulin-dependent diabetes mellitus,* is caused by peripheral resistance to insulin action, impaired insulin secretion, and increased glucose production in the liver. The insulin-producing beta cells in the pancreas are not destroyed by cell-mediated autoimmune reaction. It typically begins as insulin resistance, which leads to the reduced pancreas production of insulin as the demand increases. Type 2 diabetes is the most common form of diabetes, and it accounts for 90% to 95% of all diagnosed cases in adults. Individuals are often not aware they have the disease until severe symptoms or complications occur. Type 2 diabetes generally occurs in obese individuals, and it can often be controlled by diet and oral hypoglycemic agents. Ketosis and coma are uncommon. Type 2 diabetes can manifest with the same symptoms as type 1 diabetes but typically in a less severe form.

An additional category of diabetes is *hyperglycemia* secondary to other diseases or conditions. A prime example of this type of hyperglycemia is gestational diabetes associated with pregnancy. *Gestational diabetes* develops in 2% to 10% of all pregnancies but disappears after delivery. Women who have had gestational diabetes are at increased risk of developing type 2 diabetes. Other secondary types of diabetes are those associated with diseases that involve the pancreas and the destruction of the insulin-producing cells. Endocrine diseases (e.g., acromegaly, Cushing syndrome), tumors, pancreatectomy, and drugs or chemicals that cause altered insulin levels are included in this group. Experimentally induced types of diabetes generally belong in this category rather than in the categories of type 1 or 2 diabetes mellitus.

Key Fact

Diabetes mellitus is an extremely important disease that impacts multiple systems including periodontal health. It is a complex

metabolic disorder characterized by chronic hyperglycemia. Uncontrolled diabetes is associated with long-term complications, including microvascular diseases (retinopathy, nephropathy, or neuropathy), macrovascular diseases (cardiovascular and cerebrovascular conditions), increased susceptibility to infections, and poor wound healing. An estimated 25.8 million individuals (both children and adults)—8.3% of the US population—have diabetes.[43] Approximately 7 million of these individuals are unaware that they have the disease.

Oral Manifestations

Numerous oral changes have been described in patients with diabetes, including cheilosis, mucosal drying and cracking, burning mouth and tongue, diminished salivary flow, and alterations in the flora of the oral cavity, with greater predominance of *Candida albicans,* hemolytic streptococci, and staphylococci.[1,23,103,166] An increased rate of dental caries has also been observed in patients with poorly controlled diabetes.[77,87] It is important to note that these changes are not always present, that they are not specific, and that they are not pathognomonic for diabetes.[169] Furthermore, these changes are less likely to be observed in patients with well-controlled diabetes. Individuals with controlled diabetes have a normal tissue response, a normally developed dentition, a normal defense against infections, and no increase in the incidence of caries.[246]

The influence of diabetes on the periodontium has been thoroughly investigated. Although it is difficult to make definitive conclusions about the specific effects of diabetes on the periodontium, a variety of changes have been described, including a tendency toward an enlarged gingiva, sessile or pedunculated gingival polyps, polypoid gingival proliferations, abscess formation, periodontitis, and loosened teeth[116] (Fig. 14.1). Perhaps the most striking changes in patients with uncontrolled diabetes are the reductions in the defense mechanisms and the increased susceptibility to infections, which lead to destructive periodontal disease. In fact, periodontal disease is considered to be the sixth complication of diabetes.[152] Periodontitis in patients with type 1 diabetes appears to start after the age of 12 years, and it has a

fivefold increased prevalence in teenagers.[50] The prevalence of periodontitis has been reported as 9.8% in 13- to 18-year-old patients, and it increases to 39% in those who are 19 years old and older.

FIG. 14.1 Periodontal condition in patients with diabetes. (A) Adult with diabetes (blood glucose level >400 mg/dL). Note the gingival inflammation, spontaneous bleeding, and edema. (B) The same patient as shown in A. Improved control of diabetes was noted after 4 days of insulin therapy (blood glucose level <100 mg/dL). The clinical periodontal condition has improved without local therapy. (C) Adult patient with uncontrolled diabetes. Note the enlarged, smooth, erythematous gingival margins and papilla in the anterior area. (D) The same patient as shown in C.

This is a lingual view of the right mandibular area. Note the inflamed and swollen tissues in the anterior and premolar areas. (E) Adult patient with uncontrolled diabetes. There is a suppurating abscess on the buccal surface of the maxillary premolars.

The extensive literature on this subject and the overall impression of clinicians indicate that *periodontal disease in patients with diabetes follows no consistent or distinct pattern.* Severe gingival inflammation, deep periodontal pockets, rapid bone loss, and frequent periodontal abscesses often occur in patients with poorly controlled diabetes and poor oral hygiene[3] (Figs. 14.2 and 14.3). Children with type 1 diabetes tend to have more destruction around the first molars and incisors, but this destruction becomes more generalized at older ages.[49] In patients with juvenile diabetes, extensive periodontal destruction often occurs as a consequence of having more severe disease at a younger age.

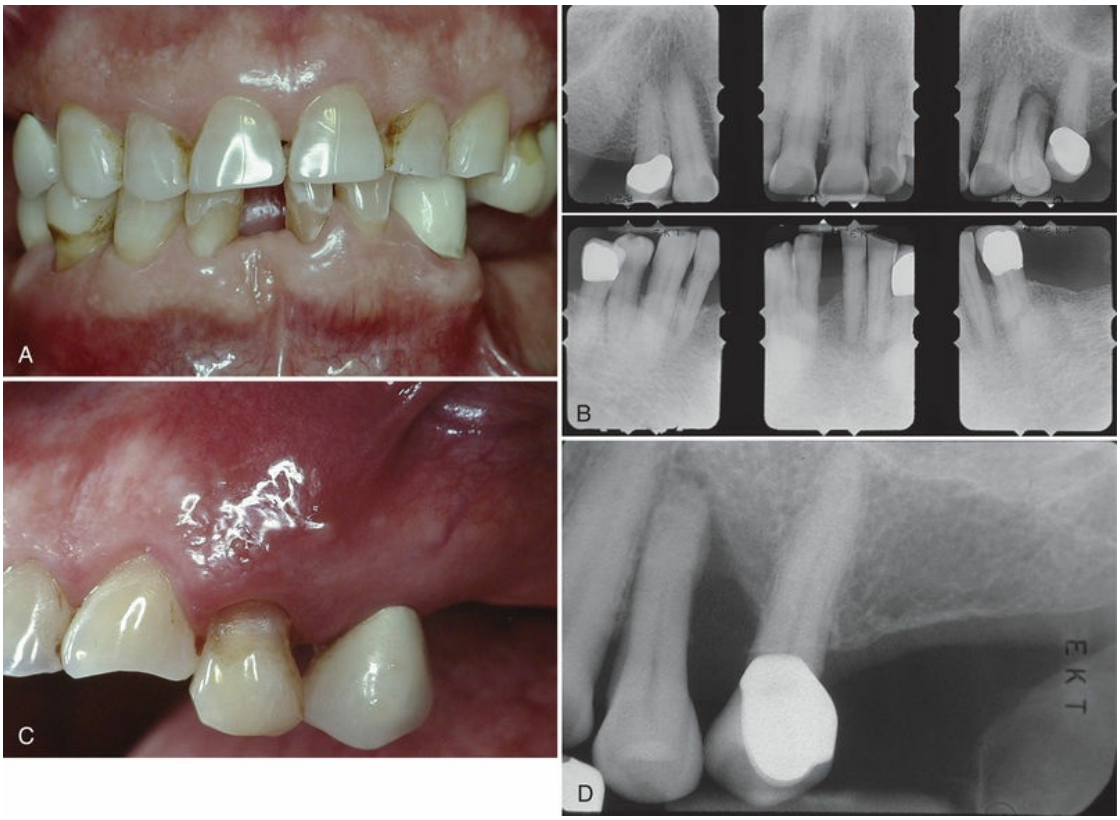

FIG. 14.2 A 60-year-old patient with a long-term history of type 2 diabetes. (A) Anterior retracted view of the patient's dental and periodontal condition. Note the

missing posterior teeth, the supereruption of the premolars, and the mild generalized gingival inflammation. (B) Periapical radiographs of the remaining teeth. Note the mild generalized bone loss with localized areas of severe bone loss. The failure to replace the posterior teeth adds to the occlusal burden of the remaining dentition. (C) Clinical photograph of the maxillary premolar area presenting with abscess. Notice the diffuse erythema and inflammation surrounding the abscess area. (D) Periapical radiograph of the maxillary premolar showing extensive bone loss associated with abscess.

FIG. 14.3 Periodontal abscess in a 28-year-old patient with poorly controlled type 1 diabetes. (A) The patient presented with pain and abscess a few weeks after scaling and root planing of the area. (B) Radiograph of the mandibular right premolar area demonstrating severe localized destruction of bone in the area of periodontal abscess. (C) Radiograph of the mandibular right premolar area taken 2 months before the presentation of the abscess. Note the presence of calculus and the level of interproximal bone before the abscess occurred.

Other investigators have reported that the rate of periodontal destruction appears to be similar for those with diabetes and those without diabetes up to the age of 30 years.[93,240] Older patients with diabetes have a greater degree of periodontal destruction, possibly related to more disease destruction over time. Patients who have had overt diabetes for more than 10 years have a greater loss of periodontal support than those with a diabetic history of less than 10 years.[93] This destruction may also be related to the diminished tissue integrity, which continues to deteriorate over time (see Altered Collagen Metabolism).

Although some studies have not found a correlation between the diabetic state and the periodontal condition, the majority of well-controlled studies show a higher prevalence and severity of periodontal disease in individuals with diabetes compared with nondiabetic persons with similar local factors.[15,23,40,52,113,183,185,187,243] Findings include a greater loss of attachment, increased bleeding on probing, and increased tooth mobility. A study of risk indicators for a group of 1426 patients between the ages of 25 and 74 years revealed that individuals with diabetes were twice as likely to exhibit attachment loss as nondiabetic individuals.[110] The lack of consistency across studies is most likely related to the different degrees of diabetic involvement, variations in the level of disease control and the diversity of indices, and patient sampling from one study to another.

Studies have suggested that uncontrolled or poorly controlled diabetes is associated with an increased susceptibility to and severity of infections, including periodontitis.[17,217] Adults who are 45 years of age or older with poorly controlled diabetes (i.e., with a glycated hemoglobin level >9%) were 2.9 times more likely to have severe periodontitis than those without diabetes. The likelihood was even greater (4.6 times) among smokers with poorly controlled diabetes.[43] As with other systemic conditions associated with periodontitis, diabetes mellitus does not cause gingivitis or periodontitis, but evidence indicates that it alters the response of the periodontal tissues to local factors, thereby hastening bone loss and delaying postsurgical healing. Frequent periodontal abscesses appear to be an important feature of periodontal disease in patients with diabetes.

Approximately 40% of adult Pima Indians in Arizona have type 2 diabetes. A comparison of individuals with and without diabetes in this Native American tribe showed a clear increase in the prevalence of destructive periodontitis as well as a 15% increase in edentulousness among patients with diabetes.[229] The risk of developing destructive periodontitis was increased threefold in these individuals.[74]

Bacterial Pathogens

The glucose content of gingival fluid and blood is higher in individuals with diabetes than in those without diabetes with similar plaque and gingival index scores.[80] The increased glucose in the gingival fluid and blood of patients with diabetes could change the environment of the microflora, thereby inducing qualitative changes in bacteria that may contribute to the severity of periodontal disease observed in those with poorly controlled diabetes.

Patients with type 1 diabetes mellitus and periodontitis have been reported to have a subgingival flora that is composed mainly of *Capnocytophaga*, anaerobic vibrios, and *Actinomyces* species. *Porphyromonas gingivalis, Prevotella intermedia,* and *Aggregatibacter actinomycetemcomitans*, which are common in periodontal lesions of individuals without diabetes, are present in low numbers in those with the disease.[112,167] However, other studies have found scarce *Capnocytophaga* and abundant *A. actinomycetemcomitans* and black-pigmented *Bacteroides* as well as *P. intermedia, Prevotella melaninogenica,* and *Campylobacter rectus*.[166,220] Black-pigmented species—especially *P. gingivalis, P. intermedia,* and *C. rectus*—are prominent in severe periodontal lesions of Pima Indians with type 2 diabetes.[90,275] Although these results may suggest an altered flora in the periodontal pockets of patients with diabetes, the exact role of these microorganisms has not been determined. To date, there is insufficient evidence to support the role of a specific altered microflora that is responsible for periodontal disease destruction in patients with diabetes.

Polymorphonuclear Leukocyte Function

The increased susceptibility of patients with diabetes to infection

has been hypothesized as being caused by polymorphonuclear leukocyte (PMN) deficiencies that result in impaired chemotaxis, defective phagocytosis, or impaired adherence.[170,243] In patients with poorly controlled diabetes, the functions of PMNs, monocytes, and macrophages are impaired.[120] As a result, the primary defense mounted by PMNs against periodontal pathogens is diminished, and bacterial proliferation is more likely. No alteration of immunoglobulin A (IgA), G (IgG), or M (IgM) has been found in patients with diabetes.[210]

Altered Collagen Metabolism

Chronic hyperglycemia impairs collagen structure and function, which may directly impact the integrity of the periodontium. Decreased collagen synthesis, osteoporosis, and a reduction in alveolar bone height have been demonstrated in diabetic animals.[94,224] Chronic hyperglycemia adversely affects the synthesis, maturation, and maintenance of collagen and extracellular matrix. In the hyperglycemic state, numerous proteins and matrix molecules undergo a nonenzymatic glycosylation, thereby resulting in *accumulated glycation end-products* (AGEs). The formation of AGEs occurs at normal glucose levels as well; however, in hyperglycemic environments, AGE formation is excessive. Many types of molecules are affected, including proteins, lipids, and carbohydrates. Collagen is cross-linked by AGE formation, which makes the collagen less soluble and less likely to be normally repaired or replaced. Cellular migration through cross-linked collagen is impeded, and, perhaps more importantly, tissue integrity is impaired as a result of damaged collagen that remains in the tissues for longer periods (i.e., collagen is not renewed at a normal rate).[110] As a result, collagen in the tissues of patients with poorly controlled diabetes is older and more susceptible to pathogenic breakdown (i.e., less resistant to destruction by periodontal infections).

AGEs and receptors for AGEs (RAGEs) play a central role in the classic complications of diabetes,[34] and they may play a significant role in the progression of periodontal disease as well. Poor glycemic control, with the associated increase in AGEs, renders the periodontal tissues more susceptible to destruction.[223] The

cumulative effects of altered cellular response to local factors, impaired tissue integrity, and altered collagen metabolism undoubtedly play a significant role in the susceptibility of patients with diabetes to infections and destructive periodontal disease.

Clinical Correlation

Chronic hyperglycemia impairs collagen structure and function. Chronic hyperglycemia causes proteins and matrix molecules to undergo a non-enzymatic glycosylation, thereby resulting in accumulated glycation end-products (AGEs). AGEs and receptors for AGEs (RAGEs) play a central role in the classic complications of diabetes, and they most likely play a significant role in the progression of periodontal disease as well.

Metabolic Syndrome

Obesity is a global concern with serious health consequences including diabetes mellitus and cardiovascular disease. It is believed that the condition of excess adipose tissue contributes to an increased systemic proinflammatory response in these individuals. Metabolic syndrome is a term used to describe a condition of abdominal obesity combined with two or more of the following metabolic disturbances: hypertension, dyslipidemia, and hyperglycemia. Individuals diagnosed with metabolic syndrome are at increased risk for developing type 2 diabetes mellitus[221] and cardiovascular disease.

Recent evidence suggests that obesity, obesity-related characteristics, and metabolic syndrome in particular may be risk indicators for the severity and progression of periodontitis.[10,142,182,266] Previous studies have documented the relationship between obesity and periodontitis as well as obesity-related characteristics such as body mass index and future progression of periodontal disease.[102] A systematic review that included the results from five prospective studies evaluating the association between weight gain and the incidence of periodontitis in adults found a clear positive relationship: subjects who became overweight and obese had a higher risk of developing periodontitis when compared with those

who did not gain weight.[181] The authors cautioned that the evidence was limited and that more prospective, longitudinal research is needed to establish obesity as a risk factor for periodontitis.

The association between periodontitis and metabolic syndrome is thought to be the result of systemic oxidative stress and an increased inflammatory response.[142] It may be explained by common risk factors such as obesity and obesity-related habits including diet, exercise, and poor oral hygiene.[136] Obesity is associated with increased cytokine production as well as T-cell and monocyte/macrophage dysfunction, factors known to contribute to periodontitis. The proinflammatory cytokines interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α), which are elevated in obese individuals, are thought to be produced by activated macrophages that have infiltrated adipose tissue.[136] Although these associations are highly suggestive, the specific mechanisms and relationship between metabolic syndrome and periodontitis remain unknown. More well-designed studies are needed to better understand this relationship.

Female Sex Hormones

Gingival alterations during puberty, pregnancy, and menopause are associated with physiologic hormonal changes in the female patient. During puberty and pregnancy, these changes are characterized by nonspecific inflammatory reactions with a predominant vascular component, which leads clinically to a marked hemorrhagic tendency. Oral changes during menopause may include thinning of the oral mucosa, gingival recession, xerostomia, altered taste, and burning mouth.

The changes associated with each phase of the female life cycle from puberty to menopause are briefly addressed in the online materials associated with this book. See Chapter 41 for a detailed description of these changes, including management considerations for the periodontal manifestations of hormonal changes in the female patient.

Puberty

Puberty is often accompanied by an exaggerated response of the

gingiva to plaque.[237] Pronounced inflammation, edema, and gingival enlargement result from local factors that might ordinarily elicit a comparatively mild gingival response (eFig. 14.1). As adulthood approaches, the severity of the gingival reaction diminishes, even when local factors persist. However, complete return to normal health requires the removal of these factors. Although the prevalence and severity of gingival disease are increased during puberty, gingivitis is not a universal occurrence for all adolescents. With good oral hygiene, it can be prevented (see Chapter 21).

EFIG. 14.1 Gingivitis during puberty, with edema, discoloration, and enlargement of the entire gingival margin and papillary areas around the mandibular incisors.

Menstruation

During the menstrual period, the prevalence of gingivitis increases. Some patients may complain of bleeding gums or a bloated, tense feeling in the gums during the days preceding menstrual flow. The exudate from inflamed gingiva is increased during menstruation, which suggests that preexisting gingivitis is aggravated by menstruation; however, the crevicular fluid of normal, healthy gingiva is unaffected.[118] Tooth mobility does not change significantly during the menstrual cycle.[86] The salivary bacterial count is increased during menstruation and at ovulation, which occurs up to 14 days earlier.[202]

Pregnancy

The gingival changes of pregnancy were described as early as the late 1800s, before any knowledge about hormonal changes in pregnancy was available.[26,201] As with other systemic conditions, *pregnancy itself does not cause gingivitis*. Gingivitis during pregnancy is caused by bacterial plaque, just as it is in nonpregnant women. The hormonal changes of pregnancy accentuate the gingival response to plaque and modify the resultant clinical picture (eFig. 14.2). *No notable changes occur in the gingiva during pregnancy in the absence of local factors.*

EFIG. 14.2 Periodontal condition during pregnancy. (A) Marginal erythema and easily bleeding gingiva in a woman who is 5 months pregnant. (B) Localized incipient gingival enlargement between the maxillary central and lateral incisors in a woman who is 4 months pregnant. (C) Generalized gingival enlargement of the interdental papilla and gingival margins on the facial surface of the maxillary incisors in a pregnant woman. (D) Extensive gingival enlargement localized on the buccal surface of the mandibular premolars in a pregnant woman. These lesions are often referred to as "pregnancy tumors."

The reported incidence of gingivitis during pregnancy in well-conducted studies varies from 50% to 100%.[151,158] Pregnancy affects the severity of previously inflamed areas, but it does not alter healthy gingiva. Impressions of increased incidence may be created by the aggravation of previously inflamed but unnoticed areas. Tooth mobility, pocket depth, and gingival fluid are also increased during pregnancy.[119,148,204] The severity of gingivitis is increased during pregnancy beginning in the second or third month. Patients with mild chronic gingivitis that attracted no particular attention before the pregnancy become aware of the gingiva because previously inflamed areas become enlarged, edematous, and more notably discolored (see eFig. 14.2A through C).

Gingivitis becomes more severe by the eighth month and decreases during the ninth month of pregnancy.[151] Plaque accumulation follows a similar pattern. Some investigators report that the greatest severity is between the second and third trimesters.[54] The correlation between gingivitis and the quantity of plaque is greater after parturition than during pregnancy, which suggests that pregnancy introduces other factors that aggravate the gingival response to local factors.[138]

Partial reduction in the severity of gingivitis occurs by 2 months postpartum, and after 1 year, the condition of the gingiva is comparable to that of patients who have not been pregnant.[54] Tooth mobility, pocket depth, and gingival fluid are also reduced after pregnancy. In a longitudinal investigation of the periodontal changes that occurred during pregnancy and for 15 months postpartum, no significant loss of attachment was observed.[54]

Pronounced ease of bleeding is the most striking clinical feature. The gingiva is inflamed and varies in color from bright red to bluish red.[276,277] The marginal and interdental gingivae are edematous; they pit on pressure, appear smooth and shiny, are soft and pliable, and sometimes have a raspberry-like appearance. The extreme redness results from marked vascularity, and there is an increased tendency to bleed. The gingival changes are usually painless unless they are complicated by acute infection. In some cases, the inflamed gingiva forms discrete tumor-like masses, which are referred to as *pregnancy tumors* (see eFig. 14.2D).

Microscopically, gingival disease during pregnancy appears as

nonspecific, vascularizing, and proliferative inflammation.[158,277] Marked inflammatory cellular infiltration occurs, with edema and degeneration of the gingival epithelium and connective tissue. The epithelium is hyperplastic, with accentuated rete pegs, reduced surface keratinization, and various degrees of intracellular and extracellular edema and infiltration by leukocytes.[251] Newly formed, engorged capillaries are present in abundance.

The possibility that bacterial–hormonal interactions may change the composition of plaque and lead to gingival inflammation has not been extensively explored. Kornman and Loesche[139] reported that the subgingival flora changes to a more anaerobic flora as pregnancy progresses. *P. intermedia* appears to be the only microorganism that increases significantly during pregnancy. This increase appears to be associated with elevations in systemic levels of estradiol and progesterone and to coincide with the peak in gingival bleeding. It has also been suggested that, during pregnancy, a depression of the maternal T-lymphocyte response may be a factor in the altered tissue response to plaque.[188]

The aggravation of gingivitis during pregnancy has been attributed principally to the increased level of progesterone, which produces dilation and tortuosity of the gingival microvasculature, circulatory stasis, and increased susceptibility to mechanical irritation, all of which favor the leakage of fluid into the perivascular tissues.[178,187] A marked increase in estrogen and progesterone occurs during pregnancy, with a reduction after parturition. Animal studies with radioactive estradiol have demonstrated that the gingiva is a target organ for female sex hormones.[83] The severity of gingivitis varies with the hormonal levels of pregnancy.[119]

It has also been suggested that the accentuation of gingivitis during pregnancy has two peaks: during the first trimester, when there is an overproduction of gonadotropins, and during the third trimester, when estrogen and progesterone levels are highest.[151] The destruction of gingival mast cells by the increased sex hormones and the resultant release of histamine and proteolytic enzymes may also contribute to the exaggerated inflammatory response to local factors.[150]

Hormonal Contraceptives

Hormonal contraceptives aggravate the gingival response to local factors in a manner similar to that seen during pregnancy; when these drugs are taken for longer than 1.5 years, there is an increase in periodontal destruction.[70,137,149] Although some brands of oral contraceptives produce more dramatic changes than others, no correlation has been found to exist on the basis of differences in the progesterone or estrogen content of various brands.[158,199] Cumulative exposure to oral contraceptives apparently has no effect on gingival inflammation or oral debris index scores.[127]

Menopause

During menopause, the usual rhythmic hormonal fluctuations of the female cycle are ended as estradiol ceases to be the major circulating estrogen.[172] As a result, women can develop a gingivostomatitis. This condition occurs during menopause or during the postmenopausal period. Mild signs and symptoms sometimes appear, and these are associated with the earliest menopausal changes. Menopausal gingivostomatitis is not a common condition. The term used for its designation has led to the erroneous impression that it invariably occurs in association with menopause, whereas the opposite is true. Oral disturbances are not a common feature of menopause.[268]

The gingiva and the remaining oral mucosa are dry and shiny, they vary in color from abnormal paleness to redness, and they bleed easily. Fissuring occurs in the mucobuccal fold in some women, and comparable changes may occur in the vaginal mucosa.[208] Microscopically, the gingiva exhibits atrophy of the germinal and prickle cell layers of the epithelium and, in some patients, areas of ulceration. The patient complains of a dry, burning sensation throughout the oral cavity that is associated with extreme sensitivity to thermal changes; abnormal taste sensations described as “salty,” “peppery,” or “sour”; and difficulty with removable partial prostheses.[168]

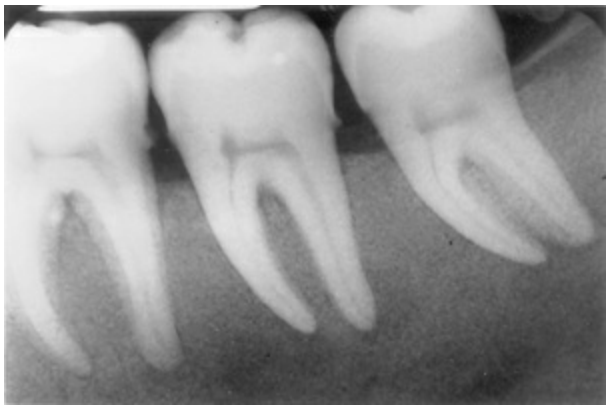
The signs and symptoms of menopausal gingivostomatitis are somewhat comparable to those of chronic desquamative gingivitis (see Chapter 22). Signs and symptoms similar to those of menopausal gingivostomatitis occasionally occur after ovariectomy

or sterilization by radiation in the treatment of malignant neoplasms.

Hyperparathyroidism

Parathyroid hypersecretion produces generalized demineralization of the skeleton, increased osteoclasis with proliferation of the connective tissue in the enlarged marrow spaces, and the formation of bone cysts and giant cell tumors.[263] The disease is called *osteitis fibrosa cystica* or *von Recklinghausen bone disease.* Loss of the lamina dura and giant cell tumors in the jaws are late signs of hyperparathyroid bone disease, which in itself is uncommon. The complete loss of the lamina dura does not occur often, and clinicians may attach too much diagnostic significance to it. The loss of lamina dura may also occur with Paget disease, fibrous dysplasia, and osteomalacia.

Reports have suggested that 25% to 50% of patients with hyperparathyroidism have associated oral changes.[211,232,236] These changes include malocclusion and tooth mobility, radiographic evidence of alveolar osteoporosis with closely meshed trabeculae, widening of the periodontal ligament space, absence of the lamina dura (eFig. 14.3), and radiolucent cystlike spaces (eFig. 14.4). Bone cysts become filled with fibrous tissue with abundant hemosiderin-laden macrophages and giant cells. These cysts have been called *brown tumors,* but they are not tumors. More accurately, they are reparative giant cell granulomas. In some cases, these lesions appear in the periapical region of teeth, and they can lead to a misdiagnosis of a lesion of endodontic origin.[153] A relationship has been suggested between periodontal disease in dogs and hyperparathyroidism secondary to calcium deficiency in the diet,[114] but this has not been confirmed by other studies.[238]



EFIG. 14.3 Secondary hyperparathyroidism in a 35-year-old woman with advanced kidney disease. This periapical radiograph shows the ground-glass appearance of the bone and the loss of lamina dura.

EFIG. 14.4 (A) Periapical radiograph of a brown tumor in a patient with hyperparathyroidism. (B) Occlusal radiographic view of the brown tumor. Note the expansion of the lingual cortical plate and the movement of the premolar. (Courtesy Dr. L. Roy Eversole, San Francisco, CA.)

Hematologic Disorders and Immune

Deficiencies

All blood cells play an essential role in the maintenance of a healthy periodontium. White blood cells (WBCs) are involved in inflammatory reactions, and they are responsible for cellular defense against microorganisms as well as for proinflammatory cytokine release. Red blood cells (RBCs) are responsible for gas exchange and nutrient supply to the periodontal tissues and platelets, and they are necessary for normal hemostasis as well as for the recruitment of cells during inflammation and wound healing. Consequently, disorders of any blood cells or blood-forming organs can have a profound effect on the periodontium.

Certain oral changes (e.g., hemorrhage) may suggest the existence of a blood dyscrasia. However, a specific diagnosis requires a complete physical examination and a thorough hematologic study. Comparable oral changes occur in more than one form of blood dyscrasia, and secondary inflammatory changes produce a wide range of variation in the oral signs.

Gingival and periodontal disturbances associated with blood dyscrasias must be viewed in terms of fundamental interrelationships among the oral tissues, the blood cells, and the blood-forming organs rather than in terms of a simple association of dramatic oral changes with hematologic disease. Hemorrhagic tendencies occur when the normal hemostatic mechanisms are disturbed. Abnormal bleeding from the gingiva or other areas of the oral mucosa that is difficult to control is an important clinical sign that suggests a hematologic disorder. Petechiae (Fig. 14.4) and ecchymosis (Fig. 14.5), observed most often in the soft palate area, are signs of an underlying bleeding disorder. It is essential to diagnose the specific etiology to appropriately address any bleeding or immunologic disorder.

