CHAPTER 16

Defense Mechanisms of the Gingiva

Marcelo Freire, Jaime Bulkacz, Fermin A. Carranza

CHAPTER OUTLINE

Sulcular Fluid
Leukocytes in the Dentogingival Area
Saliva

The gingival tissue is continuously subjected to challenge, influencing the host response type. The epithelial surface, immune response, crevicular fluid, and saliva provide active responses to maintain gingival health. Chapter 3 reviews the role of the epithelium, including its degree of keratinization and its turnover rate. This chapter describes important mechanisms of the gingival response repertoire, including the role of sulcular fluid, junctional epithelium, permeability, sulcular epithelia, sulcular fluid, saliva, and leukocytes.

Sulcular Fluid

Sulcular fluid, or *gingival crevicular fluid* (GCF), contains an array of biologic mediators, cells, and bacteria. Recognized since the 19th century, its possible role in oral defense was first elucidated by the pioneering work of Waerhaug[110] and Brill and Krasse[14] during the 1950s. The latter investigators applied filter paper to the gingival sulci of dogs that had previously been injected intramuscularly with fluorescein; within 3 minutes, the fluorescent material was recovered on the paper strips. This indicated the passage of fluid from the bloodstream through the tissues and the exiting of fluid via the gingival sulcus.

In subsequent studies, Brill[11,13] confirmed the presence of GCF in humans and considered it as "transudate." However, others[66,111] demonstrated that GCF is an inflammatory exudate rather than a continuous transudate. In strictly normal gingiva, little or no fluid can be collected.

More recently, interest in the development of tests for the detection or prediction of periodontal disease has resulted in numerous research papers about the components, origin, and function of GCF.[19] Potential markers from crevicular fluid are now used as diagnostic tools for the activity of periodontal diseases and a return to homeostasis, with potential for the evaluation of systemic markers.

Methods of Collection

The most difficult hurdle to overcome when collecting GCF is the scarcity of material that can be obtained from the sulcus. Many collection methods have been tried.[10,12,54,57,68,70,95] These methods include the use of absorbing paper strips, the placement of twisted threads around and into the sulcus, and techniques involving micropipettes and intracrevicular washings. There are limitations to the techniques, including fluid collection, collection time, flow rate, contamination, and reproducibility.

The absorbing paper strips are placed within the sulcus (intrasulcular method) or at its entrance (extrasulcular method) (Fig. 16.1). Placement of the filter paper strip in relation to the sulcus or pocket is important. The Brill technique involves inserting it into the pocket until resistance is encountered (Fig. 16.1A). This

method produces some degree of irritation of the sulcular epithelium that by itself can trigger the flow of fluid.

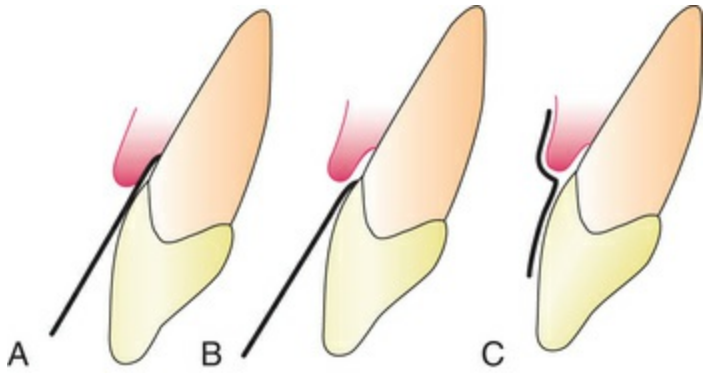

FIG. 16.1 Placement of a filter strip in the gingival sulcus for the collection of fluid. (A) Intrasulcular method. (B–C) Extrasulcular methods.

To minimize this irritation, Löe and Holm-Pedersen[66] placed the filter paper strip just at or over the pocket entrance (Fig. 16.1B–C). In this way, fluid that seeps out is picked up by the strip, but the sulcular epithelium is not in contact with the paper.

Weinstein and colleagues[111] used preweighed twisted threads. The threads were placed in the gingival crevice around the tooth, and the amount of fluid collected was estimated by weighing the sample thread.