FIG. 14.4 Petechiae evident on the soft palate of a patient with an underlying bleeding disorder (thrombocytopenia).

FIG. 14.5 Ecchymosis that is evident on the lateral aspects of the soft palate and tonsillar pillars of a patient with chemotherapy-induced thrombocytopenia.

Deficiencies in the host immune response may lead to severely destructive periodontal lesions. These deficiencies may be primary (inherited) or secondary (acquired) and may be caused by either immunosuppressive drug therapy or the pathologic destruction of the lymphoid system. Leukemia, Hodgkin disease, lymphomas, and multiple myeloma may result in secondary immunodeficiency disorders. This section discusses common hematologic and certain immunodeficiency disorders that are not related to the human

immunodeficiency virus or acquired immunodeficiency syndrome. See Chapter 30 for a detailed discussion of patients with human immunodeficiency virus infection.

Key Fact

Clinicians must be aware that certain oral manifestations (e.g., hemorrhage, ecchymosis) can suggest the existence of a systemic disorder. Atypical gingival and periodontal findings should be assessed in terms of the interrelationships among oral tissues, blood cells, and blood-forming organs rather than in terms of a simple association of dramatic oral changes with hematologic disease. Determining a specific systemic diagnosis requires a complete physical examination and a thorough hematologic study. Patients should be referred to a medical doctor for comprehensive workup.

Leukocyte (Neutrophil) Disorders

Disorders that affect the production or function of leukocytes may result in severe periodontal destruction. PMNs (i.e., neutrophils) in particular play a critical role in bacterial infections, because PMNs are the first line of defense (see Chapter 7). A quantitative deficiency of leukocytes (e.g., neutropenia, agranulocytosis) is typically associated with a more generalized periodontal destruction that affects all teeth.

Neutropenia

Neutropenia is a blood disorder that results in low levels of circulating neutrophils. It is a serious condition that may be caused by diseases, medications, chemicals, infections, idiopathic conditions, or hereditary disorders. It may be chronic or cyclic and severe or benign. It affects as many as one in three patients who are receiving chemotherapy for cancer. An absolute neutrophil count (ANC) of 1000 to 1500 cells/μL is diagnostic for mild neutropenia. An ANC of 500 to 1000 cells/μL is considered moderate neutropenia, and an ANC of <500 cells/μL indicates a severe

neutropenia. Infections are sometimes difficult to manage and may be life threatening, particularly with severe neutropenia.

Agranulocytosis

Agranulocytosis is a more severe neutropenia that involves not only neutrophils but also basophils and eosinophils. It is defined as an ANC of <100 cells/μL. It is characterized by a reduction in the number of circulating granulocytes, and it results in severe infections, including ulcerative necrotizing lesions of the oral mucosa, the skin, and the gastrointestinal and genitourinary tracts. Less severe forms of the disease are called *neutropenia* or *granulocytopenia.*

Drug idiosyncrasy is the most common cause of agranulocytosis, but, in some cases, its cause cannot be explained. Agranulocytosis has been reported after the administration of drugs such as aminopyrine, barbiturates and their derivatives, benzene ring derivatives, sulfonamides, gold salts, and arsenical agents.[140,157,174,203] It generally occurs as an acute disease. It may be chronic or periodic, with recurring neutropenic cycles (e.g., cyclic neutropenia).[244]

The onset of disease is accompanied by fever, malaise, general weakness, and sore throat. Ulceration in the oral cavity, the oropharynx, and the throat is characteristic. The mucosa exhibits isolated necrotic patches that are black and gray and that are sharply demarcated from the adjacent uninvolved areas.[130,161] The absence of a notable inflammatory reaction caused by a lack of granulocytes is a striking feature. The gingival margin may or may not be involved. Gingival hemorrhage, necrosis, increased salivation, and fetid odor are accompanying clinical features. With cyclic neutropenia, the gingival changes recur with recurrent exacerbation of the disease.[53] The occurrence of generalized aggressive periodontitis has been described in patients with cyclic neutropenia[227] (Fig. 14.6).

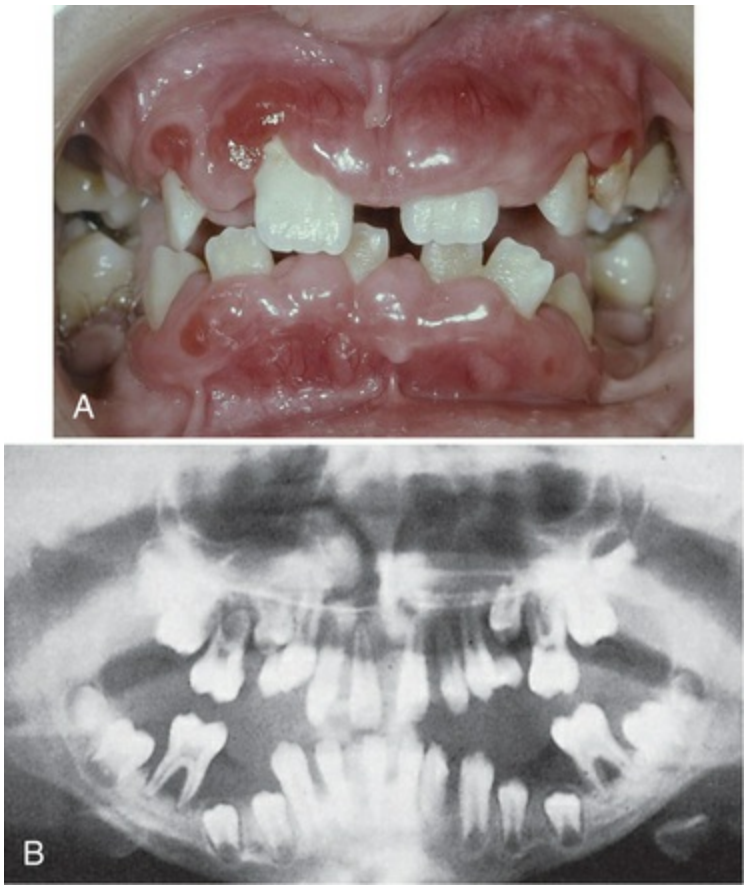

FIG. 14.6 Aggressive periodontitis in 10-year-old boy with cyclic neutropenia and agammaglobulinemia. (A) Clinical presentation of the periodontal condition. Note the severe swelling and inflammation of the marginal and papillary gingiva. There is gross migration of teeth caused by a loss of bone support. (B) Panoramic radiograph demonstrating severe bone loss around all permanent teeth that have erupted into the oral cavity.

Because infection is a common feature of agranulocytosis, the differential diagnosis involves consideration of such conditions as necrotizing ulcerative gingivitis, noma, acute necrotizing inflammation of the tonsils, and diphtheria. Definitive diagnosis depends on the hematologic findings of pronounced leukopenia and the almost complete absence of neutrophils.

Leukemia

Leukemia is an important disease to understand and appreciate because of its seriousness and its periodontal manifestations. The leukemias are malignant neoplasias of WBC precursors that are

characterized by the following: (1) diffuse replacement of the bone marrow with proliferating leukemic cells; (2) abnormal numbers and forms of immature WBCs in the circulating blood; and (3) widespread infiltrates in the liver, spleen, lymph nodes, and other body sites.[209]

According to the cell type involved, leukemias are classified as *lymphocytic* or *myelogenous*. A subgroup of the myelogenous leukemias are the *monocytic* leukemias. The term *lymphocytic* indicates that the malignant change occurs in cells that normally form lymphocytes. The term *myelogenous* indicates that the malignant change occurs in cells that normally form red blood cells (RBCs), some types of WBCs, and platelets. According to their evolution, leukemias can be *acute* (which is rapidly fatal), *subacute,* or *chronic.* In acute leukemia, the primitive blast cells released into the peripheral circulation are immature and nonfunctional; in chronic leukemia, the abnormal cells tend to be more mature and to have normal morphologic characteristics and functions when released into the circulation.

All leukemias tend to displace normal components of the bone marrow elements with leukemic cells, thereby resulting in the reduced production of normal RBCs, WBCs, and platelets, which leads to anemia, *leukopenia* (a reduction in the number of *nonmalignant* WBCs), and thrombocytopenia. Anemia results in poor tissue oxygenation, which makes tissues more friable and susceptible to breakdown. A reduction of normal WBCs in the circulation leads to a poor cellular defense and an increased susceptibility to infections. *Thrombocytopenia* leads to bleeding tendency, which can occur in any tissue but which in particular affects the oral cavity, especially the gingival sulcus (Fig. 14.7). Some patients may have normal blood counts while leukemic cells reside primarily in the bone marrow. This type of disease is called *aleukemic leukemia*.[100]

FIG. 14.7 Spontaneous bleeding from the gingival sulcus in a patient with thrombocytopenia. Normal coagulation is evident by the appearance of the large clot that forms in the mouth. However, platelets are inadequate to establish hemostasis at the site of hemorrhage.

The Periodontium in Leukemic Patients

Oral and periodontal manifestations of leukemia may include leukemic infiltration, bleeding, oral ulcerations, and infections. The expression of these signs is more common with acute and subacute forms of leukemia than with chronic forms.

Leukemic Infiltration

Leukemic cells can infiltrate the gingiva and, less frequently, the alveolar bone. Gingival infiltration often results in *leukemic gingival enlargement* (see Chapter 19).

A study of 1076 adult patients with leukemia showed that 3.6% of the patients with teeth had leukemic gingival proliferative lesions, with the highest incidence seen in patients with acute monocytic leukemia (66.7%), followed by those with acute myelocytic–monocytic leukemia (18.7%) and acute myelocytic leukemia (3.7%).[66] It should be noted, however, that monocytic leukemia is an extremely rare form of the disease. Leukemic gingival enlargement is not found in edentulous patients or in patients with chronic leukemia, suggesting that it represents the accumulation of immature leukemic blast cells in the gingiva adjacent to tooth

surfaces with bacterial plaque. Leukemic gingival enlargement consists of a basic infiltration of the gingival corium by leukemic cells that increases the gingival thickness and creates gingival pockets in which bacterial plaque accumulates, thereby initiating a secondary inflammatory lesion that contributes to the enlargement of the gingiva. It may be localized to the interdental papilla area (Fig. 14.8), or it may expand to include the marginal gingiva and partially cover the crowns of the teeth (Fig. 14.9C and D). Clinically, the gingiva appears bluish red and cyanotic, with a rounding and tenseness of the gingival margin. The abnormal accumulation of leukemic cells in the dermal and subcutaneous connective tissue is called *leukemia cutis,* and it forms elevated and flat macules and papules[66,209] (see Fig. 14.9A and B).

FIG. 14.8 Leukemic infiltration that causes localized gingival swelling of the interdental papillae between the maxillary lateral and central incisors. Note the tense induration of the area.

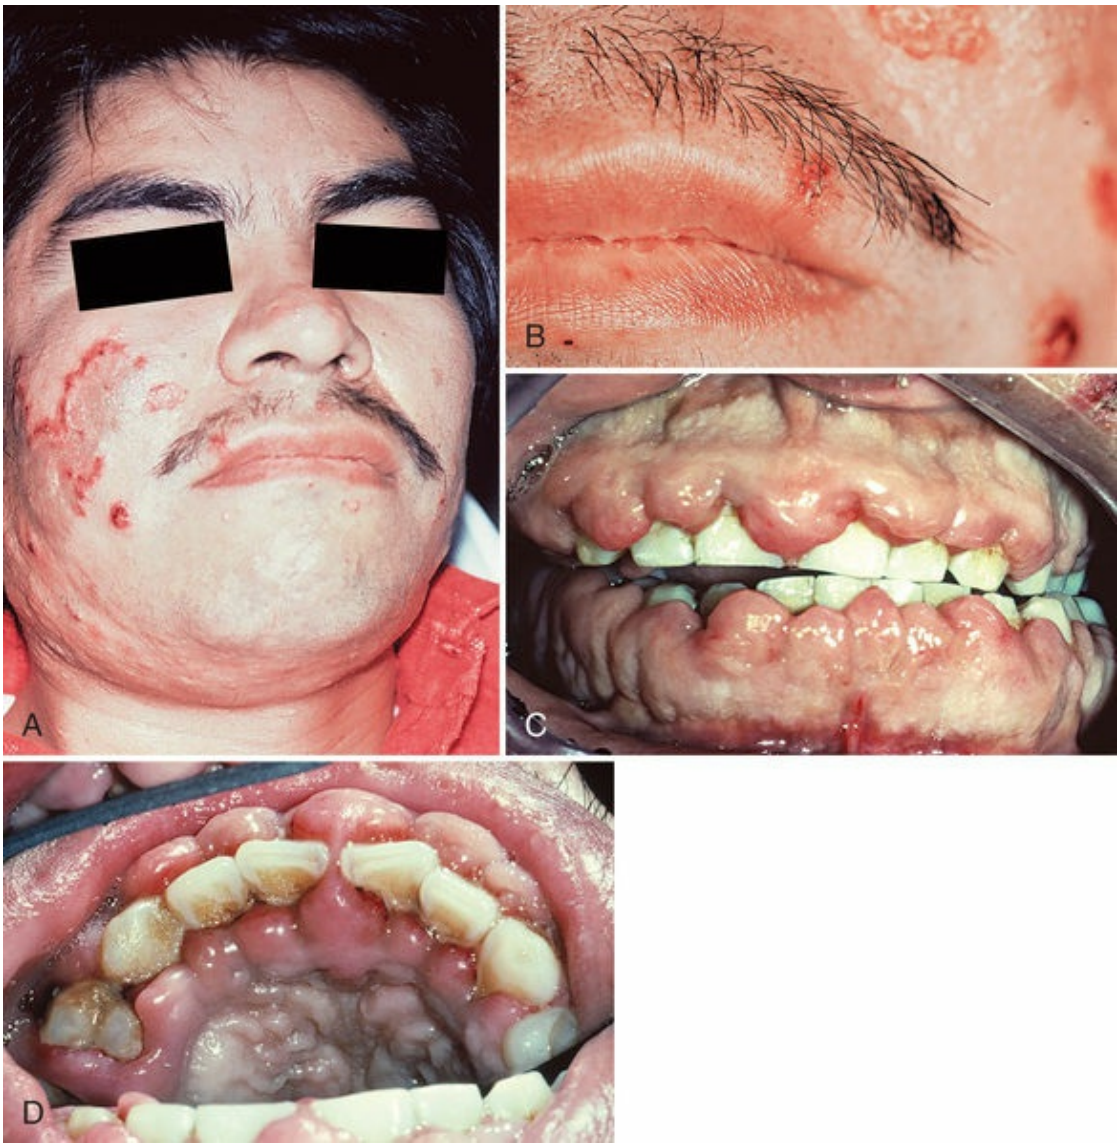

FIG. 14.9 Adult male with acute myelocytic leukemia. (A) A view of the patient's face. Note the elevated, flat macules and papules (leukemia cutis) on the right cheek. (B) Close-up view of skin lesions. (C) An intraoral view showing pronounced gingival enlargements of the entire gingival margin and interdental papilla areas of both arches. (D) Occlusal view of the maxillary anterior teeth. Note the marked enlargement in both the facial and the palatal aspects.
(Courtesy Dr. Spencer Woolfe, Dublin, Ireland.)

Microscopically, the gingiva exhibits a dense, diffuse infiltration of predominantly immature leukocytes in the attached and marginal gingiva. Occasionally, mitotic figures indicative of ectopic hematopoiesis may be seen. The normal connective tissue components of the gingiva are displaced by the leukemic cells (Fig.

14.10). The nature of the cells depends on the type of leukemia. The cellular accumulation is denser in the entire reticular connective tissue layer. In almost all cases, the papillary layer contains comparatively few leukocytes. The blood vessels are distended and contain predominantly leukemic cells, and the RBCs are reduced in number. The epithelium shows a variety of changes, and it may be thinned or hyperplastic. Common findings include degeneration associated with intercellular and intracellular edema and leukocytic infiltration with diminished surface keratinization.

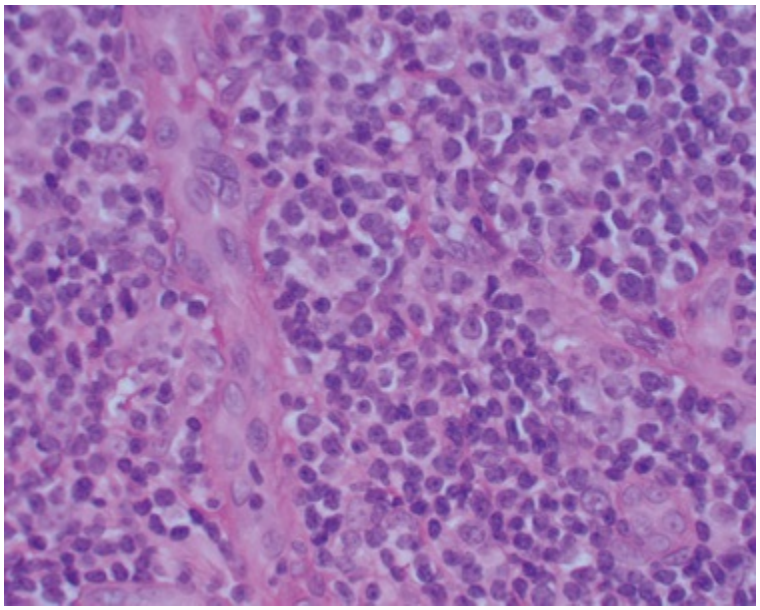

FIG. 14.10 Human histologic appearance of leukemic infiltrate with dense diffuse infiltration of predominantly immature leukocytes. The normal connective tissue components of the gingiva are displaced by the leukemic cells. The cellular accumulation is denser in the entire reticular connective tissue layer. (Courtesy Dr. Russell Christensen, University of California, Los Angeles, CA.)

The microscopic picture of the marginal gingiva differs from that of other gingival locations in that it usually exhibits a notable inflammatory component in addition to the leukemic cells. Scattered foci of plasma cells and lymphocytes with edema and degeneration are common findings. The inner aspect of the marginal gingiva is usually ulcerated, and marginal necrosis with pseudomembrane formation may also be seen.

The periodontal ligament and alveolar bone may also be involved in acute and subacute leukemia. The periodontal ligament may be infiltrated with mature and immature leukocytes. The marrow of the alveolar bone exhibits a variety of changes, such as localized areas of necrosis, thrombosis of the blood vessels, infiltration with mature and immature leukocytes, occasional RBCs, and the replacement of the fatty marrow with fibrous tissue.

In leukemic mice, the presence of infiltrate in marrow spaces and the periodontal ligament results in osteoporosis of the alveolar bone with destruction of the supporting bone and disappearance of the periodontal fibers[32,41] (Fig. 14.11).

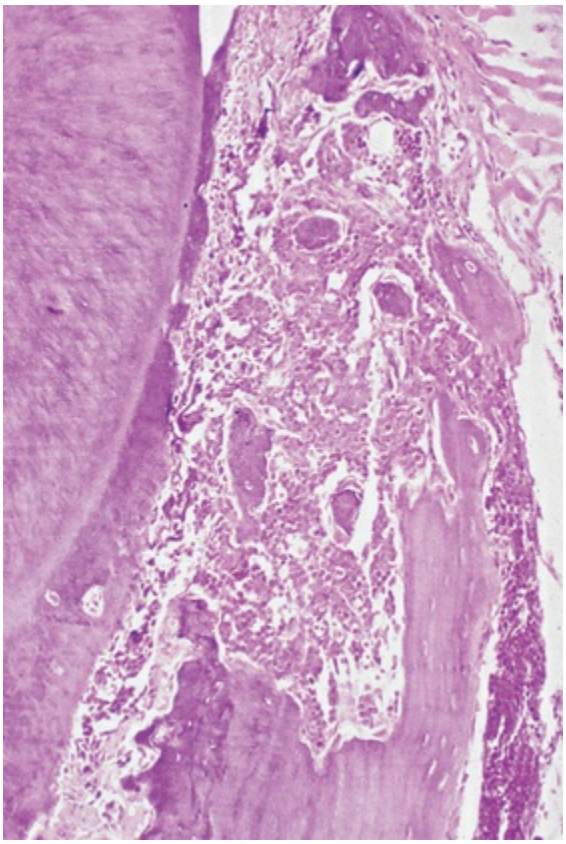

FIG. 14.11 Leukemic infiltrate in alveolar bone in a leukemic mouse. Note the leukemic infiltrate causing destruction of the bone and a loss of the periodontal ligament.

Bleeding

Gingival hemorrhage is a common finding in leukemic patients (see

Fig. 14.7), even in the absence of clinically detectable gingivitis. Bleeding gingiva can be an early sign of leukemia. It is caused by the thrombocytopenia that results from the replacement of bone marrow cells with leukemic cells and from the inhibition of normal stem cell function by leukemic cells or their products.[209] This bleeding tendency can also manifest in the skin and throughout the oral mucosa, where petechiae are often found, with or without leukemic infiltrates. A more diffuse submucosal bleeding manifests as ecchymosis (see Fig. 14.5). Oral bleeding has been reported as a presenting sign in 17.7% of patients with acute leukemia and in 4.4% of patients with chronic leukemia.[156] Bleeding may also be a side effect of the chemotherapeutic agents used to treat leukemia.

Oral Ulceration and Infection

In patients with leukemia, the response to bacterial plaque or other local irritation is altered. The cellular component of the inflammatory exudate differs both quantitatively and qualitatively from that found in nonleukemic individuals in that there is a pronounced infiltration of immature leukemic cells in addition to the usual inflammatory cells. As a result, the normal inflammatory response may be diminished.

Granulocytopenia (diminished WBC count) results from the displacement of normal bone marrow cells by leukemic cells, which increases the host susceptibility to opportunistic microorganisms and leads to ulcerations and infections. Discrete, punched-out ulcers that penetrate deeply into the submucosa and are covered by a firmly attached white slough can be found on the oral mucosa.[16] These lesions occur in sites of trauma (e.g., the buccal mucosa) in relation to the line of occlusion or on the palate. Patients with a history of herpesvirus infection may develop recurrent herpetic oral ulcers (often in multiple sites) and large atypical forms, especially after chemotherapy is instituted[106] (Fig. 14.12).

FIG. 14.12 Large ulcerations on the palate of a patient with granulocytopenia secondary to leukemia. These atypical ulcerations are caused by a herpesvirus opportunistic infection. Notice the smaller, discrete, round ulcerations that have coalesced into the larger lesion.

A gingival (bacterial) infection in leukemic patients can be the result of an exogenous bacterial infection or an existing bacterial infection (e.g., gingival or periodontal disease). Acute gingivitis and lesions that resemble necrotizing ulcerative gingivitis are more frequent and more severe in patients with terminal cases of acute leukemia[22] (Figs. 14.13 and 14.14). The inflamed gingiva in patients with leukemia differs clinically from that found in nonleukemic individuals. The gingiva is a peculiar bluish red, it is spongelike and friable, and it bleeds persistently on the slightest provocation or even spontaneously in leukemic patients. This greatly altered and degenerated tissue is extremely susceptible to bacterial infection, which can be so severe as to cause acute gingival necrosis with pseudomembrane formation (Fig. 14.15) or bone exposure (Fig. 14.16). These are secondary oral changes that are superimposed on the oral tissues that have been altered by the blood dyscrasia. They produce associated disturbances that may be a source of considerable difficulty to the patient, such as systemic toxic effects, loss of appetite, nausea, blood loss from persistent gingival bleeding, and constant gnawing pain. Eliminating or reducing local factors (e.g., bacterial plaque) can minimize the severe oral changes associated with leukemia. In some patients with severe acute leukemia, symptoms may be relieved only by treatment that leads to the remission of the disease.

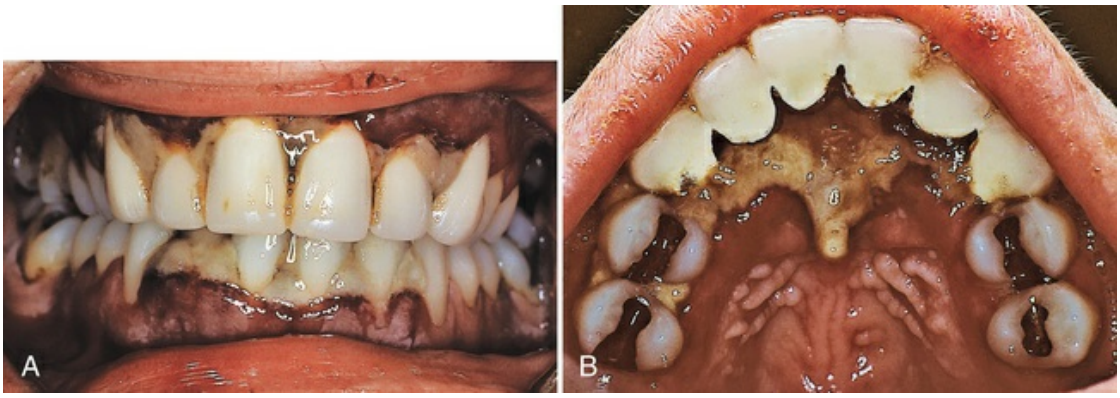

FIG. 14.13 Adult female with acute myelocytic leukemia. (A) Anterior view of a patient with acute myelocytic leukemia. The interdental papillae are necrotic, with highly inflamed and swollen gingival tissue at the base of the lesions. (B) Palatal view demonstrating extensive necrosis of the interdental and palatal tissues behind the maxillary incisors.

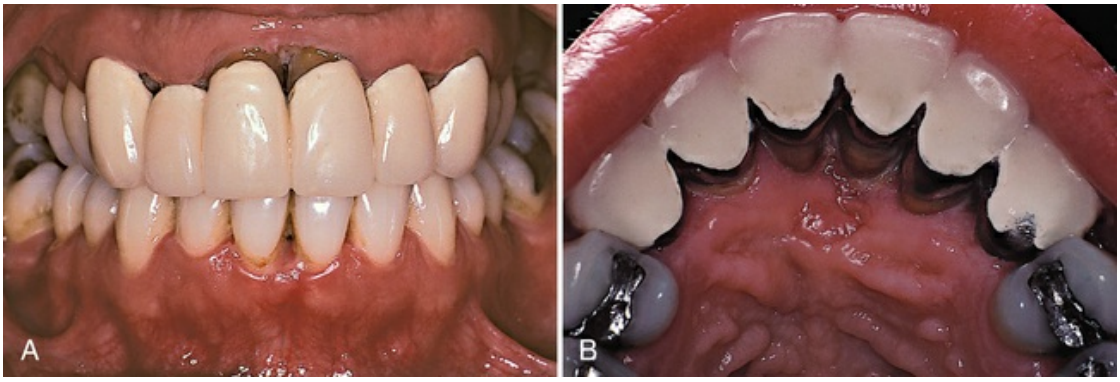

FIG. 14.14 The same patient as shown in Fig. 14.13 after chemotherapy that resulted in the remission of her leukemia. (A) An anterior view reveals dramatic improvement in gingival health after the remission of leukemia. Note the loss of interdental papillae as well as gingival recession in the anterior areas. (B) A palatal view shows the extensive loss of gingival tissue around the maxillary incisors.

FIG. 14.15 An opportunistic bacterial infection of the gingiva in a patient who has been hospitalized with leukemia. The gingival tissue is highly inflamed, bleeding, and necrotic, with pseudomembrane formation.

FIG. 14.16 An opportunistic bacterial infection in an immunosuppressed patient caused the complete destruction of the gingiva, thus exposing the underlying alveolar bone.

In those with chronic leukemia, oral changes that suggest a hematologic disturbance are rare. The microscopic changes of chronic leukemia may consist of replacing the normal fatty marrow of the jaws with islands of mature lymphocytes or lymphocytic infiltration of the marginal gingiva without dramatic clinical manifestations.

The existence of leukemia is sometimes revealed by a gingival biopsy performed to clarify the nature of a troublesome gingival condition. In such cases, the gingival findings must be corroborated

by medical examination and hematologic study. In patients with diagnosed leukemia, gingival biopsy may indicate the extent to which leukemic infiltration is responsible for the altered clinical appearance of the gingiva. *Although such findings are of interest, their benefit to the patient is insufficient to warrant routine gingival biopsy studies in patients with leukemia.* Furthermore, it is important to note that the absence of leukemic involvement in a gingival biopsy specimen does not rule out the possibility of leukemia. A gingival biopsy in a patient with chronic leukemia may reveal typical gingival inflammation without any suggestion of a hematologic disturbance.

See the online material for discussion of additional blood dyscrasias and their influence on periodontal health.

Anemia

Anemia is a deficiency in the quantity or quality of the blood as manifested by a reduction in the number of erythrocytes and in the amount of hemoglobin. Anemia may be the result of blood loss, defective blood formation, or increased RBC destruction. Anemias are classified according to cellular morphology and hemoglobin content as follows: (1) macrocytic hyperchromic anemia (pernicious anemia); (2) microcytic hypochromic anemia (iron deficiency anemia); (3) sickle cell anemia; and (4) normocytic–normochromic anemia (hemolytic or aplastic anemia).

Pernicious anemia results in tongue changes in 75% of patients. The tongue appears red, smooth, and shiny as a result of atrophy of the papillae (eFig. 14.5). There is also marked pallor of the gingiva (eFig. 14.6). *Iron deficiency anemia* induces similar tongue and gingival changes. A syndrome that consists of glossitis and ulceration of the oral mucosa and oropharynx and that induces dysphagia (Plummer–Vinson syndrome) has been described in patients with iron deficiency anemia. *Sickle cell anemia* is a hereditary form of chronic hemolytic anemia that occurs almost exclusively in blacks. It is characterized by pallor, jaundice, weakness, rheumatoid manifestations, and leg ulcers. Oral changes include generalized osteoporosis of the jaws, with a peculiar stepladder alignment of the trabeculae of the interdental septa,

along with pallor and yellowish discoloration of the oral mucosa. Periodontal infections may precipitate sickle cell crisis.[203] *Aplastic anemia* results from a failure of the bone marrow to produce erythrocytes. The etiology is usually the effect of toxic drugs on the marrow or the displacement of RBCs by leukemic cells. Oral changes include pale discoloration of the oral mucosa and increased susceptibility to infection because of the concomitant neutropenia.

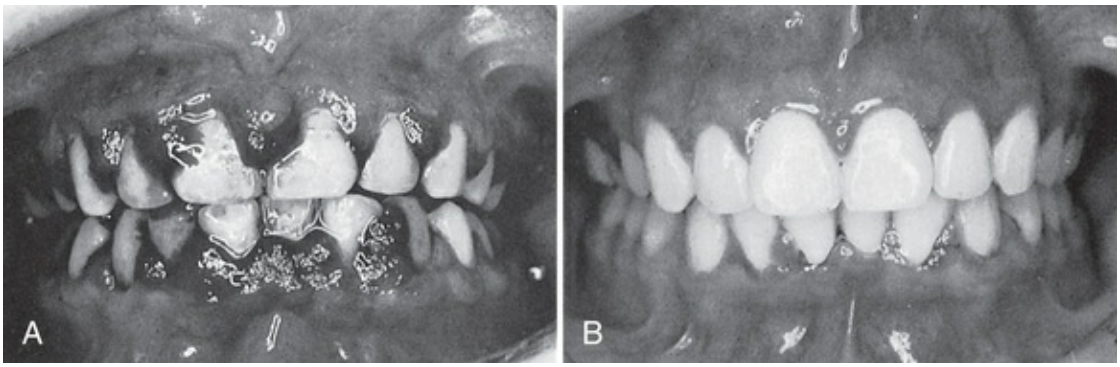
EFIG. 14.5 A smooth tongue in a patient with pernicious anemia.

EFIG. 14.6 The diffuse pallor of the gingiva in a patient with anemia. The discolored and inflamed gingival margin stands out in sharp contrast to the adjacent pale and attached gingiva.

Thrombocytopenia

Thrombocytopenia is a term that is used to describe the condition of a reduced platelet count that results from either a lack of platelet production or an increased loss of platelets. *Purpura* refers to the purplish appearance of the skin or mucous membranes where bleeding has occurred as a result of decreased platelets. *Thrombocytopenic purpura* may be idiopathic (i.e., of unknown etiology, as with Werlhof disease), or it may occur secondary to some known etiologic factor that is responsible for a reduced amount of functioning marrow and a resultant reduction in the number of circulating platelets. Such etiologic factors include aplasia of the marrow, displacement of the megakaryocytes in the marrow (as with leukemia), replacement of the marrow by tumor, and destruction of the marrow by irradiation or radium or by drugs such as benzene, aminopyrine, or arsenical agents.

Thrombocytopenic purpura is characterized by a low platelet count, a prolonged clot retraction and bleeding time, and a normal or slightly prolonged clotting time. There is spontaneous bleeding into the skin or from the mucous membranes. Petechiae and hemorrhagic vesicles occur in the oral cavity, particularly in the palate, the tonsillar pillars, and the buccal mucosa. The gingivae are swollen, soft, and friable. Bleeding occurs spontaneously or with the slightest provocation, and it is difficult to control. *Gingival changes represent an abnormal response to local irritation.* The severity of the gingival condition is dramatically alleviated by removal of the local factors (eFig. 14.7).



EFIG. 14.7 Thrombocytopenic purpura. (A) Hemorrhagic gingivitis in a patient with thrombocytopenic purpura. (B) The same patient as shown in A. There is a marked reduction in the severity of gingival disease after the removal of surface debris and careful scaling.

Antibody Deficiency Disorders

Agammaglobulinemia, or *hypogammaglobulinemia*, is an immune deficiency that results from inadequate antibody production caused by a deficiency in B cells. It can be congenital (X-linked or Bruton agammaglobulinemia) or acquired (common variable immunodeficiency).

Congenital agammaglobulinemia is caused by an X-linked, recessive gene (Bruton tyrosine kinase). It affects approximately 1 of every 100,000 individuals. Because the defect is recessive and linked to the X chromosome, only males have the disease. The gene is responsible for B-cell development. In the absence of mature B cells, patients lack lymphoid tissue and fail to develop plasma cells. Thus, the production of antibodies is deficient. Germinal centers where B cells proliferate and differentiate are poorly developed in all lymphoid tissues. The tonsils, adenoids, and peripheral lymph nodes are small or absent.

Acquired or *late-onset* agammaglobulinemia is most often known as *common variable immunodeficiency disease* (CVID). The disorder is characterized by the onset of recurrent bacterial infections during the second and third decades of life as a result of drastic decreases in immunoglobulin and antibody levels. The basic immunologic defect of CVID is the failure of B-lymphocyte differentiation into plasma cells. In contrast to patients with the X-linked form of the

disease, patients with CVID typically have an enlarged spleen and swollen glands or lymph nodes. Along with other autoimmune problems, some patients develop autoantibodies against their blood cells. Causes of the disease are unknown. Unlike the X-linked early-onset form of the disease, CVID is not genetically determined, and both males and females are susceptible.

T-cell function remains normal in individuals with agammaglobulinemia. The disease, whether congenital or acquired, is characterized by recurrent bacterial infections, especially ear, sinus, and lung infections. Patients are also susceptible to periodontal infections. Aggressive periodontitis is a common finding in children who are diagnosed with agammaglobulinemia (see Fig. 14.6).

Genetic Disorders

Systemic conditions that are associated with or that predispose an individual to periodontal destruction include genetic disorders that result in an inadequate number or reduced function of circulating neutrophils. This underscores the importance of the neutrophil in the protection of the periodontium against infection. Severe periodontitis has been observed in individuals with primary neutrophil disorders such as neutropenia, agranulocytosis, Chédiak–Higashi syndrome, and lazy leukocyte syndrome. In addition, severe periodontitis has been observed in individuals who exhibit secondary neutrophil impairment, such as those with Down syndrome, Papillon–Lefèvre syndrome, and inflammatory bowel disease.

See the online material for this chapter as well as for Chapter 11 for detailed descriptions of the periodontal manifestations of these genetic disorders and syndromes.

Chédiak–Higashi Syndrome

Chédiak–Higashi syndrome is a rare disease that affects the production of organelles found in almost every cell. It affects mostly the melanocytes, platelets, and phagocytes. It causes partial albinism, mild bleeding disorders, and recurrent bacterial

infections. Neutrophils contain abnormal, giant lysosomes that can fuse with the phagosome, but their ability to release their contents is impaired. As a result, the killing of ingested microorganisms is delayed. Patients with Chédiak–Higashi syndrome are susceptible to repeated infections that can be serious and life threatening. Aggressive periodontitis has been described in these patients. Chédiak–Higashi syndrome has been described as a genetically transmitted disease in ranch-raised mink[12,195] (see Chapter 11).

Lazy Leukocyte Syndrome

Lazy leukocyte syndrome is characterized by susceptibility to severe microbial infections, neutropenia, defective chemotactic response by neutrophils, and an abnormal inflammatory response.[198] Those who are diagnosed with lazy leukocyte syndrome are susceptible to aggressive periodontitis with destruction of bone and early tooth loss.

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency (LAD) is a very rare genetic disorder; only a few hundred cases have been diagnosed. Because LAD is an inherited disease, it is categorized as a primary immunodeficiency that is most often diagnosed at birth. Many children with LAD do not survive.

LAD results from an inability to produce or a failure to normally express an important cell surface integrin (CD18), which is necessary for leukocytes to adhere to the vessel wall at the site of infection. When leukocytes cannot effectively adhere to the vessel wall near the site of infection, they cannot migrate to the infection. As a result, bacterial infections are able to continue to destroy host tissues unimpeded by the normal host immune response. Infections act similarly to those observed in neutropenic patients, because phagocytes are unable to reach the site of infection.

Cases of periodontal disease that are attributed to LAD are rare. They begin during or immediately after the eruption of the primary teeth. Extremely acute inflammation and proliferation of the gingival tissues with rapid destruction of the bone are found. Profound defects in peripheral blood neutrophils and monocytes

and an absence of neutrophils in the gingival tissues have been noted in patients with LAD.[194,195] These patients also have frequent respiratory tract infections and sometimes otitis media. Both the primary and the permanent teeth are affected, often resulting in early tooth loss.[260]

Papillon–Lefèvre Syndrome

Papillon–Lefèvre syndrome, which was first described by French physicians Papillon and Lefèvre in 1924,[196] is a very rare inherited condition that appears to follow an autosomal-recessive pattern. Parents are not affected, and both must carry the autosomal genes for the syndrome to appear in their offspring. It may occur in siblings, and it has no gender predilection. The estimated frequency is 1 to 4 cases per 1 million individuals. Rare cases of adult onset of this syndrome, with only mild periodontal lesions, have also been described.[37]

The syndrome is characterized by hyperkeratotic skin lesions, severe destruction of the periodontium, and, in some cases, calcification of the dura.[42,78] The cutaneous and periodontal changes usually appear together when the patient is between the ages of 2 and 4 years. The skin lesions consist of hyperkeratosis and ichthyosis of localized areas on the palms, soles, knees, and elbows (eFig. 14.8).

EFIG. 14.8 Papillon-Lefèvre syndrome in a 17-year-old boy. (A) A clinical view of the palms demonstrates hyperkeratosis of skin. (B) A clinical view of the knees, which have hyperkeratotic scaly lesions.

Periodontal involvement consists of early inflammatory changes that lead to bone loss and exfoliation of teeth. The primary teeth are lost by 5 or 6 years of age. The permanent dentition then erupts normally, but within a few years the permanent teeth are also lost as a result of destructive periodontal disease (eFig. 14.9). At a very early age (usually 15 to 20 years), patients are often edentulous except for the third molars. These may be lost as well a few years after eruption. Tooth extraction sites heal uneventfully.[79]

EFIG. 14.9 The same patient as shown in eFig. 14.8. This intraoral clinical view of a 17-year-old boy with Papillon-Lefèvre syndrome shows early tooth loss and severe bone loss around the remaining teeth as evidenced by gingival recession. The missing teeth were exfoliated.

There are few case reports of successful tooth retention in patients with Papillon–Lefèvre syndrome.[248,265] The successful retention of permanent teeth may be associated with timing treatment (i.e., antibiotics and the extraction of erupted teeth) in relation to the severity of syndrome symptoms.[265] The extraction of all primary teeth followed by a period of edentulousness may partially explain the lack of recurrent infection. In their review of the literature, Wiebe and colleagues reported that the symptoms of Papillon–Lefèvre syndrome diminish with age and that teeth that erupt later may not be lost.[265]

The microscopic changes reported include marked chronic inflammation of the lateral wall of the pocket with a predominantly plasma cell infiltrate, considerable osteoclastic activity with an apparent lack of osteoblastic activity, and an extremely thin cementum.[162] Bacterial flora studies of plaque in a patient with Papillon–Lefèvre syndrome revealed a similarity to bacterial flora in patients with chronic periodontitis.[154] Spirochete-rich zones in the apical portion of the pockets as well as spirochete adherence to the cementum and microcolony formation of *Mycoplasma* species have been reported with Papillon–Lefèvre syndrome.[126] Gram-negative cocci and rods appear at the apical border of the plaque.[256] Although Schroeder and colleagues[226] failed to show defects in peripheral blood neutrophils in a 10-year-old boy with Papillon–

Lefèvre syndrome, others have implicated neutrophil defects as a contributing factor. Firatli and colleagues[81] reported depressed chemotaxis of peripheral neutrophils and suggested that this explained the pathogenesis of the Papillon–Lefèvre syndrome. Ghaffer and colleagues found significantly depressed neutrophil function in probands with Papillon–Lefèvre syndrome with respect to phagocytic and lytic activity.[92]

Down Syndrome

Down syndrome (mongolism, trisomy 21) is a congenital disease caused by a chromosomal abnormality and is characterized by mental deficiency and growth retardation. The prevalence of periodontal disease in patients with Down syndrome is high, occurring in almost 100% of patients who are younger than 30 years of age.[55,62] Although plaque, calculus, and local irritants (e.g., diastemata, crowding of teeth, high frenum attachments, malocclusion) are present and oral hygiene is poor, the severity of periodontal destruction exceeds that explainable by local factors alone.[51,52,55,207,239]

Periodontal disease in those with Down syndrome is characterized by the formation of deep periodontal pockets associated with substantial plaque accumulation and moderate gingivitis (eFig. 14.10). These findings are usually generalized, although they tend to be more severe in the lower anterior region. Moderate recession is sometimes seen in this region as well. The disease progresses rapidly. The high prevalence and increased severity of periodontal destruction associated with Down syndrome is most likely explained by poor PMN chemotaxis, phagocytosis, and intracellular killing.[13,14,56,60,107,123,131]

EFIG. 14.10 Severe periodontal destruction in a 14-year-old patient with Down syndrome. Note the extensive loss of periodontal support around the mandibular incisors as evidenced by severe gingival recession. Moderate to heavy bacterial plaque is associated with moderate gingival inflammation in the area.

Stress and Psychosomatic Disorders

Psychologic conditions, particularly psychosocial stress, have been implicated as risk indicators for periodontal disease.[88] The most notable example is the documented relationship between stress (e.g., experienced by soldiers at war or by students during examinations) and acute necrotizing ulcerative gingivitis (see Chapters 20 and 29). The presence of necrotizing ulcerative gingivitis among soldiers stressed by wartime conditions in the trenches led to one of the early diagnostic terms used to describe this condition: "trench mouth." Despite this well-known association between stress and necrotizing ulcerative gingivitis, confirming the connection between psychologic conditions and other forms of periodontal disease (e.g., chronic periodontitis) has been elusive. These relationships are difficult to elucidate, because, as with many common diseases, the etiology and pathogenesis of periodontal disease is multifactorial, and the role of individual risk factors is difficult to define.

Some studies have failed to recognize a relationship between psychologic conditions and periodontal disease despite specific

efforts to identify them. In a study of 80 patients (40 with aggressive periodontitis and 40 with chronic periodontitis), Monteiro da Silva and colleagues failed to find a relationship between psychologic factors and periodontal disease.[180] The researchers were able to identify depression and smoking as marginally significant in the aggressive periodontitis group. Their inability to find a relationship may be attributed to a lack of significant differences in psychologic characteristics between the two groups in the study. In an earlier study, the same researchers identified depression and loneliness as significant factors associated with aggressive periodontal disease in 50 patients as compared with 50 periodontally healthy individuals and 50 individuals with chronic periodontitis.[179] Another challenge when defining the relationship between psychosocial status and periodontitis is the myriad confounding factors and the difficulty of controlling for them.[68]

Psychosocial Stress, Depression, and Coping

Several clinical studies and a systematic review of the subject have documented a positive relationship between psychosocial stress and chronic forms of periodontal disease.[200] In case–control studies, individuals with stable lifestyles (based on family structure and employment status) and minimal negative life events had less periodontal disease destruction than individuals with less stable lifestyles (e.g., unmarried, unemployed) and more negative life events.[59] It is now becoming apparent that the effect is not simply a matter of the presence or absence of stress; rather, the type of stress and the ability of the individual to cope with stress correlate with destructive periodontal disease.

All individuals experience stress, but these events do not invariably result in destructive periodontitis. The types of stress that lead to periodontal destruction appear to be more chronic or long term and less likely to be controlled by the individual. Life events such as the loss of a loved one (e.g., spouse, family member), a failed relationship, loss of employment, and financial difficulties are examples of stressful life events that are typically not controllable by the individual or not perceived by the individual as

being under his or her control, thereby resulting in a feeling of helplessness. The duration of the stressful life event also has an influence on the total impact of the stress-induced disease destruction.

Financial stress is an example of a long-term, constant pressure that may exacerbate periodontal destruction in susceptible individuals. Genco and colleagues[89] found that individuals with high levels of financial stress and poor coping skills had twice as much periodontal disease as those with minimal stress and good coping skills. Psychologic tests were used to identify and weigh the causes of stress (e.g., children, spouse, finances, single life, work) and to measure individual coping skills. Individuals with problem-focused (practical) coping skills fared better than individuals with emotion-focused (avoidance) coping skills with respect to periodontal disease. As part of their analysis, the researchers also found that chronic stress and inadequate coping could lead to changes in daily habits, such as poor oral hygiene, clenching, and grinding, as well as physiologic changes such as decreased saliva flow and suppressed immunity.

When comparing 89 patients with periodontal disease to 63 periodontally healthy individuals, Wimmer and colleagues[267] found that patients with defensive (emotional) coping skills were more likely to refuse responsibility and to downplay their condition. All patients completed a comprehensive stress assessment questionnaire (given in German) to evaluate their coping behavior. Patients with periodontal disease were less likely to use active coping skills (i.e., situation control) and more likely to cope with stress by averting blame (emotional) than were periodontally healthy individuals.

These studies support the concept that one of the most important aspects related to the influence of stress on periodontal disease destruction is the manner in which the individual copes with the stress. Emotional coping methods appear to render the host more susceptible to the destructive effects of periodontal disease than do practical coping methods. Furthermore, emotional coping is more common in situations that must be accepted and among individuals who feel helpless in the situation.

Key Fact

The effect of psychosocial stress on the manifestation of disease (i.e., periodontitis) is not simply a matter of the presence or absence of stress; rather, the type of stress and the ability of the individual to cope with stress correlate with destructive periodontal disease.

Stress-Induced Immunosuppression

Stress and psychosomatic disorders most likely impact periodontal health via changes in the individual's behavior and through complex interactions among the nervous, endocrine, and immune systems. Individuals under stress may have poorer oral hygiene; they may start or increase the clenching and grinding of their teeth; and they may smoke more frequently. All of these behavioral changes increase their susceptibility to periodontal disease destruction. Likewise, individuals who are under stress may be less likely to seek professional care.

In addition to the many behavioral changes that may influence periodontal disease destruction, psychosocial stress may also impact the disease through alterations in the immune system. The influence of stress on the immune system and systemic health conditions (e.g., cardiovascular disease) is well known. Stress-related immune system changes clearly have the potential to affect the pathogenesis of periodontal disease as well. One possible mechanism involves the production of cortisol. Stress increases cortisol production from the adrenal cortex by stimulating an increase in the release of adrenocorticotropic hormone from the pituitary gland. Increased cortisol suppresses the immune response directly through the suppression of neutrophil activity, immunoglobulin G production, and salivary IgA secretion. All of these immune responses are critical for the normal immunoinflammatory response to periodontal pathogens (see Chapter 7). The resulting stress-induced immunosuppression increases the potential for destruction by periodontal pathogens. Stress may also affect the cellular immune response directly through an increased release of neurotransmitters, including epinephrine, norepinephrine, neurokinin, and substance P, which

interact directly with lymphocytes, neutrophils, monocytes, and macrophages via receptors that cause an increase in their tissue-destructive function. Thus, in a manner similar to cortisol production, the stress-induced release of these neurotransmitters results in an upregulated immune response that increases the potential for destruction by the cellular response to periodontal pathogens.

It is important to remember that, although stress may predispose an individual to more destruction from periodontitis, the presence of periodontal pathogens remains as the essential etiologic factor. In other words, stress alone does not cause or lead to periodontitis in the absence of periodontal pathogens.

Influence of Stress on Periodontal Therapy Outcomes

Psychologic conditions such as stress and depression may also influence the outcome of periodontal therapy. In a large-scale retrospective study of 1299 dental records from a health maintenance organization database, 85 individuals with depression had posttherapy outcomes that were less favorable (below median) than the outcomes of individuals without depression.[73] More than half of these records (697) were complete enough for a comprehensive evaluation that included both periodontal diagnosis and psychologic profiles. The authors concluded that depression might have a negative effect on periodontal treatment outcomes.

A study investigating the relationship between psychologic stress and wound repair in patients after routine surgery (in this case, inguinal hernia open incision repair) revealed that stress impairs the inflammatory response and matrix degradation.[31] Forty-seven adults were given a standardized questionnaire to assess their psychologic stress before surgery. Wound fluids were collected during the first 20 hours after surgery to measure inflammatory markers: IL-1, IL-6, and matrix metalloproteinase-9 (MMP-9). Greater psychologic stress was significantly associated with lower levels of IL-1 and MMP-9 as well as with a significantly more painful, poorer, and slower recovery.

Another study compared the psychiatric characteristics of

individuals with different outcomes to periodontal therapy.[11] Two groups were compared to evaluate the psychologic characteristics of 11 individuals who were responsive to periodontal treatment compared with 11 individuals who were not responsive to periodontal treatment. The members of the responsive group had more rigid personalities, whereas those in the nonresponsive group had more passive, dependent personalities. Furthermore, the nonresponsive group reported more stressful life events having occurred in their past.

These studies suggest that both stressful life events and the individual's personality and coping skills are factors to consider when assessing the risk of periodontal disease destruction and the potential for successful periodontal therapy. If patients with emotional or defensive coping skills are identified, care should be taken to ensure that they receive information in a manner that does not elicit a defensive reaction.

Psychiatric Influence of Self-Inflicted Injury

Psychosomatic disorders may result in harmful effects to the health of tissues in the oral cavity through the development of habits that are injurious to the periodontium. Neurotic habits such as grinding or clenching the teeth, nibbling on foreign objects (e.g., pencils, pipes), nail biting, and excessive use of tobacco are all potentially injurious to the teeth and the periodontium. Self-inflicted gingival injuries, such as gingival recession, have been described in both children and adults (Fig. 14.17). However, these types of self-inflicted, factitious injuries do not appear to be common among psychiatric patients.[219]

FIG. 14.17 Severe gingival recession localized to the labial surface of all mandibular incisors. This finding was discovered in an uncooperative, institutionalized adult with mental disorders who had been placed under general anesthesia. The patient was known to pace around the home with all four fingers inside his lower lip.

Nutritional Influences

Some clinicians enthusiastically adhere to the theory in periodontal disease that assigns a key role to nutritional deficiencies and imbalances. Previous research did not support this view, but numerous problems in experimental design and data interpretation could be responsible for making these research findings inadequate.[5,218] The majority of opinions and research findings regarding the effects of nutrition on oral and periodontal tissues point to the following:

1. *There are no nutritional deficiencies that by themselves can cause gingivitis or periodontitis.* However, nutritional deficiencies can affect the condition of the periodontium and thereby may accentuate the deleterious effects of plaque-induced inflammation in susceptible individuals. Theoretically, one may presume that an individual with a nutritional deficiency is less able to defend against a bacterial challenge as compared with a nutritionally competent individual.

2. *There are nutritional deficiencies that produce changes in the oral cavity.* These changes include alterations of the tissues of the lips, oral mucosa, gingiva, and bone. These alterations are considered to be the periodontal and oral manifestations of nutritional disease.

The role of nutrition in periodontal disease may be related to the effect of nutrition on inflammation. A 2009 review of the literature evaluating the effect of nutritional factors on inflammation demonstrated that subtle shifts in nutritional status are associated with the prevalence of periodontitis.[46] More specifically, the authors reported that the results of contemporary animal and human studies have demonstrated the role of specific micronutrients in the modulation of the host's inflammatory response by reducing inflammatory biomarkers, which may in turn be responsible for periodontal destruction. The evidence for the effect of nutrition on inflammation is significant. Data suggest that diets that contain foods rich in antioxidants are beneficial, whereas foods that contain high levels of refined carbohydrates are detrimental to the inflammatory process.[46]

See the online material for a review of the existing knowledge of the effects of vitamin and protein deficiencies on changes in the periodontium.

Fat-Soluble Vitamin Deficiency

Vitamins A, D, and E are fat-soluble vitamins that are required in the human diet.

Vitamin A Deficiency

A major function of vitamin A is to maintain the health of the epithelial cells of the skin and mucous membranes. A deficiency of vitamin A results in dermatologic, mucosal, and ocular manifestations. In the absence of vitamin A, degenerative changes occur in epithelial tissues, thereby resulting in a keratinizing metaplasia. Because epithelial tissues provide a primary barrier function to protect against invading microorganisms, vitamin A may play an important role in protecting against microbial invasion

by maintaining epithelial integrity.

Little information is available regarding the effects of vitamin A deficiency on the oral structures in humans. Several epidemiologic studies have failed to demonstrate any relationship between this vitamin and periodontal disease in humans.[259]

In experimental animals, vitamin A deficiency results in hyperkeratosis and hyperplasia of the gingiva, with a tendency toward increased periodontal pocket formation. The following periodontal changes have been reported in vitamin A–deficient rats: hyperplasia and hyperkeratinization of the gingival epithelium, with proliferation of the junctional epithelium, and retardation of gingival wound healing.[64,85] In the presence of local factors, vitamin A–deficient rats develop periodontal pockets that are deeper than those seen in animals that are not deficient in vitamin A and that exhibit associated epithelial hyperkeratosis.[30,97]

Vitamin D Deficiency

Vitamin D or calciferol is essential for the absorption of calcium from the gastrointestinal tract and for the maintenance of the calcium–phosphorus balance. A deficiency of vitamin D and an imbalance in calcium–phosphorus intake result in rickets in young children and osteomalacia in adults. No studies have demonstrated a relationship between vitamin D deficiency and periodontal disease.

Vitamin D deficiency or imbalance on the periodontal tissues of young dogs results in osteoporosis of alveolar bone. Osteoid forms at a normal rate but remains uncalcified and fails to resorb, which leads to excessive accumulation. A reduction in the width of the periodontal ligament space results from a normal rate of cementum formation coupled with defective calcification and distortion of the growth pattern of alveolar bone.[19,262]

In osteomalacic animals, there is rapid, generalized, severe osteoclastic resorption of alveolar bone, proliferation of fibroblasts that replace bone and marrow, and new bone formation around the remnants of unresorbed bony trabeculae.[65] Radiographically, there is generalized partial to complete disappearance of the lamina dura and reduced density of the supporting bone, a loss of trabeculae, increased radiolucency of the trabecular interstices, and increased

prominence of the remaining trabeculae. Microscopic and radiographic changes in the periodontium are almost identical to those seen with experimentally induced hyperparathyroidism.

Vitamin E Deficiency

Vitamin E serves as an antioxidant to limit free-radical reactions and to protect cells from lipid peroxidation. Cell membranes, which are high in polyunsaturated lipids, are the major site of damage in patients with vitamin E deficiency. No relationship has been demonstrated between deficiencies in vitamin E and oral disease, but systemic vitamin E appears to accelerate gingival wound healing in the rat.[132,197]

Water-Soluble Vitamin Deficiency

Vitamins B and C are water-soluble vitamins that are required in the human diet.

B-Complex Deficiency

The vitamin B complex includes thiamin, riboflavin, niacin, pyridoxine (B_6), biotin, folic acid, and cobalamin (B_{12}). Oral disease is rarely caused by a deficiency in just one component of the B-complex group; the deficiency is generally multiple.

Oral changes that are common to B-complex deficiencies are gingivitis, glossitis, glossodynia, angular cheilitis, and inflammation of the entire oral mucosa. The gingivitis in individuals with vitamin B deficiencies is nonspecific because it is caused by bacterial plaque rather than by the deficiency; however, gingivitis is subject to the deficiency's modifying effect.

The human manifestations of **thiamin deficiency,** called *beriberi,* are characterized by paralysis; cardiovascular symptoms, including edema; and loss of appetite. Frank beriberi is rare in the United States. Oral disturbances that have been attributed to thiamin deficiency include hypersensitivity of the oral mucosa; minute vesicles (simulating herpes) on the buccal mucosa, under the tongue, or on the palate; and erosion of the oral mucosa.[104,159]

The symptoms of **riboflavin deficiency** *(ariboflavinosis)* include glossitis, angular cheilitis, seborrheic dermatitis, and a superficial

vascularizing keratitis. The glossitis is characterized by a magenta discoloration and atrophy of the papillae. In mild to moderate cases, the dorsum exhibits a patchy atrophy of the lingual papillae and engorged fungiform papillae, which project as pebble-like elevations.[166] With severe deficiency, the entire dorsum is flat, with a dry and often fissured surface. Changes observed in riboflavin-deficient monkeys include severe lesions of the gingiva, the periodontal tissues, and the oral mucosa, including noma.[45,250]

Angular cheilitis begins as an inflammation of the commissure of the lips, and this is followed by erosion, ulceration, and fissuring. Riboflavin deficiency is not the only cause of angular cheilitis. A loss of vertical dimension, together with the drooling of saliva into the angles of the lips, may produce a condition similar to angular cheilitis. Candidiasis may develop in the commissures of debilitated persons; this lesion has been termed *perlèche.*[101] Supplemental riboflavin is ineffective to resolve cases of glossitis and angular cheilitis that are not caused by vitamin deficiency.[272]

Niacin deficiency results in *pellagra,* which is characterized by symptoms of dermatitis, gastrointestinal disturbances, neurologic and mental disturbances (dermatitis, diarrhea, or dementia), glossitis, gingivitis, and generalized stomatitis. This condition is rare, but it may occasionally result from malabsorption or alcoholism. Glossitis and stomatitis may be the earliest clinical signs of niacin deficiency.[160] The gingiva may be involved in *aniacinosis* with or without tongue changes.[134] The most common finding is necrotizing ulcerative gingivitis, usually in areas of local irritation.