The use of micropipettes permits the collection of fluid by capillarity. Capillary tubes of standardized length and diameter are placed in the pocket, and their contents are later centrifuged and analyzed.[10-12]

Crevicular washings can be used to study GCF from clinically normal gingiva. One method involves the use of an appliance that consists of a hard acrylic plate that covers the maxilla, with soft borders and a groove that follows the gingival margins; it is connected to four collection tubes. Washings are obtained by rinsing the crevicular areas from one side to the other with the use of a peristaltic pump.[20]

A modification of the previous method involves the use of two injection needles that have been fitted one within the other so that, during sampling, the inside (ejection) needle is at the bottom of the pocket and the outside (collecting) needle is at the gingival margin.

The collection needle is drained into a sample tube via continuous suction.[95]

Permeability of Junctional and Sulcular Epithelia

The initial studies by Brill and Krasse[14] involving the use of fluorescein were later confirmed with substances such as India ink[89] and saccharated iron oxide.[20] Substances that have been shown to penetrate the sulcular epithelium include albumin,[88] endotoxin,[87,92] thymidine,[45] histamine,[25] phenytoin,[105] and horseradish peroxidase.[72] These findings indicate permeability to substances with a molecular weight of up to 1000 kD.

Squier and Johnson[104] reviewed the mechanisms of penetration through an intact epithelium. The intercellular movement of molecules and ions along intercellular spaces appears to be a possible mechanism. Substances that take this route do not traverse the cell membranes.

Amount

The amount of GCF collected on a paper strip can be studied in multiple ways. The wetted area can be made more visible by staining with Ninhydrin; it is then measured planimetrically on an enlarged photograph or with a magnifying glass or a microscope.

An electronic method has been devised for measuring the fluid collected on a "blotter" (Periopaper) with the use of an electronic transducer (Periotron, Harco Electronics, Winnipeg, Manitoba, Canada) (Fig. 16.2). The wetness of the paper strip affects the flow of an electric current and provides a digital readout. A comparison between the Ninhydrin-staining method and the electronic method performed in vitro revealed no significant differences between the two techniques.[107]

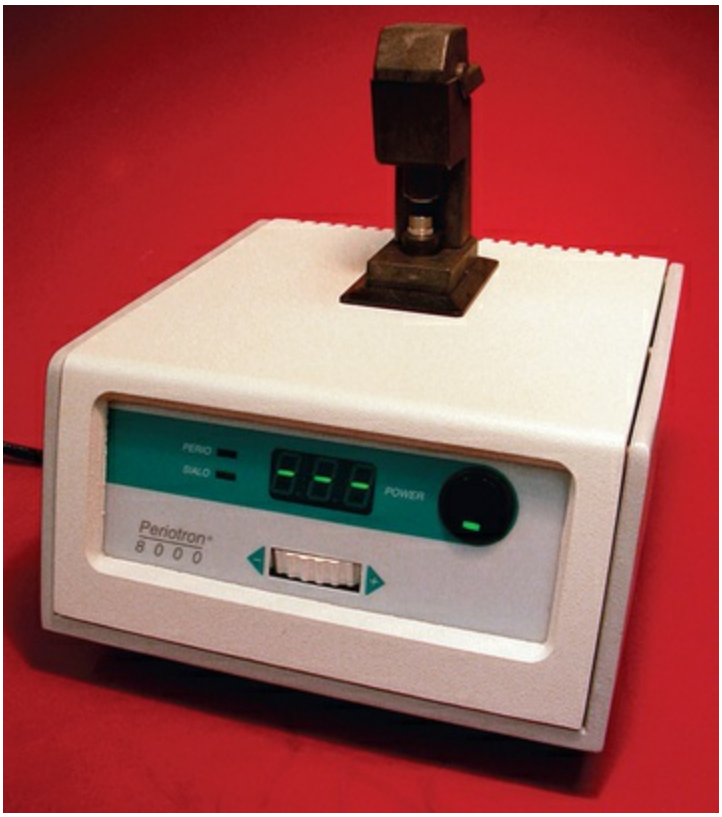

FIG. 16.2 Electronic device for measuring the amount of fluid collected on filter paper.

The amount of GCF collected is extremely small. Measurements performed by Cimasoni[20] showed that a strip of paper 1.5-mm wide and inserted 1 mm within the gingival sulcus of a slightly inflamed gingiva absorbs about 0.1 mg of GCF in 3 minutes. Challacombe[18] used an isotope dilution method to measure the amount of GCF present in a particular space at any given time. His calculations for human volunteers with mean gingival indices of less than 1 showed that the mean GCF volume in the proximal spaces from the molar teeth ranged from 0.43 to 1.56 μL.