Oral manifestations of vitamin B complex and niacin deficiency in experimental animals include black tongue and gingival inflammation with destruction of the gingiva, the periodontal ligament, and the alveolar bone.[20,63] Necrosis of the gingiva and other oral tissues as well as leukopenia are terminal features of niacin deficiency in experimental animals.

Folic acid deficiency results in macrocytic anemia with megaloblastic erythropoiesis accompanied by oral changes, gastrointestinal lesions, diarrhea, and intestinal malabsorption.[64] Folic acid–deficient animals demonstrate necrosis of the gingiva, the periodontal ligament, and the alveolar bone without inflammation.[228] The absence of inflammation is the result of

deficiency-induced granulocytopenia. In humans with sprue and other folic acid deficiency states, generalized stomatitis occurs, which may be accompanied by ulcerated glossitis and cheilitis. Ulcerative stomatitis is an early indication of the toxic effect of the folic acid antagonists (e.g., methotrexate) used for the treatment of leukemia.

In a series of human studies, Vogel and colleagues[254,255] reported a significant reduction of gingival inflammation after the systemic or local use of folic acid as compared with placebo. This reduction occurred with no change in plaque accumulation. The authors also postulated that the gingival changes associated with pregnancy and oral contraceptives may be partly related to suboptimal levels of folic acid in the gingiva.[253] In a clinical study of pregnant women, a reduction in gingival inflammation occurred with the use of topical folate mouthrinses; no change was found with systemic folic acid.[192] A relationship has also been suggested between phenytoin-induced gingival overgrowth and folic acid on the basis of the interference of folic acid absorption and the use of phenytoin.[252] However, a more recent double-blind, randomized, placebo-controlled study of 20 institutionalized epileptic adults taking phenytoin found no difference in gingival conditions (i.e., gingival overgrowth and health or plaque index) between the group taking 3 mg of folic acid daily and the placebo group at 4-week intervals over a 16-week period.[33]

Vitamin C Deficiency

Severe vitamin C (ascorbic acid) deficiency in humans results in scurvy, a disease that is characterized by hemorrhagic diathesis and delayed wound healing. Vitamin C is required in the diet of humans as well as other primates, guinea pigs, and some rare flying mammals.[57] Because vitamin C is abundant in fruits and vegetables, scurvy is uncommon in developed countries. It may occur in infants during their first year of life if infant formulas are not fortified with vitamins and in older persons, especially those living alone and with restricted diets.[57] Malnutrition associated with alcoholism may predispose an individual to scurvy.

Scurvy results in the defective formation and maintenance of collagen, the impairment or cessation of osteoid formation, and

impaired osteoblastic function.[82,269] Vitamin C deficiency is also characterized by increased capillary permeability, susceptibility to traumatic hemorrhages, hyporeactivity of the contractile elements of the peripheral blood vessels, and sluggishness of blood flow.[144] Clinical manifestations of scurvy include hemorrhagic lesions into the muscles of the extremities, the joints, and sometimes the nailbeds; petechial hemorrhages, often around the hair follicles; increased susceptibility to infections; and impaired wound healing.[57] Bleeding, swollen gingiva, and loosened teeth are common features of scurvy.

Possible Etiologic Factors

Ascorbic acid may play a role in periodontal disease through one or more of the following suggested mechanisms[270]:

1. Low levels of ascorbic acid influence the metabolism of collagen within the periodontium, thereby affecting the ability of the tissue to regenerate and repair itself. No experimental evidence supports this view of the role of ascorbic acid. Furthermore, it has been shown that collagen fibers in the periodontal ligament of scorbutic monkeys are the last to be affected before the death of the animals.[258]
2. Ascorbic acid deficiency interferes with bone formation and leads to the loss of periodontal bone. Changes that do occur in alveolar bone and other bones as a result of failure of the osteoblasts to form osteoid take place very late in the deficiency state.[95] Osteoporosis of alveolar bone in scorbutic monkeys results from increased osteoclastic resorption; it is not associated with periodontal pocket formation.[258]
3. Ascorbic acid deficiency increases the permeability of the oral mucosa to tritiated endotoxin and tritiated inulin and of normal human crevicular epithelium to tritiated dextran.[6,9] Optimal levels of vitamin C would therefore maintain the epithelium's barrier function to bacterial products.
4. Increasing levels of ascorbic acid enhance the chemotactic and migratory actions of leukocytes without influencing their phagocytic activity.[99] Megadoses of vitamin C seem to impair the bactericidal activity of leukocytes.[230] The

significance of these findings for the pathogenesis and treatment of periodontal diseases is not understood.

5. An optimal level of ascorbic acid is apparently required to maintain the integrity of the periodontal microvasculature as well as the vascular response to bacterial plaque and wound healing.[39]
6. Depletion of vitamin C may interfere with the ecologic equilibrium of bacteria in plaque and thus increase its pathogenicity. However, no evidence demonstrates this effect.

Epidemiologic Studies

Several studies in large populations have analyzed the relationship between gingival or periodontal status and ascorbic acid levels.[259] These studies used different methods for the biochemical analysis of ascorbic acid and various indices for the assessment of periodontal changes; they were made in persons of different socioeconomic statuses, races, and ages. All of the epidemiologic surveys failed to establish a causal relationship between the levels of vitamin C and the prevalence or severity of periodontal disease.[38,75,215] Megadoses of ascorbic acid have also been found to be unrelated to better periodontal health.[122,271]

Gingivitis

The legendary association of severe gingival disease with scurvy led to the presumption that vitamin C deficiency is an etiologic factor in gingivitis, which is common at all ages. Gingivitis with enlarged, hemorrhagic, bluish-red gingiva is described as one of the classic signs of vitamin C deficiency, but *gingivitis is not caused by vitamin C deficiency.* Vitamin C–deficient patients do not necessarily have gingivitis. Acute vitamin C deficiency does not cause or increase the incidence of gingival inflammation, but it does increase its severity.[47,95,96] Gingivitis in vitamin C–deficient patients is caused by bacterial plaque. Vitamin C deficiency may aggravate the gingival response to plaque and worsen the edema, enlargement, and bleeding. In addition, although correcting the deficiency may reduce the severity of the disorder, gingivitis will remain as long as bacterial factors are present.

Periodontitis

Changes in the supporting periodontal tissues and gingiva in individuals with vitamin C deficiency have been documented extensively in experimental animals.[95,258] Acute vitamin C deficiency results in edema and hemorrhage in the periodontal ligament, osteoporosis of the alveolar bone, and tooth mobility; hemorrhage, edema, and degeneration of the collagen fibers occur in the gingiva. Vitamin C deficiency also impairs gingival healing. The periodontal fibers that are least affected by vitamin C deficiency are those just below the junctional epithelium and above the alveolar crest, which explains the infrequent apical downgrowth of the epithelium.[258]

Vitamin C deficiency alone does not cause periodontal destruction. Local bacterial factors are required for increased probing depth and attachment loss to occur. However, acute vitamin C deficiency accentuates the destructive effect of gingival inflammation on the underlying periodontal ligament and alveolar bone.[96]

Experimental studies conducted in humans failed to show the dramatic clinical changes that have traditionally been described with scurvy.[58,117,206] A case report by Charbeneau and Hurt[47] showed worsening of a preexisting moderate periodontitis with the development of scurvy. In a retrospective analysis of 12,419 adults studied in the Third National Health and Nutrition Examination Survey (NHANES III), Nishida and colleagues[184] found that there was a weak but statistically significant dose–response relationship between the level of dietary vitamin C intake and periodontal disease in current and former smokers as measured by clinical attachment. This suggests that vitamin C deficiency has its greatest impact on periodontal disease when preexisting disease and other codestructive factors are present.

Summary

Analysis of the literature indicates that the microscopic signs of vitamin C deficiency are quite different from those that occur with plaque-induced periodontal disease in humans. Patients with acute or chronic vitamin C–deficient states and no plaque accumulation demonstrate minimal (if any) changes in their gingival health status.

Protein Deficiency

Protein depletion results in hypoproteinemia with many pathologic changes, including muscular atrophy, weakness, weight loss, anemia, leukopenia, edema, impaired lactation, decreased resistance to infection, slow wound healing, lymphoid depletion, and reduced ability to form certain hormones and enzyme systems. Protein deprivation has been shown to cause changes in the periodontium of experimental animals.[48] The following observations have been made in protein-deprived animals: degeneration of the connective tissue of the gingiva and the periodontal ligament, osteoporosis of the alveolar bone, impaired deposition of the cementum, delayed wound healing, and atrophy of the tongue epithelium.[41,234,235] Similar changes occur in the periosteum and bone in nonoral areas. Osteoporosis results from the reduced deposition of osteoid, a reduction in the number of osteoblasts, and impairment in the morphodifferentiation of connective tissue cells to form osteoblasts rather than from increased osteoclastic activity.

These observations are of interest in that they reveal a loss of alveolar bone that results from the inhibition of normal bone-forming activity rather than from the introduction of destructive factors. Protein deficiency also accentuates the destructive effects of bacterial plaque and occlusal trauma on the periodontal tissues, but the initiation of gingival inflammation and its severity depend on the bacterial plaque.[235] In other words, protein deprivation results in periodontal tissues that lack integrity and that, as a result, are more vulnerable to breakdown when challenged by bacteria.

Medications

Some medications that are prescribed to cure, manage, or prevent diseases may have adverse effects on periodontal tissues, wound healing, or the host immune response. Bisphosphonates are a class of medications widely prescribed for the treatment of osteoporosis and various types of cancer. They have recently been implicated in osteonecrosis of the jaw (ONJ), a serious condition that is characterized by non-healing and often painful exposure of

nonvital and often sequestrating bone in the jaws. Corticosteroids have long been prescribed to suppress the immune system for the control and management of autoimmune disease, during cancer treatment, and as an antirejection medication after organ transplantation. This section discusses the effect of bisphosphonates and corticosteroids on the periodontium. Readers are referred to Chapter 39 for additional information about these and other important medications.

Bisphosphonates

Bisphosphonate medications are primarily used to treat cancer (via intravenous [IV] administration) and osteoporosis (via oral administration). They act by inhibiting osteoclastic activity, which leads to less bone resorption, less bone remodeling, and less bone turnover.[216] The use of bisphosphonates in cancer treatment is aimed at preventing the often lethal imbalance of osteoclastic activity. During the treatment of osteoporosis, the goal is simply to harness osteoclastic activity to minimize or prevent bone loss and, in many cases, to increase bone mass by creating an advantage for osteoblastic activity. The major differences in the use of bisphosphonates for cancer versus osteoporosis are the potency and route of administration of the specific bisphosphonate medication used. Potency is influenced by the chemical properties as well as by the binding and release pharmacokinetic properties of these agents as they apply to bone. Specifically, the strength of binding and the ease of release of bisphosphonates with hydroxyapatite make these drugs more or less potent.

Bisphosphonates were first synthesized during the 1950s as a substitute for pyrophosphate, a compound used in detergent. The ability of bisphosphonates to increase bone mass was discovered after animal studies that took place in 1966, but the potential advantage of using bisphosphonates in humans with low bone mass was not appreciated until 1984.[257] The US Food and Drug Administration approved the use of alendronate for osteoporosis in 1995.

The chemical structure of bisphosphonate consists of two phosphate groups covalently bonded to a central carbon (Fig.

14.18). In addition to the two phosphate groups, the central carbon also has two side chains, R1 and R2. Both the short R1 side chain and the long R2 side chain influence the chemical properties and pharmacokinetics. The long R2 side chain also influences the mode of action and determines the strength or potency of the medication. Bisphosphonates inhibit osteoclasts by two mechanisms that depend on whether the R2 side chain contains nitrogen. Nonaminobisphosphonates are metabolized by osteoclasts to form an adenosine triphosphate analog that interferes with energy production and causes osteoclast apoptosis. Aminobisphosphonates (i.e., risedronate, zoledronate, ibandronate, and alendronate) are more potent and have multiple effects on osteoclasts, including the following: (1) inactivation of adenosine triphosphate; (2) osteoclast cytoskeletal disruption; (3) impairment of osteoclast recruitment; and (4) induction of osteoblasts to produce osteoclast-inhibiting factor.[190] Bisphosphonates also inhibit bone metabolism via antiangiogenic activity.[35]

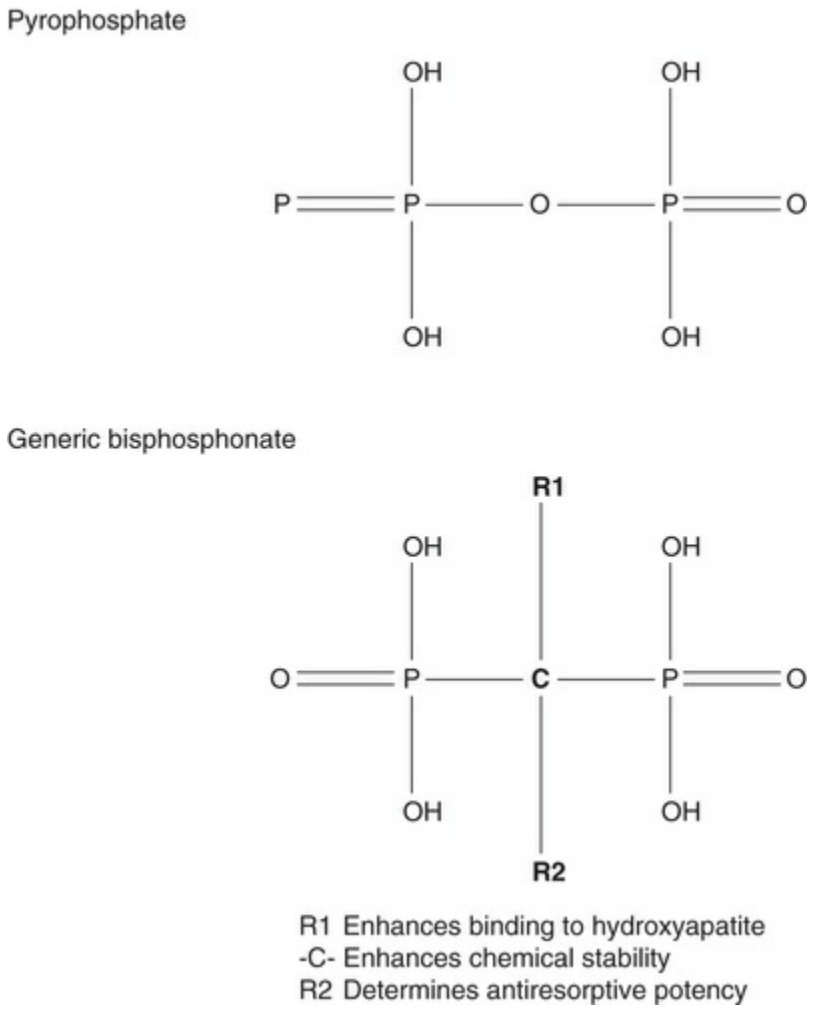


FIG. 14.18 Chemical structure of a bisphosphonate molecule. Two phosphate groups are covalently bonded with a central carbon. The carbon also has two side chains, R1 and R2.

Table 14.1 lists some of the common bisphosphonate medications used for osteoporosis and cancer treatment that are currently available in the United States.

TABLE 14.1

Current Nonaminobisphosphonate and Aminobisphosphonate Medications and Common Therapeutic Uses

Generic Name	Commercial Name	Route of Administration	Therapeutic Use	Nitrogen-Containing R2 Side Chain	Relative Antiresorptive Potency
Etidronate	Didronel	PO	Paget disease	No	1
Tiludronate	Skelid	PO	Paget disease	No	10

Risedronate	Actonel	PO	Osteoporosis, Paget disease	Yes	5,000
Ibandronate	Boniva	PO	Osteoporosis	Yes	10,000
Alendronate	Fosamax	PO	Osteoporosis, Paget disease	Yes	1000
Pamidronate	Aredia	IV	Paget disease, cancer	Yes	100
Zoledronate	Zometa	IV	Cancer	Yes	10,000+

IV, Intravenous; *PO*, by mouth.

There is growing evidence that bisphosphonates also affect soft tissues and that they may contribute to ONJ via inhibition of soft tissue healing.[143] An in vitro study by Kim and colleagues suggested that bisphosphonates may act on oral keratinocytes to impair wound healing by inhibiting epithelial migration and wound closure.[133] Interestingly, the effects of bisphosphonates on oral mucosal cells and bone cells share the common mechanism of interference with products of the mevalonate pathway, which may be more significant to the overall problem than the reported apoptosis effects on osteoclasts. The inhibition of farnesyl pyrophosphate synthase leads to inhibition of the mevalonate pathway end product, geranylgeranyl pyrophosphate (Fig. 14.19). This bisphosphonate-inhibited pathway is required for many essential cellular functions in a variety of tissues. In the case of soft tissues, the bisphosphonate-induced senescence of human oral keratinocytes was found to be mediated, at least in part, by inhibition of the mevalonate pathway. Similarly, Fisher and colleagues reported that bisphosphonates inhibit bone resorption via prevention of protein prenylation in osteoclasts that is caused by the inhibition of farnesyl pyrophosphate synthase, resulting in interference with the production of geranylgeranyl pyrophosphate.

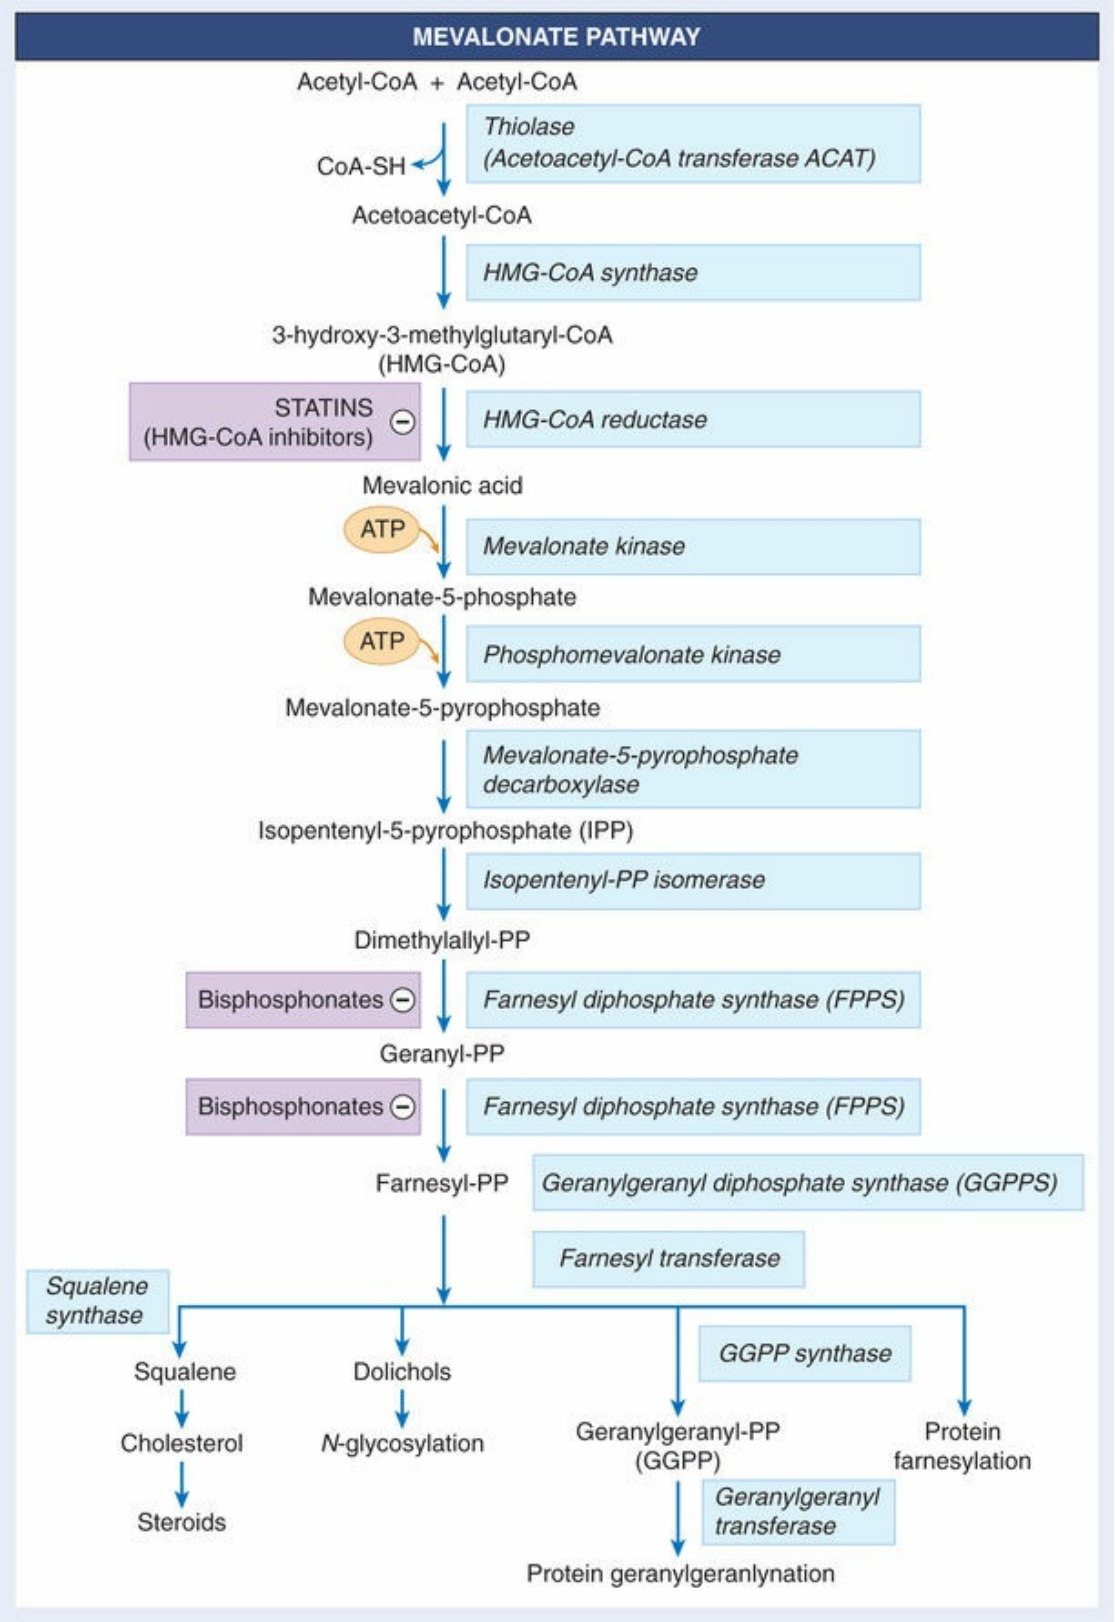

FIG. 14.19 Mevalonate pathway. Bisphosphonates interfere with the farnesyl pyrophosphate synthase enzyme, which leads to the inhibition of geranylgeranyl pyrophosphate, an important end product for cellular functions.

Bisphosphonates have a high affinity for hydroxyapatite. They are rapidly absorbed in bone, especially in areas of high activity, which may help to explain why bisphosphonate-induced osteonecrosis is found only in the jaws.[257] The bisphosphonate molecule gets incorporated into bone without being metabolized or modified. During the osteoclastic resorption of bone, the trapped bisphosphonate is released and able to affect osteoclasts again. As a result, the half-life of bisphosphonates in the bone is estimated to be 10 years or longer.

ONJ associated with bisphosphonates was first described in 2003 by Marx in a report of 36 patients with avascular necrosis of the jaw who had been treated with IV bisphosphonate for malignant tumors.[163] Several case series reporting an association between bisphosphonates and ONJ were published subsequently.[165,214] Various terms have been used to describe this type of ONJ, including *avascular necrosis, bisphosphonate-associated ONJ, bisphosphonate-induced ONJ,* and *bisphosphonate-related ONJ (BRONJ).*[257] Today, with the widespread recognition of BRONJ, it is important to remember that necrotic bone exposure of the jaw (ONJ) is a condition with multiple possible etiopathogenic factors, including systemic medications, radiation, infection, trauma, direct chemical toxicity, and other idiopathic mechanisms; clinicians should carefully consider all factors before making a diagnosis of BRONJ.[8]

The condition of BRONJ has been defined as the exposure and necrosis of portions of the jaw bone in patients who have been exposed to bisphosphonates that has persisted for longer than 8 weeks with no history of radiation therapy to the jaws.[212] The stage of osteonecrosis is used to categorize patients and to make treatment decisions.[2,164,165,212] Stage 0 patients are patients at risk who have been treated with IV or oral bisphosphonates but who have no apparent exposed or necrotic bone. Stage 1 involves exposed or necrotic bone in patients who are asymptomatic with no infection. Stage 2 involves exposed or necrotic bone in patients with pain and clinical evidence of infection. Stage 3 involves exposed or necrotic bone in patients with pain, infection, and one or more of the following: pathologic fracture, extraoral fistula, or osteolysis that extends to the inferior border.

Clinically, BRONJ manifests as exposed alveolar bone that occurs spontaneously or after a traumatic event such as a dental procedure (Figs. 14.20 and 14.21). The sites may be painful, with surrounding soft tissue induration and inflammation. Infection with drainage may be present. Radiographically, lesions appear radiolucent, with sclerosis of the lamina dura, a loss of the lamina dura, or a widening of the periodontal ligament in areas where teeth are present. Histologically, bone appears necrotic, with empty lacunae demonstrating a lack of living osteocytes. In advanced cases, pathologic fracture may be present through the area of exposed or necrotic bone.

FIG. 14.20 Clinical photograph of exposed bone on the palatal surface of the maxilla adjacent to the molar root in a 60-year-old female with bisphosphonate-induced osteonecrosis of the bone (maxilla). The bone exposures were noted after about 1 year of treatment with bisphosphonate (Aredia and Zometa). (Courtesy Drs. Eric S. Sung and Evelyn M. Chung, University of California, Los Angeles, CA.)

FIG. 14.21 Clinical photograph of exposed bone on the lingual surface of the posterior mandible of a 70-year-old male with bisphosphonate-induced osteonecrosis of the bone (mandible). The bone exposure was noted after 3 years of bisphosphonate treatment (Aredia and Zometa) for multiple myeloma. (Courtesy Drs. Eric S. Sung and Evelyn M. Chung, University of California, Los Angeles, CA.)

The high potency of nitrogen-containing bisphosphonates—especially those administered intravenously for cancer treatment (e.g., zoledronate)—may explain the high incidence of BRONJ in these patients compared with osteoporotic patients taking oral bisphosphonates. The incidence among patients who are being treated for cancer has been reported to range from 2.5% to 5.4%[261] or from 1% to 10%.[35] Estimating the incidence among patients who are taking oral bisphosphonates for osteoporosis is more difficult due to the large number of patients taking this prescription medication and a lack of good reporting or documentation for these patients. Some reports estimate the incidence of BRONJ from oral bisphosphonates to range from 0.007% to 0.04%,[257] whereas other reports suggest a slightly higher incidence that ranges from 0.004% to 0.11%.[233] Clearly, the incidence among patients taking oral

bisphosphonates appears to be low.

It has been observed that BRONJ lesions occur most often in areas with dense bone and thin overlying mucosa, such as tori, bony exostoses, and the mylohyoid ridge.[165,213,214] Lesions are found more commonly in the mandible than in the maxilla at a 2 : 1 ratio.[212] Work by Schaudinn and colleagues suggests that there may be a toxic threshold of accumulated bisphosphonate in the bone that leads to the induction of BRONJ lesions and that measuring or calculating the concentration in bone may be a means of assessing an individual's risk for the development of BRONJ.[222]

In addition to bisphosphonate therapy, other factors are thought to increase individual susceptibility to BRONJ. Potential risk factors that may contribute to BRONJ include systemic corticosteroid therapy, smoking, alcohol, poor oral hygiene, chemotherapy, radiotherapy, diabetes, and hematologic disease.[29] The precipitating factors or trauma-inducing events that lead to BRONJ are reported to include extractions, root canal treatment, periodontal infections, periodontal surgery, and dental implant surgery; however, some cases appear to be idiopathic, with spontaneous exposures.[165] In a retrospective evaluation of patients treated with IV bisphosphonates for metastatic bone cancer from 1996 to 2006, Estilo and colleagues[76] found that the type of cancer, the duration of bisphosphonate therapy, sequential IV bisphosphonate treatment with pamidronate followed by zoledronate, comorbid osteoarthritis, rheumatoid arthritis, and benign hematologic conditions were significantly associated with an increased likelihood of ONJ. In their study, the systemic administration of corticosteroids was not found to be associated with an increased risk of BRONJ.[76]

As stated previously, patients who are being treated for cancer with IV bisphosphonates are at greater risk than patients being treated for osteoporosis with oral bisphosphonates. Dental health care providers should evaluate patients carefully, consider the risks, communicate with medical health care providers, inform patients, and consider treatment options and risks carefully.

Key Fact

The effects of bisphosphonates on oral hard and soft tissue cells share the common mechanism of interference with products of the mevalonate pathway, which may be more significant to the overall problem than the reported apoptosis effects on osteoclasts. The inhibition of farnesyl pyrophosphate synthase leads to the inhibition of the mevalonate pathway end product, geranylgeranyl pyrophosphate (see Fig. 14.19). This bisphosphonate-inhibited pathway is required for many essential cellular functions in a variety of tissues.

Bisphosphonates and Periodontal Bone Loss

Not surprisingly, the bone-preserving action of bisphosphonates has been studied and advocated for use in the prevention of bone loss from periodontal disease.[245] Several animal studies have shown that bisphosphonates, either applied topically or administered systemically, have the potential to prevent the alveolar bone loss caused by periodontitis.[44,105,173,175,191,231,264] The use of bisphosphonates for bone regeneration has been proposed as well.[245] Although some studies have demonstrated bone preservation with low doses of bisphosphonate, higher doses and longer administration may have a neutral or detrimental effect on bone loss caused by periodontitis.[36,44] In a 2- to 3-year follow-up report of four female patients with periodontitis treated with etidronate (200 mg daily for periods of 2 weeks with 10-week off-drug periods), the potential of this agent to prevent periodontal bone loss was reported.[242] In a 2-year, randomized, placebo-controlled clinical trial of 335 patients treated with alendronate (70 mg once weekly), no significant difference in alveolar bone loss or alveolar bone density was found.[124] Interestingly, alendronate was found to significantly reduce bone loss relative to controls in a subset of this group (i.e., patients with low mandibular bone mineral density [BMD] at baseline), suggesting that the effect may be more perceptible in cases with less bone mass or less bone density. In another clinical trial of 24 patients (12 experimental and 12 control), alendronate was shown to have a significant positive (bone-preserving) effect on bone density in jaws.[71] The BMD of the maxilla and mandible was measured for all patients with the use of dual-energy x-ray absorptiometry (DEXA) at baseline and after 6 months of treatment

(10 mg daily for 6 months).

Corticosteroids

In humans, the systemic administration of cortisone and adrenocorticotropic hormone appears to have no effect on the incidence or severity of gingival and periodontal disease. However, renal transplantation patients receiving immunosuppressive therapy (either prednisone or methylprednisone combined with either azathioprine or cyclophosphamide) have significantly less gingival inflammation than control subjects with similar amounts of plaque.[21,129,141,189,249]

Exogenous cortisone may have an adverse effect on bone quality and physiology. The systemic administration of cortisone in experimental animals resulted in the osteoporosis of alveolar bone.[98] There was capillary dilation and engorgement with hemorrhage into the periodontal ligament and gingival connective tissue, degeneration and a reduction in the number of collagen fibers in the periodontal ligament, and increased destruction of the periodontal tissues associated with inflammation.[98]

Stress increases circulating endogenous cortisol levels through stimulation of the adrenal glands (i.e., the hypothalamic–pituitary–adrenal axis). This increased exposure to endogenous cortisol may have adverse effects on the periodontium by diminishing the immune response to periodontal bacteria (see the section about Psychosocial Stress, Depression, and Coping).

See the online material for discussion of additional systemic conditions and their influence on periodontal health.

Other Systemic Conditions

Osteoporosis

Osteoporosis is a disease that is characterized by low bone mass and structural deterioration leading to an increased risk of bone fracture. It affects approximately 10 million people in the United States. The condition has a higher predilection for females (80%) compared with males (20%). An additional 34 million individuals in

the United States are estimated to have osteopenia or low bone density. The loss of bone mass and the incidence of osteoporosis increases with age for both men and women, with women being affected earlier than men. The rate of bone loss is greatest for women during the perimenopausal years, when estrogen levels decrease.

A BMD test is used to measure an individual's bone mass. BMD is measured with the use of a DEXA scan. The DEXA value or T-score is a comparison of the patient's BMD with that of a healthy 30-year-old adult with peak bone mass. The World Health Organization defines osteoporosis and osteopenia by measures of standard deviation rather than comparison with a normal, healthy, young adult. Thus, a T-score between +1 and −1 is considered normal, whereas a T-score between −1 and −2.5 indicates low bone density or osteopenia and a T-score of less than −2.5 (i.e., more than 2.5 standard deviations below normal) is diagnostic for osteoporosis (eTable 14.1).

eTABLE 14.1

Definitions of Osteoporosis and Osteopenia Indicated by T-Scores*

T-Score	Bone Mineral Density Category
≥−1	Normal
−1 to −2.5	Low (osteopenia)
≤−2.5	Osteoporosis

*Ranges of T-scores are based on standard deviations from the normal value, which is based on the bone mineral density of a healthy 30-year-old adult.

(Adapted from World Health Organization Scientific Group on the Assessment of Osteoporosis at Primary Health Care Level: *Summary Meeting Report*, Brussels, May 5–7, 2004.)

One of the most significant consequences of osteoporosis is the increased risk of bone fracture. All bones affected by osteoporosis are susceptible to fracture, but fractures of the pelvis and vertebrae carry the most serious risk of morbidity and mortality. Studies have reported that approximately 20% of patients with hip fractures die within a year and that 50% experience significant disability (e.g., an inability to walk unassisted).[145]

Although it is logical to surmise a relationship between osteoporosis and periodontitis, it has been a challenging hypothesis

to prove. One of the difficulties is the fact that both osteoporosis and periodontitis are chronic, multifactorial diseases that result in bone loss, and bone loss in each condition is exacerbated by local and systemic factors.[186] Gender, genetic predisposition, inactivity, deficient diets (e.g., deficient in calcium or vitamin D), alcohol, smoking, hormones, and medications put individuals at risk for osteoporosis, with some of these factors putting them at risk for the progression of periodontitis as well. Variations in populations studied, measurements used to assess disease, and study design have also hindered the ability to clearly define a relationship between osteoporosis and periodontitis.

Attempts to use tooth loss as an indirect measure of periodontitis in individuals with osteoporosis have offered mixed conclusions. Several studies have reported greater tooth loss, more alveolar bone loss, and edentulism in individuals with osteoporosis.[61,67,111,274] However, some other studies have suggested that tooth loss is not correlated with osteoporosis or BMD.[28,69,176] One large study of 1365 Caucasian postmenopausal females that investigated systemic BMD (lumbar spine and proximal femur) and tooth loss found no significant correlation.[69] Part of the challenge and the reason for conflicting results in these studies may be differences in measurement methods. Another problem with translating any tooth loss study conclusions to address the question of whether osteoporosis contributes to periodontitis is that the cause of tooth loss in these studies is often unknown (i.e., tooth loss may or may not be related to periodontal disease).

Studies that attempt to correlate osteoporosis with periodontitis are fraught with similar if not greater challenges. Again, some studies have concluded or suggested that osteoporosis does contribute to the progression of periodontitis,[121,135,177,247] whereas others refute this conclusion.[72,155] One study by Elders and colleagues failed to show a correlation between lumbar BMD and clinical parameters of periodontitis in a dentate group of 286 females between the ages of 46 and 55 years.[72] The researchers used intraoral periodontal examinations (i.e., probing depth, bleeding on probing, and missing teeth) and bitewing radiographs to assess clinical parameters of periodontitis and interproximal alveolar bone loss. This study included edentulous subjects as well, but no

significant difference in BMD was found between edentulous (60) and dentate (226) subjects, suggesting that neither periodontitis nor tooth loss was related to osteoporosis. The mean age of the subjects in this study was relatively young, which may have contributed to the lack of correlation.[91]

Most studies citing a positive correlation between osteoporosis or BMD and periodontitis are cross-sectional studies of postmenopausal females. Klemetti and colleagues evaluated 227 healthy postmenopausal women between the ages of 48 and 56 years and found that women with higher skeletal BMD were more likely to retain their teeth in the presence of periodontitis (i.e., deep periodontal pockets) compared with women with osteoporosis.[135] Tezal and colleagues concluded that skeletal BMD (measured by DEXA at multiple sites) is related to alveolar bone loss and, to a lesser extent, to clinical attachment loss, thereby implicating postmenopausal osteopenia as a risk indicator for periodontal disease in 70 postmenopausal white women between the ages of 51 and 78 years.[247] Periodontal parameters included probing depth, supragingival plaque, calculus, bleeding on probing, clinical attachment loss, and interproximal alveolar bone loss. Analysis was adjusted for age, age at menopause, estrogen supplementation, cigarette smoking, body mass, and supragingival plaque. Inagaki and colleagues evaluated the association between periodontal conditions, tooth loss, and metacarpal BMD in a cross-sectional study of 356 Japanese women: 171 premenopausal women (mean age, 37.9 years) and 185 postmenopausal women (mean age, 63.3 years). The authors concluded that periodontal status and tooth loss after menopause could be a useful indicator of metacarpal BMD loss in Japanese women.[121] These cross-sectional studies are suggestive but do not consider the periodontal condition or existence of periodontitis before the onset of osteoporosis or the loss of systemic BMD.

The effect of estrogen deficiency and osteopenia or osteoporosis on periodontitis is not known, but it may be an important factor to consider. Reinhardt and colleagues[205] conducted a 2-year, prospective, longitudinal study of postmenopausal women (59 with moderate or advanced periodontitis and 16 with no periodontitis) to evaluate the effect of estrogen (serum estradiol) levels on

periodontitis in these patients. Clinical measurements—including supragingival plaque, bleeding on probing, and relative clinical attachment—were taken at baseline and every 6 months for 2 years. The authors concluded that estrogen deficiency and osteopenia or osteoporosis together are risk factors for alveolar bone loss in postmenopausal women with a history of periodontitis.[205] Lerner[146] also proposed that estrogen deficiency may play a significant role in the progression of periodontitis in osteopenic or osteoporotic women, citing the fact that the cytokines thought to be involved in inflammation-induced remodeling are very similar to those suggested to play crucial roles in postmenopausal osteoporosis. In patients with periodontal disease and concomitant postmenopausal osteoporosis, the possibility exists that the lack of estrogen influences the activities of bone cells and immune cells in such a way that the progression of alveolar bone loss is enhanced.[146] In fact, there are numerous studies that report less risk for tooth loss and improved oral health among postmenopausal women receiving hormone replacement therapy.[7,18,25,108,109,241] More prospective, longitudinal studies evaluating the effect of estrogen and osteopenia or osteoporosis on periodontitis are needed to improve the current understanding.

Congenital Heart Disease

Congenital heart disease occurs in about 1% of live births. Approximately 40% of individuals born with heart defects would die without treatment. However, the prognosis has been dramatically improved with advances in cardiac surgery. Cardiac defects can involve the heart, the adjacent vessels, or a combination of both. The most striking feature of congenital heart disease is cyanosis caused by the shunting of deoxygenated blood from the right to the left, which results in the return of poorly oxygenated blood to the systemic circulation. In severe cases, cyanosis is obvious at birth, particularly in the presence of tetralogy of Fallot. Chronic hypoxia causes impaired development, compensatory polycythemia (i.e., an increase in RBCs and hemoglobin), and clubbing edema of toes and fingers (eFig. 14.11). Polycythemia is significant because it can result in hemorrhagic or thrombotic

tendencies. Patients with congenital heart defects are often at risk for infective endocarditis as a result of turbulent blood flow in the heart and the associated cardiovascular defects. The need for prophylactic antibiotics should be evaluated before dental therapy.

EFIG. 14.11 Characteristic clubbing of the fingers in an adolescent patient with tetralogy of Fallot. This is consistent with untreated congenital cyanotic heart disease.

In addition to the obvious cyanosis of the lips and the oral mucosa, oral abnormalities associated with cyanotic congenital heart disease include delayed eruption of both primary and permanent dentitions, increased positional abnormalities, and enamel hypoplasia. The teeth often have a bluish-white appearance with an increased pulp vascular volume. Gingival disease and other oral symptoms have been reported in children with congenital heart disease.[27,128] Reports seem to indicate more severe caries and periodontal disease in patients with cyanotic congenital heart defects. However, the apparent increase in dental disease may be attributed to poor oral hygiene and a general lack of dental care rather than a disease-related etiology.

Tetralogy of Fallot

As its name implies, tetralogy of Fallot is characterized by four cardiac defects: (1) ventricular septal defect, (2) pulmonary stenosis, (3) malposition of the aorta to the right, and (4) compensatory right ventricular enlargement. Clinical features include severe cyanosis,

audible heart murmurs, and breathlessness. Cyanosis and breathlessness cause cerebral anoxia and syncope. Oral changes include a purplish-red discoloration of the lips and the gingiva. Severe marginal gingivitis and periodontal destruction have been reported (eFig. 14.12). The discoloration of the lips and the gingiva corresponds to the general degree of cyanosis and returns to normal after corrective heart surgery. The tongue appears coated, fissured, and edematous, and there is extreme reddening of the fungiform and filiform papillae. The number of subepithelial capillaries is increased, but this also returns to normal after heart surgery.[84]

EFIG. 14.12 Extensive marginal inflammation with ulceronecrotic lesions and periodontal destruction in the same patient with tetralogy of Fallot as shown in eFig. 14.11.

Eisenmenger Syndrome

Among patients with ventricular septal defects, about half of those with large defects (i.e., >1.5 cm in diameter) develop Eisenmenger syndrome. This syndrome is distinguished by a greater blood flow from the stronger left ventricle to the right ventricle (backward flow) through the septal defect. This causes increased pulmonary blood flow, which in turn leads to progressive pulmonary fibrosis, small vessel occlusion, and high pulmonary vascular resistance. With increasing pulmonary resistance, the right ventricle hypertrophies, the shunt becomes bidirectional, and ultimately blood flow is reversed (i.e., it flows from right to left). The increased vascular resistance builds pressure in the right ventricle, thereby

causing right ventricular hypertrophy and a reversal in the direction of the blood flow, which results in a right-to-left shunt.

The natural history of a patient with untreated Eisenmenger syndrome is a gradual increase in cyanosis over many years that eventually leads to cardiac failure. Cyanosis of the lips, cheeks, and buccal mucous membranes is observed in these patients, but it is much less severe than in those with tetralogy of Fallot. Severe, generalized periodontitis has been reported in patients with Eisenmenger syndrome.[49] However, as in patients with other types of congenital heart disease, the incidence of periodontal disease reported in those with Eisenmenger syndrome may be related more to poor oral hygiene and a general lack of dental care than to any specific, syndrome-related etiology.

Hypophosphatasia

Hypophosphatasia is a rare familial skeletal disease that is characterized by rickets, poor cranial bone formation, craniostenosis, and the premature loss of the primary teeth, particularly the incisors. Patients have a low level of serum alkaline phosphatase, and phosphoethanolamine is present in serum and urine.

Teeth are lost with no clinical evidence of gingival inflammation, and they show reduced cementum formation.[24] In patients with minimal bone abnormalities, the premature loss of the deciduous teeth may be the only symptom of hypophosphatasia. In adolescents, this disease resembles localized juvenile (aggressive) periodontitis.[273]

Metal Intoxication

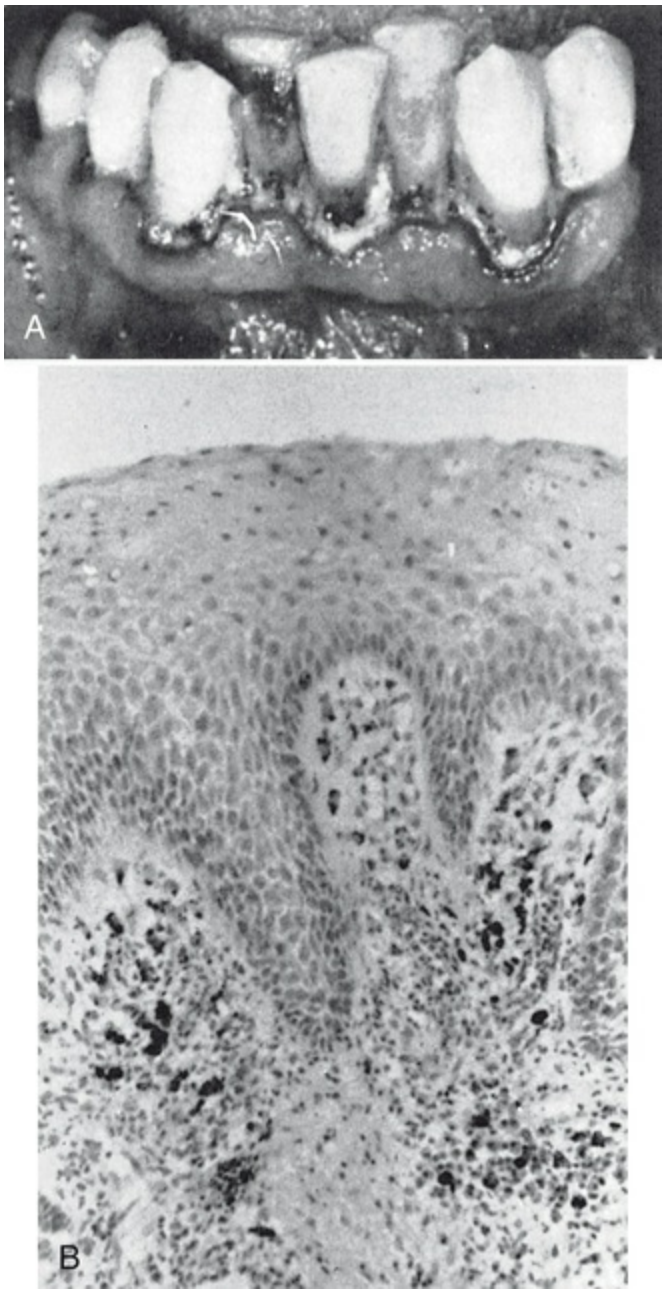
The ingestion of metals such as mercury, lead, and bismuth in medicinal compounds and through industrial contact may result in oral manifestations caused by either intoxication or absorption without evidence of toxicity.

Bismuth Intoxication

Chronic bismuth intoxication is characterized by gastrointestinal

disturbances, nausea, vomiting, and jaundice as well as by an ulcerative gingivostomatitis, generally with pigmentation and accompanied by a metallic taste and burning sensation of the oral mucosa. The tongue may be sore and inflamed. Urticaria, different types of exanthematous eruptions, bullous and purpuric lesions, herpes zoster–like eruptions, and pigmentation of the skin and mucous membranes are among the dermatologic lesions attributed to bismuth intoxication. Acute bismuth intoxication, which is seen less frequently, is accompanied by methemoglobin formation, cyanosis, and dyspnea.[115]

Bismuth pigmentation in the oral cavity usually appears as a narrow, bluish-black discoloration of the gingival margin in areas of preexisting gingival inflammation (eFig. 14.13). Such pigmentation results from the precipitation of particles of bismuth sulfide associated with vascular changes in inflammation; it is not evidence of intoxication but simply indicates the presence of bismuth in the bloodstream. Bismuth pigmentation in the oral cavity also occurs in cases of intoxication; it assumes a linear form if the marginal gingiva is inflamed.



EFIG. 14.13 Bismuth line. (A) Linear discoloration of the gingiva in relation to local irritation in a patient receiving bismuth therapy. (B) Biopsy specimen showing bismuth particles engulfed by monocytes and macrophages.

Lead Intoxication

Lead is slowly absorbed, and toxic symptoms are not particularly definitive when they do occur.[125] There is a pallor of the face and lips and gastrointestinal symptoms that consist of nausea, vomiting, loss of appetite, and abdominal colic. Peripheral neuritis,

psychologic disorders, and encephalitis have been reported. Oral signs include salivation, coated tongue, a peculiar sweetish taste, gingival pigmentation, and ulceration. Gingival pigmentation is linear (Burtonian line), steel gray, and associated with local inflammation. Oral signs may occur without toxic symptoms.

Mercury Intoxication

Mercury intoxication is characterized by headache, insomnia, cardiovascular symptoms, pronounced salivation (ptyalism), and a metallic taste.[4] Gingival pigmentation in linear form results from the deposition of mercuric sulfide. The chemical also acts as an irritant, which accentuates the preexisting inflammation and often leads to notable ulceration of the gingiva and the adjacent mucosa as well as the destruction of the underlying bone. Mercurial pigmentation of the gingiva also occurs in areas of local irritation in patients without symptoms of intoxication.

Other Chemicals

Other chemicals (e.g., phosphorus, arsenic, chromium) may cause necrosis of the alveolar bone, with loosening and exfoliation of the teeth.[147,225] Inflammation and ulceration of the gingiva are usually associated with the destruction of the underlying tissues. Benzene intoxication is accompanied by gingival bleeding and ulceration with the destruction of the underlying bone.[225]

Conclusion

Today, we have a better appreciation for the complexity and significance of interrelationships between periodontal infections and host defense. Genetic, environmental, physical, and psychosocial factors have the potential to alter periodontal tissues and the host immune response, thereby resulting in more severe periodontal disease. It is important to recognize that the systemic diseases, disorders, or conditions themselves do not cause periodontitis; rather, they may predispose, accelerate, or otherwise increase disease progression. This chapter reviewed important systemic diseases, disorders, and conditions that influence

periodontal health.

Case Scenario 14.1

Patient:
38-year-old Caucasian male

Chief Complaint:
“My gums are swollen and they bleed a lot”

Background Information:
The patient noticed swelling of the gingiva 3 months after he started taking Dilantin 500 mg daily for seizures. He was initially diagnosed with epilepsy 16 years ago. He reports brushing once a day and does not floss.

Clinical Findings:
Exam reveals generalized moderate bleeding on probing. There is moderate to heavy plaque and calculus. Probing pocket depths are generalized 3–6 mm with localized 7–9 mm around posterior teeth. Class 1–2 furcation involvement, Miller class 1–3 tooth mobility, and localized moderate gingival recession are present. There are localized areas with moderate to severe erythema, edema, and overgrowth of the gingiva, especially in the mandibular anterior area.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Drug induced gingival overgrowth is more severe in: A. Edentulous areas B. Anterior region C. Premolar region D. Molar region	**Answer: B** **Explanation:** Gingival overgrowth can be present throughout the mouth but tends to be more severe in the maxillary and mandibular anterior regions.

Periodontal Disease and Chronic Obstructive Pulmonary Disease *(e-only)*
Periodontal Disease and Acute Respiratory Infections *(e-*

only)
Periodontal Disease and Asthma
Periodontal Medicine in Clinical Practice
Conclusions

Knowledge of the pathogenesis of periodontal diseases has evolved markedly over the last 50 years.[82] Periodontal disease is an inflammatory disease initiated by bacterial pathogens. Environmental, physical, social, and host stresses may affect and modify disease expression through a multitude of pathways. Certain systemic conditions can affect the initiation and progression of gingivitis and periodontitis (see Chapter 14). Systemic disorders that affect neutrophil, monocyte, macrophage, and lymphocyte function result in the altered production or activity of host inflammatory mediators.[82,125] These alterations may manifest clinically as the early onset of periodontal destruction or as a more rapid rate of destruction than would occur in the absence of such disorders.

Evidence has also shed light on the converse side of the relationship between systemic health and oral health: the potential effects of inflammatory periodontal diseases on a wide range of organ systems. This field of periodontal medicine addresses the following important questions:

- Can the inflammatory response to bacterial infection of the periodontium have an effect that is remote from the oral cavity?
- Is periodontal infection a risk factor for systemic diseases or conditions that affect human health?

Pathobiology of Periodontitis

Our understanding of the pathogenesis of periodontitis has changed remarkably over the last 30 years.[82,125,131] The nonspecific

accumulation of bacterial plaque was once thought to be the cause of periodontal destruction, but it is now recognized that periodontitis is an infectious disease associated with a small number of predominantly gram-negative microorganisms that exist in a subgingival biofilm.[54] Furthermore, the importance of the host in disease initiation and progression is clearly recognized. Although pathogenic bacteria are necessary for periodontal disease, they are not sufficient alone to cause the disease. A susceptible host is also imperative. In a host who has relatively low susceptibility to disease, bacterial pathogens may have no clinical effect. This may be due to a particularly effective host immunoinflammatory response that eliminates pathogenic organisms while minimizing destruction of native tissues. Conversely, in a host with relatively high disease susceptibility, marked destruction of periodontal tissues may result.

Key Fact

Whereas pathogenic bacteria are necessary for periodontal disease, bacteria alone are not sufficient to cause disease. A susceptible host is imperative. In a host with relatively low susceptibility, bacterial pathogens may have little or no clinical effect.

Recognizing the importance of host susceptibility opens a door to understanding the differences in the onset, natural history, and progression of periodontitis seen throughout the scientific literature. Because of differences in host susceptibility, not all individuals are equally vulnerable to the destructive effects of periodontal pathogens and the immunoinflammatory response to those organisms. Thus, patients may not necessarily have similar disease expression despite the presence of similar bacteria. Likewise, the response to periodontal treatment may vary depending on the wound-healing capacity and susceptibility of the host to further disease progression. The importance of host susceptibility is clearly evident in the medical literature. For example, respiratory tract pathogens may have a minimal effect on many individuals, but in a susceptible host such as an elderly patient, these same pathogens may cause life-threatening

respiratory tract illnesses.

There are many systemic conditions that can modify the host's susceptibility to periodontitis. For example, patients with immune suppression may not be able to mount an effective host response to subgingival microorganisms, thereby resulting in more rapid and severe periodontal destruction. Conversely, individuals with a significant increase in the production of proinflammatory mediators may respond to periodontal pathogens with an exuberant inflammatory response that results in the destruction of periodontal tissues. Although the potential impact of many systemic disorders on the periodontium is well documented, evidence suggests that periodontal infection may significantly enhance the risk for certain systemic diseases or alter the natural course of systemic conditions.[90,110,121,133,150,173] Although more than 50 different systemic conditions have been associated with periodontal diseases, the evidence base is quite large for many of these conditions and small for others. For example, conditions in which the influences of periodontal infection are well documented include coronary heart disease (CHD) and CHD-related events such as angina, infarction, atherosclerosis, and other vascular conditions; stroke; diabetes mellitus; preterm labor, low-birth-weight delivery, and preeclampsia; and respiratory conditions such as chronic obstructive pulmonary disease[90,110,132] (Box 15.1). A smaller but growing evidence base supports an association between poor oral health, tooth loss, or periodontitis and conditions such as chronic kidney disease and renal insufficiency[20,43,44,84,85,153]; certain forms of cancer[2,45,118,119,160] affecting the liver, pancreas, and colorectal region; rheumatoid arthritis[29,30]; and altered cognitive function, dementia, and Alzheimer disease.[75,76,90,157,159,178] This chapter focuses on those conditions with the strongest evidence base, recognizing that ongoing research will further elucidate relationships between inflammatory periodontal diseases and systemic health.

Box 15.1

Organ Systems and Conditions Possibly Influenced by Periodontal Infection

Cardiovascular and Cerebrovascular Systems

Atherosclerosis
Coronary heart disease
Angina
Myocardial infarction
Cerebrovascular accident (stroke)
Erectile dysfunction
Anemia

Endocrine System

Metabolic syndrome
Diabetes mellitus

Reproductive System

Preterm and low-birth-weight infants
Preeclampsia

Respiratory System

Chronic obstructive pulmonary disease
Acute bacterial pneumonia

Kidney Diseases

Renal insufficiency
Chronic kidney disease
End-stage kidney disease

Autoimmune Diseases

Rheumatoid arthritis
Ankylosing spondylitis

Cognitive Function

Dementia
Alzheimer disease

Cancers

Colorectal
Pancreatic
Hepatocellular
Others

Focal Infection Theory Revisited

Research in the area of periodontal medicine marks a resurgence in the concept of focal infection. In 1900, British physician William Hunter first developed the idea that oral microorganisms were responsible for a wide range of systemic conditions that were not easily recognized as being infectious in nature.[123,173] He claimed that restoration of carious teeth, instead of extraction, resulted in the trapping of infectious agents under restorations. In addition to caries, pulpal necrosis, and periapical abscesses, Hunter identified gingivitis and periodontitis as foci of infection. He advocated the extraction of teeth with these conditions to eliminate the source of sepsis. Hunter thought that teeth were prone to septic infection primarily because of their structure and their relationship to alveolar bone. He stated that the degree of systemic effect produced by oral sepsis depended on the virulence of the oral infection and the individual's degree of resistance. He also thought that oral organisms had specific actions on different tissues and that these organisms acted by producing toxins, thereby resulting in low-grade “subinfections” that produced systemic effects over prolonged periods. Finally, Hunter thought that the connection between oral sepsis and resulting systemic conditions could be shown via removal of the causative sepsis through tooth extraction and observation of the improvement in systemic health. Because it explained a wide range of disorders for which there was no known explanation at the time, Hunter's theory became widely accepted in Britain and eventually in the United States, leading to the wholesale extraction of teeth.