Composition

The components of GCF are characterized by individual proteins, metabolites,[66,79,96] specific antibodies, antigens,[32,86] and enzymes of several specificities.[15] The GCF also contains cellular elements.[25,28,113]

Multiple research efforts have attempted to use GCF components to detect or diagnose active disease or to predict which patients are at risk for periodontal disease (Table 16.1).[3] So far, more than 40 compounds found in GCF have been analyzed,[83] but their origin is

not known with certainty. These compounds can be derived from the host or produced by bacteria in the gingival crevice, but their source can be difficult to elucidate; examples include β-glucuronidase, which is a lysosomal enzyme, and lactic acid dehydrogenase, which is a cytoplasmic enzyme. The sources of collagenases may be fibroblasts or polymorphonuclear leukocytes (PMNs [neutrophils]),[5,81] or collagenases may be secreted by bacteria.[32] Phospholipases are lysosomal and cytoplasmic enzymes, but they are also produced by microorganisms.[15] The majority of GCF elements detected thus far have been enzymes, but there are nonenzymatic substances as well.

MMP, Mucous membrane pemphigoid.

Cellular Elements

Cellular elements found in GCF include bacteria, desquamated epithelial cells, and leukocytes (i.e., PMNs, lymphocytes, and monocytes/macrophages), which migrate through the sulcular epithelium.[25,28]

Electrolytes

Potassium, sodium, and calcium have been studied in the GCF. Most studies have demonstrated a positive correlation of calcium

and sodium concentrations with the sodium/potassium ratio seen with inflammation.[51-53] (For more information, see references 51 and 52.)

Organic Compounds

Both carbohydrates and proteins have been investigated. Glucose hexosamine and hexuronic acid are two compounds that are found in GCF.[43] Blood glucose levels do not correlate with GCF glucose levels; glucose concentration in GCF is three to four times greater than that in serum.[43] This is interpreted not only as a result of the metabolic activity of adjacent tissues but also as a function of the local microbial flora.

The total protein content of GCF is much less than that of serum.[12,14] No significant correlations have been found between the concentration of proteins in GCF and the severity of gingivitis, pocket depth, or extent of bone loss.[8] Metabolic and bacterial products identified in GCF include lactic acid,[44] urea,[38] hydroxyproline,[85] endotoxins,[101] cytotoxic substances, hydrogen sulfide,[103] and antibacterial factors.[24] Many enzymes have also been identified.

The methodology used to analyze GCF components is as varied as the diversity of those components. Examples include fluorometry to detect metalloproteinases,[25] enzyme-linked immunosorbent assays to detect enzyme levels and interleukin-1β (IL-1β),[64] radioimmunoassays to detect cyclooxygenase derivatives[80] and procollagen III,[108] high-pressure liquid chromatography to detect timidazole,[61] and direct and indirect immunodot tests to detect acute-phase proteins.[100]

Cellular and Humoral Activity in Gingival Crevicular Fluid

Monitoring periodontal disease is a complicated task, because few noninvasive procedures can follow the initiation and progress of the disease. Analyzing GCF constituents in health and disease may be extremely useful as a result of GCF's simplicity and because GCF can be obtained with noninvasive methods.

The analysis of GCF has identified cell and humoral responses in

both healthy individuals and those with periodontal disease.[59] The cellular immune response includes the appearance of cytokines in GCF, but there is no clear evidence of a relationship between cytokines and disease. However, IL-1α and IL-1β are known to increase the binding of PMNs and monocytes/macrophages to endothelial cells, to stimulate the production of prostaglandin E_2 and the release of lysosomal enzymes, and to stimulate bone resorption.[62] Preliminary evidence also indicates the presence of interferon-α in GCF,[59] which may have a protective role in periodontal disease because of its ability to inhibit the bone resorption activity of IL-1β.[40]

Because the amount of fluid recoverable from gingival crevices is small, only the use of very sensitive immunoassays permits the analysis of the specificity of antibodies.[24,26,27] A study that compared antibodies in different crevices with serum antibodies directed at specific microorganisms did not provide any conclusive evidence regarding the significance of the presence of antibodies in GCF among individuals with periodontal disease.[59]

Although the role of antibodies in the gingival defense mechanisms is difficult to ascertain, the consensus is that in a patient with periodontal disease, a reduction in antibody response is detrimental, and an antibody response plays a protective role.[58]

Clinical Significance

As an exudate, GCF is a biologic fluid that has potential in diagnostics and disease management.[66] Its presence in clinically normal sulci can be explained, because gingiva that appears clinically normal invariably exhibits inflammation when it is examined microscopically. Commercially available kits for diagnosis are now available (see Table 16.1).