The focal infection theory fell into disrepute during the 1940s and 1950s, when widespread extraction—often of the entire dentition—failed to reduce or eliminate the systemic conditions to which the supposedly infected dentition had been linked.[173] The theory, while offering a possible explanation for perplexing systemic disorders, had been based on very little (if any) scientific evidence. Hunter and other advocates of the theory were unable to explain how focal oral sepsis produced these systemic maladies. They were also unable to elucidate possible interactive mechanisms between oral and systemic health. Furthermore, the suggested intervention of tooth extraction often had no effect on the systemic conditions for which patients sought relief. However, Hunter's ideas did encourage extensive research in the areas of microbiology and immunology.

« Flash Back
The focal infection theory fell into disrepute during the 1940s and 1950s, when widespread extraction—often of the entire dentition—failed to reduce or eliminate the systemic conditions. The theory, while offering a possible explanation for perplexing systemic disorders, had been based on very little (if any) scientific evidence.

Evidence-Based Clinical Practice

Many of the precepts of the focal infection theory are being revived today in light of recent research demonstrating links between oral and systemic health. However, as expressed by Newman, for the "hypothesis not to fall into disrepute for a second time, there must be no unsubstantiated attributions, no theories without evidence."[123] Today's era of evidence-based medicine and dentistry provides an excellent environment in which to examine the possible relationships between oral infection and systemic disorders. To establish a relationship between conditions A and B, different levels of evidence must be examined. All scientific evidence is not given the same weight.[64,114,124] The stronger the evidence, the more likely it is that a true relationship exists between the conditions. Table 15.1

describes these various levels of evidence.

TABLE 15.1
Evaluation of Evidence

Type of Evidence	Strength of Evidence	Description
Case report	+/−	• Provides relatively weak retrospective anecdotal evidence • May suggest that further study is needed
Cross-sectional study	+	• Compares groups of subjects at a single point in time
		• Stronger than a case report
		• Fairly easy to conduct
		• Relatively inexpensive to conduct
Longitudinal study	++	• Follows groups of subjects over time
		• Stronger than a cross-sectional study
		• Studies with a control group much stronger than studies without controls
		• More difficult and expensive to conduct
Intervention trial	+++	• Examines the effects of some intervention
		• Studies with a control group (i.e., placebo) much stronger than studies without controls
		• Strongest form of evidence is the randomized controlled intervention trial
		• Difficult and expensive to conduct
Systematic review	++++	• Systematically evaluates evidence from multiple studies, especially randomized controlled trials
		• Uses clearly defined guidelines for the selection of evidence to be included or excluded from the review
		• Examines for heterogeneity in the overall data to indicate variations in study design, sample populations, and assessment methodologies

For example, when examining the relationship between elevated cholesterol levels and CHD-related events, the literature might initially consist entirely of *case reports* or similar anecdotal information in which individual patients with recent myocardial infarction (MI) are found to have elevated cholesterol levels. These anecdotal reports suggest a possible relationship between elevated cholesterol and MI, but the evidence is weak. The case reports may lead to *cross-sectional studies*, in which a large subject population is examined to determine whether those individuals who had an MI have higher cholesterol levels than other individuals (control subjects) who did not have an MI. Ideally, these cross-sectional

studies are controlled for other potential causes or factors associated with MI, such as age, gender, and smoking history. In other words, the subjects with a previous MI would be retrospectively matched with subjects of similar age, gender, and smoking history, and their cholesterol levels would then be examined for similarities or differences. Significantly higher cholesterol levels in subjects with a previous MI compared with those without MI offer stronger evidence than case reports; such evidence further substantiates a possible link between elevated cholesterol and MI.

Even stronger evidence is provided by *longitudinal studies,* in which subject populations are examined over time. For example, a group of subjects might periodically have their cholesterol levels evaluated over several years. If individuals with elevated cholesterol levels have a significantly higher rate of MI over time compared with subjects with normal cholesterol levels, then even stronger evidence is available to substantiate the link between cholesterol and MI. Finally, *intervention trials* may be designed to alter the potentially causative condition and to determine the effect of this change on the resultant condition. For example, patients with elevated cholesterol levels may be divided into two groups: a group that uses a cholesterol-lowering drug or diet and a control group that uses no intervention. These two groups might also be compared with a third group of subjects with normal cholesterol levels. Over time, the rate of MI in each group would be determined. If the group receiving the cholesterol-lowering regimen has a significantly lower rate of MI than the group with continued elevations in cholesterol level, strong evidence of a link between cholesterol and MI is established.

Finally, the highest level of evidence is the *systematic review*. A systematic review is not a standard literature review in which the articles selected for review are based on the desires and search methods chosen by the author, often for convenience. In a systematic review, the topic in question is selected before the review begins. For example, the authors may state the question as follows: "As compared with subjects not taking cholesterol-lowering medications, do subjects taking such medications demonstrate a difference in the rate of myocardial infarction?" A

specific search strategy is then determined to reveal as much potential data as possible to answer the stated question. The authors state specifically why research papers were included or excluded from the review. If possible, the data are subjected to meta-analysis, a statistical method that combines the results of multiple studies that address a similar research hypothesis. This provides a more robust evaluation of the overall data than one can glean from individual research articles.

At each level of evidence, it is important to determine whether a biologically plausible link exists between conditions A and B. For example, if case reports, cross-sectional studies, longitudinal studies, and intervention trials all support a link between cholesterol levels and MI, the following questions remain:

- How is cholesterol related to MI?
- What are the mechanisms by which cholesterol affects the cardiovascular system and thus increases the risk for MI?

These studies evaluate the mechanisms by which conditions A and B might be linked and provide explanatory data that further substantiate the association between the two conditions.

The focal infection theory, as proposed and defended during the early part of the 20th century, was based on almost no evidence. Only the occasional case report and other anecdotes were available to substantiate the theory. Although explanatory mechanisms were proposed, none were validated with scientific research. This theory predated current concepts of evidence-based clinical practice and led to the unnecessary extraction of millions of teeth. Currently, when reexamining the potential associations between oral infections and systemic conditions, it is important (1) to determine what evidence is available; (2) to determine what evidence is still needed to substantiate the associations; and (3) to validate the possible mechanisms of association. This chapter reviews current knowledge that relates periodontal infection to overall systemic health.

Subgingival Environment as a Reservoir for Bacteria

The subgingival microbiota in patients with periodontitis provides a significant and persistent gram-negative bacterial challenge to the host that is met with a potent immunoinflammatory response.[126] These organisms and their products, such as *lipopolysaccharides* (LPSs), have ready access to the periodontal tissues and to the circulation via the sulcular epithelium, which is frequently ulcerated and discontinuous. Even with treatment, complete eradication of these organisms is difficult, and their reemergence is often rapid. The total surface area of pocket epithelium in contact with subgingival bacteria and their products in a patient with generalized moderate periodontitis has been estimated to be approximately the size of the palm of an adult hand, with even larger areas of exposure in cases of more advanced periodontal destruction.[131] Bacteremias are common after mechanical periodontal therapy, and they also occur frequently during normal daily function and oral hygiene procedures.[39,92,109] Just as the periodontal tissues mount an immunoinflammatory response to bacteria and their products, systemic challenge with these agents also induces a major vascular response.[35,59,139] This host response may offer explanatory mechanisms for the interactions between periodontal infection and a variety of systemic disorders.

Key Fact

The subgingival microbiota in patients with periodontitis provides a significant and persistent gram-negative bacterial challenge to the host. These organisms and their products, such as LPSs, have access to the periodontal tissues and to the circulation via ulcerations in the sulcular epithelium.

Periodontal Disease and Mortality

The ultimate medical outcome measure is mortality. A number of studies suggest that an increased mortality rate from various causes

is associated with inflammatory periodontal diseases.[2,20,37,46,71,89,142] The Normative Aging Study examined 2280 healthy men every 3 years for longer than 30 years after baseline clinical, radiographic, laboratory, and electrocardiographic examinations. A subset of this population was examined in the Veterans Affairs Dental Longitudinal Study to determine age-related changes in the oral cavity and identify risk factors for oral disease. Clinical examinations were performed, and alveolar bone level measurements were determined from full-mouth radiographs. The mean percentage of alveolar bone loss and mean probing depth were determined for each subject. From the original sample of 804 dentate, medically healthy subjects, a total of 166 died during the study.[46] Periodontal status at the baseline examination was a significant predictor of mortality independent of other factors such as smoking, alcohol use, cholesterol levels, blood pressure, family history of heart disease, education level, and body mass. For those subjects with the most alveolar bone loss (>21% alveolar bone loss at baseline), the risk of dying during the follow-up period was 70% higher than for all other subjects. Interestingly, alveolar bone loss increased the risk of mortality more than smoking (52% increased risk), which is a well-known risk factor for mortality. A later evaluation of these same subjects confirmed a higher incidence of CHD-related events such as MI and unstable angina among men younger than 60 years of age with alveolar bone loss compared with those without bone loss.[37]

In a prospective cohort study of 1400 dentate men from Northern Ireland, subjects were divided into thirds (tertiles) based on average periodontal attachment loss.[89] Those with the highest levels of periodontal attachment loss has a significantly higher risk of death compared with those with the least attachment loss. The mortality rate over a 9-year period was 15.7% in those with the greatest attachment loss and 7.9% in those with the lowest level of periodontal attachment loss. In these studies, periodontitis preceded and increased the risk of mortality. However, this finding only establishes an association; it does not confirm causation. It is possible that periodontal disease reflects other health behaviors not evaluated in this study rather than acting as a specific cause of mortality. In other words, patients with poor periodontal health

may also have other risk factors that increase mortality rate (e.g., smoking).

When examining research that suggests oral health status is a possible risk factor for systemic conditions, it is important to recognize when other known risk factors for those systemic conditions have been accounted for in the analysis. Host susceptibility factors that place individuals at risk for periodontitis may also place them at risk for systemic diseases such as cardiovascular disease. In these patients, the association may actually be among the risk factors rather than among the diseases. For example, periodontitis and cardiovascular disease share such risk factors as smoking, age, race, male gender, and stress. Genetic risk factors may also be shared.[83] In the Veterans Affairs Dental Longitudinal Study, smoking was an independent risk factor for mortality. When the data were examined to determine whether periodontal status was a risk factor, smoking status and other known risk factors for mortality were removed from the equation to allow for the independent evaluation of periodontal status. Other studies support an association between poor oral health and an increased risk of mortality.[142] In a prospective longitudinal study of subjects with type 2 diabetes, those with severe periodontitis had 3.2 times the risk of death from ischemic heart disease or kidney disease as subjects without periodontitis or with only slight periodontitis, after adjusting for other risk factors, including age, sex, duration of diabetes, glycemic control, macroalbuminuria, body mass index, serum cholesterol concentration, hypertension, and current smoking.[142]

Periodontal Disease, Coronary Heart Disease, and Atherosclerosis

To further explore the association between periodontal disease and CHD or atherosclerosis, investigators have studied specific systemic disorders and medical outcomes to determine their relationship to periodontal status. The proceedings of the first international Workshop on Periodontitis and Systemic Disease held by the American Academy of Periodontology (AAP) and the European

Federation of Periodontology (EFP) were published in 2013, a major focus of which was the relationship between periodontitis and atherosclerotic cardiovascular disease.[32,38,136,147] CHD-related events are a major cause of death. MI has been associated with acute systemic bacterial and viral infections and is sometimes preceded by influenza-like symptoms.[102,158] Is it possible that oral infection is similarly related to MI? Traditional risk factors such as smoking, dyslipidemia, hypertension, and diabetes mellitus do not explain the presence of coronary atherosclerosis in a large number of patients. Localized infection that results in a chronic inflammatory reaction has been suggested as a mechanism underlying CHD in these individuals.[113]

In cross-sectional studies of patients with acute MI or confirmed CHD who were compared with age- and gender-matched control patients, patients with MI had significantly worse dental health (e.g., periodontitis, periapical lesions, caries, pericoronitis) than controls.[70,103,104] This association between poor dental health and MI was independent of known risk factors for heart disease, such as age, cholesterol levels, hypertension, diabetes, and smoking. Because atherosclerosis is a major determinant of CHD-related events, dental health has also been related to coronary atheromatosis. Mattila and colleagues[105] performed oral radiographic examinations and diagnostic coronary angiography on men with known CHD and found a significant correlation between the severity of dental disease and the degree of coronary atheromatosis. This relationship remained significant after accounting for other known risk factors for coronary artery disease. Similarly, Malthaner and colleagues[101] found an increased risk of angiographically defined coronary artery disease in subjects with greater bone loss and attachment loss; however, after adjusting for other known cardiovascular risk factors, the relationship between periodontal status and coronary artery disease was no longer statistically significant. There is evidence that the extent of periodontal disease may be associated with CHD. For example, there may be a greater risk for CHD-related events, such as MI, in subjects who have periodontitis affecting a greater number of teeth in the mouth compared with those who have periodontitis involving fewer teeth.[7]

Cross-sectional studies thus suggest a possible link between oral health and CHD; however, such studies cannot determine causality in this relationship. Rather, dental diseases may be indicators of general health practices. For example, periodontal disease and CHD are both related to lifestyle and share numerous risk factors, including smoking, diabetes, and low socioeconomic status. Bacterial infections have significant effects on endothelial cells, blood coagulation, lipid metabolism, and monocytes and macrophages.

Longitudinal studies provide compelling data regarding this relationship. In a 7-year follow-up study of the patients from the study by Mattila and colleagues, dental disease was significantly related to the incidence of new fatal and nonfatal coronary events as well as overall mortality.[106] In a prospective study of a national sample of adults, subjects with periodontitis had a 25% increased risk for CHD compared with those with no or minimal periodontal disease, after adjusting for other known risk factors.[36] Among males between the ages of 25 and 49 years, periodontitis increased the risk of CHD by 70%. The level of oral hygiene was also associated with heart disease. Patients with poor oral hygiene, as indicated by higher debris and calculus scores, had a twofold increased risk for CHD.

In another large prospective study, 1147 men were followed for 18 years.[11] During that time, 207 men (18%) developed CHD. When periodontal status at baseline was related to the presence or absence of CHD-related events during the follow-up period, a significant relationship was found. Subjects with more than 20% mean bone loss had a 50% increased risk of CHD compared with those with <20% bone loss. The extent of sites with probing depths >3 mm was strongly related to the incidence of CHD. Subjects with probing depths >3 mm on at least half of their teeth had a twofold increased risk, whereas those with probing depths of >3 mm on all of their teeth had more than a threefold increased risk of CHD. This study and others in which the periodontal condition was known to have preceded the CHD-related events have supported the concept that periodontal disease is a risk factor for CHD, independent of other classic risk factors. Not all studies, however, support this concept; some show little independent effect of periodontal status on the risk

for CHD after adjusting for commonly accepted cardiovascular risk factors.[65,66] It is particularly difficult to control for smoking as a confounding variable in these studies, because it is such an important risk factor for both periodontal disease and cardiovascular disease. This confounding influence of smoking makes it difficult to clarify the significance of the relationship between the diseases.

Perhaps the best evidence available comes from systematic reviews of studies examining the relationship between periodontal infection and cardiovascular disease. A systematic review and meta-analysis of data from 15 studies showed a significant 14% to 222% increase in the risk of CHD-related events in patients with periodontal disease as compared with those without periodontal disease.[9] A similar systematic review of longitudinal cohort and case–control studies showed a significant increase in the risk of incident MI, angina, or CHD-related death in subjects with periodontitis in five of the six studies reported.[38] This increased risk was noted mainly in younger subjects (i.e., <65 years old). Janket and colleagues[69] performed a meta-analysis of periodontal disease as a risk factor for future cardiovascular events and found an overall 19% increased risk of such events among individuals with periodontitis. The increase in risk was greater (44%) among people younger than 65 years of age. Although this increased risk is fairly modest, the extensive prevalence of periodontal disease in the population may increase the significance of the risk from a public health perspective. Extensive systematic reviews by Scannapieco and colleagues[143] and by an American Heart Association working group[91] concluded that a moderate degree of evidence exists to support an association between periodontal disease and atherosclerosis, MI, and cardiovascular disease independent of known confounders; however, causality is unclear. The results of the 2103 AAP/EFP Workshop on Periodontitis and Systemic Diseases concluded that "there is consistent and strong epidemiologic evidence that periodontitis imparts increased risk for future cardiovascular disease," but whereas many studies support multiple biologic mechanisms to explain this relationship, "intervention trials to date are not adequate to draw further conclusions."[169] That is, insufficient evidence exists to show that the

treatment of periodontal disease has any impact on the risk of heart disease.

Key Fact

There is consistent and strong epidemiologic evidence that periodontitis imparts increased risk for future cardiovascular disease.

Effects of Periodontal Infection

There are numerous mechanisms—both direct and indirect—through which periodontal infection may affect the onset or progression of atherosclerosis and CHD.[77,136,147] Periodontitis and atherosclerosis both have complex etiologic factors that combine genetic and environmental influences. In addition to smoking, the diseases share many risk factors and have distinct similarities with regard to their basic pathogenic mechanisms.

Ischemic Heart Disease

Ischemic heart disease is associated with the processes of atherogenesis and thrombogenesis (Fig. 15.1). Damage to the vascular endothelium, with a subsequent inflammatory reaction, plays a major role in atherosclerosis and ischemic organ damage.[169] Increased viscosity of blood may promote major ischemic heart disease and cerebrovascular accident (stroke) by increasing the risk of thrombus formation.[98] Fibrinogen is a major factor in the promotion of this hypercoagulable state. *Fibrinogen* is the precursor to fibrin, and increased fibrinogen levels increase blood viscosity. Increased plasma fibrinogen is a recognized risk factor for cardiovascular events and peripheral vascular disease[97] (Fig. 15.2). An elevated white blood cell count is also a predictor of heart disease and stroke, and circulating leukocytes may promote the occlusion of blood vessels. Coagulation factor VIII (von Willebrand factor) has likewise been associated with a risk of ischemic heart disease.[137]

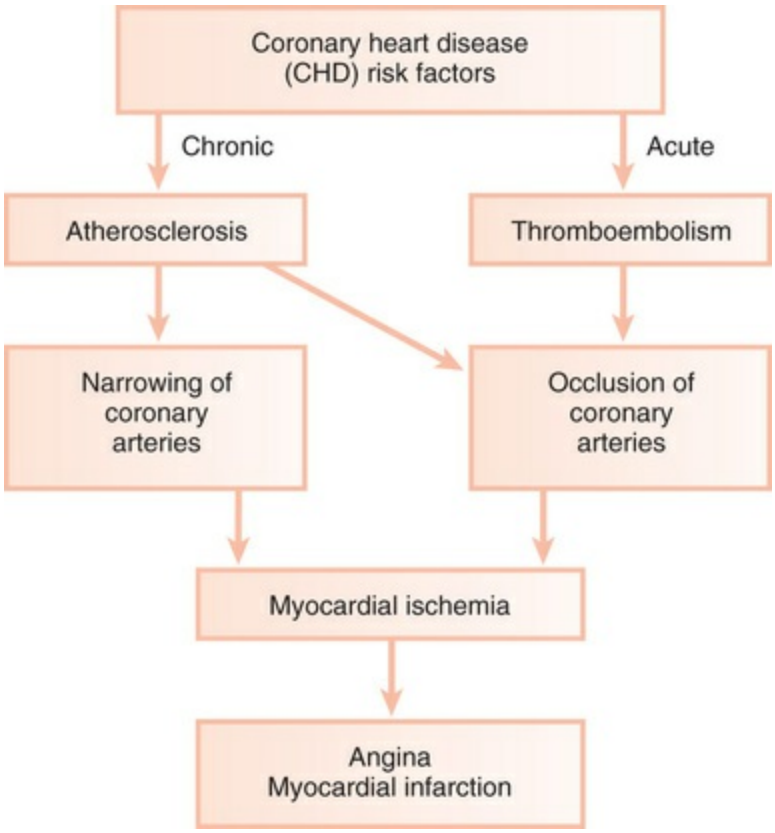

FIG. 15.1 Acute and chronic pathways to ischemic heart disease. Coronary heart disease–related events, such as angina and myocardial infarction, may be precipitated by either pathway or both pathways.

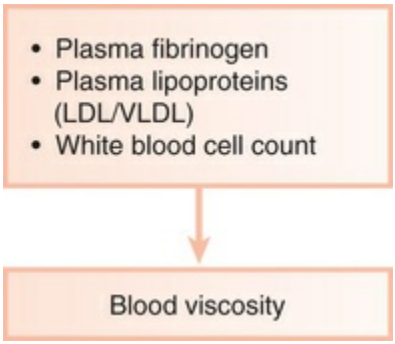

FIG. 15.2 Factors that affect blood viscosity in health. *LDL,* Low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

Systemic Infections

Systemic infections are known to induce a hypercoagulable state

and increase blood viscosity (Fig. 15.3). Fibrinogen levels and white blood cell counts are often increased in patients with periodontal disease.[22,88] Individuals with poor oral health may also have significant elevations in coagulation factor VIII/von Willebrand factor antigen, thereby increasing the risk of thrombus formation. Thus, periodontal infection may also promote increased blood viscosity and thrombogenesis, which leads to an increased risk for central and peripheral vascular disease.

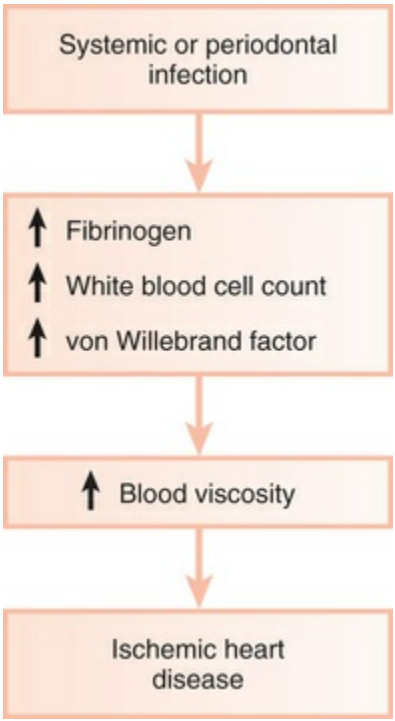

FIG. 15.3 The effect of infection on blood viscosity. Increased plasma fibrinogen and von Willebrand factor cause hypercoagulability. When they are combined with an increased white blood cell count, the blood viscosity increases, thereby increasing the risk of coronary ischemia.

Daily Activity

Routine daily activities such as mastication and oral hygiene procedures result in frequent bacteremia with oral organisms.[92] Periodontal disease may predispose the patient to an increased incidence of bacteremia, including the presence of virulent gram-negative organisms associated with periodontitis. There is a greater

risk of bacteremia after toothbrushing in patients with higher levels of plaque, calculus, and gingivitis as compared with those with minimal plaque and gingival inflammation.[93] In fact, subjects with generalized gingival bleeding after brushing showed an almost eightfold increase in their incidence of bacteremia as compared with those with minimal gingival bleeding. An estimated 8% of all cases of infective endocarditis are associated with periodontal or dental disease without a preceding dental procedure.[39] The periodontium, when affected by periodontitis, also acts as a reservoir of *endotoxins* (LPSs) from gram-negative organisms. Endotoxins can pass readily into the systemic circulation during normal daily function, thereby inducing damage to the vascular endothelium and precipitating many negative cardiovascular effects. In a study of the incidence of endotoxemia after simple chewing, subjects with periodontitis were four times more likely to have endotoxin present in the bloodstream than subjects without periodontitis. Furthermore, the concentration of endotoxin in the bloodstream was more than fourfold greater in those with periodontitis as compared with healthy subjects.[47]

Thrombogenesis

Platelet aggregation plays a major role in thrombogenesis, and most cases of acute MI are precipitated by thromboembolism. Oral organisms may be involved in coronary thrombogenesis. Platelets selectively bind some strains of *Streptococcus sanguinis,* which is a common component of supragingival plaque, and *Porphyromonas gingivalis,* which is a pathogen closely associated with periodontitis.[60,61] The aggregation of platelets is induced by the *platelet aggregation–associated protein* (PAAP) expressed on some strains of these bacteria.[140] In animal models, intravenous infusion of PAAP-positive bacterial strains resulted in alterations of heart rate, blood pressure, cardiac contractility, and electrocardiogram readings consistent with MI. Platelet accumulation also occurred in the lungs and led to tachypnea. No such changes were seen with the infusion of PAAP-negative strains. PAAP-positive bacteria caused aggregation of circulating platelets, which resulted in the formation of thromboemboli and resultant cardiac and pulmonary changes. Thus, periodontitis-associated bacteremia with certain

strains of *S. sanguinis* and *P. gingivalis* may promote acute thromboembolic events via interaction with circulating platelets.

Atherosclerosis

Atherosclerosis is a focal thickening of the arterial *intima,* the innermost layer lining the vessel lumen, and the *media,* the thick layer under the intima that consists of smooth muscle, collagen, and elastic fibers (Fig. 15.4).[140] The formation of atherosclerotic plaques is precipitated by damage to vascular endothelium that results in an inflammatory response in which circulating monocytes adhere to the vascular endothelium. Damage to vascular endothelium can occur because of the presence of intravascular microorganisms and their products; chemical damage, often resulting from elements of tobacco and other exogenous toxins; and increased shear force along the vascular lining, such as that occurring in hypertension. The adherence of monocytes to the damaged vascular endothelium is mediated by several adhesion molecules on the endothelial cell surface, including intercellular adhesion molecule-1 (ICAM-1), endothelial leukocyte adhesion molecule-1 (ELAM-1), and vascular cell adhesion molecule-1 (VCAM-1).[12,80] These adhesion molecules are up-regulated by a number of factors, including bacterial LPSs, prostaglandins, and proinflammatory cytokines. After binding to the endothelial cell lining, monocytes penetrate the endothelium and migrate under the arterial intima. The monocytes ingest circulating low-density lipoprotein in its oxidized state and become engorged, thereby forming the foam cells that are characteristic of atheromatous plaque. After entering the arterial media, monocytes may also transform to macrophages.

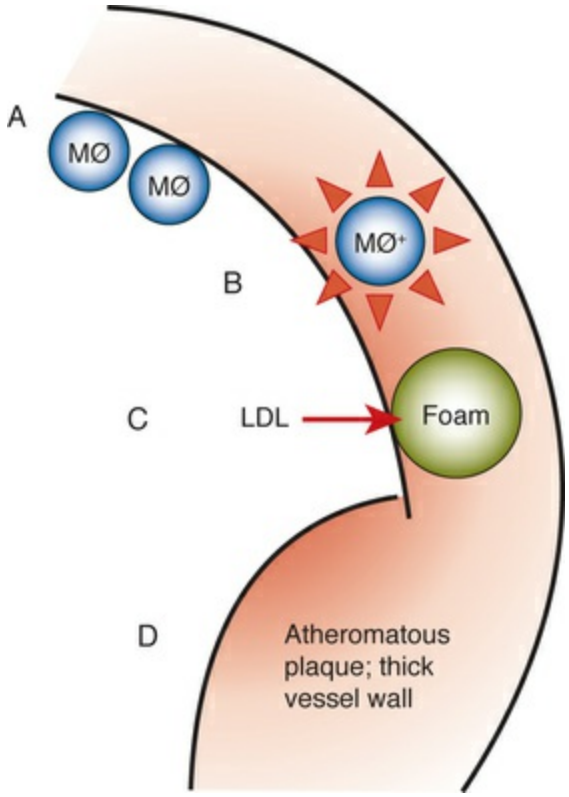

FIG. 15.4 Pathogenesis of atherosclerosis. (A) Monocytes and macrophages *(MØ)* adhere to the vascular endothelium. (B) Monocytes and macrophages penetrate into the arterial media and produce proinflammatory cytokines and growth factors. (C) The ingestion of oxidized low-density lipoprotein *(LDL)* enlarges monocytes to form foam cells. (D) Smooth muscle proliferation and plaque formation thicken vessel walls and narrow the lumen. *MØ⁺*, Hyperinflammatory monocyte/macrophage phenotype.

A host of proinflammatory cytokines such as interleukin-1 (IL-1), tumor necrosis factor alpha (TNF-α), and prostaglandin E_2 (PGE_2) are then produced, and they propagate the atheromatous lesion. Mitogenic factors such as fibroblast growth factor and platelet-derived growth factor stimulate smooth muscle and collagen proliferation within the media, thereby thickening the arterial wall.[97] Atheromatous plaque formation and thickening of the vessel wall narrow the lumen and dramatically decrease blood flow through the vessel.[140] Arterial thrombosis often occurs after an atheromatous plaque ruptures. Plaque rupture exposes circulating blood to arterial collagen and tissue factor from monocytes and macrophages that activate platelets and the coagulation pathway.

Platelet and fibrin accumulation forms a thrombus that may occlude the vessel and result in an ischemic event such as angina or MI. The thrombus may separate from the vessel wall and form an embolus, which may also occlude vessels, again leading to an acute event such as MI or cerebral infarction (stroke).

Role of Periodontal Disease in Atherosclerotic Myocardial or Cerebral Ischemia

In animal models, gram-negative bacteria and associated LPSs cause infiltration of inflammatory cells into the arterial wall, proliferation of arterial smooth muscle, and intravascular coagulation. These changes are identical to those seen with naturally occurring atheromatosis. There is strong evidence that periodontal bacteria disseminate from the oral cavity to the systemic vasculature, can be found within distant tissues, and can live within those affected tissues.[136] Furthermore, in animal models, dissemination of periodontal bacteria can induce atherosclerosis in distant vessels. Patients with periodontitis are at increased risk for thickening of the walls of the major coronary arteries.[11] In several studies of atheromas obtained from humans during endarterectomy, more than half of the lesions contained periodontal pathogens, and many atheromas contained multiple different periodontal species.[21,57,180] Periodontal diseases result in chronic systemic exposure to products of these organisms. Low-level bacteremia may initiate host responses that alter coagulability, endothelial and vessel wall integrity, and platelet function, thereby resulting in atherogenic changes and possible thromboembolic events (Fig. 15.5).

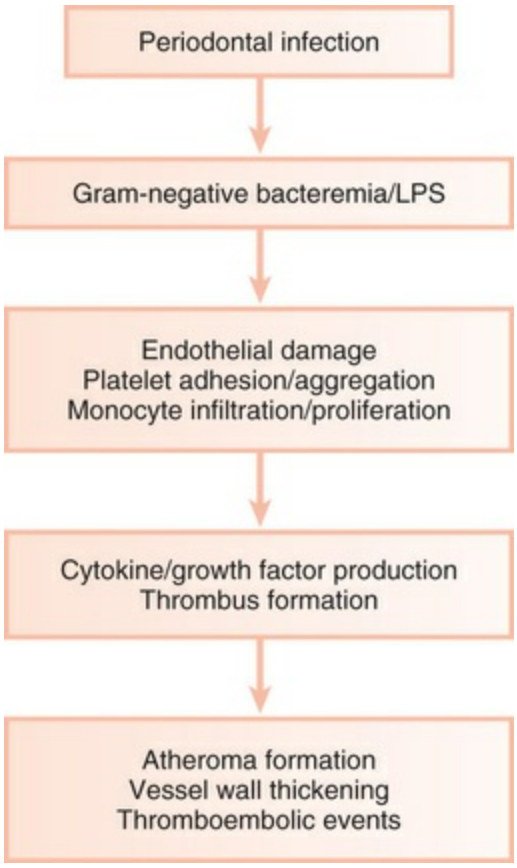

FIG. 15.5 The influence of periodontal infection on atherosclerosis. Periodontal pathogens and their products result in damage to the vascular endothelium. Monocytes and macrophages enter the vessel wall and produce cytokines that further increase the inflammatory response and propagate the atheromatous lesion. Growth factor production leads to smooth muscle proliferation in the vessel wall. Damaged endothelium also activates platelets, thereby resulting in platelet aggregation and potentiating thromboembolic events. *LPS,* Lipopolysaccharide.

Clinical Correlation

There is strong evidence that periodontal bacteria disseminate from the oral cavity to the systemic vasculature, can be found within distant tissues, and can live within those affected tissues.

Research has clearly shown a wide variation in host response to bacterial challenge. Some individuals with heavy plaque

accumulation and high proportions of pathogenic organisms appear relatively resistant to bone and attachment loss. Others develop extensive periodontal destruction in the presence of small amounts of plaque and low proportions of putative pathogens. Patients with an abnormally exuberant inflammatory response often have a hyperinflammatory monocyte and macrophage phenotype (MØ$^+$). Monocytes and macrophages from these individuals secrete significantly increased levels of proinflammatory mediators (e.g., IL-1, TNF-α, PGE_2) in response to bacterial LPSs compared with patients with a normal monocyte and macrophage phenotype. Patients with aggressive periodontitis, refractory periodontitis, and type 1 diabetes mellitus often possess the MØ$^+$ phenotype,[13] which appears to be under both genetic and environmental control.

The monocyte and macrophage cell line is intimately involved in the pathogenesis of both periodontal disease and atherosclerosis. Diet-induced elevations in serum low-density lipoprotein levels up-regulate monocyte and macrophage responsiveness to bacterial LPSs. Thus, elevated low-density lipoprotein levels, which is a known risk factor for atherosclerosis and CHD, may increase the secretion of destructive and inflammatory cytokines by monocytes and macrophages. This may result not only in the propagation of atheromatous lesions, but also in enhanced periodontal destruction in the presence of pathogenic organisms. This is one example of a potential shared mechanism in the pathogenesis of cardiovascular and periodontal diseases. The presence of an MØ$^+$ phenotype may place patients at risk for both CHD and periodontitis (Fig. 15.6). Periodontal infections may contribute to atherosclerosis and thromboembolic events by repeatedly challenging the vascular endothelium and arterial wall with bacterial LPSs and proinflammatory cytokines. Vascular monocytes and macrophages in patients with an MØ$^+$ phenotype meet this challenge with an abnormally elevated inflammatory response that may directly contribute to atherosclerosis and may precipitate thromboembolic events.[110]

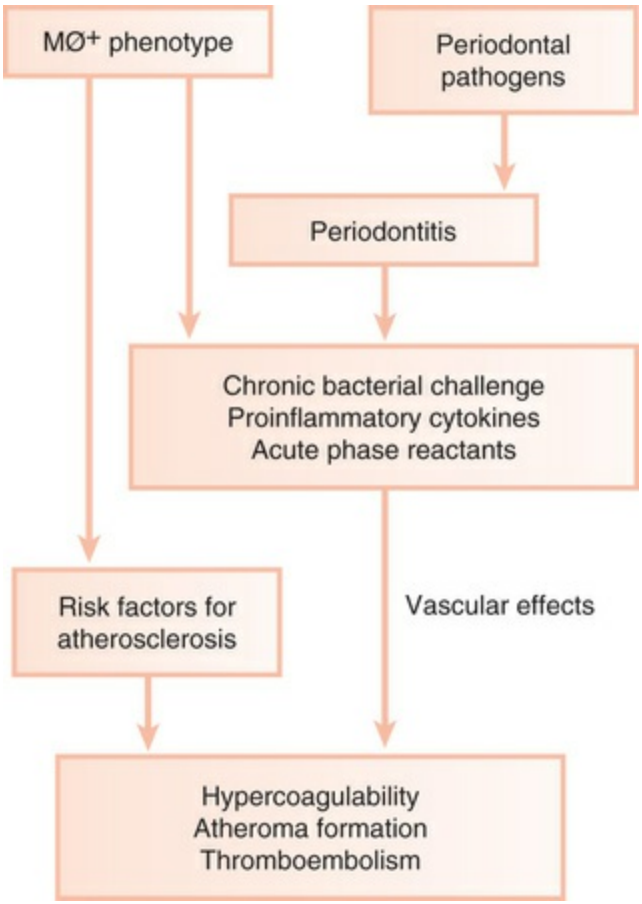

FIG. 15.6 The cardiovascular and periodontal consequences of the hyperresponsive monocyte/macrophage phenotype *(MØ⁺)*. In combination with other risk factors, the MØ⁺ phenotype predisposes individuals to both atherosclerosis and periodontitis. Bacterial products and inflammatory mediators associated with periodontitis affect vascular endothelium, monocytes and macrophages, platelets, and smooth muscle and may increase blood coagulability. This may further increase atherosclerosis and may result in thromboembolism and ischemic events.

Cardiovascular diseases are increasingly recognized as having a major systemic inflammatory component, further emphasizing possible similarities with inflammatory periodontal diseases.[140] As such, the detection of systemic inflammatory markers plays an increasingly important role in risk assessment for vascular events such as MI and cerebral infarction. Acute-phase proteins such as *C-reactive protein* (CRP) and fibrinogen are produced in the liver in response to inflammatory or infectious stimuli and act as

inflammatory markers.[139] CRP induces monocytes and macrophages to produce tissue factor, which stimulates the coagulation pathway and increases blood coagulability. Increased fibrinogen levels may contribute to this process. CRP also stimulates the complement cascade, further exacerbating inflammation.

Elevations in serum CRP and fibrinogen levels are well-accepted risk factors for cardiovascular disease.[138,139] Research has focused on periodontitis as a potential trigger for systemic inflammation. Serum CRP and fibrinogen levels are often elevated in subjects with periodontitis as compared with subjects without periodontitis.[27,94,175] These acute-phase proteins may act as intermediary steps in the pathway from periodontal infection to cardiovascular disease (see Figs. 15.5 and 15.6). Thus, periodontal diseases may have both direct effects on the major blood vessels (e.g., atheroma formation) and indirect effects that stimulate changes in the cardiovascular system (e.g., elevation of systemic inflammatory responses).

Interesting supportive evidence for these mechanisms can be derived from intervention trials in which serum levels of inflammatory mediators and markers are assessed before and after treatment that is aimed at decreasing periodontal inflammation. For example, in subjects with chronic periodontitis, serum levels of IL-6 and CRP are reduced after scaling and root planing.[33] A systematic review and meta-analysis of 25 intervention studies examining periodontitis patients with and without periodontal treatment demonstrated that periodontal treatment was associated with a significant reduction in serum levels of CRP, IL-6, fibrinogen, and TNF-α.[164] Inflammatory periodontal disease (compared with periodontal health) is also associated with altered vascular endothelial function.[34] Altered vascular endothelial function is a major risk factor for acute thrombotic events. After scaling and root planing with a resultant decrease in periodontal inflammation, markers of vascular health improve significantly over time.[34,168] The functional assessment of vascular endothelial function also returns to normal after scaling and root planing.[148,168] These results suggest that periodontal inflammation adversely affects the health of the vascular endothelium, whereas a reduction in inflammation improves endothelial health. Whether these changes directly impact

the risk of acute cardiovascular events remains to be determined in prospective controlled clinical intervention trials over long periods; such studies do not currently exist.

Role of Periodontal Disease in Erectile Dysfunction

Erectile dysfunction (ED) is associated with endothelial dysfunction, and elevated levels of oxidative stress and systemic inflammation are common to both periodontal disease and ED. Studies have shown a relationship between ED and periodontitis. In a large case–control study of almost 200,000 subjects in Taiwan, those with ED were significantly more likely to have chronic periodontitis than those without ED, with an overall significant odds ratio of 3.35 after adjusting for confounding variables.[78] Other studies have supported these findings in smaller populations in other countries,[129,152,179] and a systematic review of four studies found a significant association between periodontitis and ED, with an odds ratio of 3.07.[171] An intervention trial was conducted in 120 subjects with ED and chronic periodontitis; 60 subjects received scaling and root planing, and 60 control subjects received no periodontal treatment.[1] Three months later, the treatment group had significant improvement in ED, whereas the control group had no change. These preliminary studies suggest a relationship between periodontitis and ED, but more research is needed to understand the mechanisms of interaction.

Periodontal Disease and Stroke

Ischemic cerebral infarction, or stroke, is often preceded by systemic bacterial or viral infection. In one study, patients with cerebral ischemia were five times more likely to have had a systemic infection within 1 week before the ischemic event than nonischemic control subjects.[52] Recent infection was a significant risk factor for cerebral ischemia; it was independent of other known risk factors such as hypertension, history of a previous stroke, diabetes, smoking, and CHD. Interestingly, the presence of systemic infection before the stroke resulted in significantly greater ischemia

and a more severe postischemic neurologic defect than stroke not preceded by infection.[53] Stroke patients with a preceding infection had slightly higher levels of plasma fibrinogen and significantly higher levels of CRP compared with those without infection.

Periodontal Infection Associated With Stroke

Stroke is classified as either hemorrhagic or nonhemorrhagic. Nonhemorrhagic stroke, or ischemic stroke, is usually caused by thromboembolic events and cerebrovascular atherosclerosis, whereas hemorrhagic stroke often results from a vascular bleed such as an aneurysm. Periodontal disease has been associated primarily with an increased risk of nonhemorrhagic stroke. Numerous studies have shown that periodontal disease is associated with an increased risk of stroke. In a case–control study, subjects with severe periodontitis had a 4.3 times higher risk of stroke than subjects with mild or no periodontitis.[51] Severe periodontitis was a risk factor in men but not women, and in those younger but not older than 65 years of age. In a longitudinal study of 1137 dentate men who were followed for a mean of 24 years, subjects with >20% mean radiographic bone loss at baseline were more than three times as likely to have a stroke than subjects with <20% bone loss.[74] There was a stronger effect of periodontitis on the risk for stroke among men younger than 65 years of age compared with older subjects. Both large epidemiologic studies and systematic reviews of the evidence have suggested an approximate threefold increased risk of stroke in subjects with periodontitis.[69,176]

As previously discussed, periodontal infection may contribute directly to the pathogenesis of atherosclerosis by providing a persistent bacterial challenge to the arterial endothelium, thereby contributing to the monocyte- and macrophage-driven inflammatory process that results in atheromatosis and narrowing of the vessel lumen. Furthermore, periodontal infection may stimulate a series of indirect systemic effects, such as elevated production of fibrinogen and CRP, which increases the risk of stroke (see Figs. 15.5 and 15.6). Finally, bacteremia with PAAP-positive bacterial strains from supragingival and subgingival plaque can increase platelet aggregation, thereby contributing to

thrombus formation and subsequent thromboembolism, which is the leading cause of stroke.[110]

Clinical Correlation

Periodontal infection may contribute directly to the pathogenesis of atherosclerosis by providing a persistent bacterial challenge to the arterial endothelium, thereby contributing to the monocyte- and macrophage-driven inflammatory process that results in atheromatosis and narrowing of the vessel lumen.

Periodontal Disease and Diabetes Mellitus

The relationship between diabetes mellitus and periodontal disease has been extensively examined. It is clear from epidemiologic research that diabetes increases the risk for and severity of periodontal diseases.[112] The biologic mechanisms through which diabetes influences the periodontium are discussed in Chapter 14. The increased prevalence and severity of periodontitis typically seen in patients with diabetes—especially those with poor metabolic control—has led to the designation of periodontal disease as the "sixth complication" of diabetes.[99] In addition to the five "classic" complications of diabetes (Box 15.2), the American Diabetes Association has officially recognized that periodontal disease is common among patients with diabetes, and its Standards of Care include taking a history of current or past dental infections as part of the physician's examination.[4] Since 2009, the American Diabetes Association's Standards of Medical Care in Diabetes have specifically recommended that physicians refer patients with diabetes to a dentist for a comprehensive dental and periodontal examination.[5]

From Löe H: Periodontal disease: the sixth complication of diabetes mellitus. *Diabetes Care* 16(Suppl 1):329, 1993.

Many studies have examined the effects of diabetes on the periodontium, whereas others have examined the effect of periodontal infection on the control of diabetes.[112] Such studies are difficult to perform because of the influence of ongoing medical management of diabetes during the study. The following questions remain:

- Does the presence or severity of periodontal disease affect the metabolic state of diabetic patients?
- Does periodontal treatment aimed at reducing the bacterial challenge and minimizing inflammation have a measurable effect on glycemic (blood glucose) control?

A review of four studies including more than 22,000 subjects found that the incidence of type 2 diabetes (i.e., new diagnoses) was significantly greater in individuals with periodontal disease than in those without periodontal disease.[15] In a longitudinal study of patients with type 2 diabetes, severe periodontitis was associated with the significant worsening of glycemic control over time.[161] Individuals with severe periodontitis at the baseline examination had a greater incidence of worsening glycemic control over a 2- to 4-year period as compared with those without periodontitis at baseline. In this study, periodontitis was known to have preceded the worsening of glycemic control. Periodontitis has also been associated with the classic complications of diabetes. Diabetic

adults with severe periodontitis at baseline had a significantly greater incidence of kidney and macrovascular complications over the subsequent 1 to 11 years than did diabetic adults with only gingivitis or mild periodontitis.[167] This was true despite both groups' having similar glycemic control. One or more cardiovascular complications occurred in 82% of patients with severe periodontitis versus 21% of patients without severe periodontitis. Again, severe periodontitis preceded the onset of clinical diabetic complications in these subjects.

Among diabetic patients with periodontitis, periodontal therapy may have beneficial effects on glycemic control.[41,112,151,154,163] This may be especially true for patients with relatively poor glycemic control and more advanced periodontal destruction before treatment. A large number of studies, starting as far back as 1960,[174] have examined the impact of periodontal therapy on glycemic control in patients with diabetes. Most of these studies compared scaling and root planing (with or without adjunctive systemic antibiotics) with no periodontal therapy and followed patients for several months to assess changes in glycemic control measured by glycated hemoglobin (HbA1c) values. Others included in the treatment regimen not only scaling and root planing but also extraction of periodontally hopeless teeth and even periodontal surgery. Many of these studies showed a significant improvement in glycemic control, as determined by reductions in HbA1c values, in the periodontal treatment group compared with the nontreatment group.[55,81,120] Other studies showed minimal change in glycemic control in periodontally treated patients.[3,23,42,156]

When studies of similar treatment regimens demonstrate conflicting results, systematic reviews with meta-analyses of the data are essential to aid the clinician in evaluating the evidence. Numerous systematic reviews and meta-analyses have consistently shown that periodontal therapy is associated with a statistically significant and clinically relevant improvement in glycemic control in patients with diabetes and periodontitis.[41,151,163] However, clinicians must understand that individual patients may or may not have outcomes similar to the average outcome in any given study or systematic review. That is, treatment results vary from patient to patient, and clinicians should not expect the same result in all

patients. These studies suggest that periodontal therapy is most likely to result in short-term improvement in glycemia in those diabetic patients with severe periodontitis and poor metabolic control who demonstrate marked reduction in periodontal inflammation after treatment. Conversely, individuals with moderately well-controlled or well-controlled diabetes and periodontitis who have less reduction in inflammation may demonstrate no or only minimal changes in glycemic control.

Flash Back

Periodontal disease was designated as the "sixth complication" of diabetes because of the increased prevalence and severity of periodontitis typically seen in patients with diabetes, especially those with poor metabolic control.

Most of the studies evaluating the treatment of periodontal disease and its impact on glycemic control have been performed in subjects with type 2 diabetes. However, research suggests that periodontal therapy may have a smaller impact on glycemic control in patients with type 1 diabetes than in those with type 2 disease.[16] In a study of subjects with type 1 and type 2 diabetes with periodontitis, periodontal therapy was associated with a significant improvement in glycemic control overall in those with type 2 diabetes but not in those with type 1 disease, despite improvement in the periodontal condition of both groups.[16]

It is common to observe wide interindividual variability in responses to various medical management approaches in patients with type 1 diabetes. Similarly, wide variability in the impact of periodontal therapy on glycemic control can be expected in the type 1 diabetic population. For example, a study of periodontal therapy in 65 people with type 1 diabetes and chronic periodontitis showed highly variable responses.[166] Although there was an overall improvement in periodontal health after therapy, approximately 35% of subjects had an improvement in glycemic control after treatment, 37% had no significant change, and 28% showed a worsening of glycemic control. In this study, subjects were divided into those with better baseline glycemic control (i.e., glycated

hemoglobin values <8.5%) and those with poorer glycemic control (i.e., glycated hemoglobin values ≥8.5%). Interestingly, twice as many subjects showed improved glycemic control among those whose glycemic control before periodontal treatment was poor compared with those among whom baseline glycemic control was good. Therefore, the clinician may anticipate a greater glycemic response to periodontal therapy among those patients with type 1 diabetes whose glycemic control is relatively poor than among those whose glycemic control is already good before periodontal treatment.

Although the routine use of systemic antibiotics for treatment of chronic periodontitis is not justified, patients with poorly controlled diabetes and severe periodontitis may constitute one patient group for whom such therapy is appropriate. Antibiotics remain an adjunct to the necessary mechanical removal of plaque and calculus. The mechanisms by which adjunctive antibiotics may induce positive changes in glycemic control when they are combined with mechanical debridement are unknown at this time. Systemic antibiotics may eliminate residual bacteria after scaling and root planing, thereby further decreasing the bacterial challenge to the host. Tetracyclines are also known to suppress the glycation of proteins and decrease the activity of tissue-degrading enzymes such as matrix metalloproteinases. These changes may contribute to improvements in the metabolic control of diabetes.

Periodontal Infection Associated With Glycemic Control in Diabetes

An understanding of the effects of other infections is useful to delineate the mechanisms by which periodontal infection influences glycemia. It is well known that systemic inflammation plays a major role in insulin sensitivity and glucose dynamics. As discussed previously, periodontal diseases can induce or perpetuate an elevated systemic chronic inflammatory state, which is reflected in increased serum CRP, IL-6, and fibrinogen levels seen in many people with periodontitis.[33,94,162] Inflammation induces insulin resistance, and such resistance often accompanies systemic infections. For example, acute nonperiodontal bacterial and viral

infections have been shown to increase insulin resistance and aggravate glycemic control.[141,177] This occurs in individuals either with or without diabetes. Systemic infections increase tissue resistance to insulin through a variety of mechanisms, thereby preventing glucose from entering target cells, causing elevated blood glucose levels, and requiring increased pancreatic insulin production to maintain normoglycemia. Insulin resistance may persist for weeks or even months after the patient has recovered clinically from the illness. In an individual with type 2 diabetes who already has significant insulin resistance, further tissue resistance to insulin as a result of infection may considerably exacerbate poor glycemic control.

It is possible that chronic gram-negative periodontal infections may also result in increased insulin resistance and poor glycemic control.[54,162] In patients with periodontitis, persistent systemic challenge with periodontopathic bacteria and their products results in an up-regulation of the immunoinflammatory response, with elevation in serum levels of proinflammatory mediators such as IL-1β, TNF-α, and IL-6, similar to well-recognized systemic infections but on a more persistent, chronic basis (Fig. 15.7). Increased serum levels of several cytokines, including TNF-α and IL-6, are associated with increased insulin resistance. This mechanism would explain the worsening of glycemic control associated with severe periodontitis. Periodontal treatment designed to decrease the bacterial insult and reduce inflammation may result in decreased systemic inflammation, restoring insulin sensitivity over time and thereby resulting in improved metabolic control. The improved glycemic control seen in many studies of periodontal therapy would support such a hypothesis. This mechanism may also explain differences in the glycemic response to periodontal therapy between individuals with type 1 and type 2 diabetes.[16] Because type 2 diabetes is strongly associated with insulin resistance, periodontal therapy that reduces systemic inflammation may improve insulin sensitivity and result in improved glycemic control. Conversely, type 1 diabetes is not strongly associated with insulin resistance, so reduced inflammation after periodontal therapy may not have a major effect on insulin sensitivity in patients with type 1 disease, which would minimize the impact of periodontal treatment in these

patients.

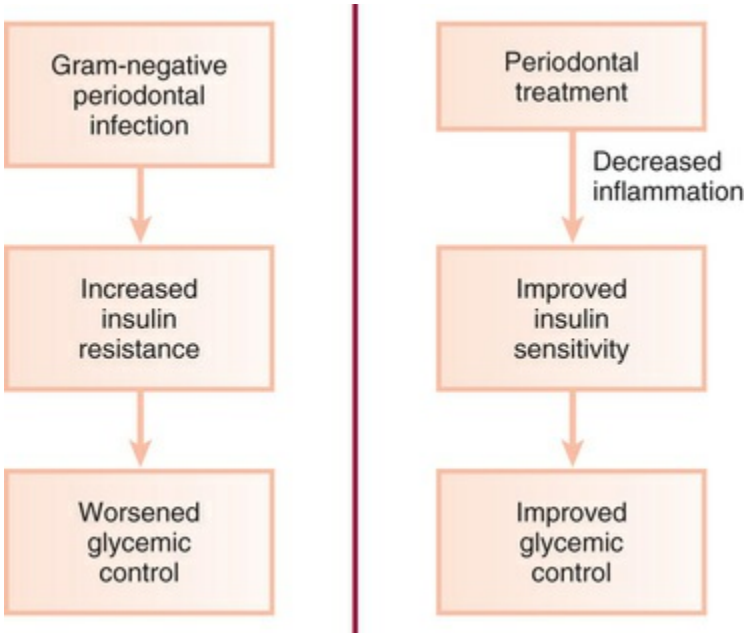

FIG. 15.7 Potential effects of periodontal infection and periodontal therapy on glycemia in patients with diabetes.

Periodontal Disease and Pregnancy Outcome

Low-birth-weight (LBW) infants (i.e., those weighing <2500 g at birth) are 40 times more likely to die during the neonatal period than normal-birth-weight (NBW) infants.[107] LBW infants who survive the neonatal period are at increased risk for congenital anomalies, respiratory disorders, and neurodevelopmental disabilities. The social and financial costs of LBW infants are enormous, and an emphasis on the prevention of low birth weight is preferred to the high-cost intensive care often required to allow for the survival of LBW infants.

The primary cause of LBW deliveries is *preterm labor* or *premature rupture of membranes* (PROM). Factors such as smoking, alcohol, or drug use during pregnancy; inadequate prenatal care; race; low socioeconomic status; hypertension; old or young maternal age;

diabetes; and genitourinary tract infections increase the risk of preterm LBW delivery. However, these risk factors are not present in approximately one-fourth of preterm LBW cases, which results in a continued search for other causes.[48,127]

Research has examined the relationship between maternal infection and preterm labor, PROM, and LBW delivery. The true extent of this relationship is difficult to determine, because the majority of maternal infections may be subclinical. Genitourinary tract infections have been associated with adverse pregnancy outcomes. Women with bacteriuria have increased rates of preterm delivery, and the antibiotic treatment of bacteriuria has resulted in a significant decrease in preterm delivery rates as compared with placebo treatment.[63,127] Vaginal colonization with group B streptococci or *Bacteroides* species increases the risk of PROM, preterm delivery, and LBW infants.[108]

Bacterial Vaginosis

Bacterial vaginosis is the most common vaginal disorder in women of reproductive age. It is caused by changes in the vaginal microflora in which normally predominant facultative lactobacilli are replaced by *Gardnerella vaginalis*; anaerobic organisms, including species of *Prevotella*, *Bacteroides*, *Peptostreptococcus*, *Porphyromonas*, and *Mobiluncus*; and other organisms.[62] Bacterial vaginosis is a known risk factor for preterm labor, PROM, and LBW delivery.[54,172] The incidence of preterm birth is approximately three times greater among women with bacterial vaginosis as compared with those without.[6] Treatment of bacterial vaginosis with metronidazole in pregnant women resulted in decreased preterm birth rates as compared with placebo treatment.[122]

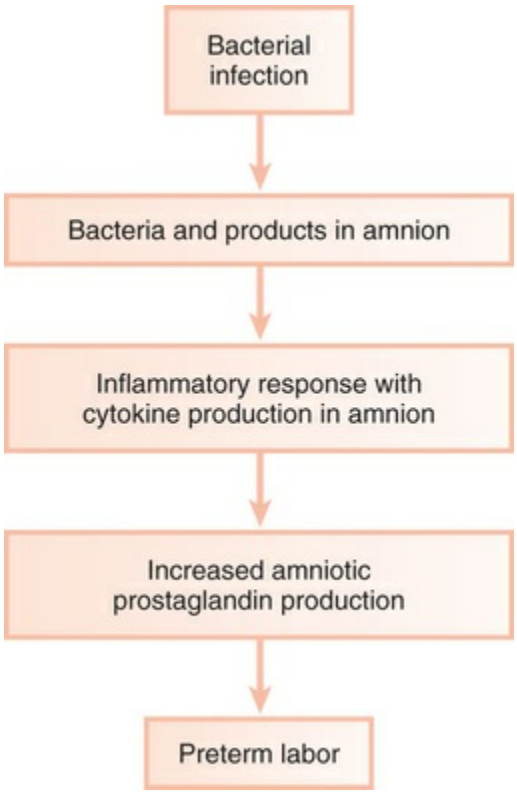
The exact mechanism by which vaginal colonization or genitourinary tract infection may cause PROM and preterm labor is not known.[100,172] The primary mechanism has traditionally been thought to be ascending infection from the vagina and the endocervix. Endotoxins (LPSs) and bioactive enzymes produced by many organisms associated with vaginosis may directly injure tissues and induce the release of proinflammatory cytokines and prostaglandins. Throughout normal gestation, amniotic prostaglandin levels rise steadily until a sufficient threshold is

reached that induces labor and delivery. Maternal infection may cause increased amniotic prostaglandin production, and it may also result in labor-inducing levels being reached before full gestation. In addition to prostaglandins, various proinflammatory cytokines (e.g., IL-1, IL-6, TNF-α) have been found in the amniotic fluid of women with preterm labor. Women with preterm labor often have culture-positive amniotic fluid, even in the absence of clinical infection. Among culture-positive patients, the species that is most often isolated is *Fusobacterium nucleatum*.[63] Although *F. nucleatum* is occasionally isolated from the vaginal flora in a patient with bacterial vaginosis, its prevalence among women with preterm labor is much higher than that found among women with vaginosis. *F. nucleatum* is even less frequently isolated from the vaginal flora of women without bacterial vaginosis.

Many of the other species isolated from amniotic fluid in women with preterm labor are those often found with bacterial vaginosis, which supports an ascending route of infection. However, the frequency of *F. nucleatum* detection suggests other possible routes of infection. Some investigators have suggested infection by a hematogenous route from a location in which the organism is often detected.[63] *F. nucleatum* is a common oral species that is highly prevalent in patients with periodontitis, and it could reach the amniotic fluid via hematogenous spread from the oral cavity. This route is also suggested by the occasional isolation of *Capnocytophaga* species in the amniotic fluid of women with preterm labor; this is an organism that is rarely isolated from the vagina but is common in the oral cavity. The species and subspecies of *F. nucleatum* isolated from amniotic fluid cultures of women with preterm labor more closely match those found in subgingival plaque than strains identified from the lower genital tract. In addition to hematogenous spread, another possible route of infection is by oral–genital contact involving the transfer of oral organisms to the vagina.[63]

Although the direct effects of microorganisms may play an important role in many cases of preterm labor, PROM, and LBW delivery, indirect mechanisms may also be operative.[127] Bacterial infection of the chorioamnion, or extraplacental membrane, may lead to chorioamnionitis, a condition that is strongly associated with PROM and preterm delivery. However, many cases of

histologic chorioamnionitis demonstrate negative bacterial cultures, indicating that infection is not the sole cause of this condition. It is likely that an indirect mechanism may be active in which the cascade of host products produced in response to infection is often responsible for preterm labor. Maternal infection may lead to the presence of amniotic bacterial products, such as LPSs from gram-negative organisms, which stimulate the production of host-derived cytokines in the amnion and the decidua (eFig. 15.1). These cytokines, including IL-1, TNF-α, and IL-6, stimulate increased prostaglandin production from the amnion and the decidua, which leads to the onset of preterm labor. A premature rise in PGE_2 and $PGF_{2\alpha}$ is characteristic of preterm labor, regardless of whether clinical or subclinical maternal genitourinary tract infection is detected.



EFIG. 15.1 Mechanisms by which infection may induce preterm labor.

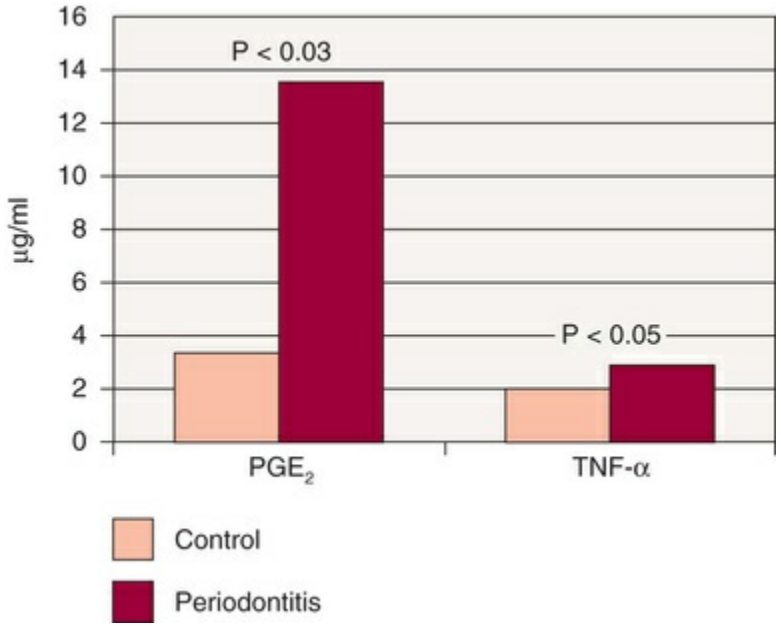
The question then arises as to what stimulates the increased cytokine levels and the resultant increased prostaglandin levels seen during preterm delivery in patients with no evidence of

genitourinary infection. Many cases of preterm LBW could result from infections of unknown origin, such as those that originate in areas other than the genitourinary tract.

Role of Periodontitis

Periodontitis is a remote gram-negative infection that may play a role in LBW infants.[100] As discussed previously, periodontopathic organisms and their products may have wide-ranging effects that are most likely mediated through the stimulation of host cytokine production in target tissues. Animal studies suggest that remote reservoirs of gram-negative organisms and their products may have a negative impact on pregnancy outcome. *P. gingivalis* implanted in subcutaneous chambers during gestation caused significant increases in TNF-α and PGE_2 levels.[25] This localized subcutaneous infection resulted in a significant increase in fetal death and a decrease in birth weight for those fetuses that remained viable, compared with control animals that were not inoculated. There was a significant correlation between TNF-α and PGE_2 levels and between these levels and fetal death and growth retardation. These data suggest that a remote nondisseminated infection with *P. gingivalis* may result in abnormal pregnancy outcomes in this model.

Decreased birth weight and increased fetal death were also seen after intravenous injections with LPSs derived from *P. gingivalis*.[24] This effect was greatly increased when the LPSs were administered before mating and during gestation, indicating that repeated immunization with *P. gingivalis* LPSs does not provide protection during pregnancy but rather potentiates the negative effects of LPS exposure during gestation. *P. gingivalis*–induced experimental periodontitis in animal models resulted in decreased fetal birth weight and increased amniotic fluid levels of TNF-α and PGE_2 (eFig. 15.2).[127] This provides direct evidence that periodontal infection can affect the fetal environment and pregnancy outcomes.



EFIG. 15.2 Amniotic fluid levels in experimental periodontitis. Experimental periodontitis resulted in increased amniotic fluid levels of tumor necrosis factor alpha *(TNF-α)* and prostaglandin E_2 *(PE_2)* in the pregnant hamster model, thereby providing evidence that periodontal infection can affect the fetal environment. (From Offenbacher S, Jarad HL, O'Reilly PG, et al.: Potential pathogenic mechanisms of periodontitis-associated pregnancy complications. *Ann Periodontol* 3:233, 1998.)

These animal studies have led to an examination of the potential effects of periodontitis on pregnancy outcomes in humans.[68] This relationship has been examined in numerous studies from many countries around the world. In an initial case–control study of 124 women in the United States (93 cases with at least one LBW delivery and 31 controls with at least one NBW delivery), Offenbacher and colleagues[128] found that women who had LBW infants also had significantly greater clinical attachment loss than women who had NBW infants. After adjusting for known risk factors for LBW delivery, women with periodontitis that resulted in more than 3 mm of attachment loss in at least 60% of sites had a 7.5-fold increased risk of having an LBW infant. In a large prospective study of more than 1300 pregnant women, those with generalized periodontitis had a fivefold increased risk of preterm birth before 35 weeks' gestation and a sevenfold increased risk of delivery before 32 weeks' gestation as compared with women without

periodontitis.[73] These studies and others[31,68,95] indicate a strong association between periodontal infection and adverse pregnancy outcomes. However, not all studies have demonstrated such a relationship. For example, a large case–control study that included more than 900 Brazilian women showed no significant differences in periodontal status among women with normal deliveries as compared with those who had preterm or LBW deliveries.[10]

Excellent systematic reviews with meta-analyses have examined the wide range of studies evaluating the relationship between periodontitis and pregnancy outcomes.[68] These studies consistently demonstrated a significant association between periodontitis and adverse pregnancy outcomes. A meta-analysis of 17 studies that involved more than 7000 subjects confirmed a significant relationship between periodontitis and preterm birth or LBW infants.[170] The pooled estimate for the risk of having a preterm birth or LBW infant in mothers with periodontal disease was 2.83 compared with mothers without periodontal disease. In a systematic review and meta-analysis of 11 prospective studies involving more than 12,000 women, 9 of the studies showed a statistically significant increase in the risk of adverse pregnancy outcomes in women with maternal periodontitis.[18] Periodontitis was associated with a significantly increased risk of preterm birth (risk ratio, 1.70) and LBW (risk ratio, 2.11).

There are two major pathways by which periodontal diseases may be associated with increased adverse pregnancy outcomes: (1) a direct pathway in which oral microorganisms disseminate to the fetal-placental unit either through a hematogenous route from the oral cavity or by an ascending route via the genitourinary tract, or (2) an indirect pathway in which elevated inflammatory mediators from the periodontal tissues reach the fetal-placental unit directly through the systemic vasculature or reach the liver and stimulate hepatic production of even more proinflammatory cytokines, which subsequently affects the fetal-placental unit.

In a cross-sectional study, women who had LBW infants had significantly higher levels of *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans, Tannerella forsythia, P. gingivalis,* and *Treponema denticola* in their subgingival plaque than did the control women who had NBW infants.[127] Studies of fetal immunoglobulin

M (IgM) antibody levels have found remarkably high fetal antibody seropositivity to oral bacteria.[100] This indicates that the fetal immune response is activated in utero by bacterial antigens derived from the oral cavity. In fact, preterm babies have been shown to have a threefold increased prevalence of IgM seropositivity to many of the classic periodontopathogens as compared with full-term babies.[100] In particular, 20% of preterm infants had a positive IgM response to *Campylobacter rectus* as compared with 6.3% of term infants. The prevalence of fetal IgM seropositivity to other periodontopathogens such as *P. intermedia, Peptostreptococcus micros,* and *F. nucleatum* was fourfold to eightfold higher in preterm infants compared with normal-term neonates. This suggests that the immune system of preterm infants is often challenged by organisms from the mother's oral cavity.

Women who had LBW infants also had higher levels of gingival crevicular fluid (GCF), PGE_2, and IL-1.[127] In primiparous women (those experiencing a first birth), GCF levels of PGE_2 were inversely related to their infants' birth weight. Women with higher PGE_2 levels in their GCF had smaller and more premature infants. GCF levels of IL-1 and PGE_2 have been shown to correlate highly with intraamniotic IL-1 and PGE_2 levels. In fact, measuring the GCF levels of these inflammatory mediators has been suggested as a means that is less invasive than amniocentesis for screening expectant mothers for elevated amniotic IL-1 and PGE_2 levels.[127] Thus, women who had LBW infants often had a higher prevalence and severity of periodontitis, more gingival inflammation, higher levels of putative periodontal pathogens, and an elevated subgingival inflammatory response than women who had NBW infants; furthermore, the increased bacterial challenge may have broader systemic effects, thereby resulting in an elevated challenge to the fetal immune system.

Periodontal disease may also increase the risk for preeclampsia.[68] This hypertensive disorder affects about 5% to 10% of pregnancies, and it is a major cause of perinatal and maternal morbidity and mortality. Preeclampsia has multiple potential etiologies, several of which involve vascular changes in the placenta that are similar to those seen with atherosclerosis. The presence of periodontitis

during pregnancy or a worsening of periodontal disease during pregnancy is associated with a twofold to 2.5-fold increased risk for preeclampsia.[14] In one study, women with severe preeclampsia were 3.8 times more likely to present with extensive periodontal disease than were normotensive women, whereas women with mild preeclampsia were 2.4 times more likely to have extensive periodontal disease than normotensive women.[17] One systematic review found a significant relationship between periodontal disease and risk of preeclampsia in 8 of the 12 studies reviewed.[87] Other large systematic reviews with meta-analyses found that periodontal disease was associated with a significant 60% to 76% overall increase in the risk of preeclampsia.[26,68]

Numerous intervention trials have examined the effects of treating periodontal disease during gestation rather than waiting until after parturition to provide needed care. In a study of 351 pregnant women with periodontitis, women who received scaling and root planing before 28 weeks' gestation, followed by prophylaxis every 2 weeks until parturition, had an LBW rate of 1.8%.[96] Conversely, women who did not receive periodontal therapy during gestation but instead were treated after parturition had an LBW rate of 10.1%. Similarly, Jeffcoat and colleagues[72] found a reduced preterm birth rate among women who received mechanical periodontal therapy during gestation. Conversely, other studies have shown that providing periodontal treatment during pregnancy improves periodontal health but has minimal impact on pregnancy outcome.[116]

Systematic reviews with meta-analyses have produced conflicting results regarding the impact of periodontal therapy on pregnancy outcome.[19,79,115] They have also emphasized the difficulty inherent in analyzing such studies due to the variability among studies with regard to the definitions of periodontal disease used and the types of periodontal treatment provided to patients. In addition, there are large differences in the overall rates of adverse pregnancy outcomes in the various populations studied. For example, one systematic review of 13 randomized controlled trials that included more than 6800 live births and examined the effect of maternal periodontal treatment or no periodontal treatment on birth weight and preterm delivery demonstrated that periodontal

treatment was associated with a decreased adverse pregnancy outcome rate in 8 of the 13 studies.[19] However, meta-analysis of the total dataset showed no significant effect of periodontal therapy on preterm birth or LBW. Another excellent systematic review of 11 randomized controlled trials distinguished between study subject populations with an overall low rate of adverse pregnancy outcomes and populations with a high rate of adverse outcomes.[79] Overall, periodontal therapy during gestation was not associated with decreased preterm birth rates. However, when studies with a high incidence of preterm birth (i.e., 22% to 62%) were compared with studies with a lower incidence (i.e., 4% to 10%), periodontal therapy was associated with a significant reduction in the rates of preterm birth and LBW in the high-risk group but not in the low-risk group. This suggests that periodontal treatment during gestation may be most appropriate for women at greater risk for adverse pregnancy outcomes.

Given the conflicting evidence, it is currently unclear whether periodontal therapy provided during gestation has a beneficial effect on pregnancy outcome. What is clear is that scaling and root planing provided during the second and third trimesters of gestation are safe procedures. Every intervention trial published to date has shown that scaling and root planing during pregnancy are associated with either a decrease or no change in adverse pregnancy outcome rates. Not a single study has shown an increase in adverse outcome rates. In addition, the children of women who received scaling and root planing during gestation had similar cognitive, motor, and language development during the first 2 years of life when compared with the children of women who did not receive periodontal therapy until the postpartum period.[117] Thus, the clinician should feel comfortable providing scaling and root planing during the second and third trimesters of pregnancy. Use of local anesthetics is acceptable during such treatment, because research has demonstrated no increase in birth weight, gestational age at delivery, or miscarriage rate in pregnant women receiving dental local anesthetics compared with pregnant women not receiving anesthetics.[56]

Periodontal Disease and Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is characterized by airflow obstruction that results from chronic bronchitis or emphysema. Bronchial mucous glands enlarge, and an inflammatory process occurs during which neutrophils and mononuclear inflammatory cells accumulate within the lung tissue.[58,165] About 15 million Americans have COPD, and tobacco smoking is the primary risk factor.

COPD shares similar pathogenic mechanisms with periodontal disease. With both diseases, a host inflammatory response is mounted in response to chronic challenge by bacteria in periodontal disease and by factors such as cigarette smoking in COPD. The resulting neutrophil influx leads to the release of oxidative and hydrolytic enzymes that cause tissue destruction directly. The recruitment of monocytes and macrophages leads to further release of proinflammatory mediators.

Less is known about the clinical relationship between periodontal disease and COPD as compared with CHD and other systemic conditions. A case–control study showed significantly deeper probing depth and more clinical attachment loss in patients with COPD than in controls without COPD.[134] A longitudinal study of >1100 men showed that more severe bone loss found during the baseline dental examination was associated with an increased risk of subsequently developing COPD as compared with less bone loss, independent of age, smoking status, and other known risk factors for COPD.[58] Individuals with poor oral hygiene have also been found to be at increased risk for chronic respiratory diseases such as bronchitis and emphysema.[145] Conversely, a large epidemiologic study revealed no significant overall association between periodontal disease and COPD.[67] Among nonsmokers and former smokers, even severe periodontitis did not increase the risk for COPD. In current smokers, however, the presence of severe periodontitis was associated with an increased risk of COPD. These results suggest that smoking may act as a major effect modifier in the relationship between COPD and periodontal disease and that this modifier's presence may be required to generate an effect.

Conversely, tooth loss may modify the effect of smoking on COPD. In a large epidemiologic study of more than 400,000 people, both smoking and tooth loss were associated with an increased likelihood of COPD. Compared with nonsmokers with no tooth loss, smokers with tooth loss were at much higher risk for COPD, and the risk of COPD increased as the number of missing teeth increased.[28] A systematic review of 14 studies and almost 4000 subjects showed a significant twofold increased risk of COPD in those with periodontal disease as compared with those without.[181] However, more evidence is needed to establish a strong relationship between the two diseases.[144]

In COPD patients with periodontitis, periodontal therapy may impact respiratory health. COPD exacerbation is an acute event in which respiratory symptoms are worsened, usually to the point where a change in medication is needed. Most COPD exacerbations are caused by infections. In controlled clinical trials, scaling and root planing was associated with a decrease in the frequency of COPD exacerbations compared with nontreatment.[86,182]

Periodontal Disease and Acute Respiratory Infections

The upper respiratory passages are often contaminated with organisms derived from the oral, nasal, and pharyngeal regions. Conversely, the lower airways, in which gas exchange occurs, are generally maintained free of microorganisms by a combination of host immune factors and mechanical clearance through the cough reflex, the ciliary transport of aspirated contaminants, and the movement of secretions from the lower airways into the trachea.[165] Pneumonia is an infection of the lungs that is caused by bacteria, viruses, fungi, or mycoplasma and is broadly categorized as either community-acquired or hospital-acquired. A wide variety of bacteria can cause pneumonia, and the spectrum of offending organisms differs greatly between community-acquired and hospital-acquired infections.

Community-acquired bacterial pneumonia is caused primarily by the inhalation of infectious aerosols or the aspiration of oropharyngeal

organisms. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common, although numerous other species may be found, including anaerobic bacteria.[130] Antibiotic therapy is highly successful for the resolution of most cases of community-acquired bacterial pneumonia. To date, no associations have been found between oral hygiene or periodontal disease and the risk for acute respiratory conditions such as pneumonia in community-dwelling individuals.[145]

The same cannot be said for individuals in the hospital setting. *Hospital-acquired (nosocomial) bacterial pneumonia* has a very high morbidity and mortality rate. The incidence of nosocomial pneumonia is highest among severely ill patients, such as those in intensive care units or on ventilatory support. Although nosocomial pneumonia is most often caused by gram-negative aerobic organisms, many cases are the result of infection by anaerobic bacteria, including those that are typically found in the subgingival environment.

Hospital-acquired pneumonia is usually caused by the aspiration of oropharyngeal contents.[144] Oropharyngeal colonization with *potential respiratory pathogens* (PRPs) is generally a transient phenomenon; however, such colonization increases during hospitalization. The longer the hospital stay, the greater the prevalence of PRPs. PRPs are found predominantly in the gastrointestinal tract, and they may be passed via esophageal reflux into the oropharynx, where they colonize. Subsequent aspiration may lead to pneumonia. Patients whose posterior oropharynx becomes colonized with PRPs have a significantly increased risk of developing nosocomial pneumonia as compared with those without oropharyngeal colonization by PRPs.[146] Dental plaque has been shown to serve as a reservoir of PRPs; such colonization in plaque results in a persistent source of potential aspiration.[40]

Selective decontamination is a technique that combines systemic antibiotics with orally administered nonabsorbable antibiotics in an attempt to eradicate PRPs from the digestive tract and the oropharynx and thereby minimize the risk of nosocomial respiratory infections. The technique is used primarily for patients who are intubated and on mechanical ventilators. Selective decontamination significantly decreases the incidence of

nosocomial pneumonia.[149] Decontamination of only the digestive tract does not reduce the incidence of pneumonia, but decontamination of the oropharynx alone does.[135] This provides further evidence that the oropharynx is the primary site of PRP colonization, with the subsequent aspiration of causative organisms leading to pneumonia.

PRPs may also originate in the oral cavity, with dental plaque serving as a reservoir of these organisms.[8] Poor oral hygiene is common in hospital and nursing home settings, especially among severely ill patients.[146] PRPs are more often isolated from the supragingival plaque and buccal mucosa of patients in intensive care units than from those in outpatient settings. Organisms that are not routinely found in dental plaque become plaque colonizers after prolonged hospitalization. Subgingival plaque may also harbor PRPs, and putative periodontal pathogens have been associated with nosocomial pneumonia. Furthermore, anaerobic organisms from periodontal pockets may serve as the primary inoculum for suppurative respiratory diseases (e.g., pulmonary abscesses) that involve significant morbidity and mortality.

Few studies have examined the potential impact of periodontitis on the risk for nosocomial pneumonia. A case–control study of 85 patients with nosocomial pneumonia and 230 healthy controls found that the patients had more extensive deep probing depths and attachment loss.[49] After adjusting for age and smoking, a statistically significant odds ratio of 2.9 was found for the association between periodontitis and nosocomial pneumonia.

Systematic reviews of the evidence have determined that interventions used to improve oral hygiene, such as mechanical toothbrushing and chemical antimicrobial rinses, have the potential to decrease the risk of nosocomial pneumonia in high-risk patients, such as those in intensive care units or those on ventilators.[8,144] Improved oral hygiene by the patient in combination with frequent professional oral health care reduces both the incidence and progression of respiratory diseases in older patients living in nursing homes, and these practices have a major impact on individuals in intensive care units, for whom the risk for nosocomial pneumonia is markedly elevated. One systematic review showed that mechanical oral hygiene performed in nursing

homes and hospitals significantly decreased the occurrence and progression of respiratory tract infections and pneumonia; the review of evidence suggested that "one in 10 cases of death from pneumonia in elderly nursing home residents may be prevented by improving oral hygiene."[155]

Periodontal Disease and Asthma

Evidence evaluating the relationship between periodontal disease and asthma is relatively sparse. The largest study has been a case–control study of 220 adults, half with severe asthma and half without asthma.[50] After adjusting for age, smoking habit, education level, and body mass index, people with periodontitis were 4.8 times more likely to have severe asthma than those without periodontitis. Although this study does not demonstrate causation, it suggests a possible link between inflammatory periodontal disease and asthma in adults.

Periodontal Medicine in Clinical Practice

The concept of periodontal diseases as localized entities that affect only the teeth and the supporting apparatus is oversimplified. Rather than being confined to the periodontium, inflammatory periodontal diseases may have wide-ranging systemic effects. In most people, these effects are relatively inconsequential, or at least not clinically evident. In susceptible individuals, however, periodontal infection may act as an independent risk factor for systemic disease, and it may be involved in the basic pathogenic mechanisms of these conditions. Furthermore, periodontal infection may exacerbate existing systemic disorders.

Periodontal Disease and Systemic Health

Proper use of the knowledge of potential relationships between periodontal disease and systemic health requires the dental professional to recognize the oral cavity as one of many interrelated

organ systems. A palm-sized infection on the leg of a pregnant woman would be of major concern to the patient and her health care provider, given the potential negative consequences of this localized infection on fetal and maternal health. Similarly, a suppurating infection on the foot of a person with diabetes would be cause for immediate evaluation and aggressive treatment, considering the effects of such infections on the metabolic control of diabetes.

Periodontal infection must be viewed in a similar manner. Periodontitis is a gram-negative infection that often results in severe inflammation, and it potentially involves the intravascular dissemination of microorganisms and their products throughout the body. However, periodontitis tends to be a "silent" disease until destruction results in acute oral symptoms. Most patients—and many medical professionals—do not recognize the potential infection that may exist within the oral cavity.

Patient Education

Patient education is a priority. Only 30 years ago, the factors involved in CHD were unclear. At present, however, it would be difficult to find an individual who was unfamiliar with the link between cholesterol and heart disease. This change was precipitated by research that clearly demonstrated the increased risk for heart disease among individuals with high cholesterol levels, followed by intensive education efforts to spread the message from the scientific community to the public at large. It is important to recognize that high cholesterol levels have not been shown to *cause* heart disease in all individuals; rather, they significantly *increase the risk* of disease. Cholesterol has also been demonstrated to have a biologically plausible role in the pathogenesis of CHD.

Similarly, patient education efforts in the realm of periodontal medicine must emphasize the inflammatory nature of periodontal infections, the increased risk for systemic disease associated with the infection, and the biologically plausible role that periodontal infection may play in systemic disease. Few individuals had their cholesterol levels evaluated until knowledge of the link between

cholesterol and heart disease became widespread. Likewise, an increased appreciation of the potential effects of periodontal infection on systemic health may result in increased patient demand for periodontal evaluation.

Enhanced community awareness may be derived from newspapers, magazines, and other lay sources. However, the most reliable origin of information should be dental and medical professionals, through daily contact with patients. A pregnant woman usually knows that infections may adversely affect her pregnancy. Individuals with diabetes generally know that infections impair glycemic control. However, many of these patients do not know that occult periodontal infections can have the same effect as more clinically evident infections. The dentist is responsible for diagnosing periodontal infections, providing appropriate treatment, and preventing disease recurrence or progression. Because many medical professionals are unfamiliar with the oral cavity and oral health research, dentists must reach out to the medical community to improve patient care through education and communication.[111] Likewise, patients must be educated about disease prevention. Just as patients know that lowering their cholesterol levels may decrease their risk for heart disease, similar knowledge regarding the prevention of periodontal infection should be emphasized. A physician would be remiss if he or she did not provide education about decreasing cholesterol level, losing weight, and ceasing a smoking habit to a patient at risk for CHD. Likewise, controlling the risk factor of periodontal infection requires the dentist to emphasize personal and professional preventive measures that are focused on oral hygiene and regular recall.

Conclusions

Does periodontal disease *cause* CHD, COPD, or adverse pregnancy outcomes? This question may be answered only by use of the evidence that is currently available, with the full knowledge that conclusions may change as future evidence dictates. Periodontal disease may increase the risk for many systemic disorders. Biologically plausible mechanisms support the role of periodontal

infection in these conditions, but it should not be presented as the cause of such systemic diseases, any more than cholesterol should be said to cause heart disease. Periodontal infection is one of many potential risk factors for a number of systemic conditions. Fortunately, it is a readily modifiable risk factor, unlike age, gender, and genetic influences.

The focal infection theory of the early 20th century was widely and appropriately discredited when treatment based on the theory, which consisted almost solely of tooth extraction, had no effect on the underlying diseases that oral sepsis supposedly caused. Similarly, the clinical utility of our current knowledge base is only now evolving. Future research will further delineate the role of periodontal infection in systemic health. The associations between periodontal infection and conditions such as LBW delivery, diabetes, cardiovascular and cerebrovascular diseases, and respiratory diseases may be further substantiated. Longitudinal studies and intervention trials are needed before any causative role can be assigned.

The field of periodontal medicine offers new insights into the concept of the oral cavity as one system that is interconnected with the whole human body. For many years, the dental profession has recognized the effects of systemic conditions on the oral cavity. Only now, however, are dental professionals beginning to understand more fully the impact of the periodontium on systemic health.

Finally, it is important to appreciate the differences between the science and the art of dental practice as they relate to periodontal medicine. Science is based, in general, on means and standard deviations or standard errors. Thus, science may determine that, on average, diabetic patients with periodontal disease have poorer glycemic control than diabetic patients who are periodontally healthy. However, the patient who is sitting in the dental chair at any given time may or may not be a "mean" patient: in other words, she may or may not demonstrate the same relationship that science has determined to exist as an average within the population. She may lie somewhere within or outside the standard deviation. She may have extremely poor glycemic control that is directly related to her extensive periodontal inflammation; she may have

average glycemic control; or she may have good glycemic control. The clinical practice of periodontal medicine recognizes that, while using an evidence-based approach is absolutely key to modern dentistry, each patient is an individual, and he or she may not always fit the average determined by science.

Case Scenario 15.1

Patient:
38-year-old female

Chief Complaint:
"I have swelling and pain in my gums."

Background Information:
Patient is a nonsmoker with poorly controlled diabetes mellitus (HbA1c = 8.4). Patient is overweight. She indicates brushing one to two times per day but does not floss. She reports infrequent dental visits. Her last professional dental cleaning was at least 3 years ago.

Current Findings:
Probing depths were generally in the range of 2 to 4 mm with localized 5 to 7 mm, BOP was 43%.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Does the patient's diabetes pose an increased risk for periodontitis? A. Yes B. No	**Answer: A** **Explanation:** There is increased prevalence of periodontitis in patients with diabetes mellitus, especially if poorly controlled.
2. This patient requires nonsurgical periodontal therapy. Could periodontal therapy improve glycemic control? A. Yes B. No	**Answer: A** **Explanation:** Although there are conflicting results from different studies, numerous systematic reviews and meta-analyses have consistently shown that periodontal therapy is associated with statistically significant and clinically relevant improvement in glycemic control in patients with diabetes and periodontitis.
3. Which of the following are complications of diabetes mellitus? A. Retinopathy B. Nephropathy C. Periodontal disease D. All of the above E. A and B	**Answer: D** **Explanation:** Complications of diabetes mellitus include retinopathy, nephropathy, neuropathy, macrovascular disease, altered wound healing, and periodontal disease.

Case Scenario 15.2

Patient:
49-year-old African American female

Chief Complaint:
"I am feeling discomfort in my gums. They bleed a lot when I brush, and they are always sore."

Background Information:
Patient is a smoker with controlled hypertension and uncontrolled type 2 diabetes mellitus with an HbA1c of 7.8. She is currently taking metoprolol and metformin to treat these inflammatory diseases. She reports brushing twice daily but often skips flossing or other dental aids because it hurts her gums.

Clinical Findings:

Generalized probing depths ranging from 2 to 7 mm. Bleeding on probing was 52% and patient exhibits poor oral hygiene (biofilm control). Gingival tissues are erythematous, edematous, and tender.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Which of the following diseases have been linked to (adversely affected by) periodontal disease? A. Coronary heart disease B. Diabetes C. Myocardial infarction D. All of the above	**Answer: D** **Explanation:** Periodontal disease has been associated with each of these disease processes. However, causal studies still need to performed. It is difficult, because these disease processes share many of the same risk factors. Thus, the association may be among the risk factors rather than the diseases themselves.
2. Periodontal disease is one of the six complications of diabetes mellitus. A. True B. False	**Answer: A** **Explanation:** Yes, along with retinopathy, nephropathy, neuropathy, macrovascular disease, and altered wound healing, periodontal disease is officially recognized by the American Diabetes Association as a common complication among patients with poorly controlled diabetes mellitus.
3. Periodontal therapy has a beneficial effect on glycemic control. A. True B. False	**Answer: A** **Explanation:** This may be true for patients with poor glycemic control and more advanced periodontal destruction. Patients who improved periodontal health with treatment also experienced improvements in glycemic control.