Clinical Correlation

- Novel diagnostics tools allow evaluations of biomarkers from tissue and oral biofluids.

- Drug delivery targeting oral tissues has optimal absorption and bioavailability.
- Gingival fluid and saliva are biologic fluids that can provide information on human genomics and metagenomics (microbiome, transcriptome, metabolome and proteome).
- Oral immunity is activated through rapid response from innate immune components (fluids, mucosal surfaces, epithelium, cell mediators, molecules, host-bacterial interactions).

The amount of GCF is greater when inflammation is present,[31,98] and it is sometimes proportional to the severity of inflammation.[82] GCF production is not increased by trauma from occlusion,[71] but it is increased by the mastication of coarse foods, toothbrushing and gingival massage, ovulation,[64] hormonal contraceptives,[65] prosthetic appliances,[77] and smoking.[73] Other factors that influence the amount of GCF are circadian periodicity and periodontal therapy.

Circadian Periodicity

There is a gradual increase in the amount of GCF from 6 a.m. to 10 p.m. and a decrease thereafter.[9]

Sex Hormones

Female sex hormones increase GCF flow, probably because they enhance vascular permeability.[62] Pregnancy, ovulation,[61] and hormonal contraceptives[63] all increase GCF production.

Mechanical Stimulation

Chewing[11] and vigorous gingival brushing stimulate the flow of GCF. Even minor stimuli represented by intrasulcular placement of paper strips increases the production of fluid.

Smoking

Smoking produces an immediate transient but marked increase in GCF flow but, in the long term, a decrease of salivary and GCF flow.[73]

Periodontal Therapy

There is an increase in GCF production during the healing period after periodontal surgery.[4]

Drugs in Gingival Crevicular Fluid

Drugs that are excreted through the GCF may be used advantageously in periodontal therapy. Bader and Goldhaber[7] demonstrated in dogs that tetracyclines are excreted through the GCF; this finding triggered extensive research that showed a concentration of tetracyclines in GCF as compared with serum.[39] Metronidazole is another antibiotic that has been detected in human GCF[29] (see Chapter 52).

Leukocytes in the Dentogingival Area

Leukocytes have been found in clinically healthy gingival sulci in humans and experimental animals. The leukocytes found are predominantly PMNs. They appear in small numbers extravascularly in the connective tissue adjacent to the apical portion of the sulcus; from there, they travel across the epithelium[17,41] to the gingival sulcus, where they are expelled (Figs. 16.3 and 16.4).

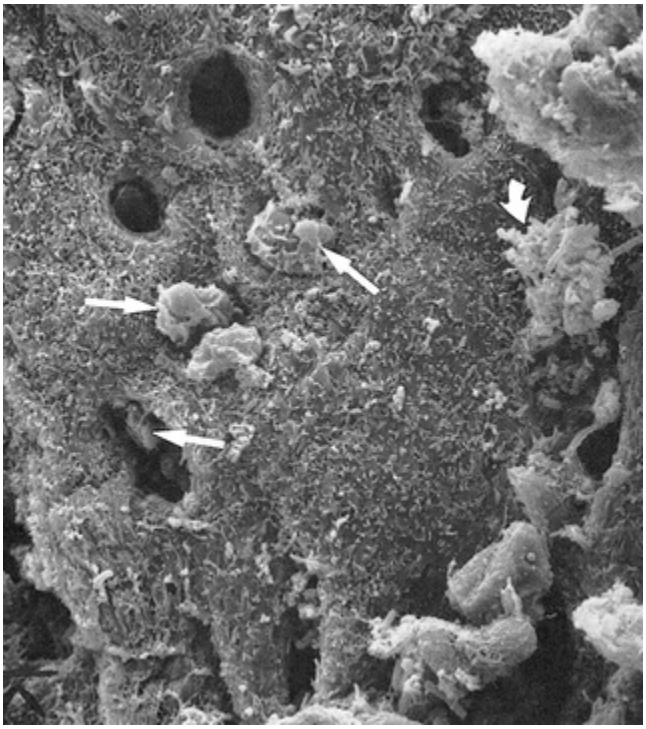

FIG. 16.3 Scanning electron microscope view of the periodontal pocket wall. Several leukocytes are emerging *(straight arrows),* some of which are partially covered by bacteria *(curved arrow).* Empty holes correspond to tunnels through which leukocytes have emerged.

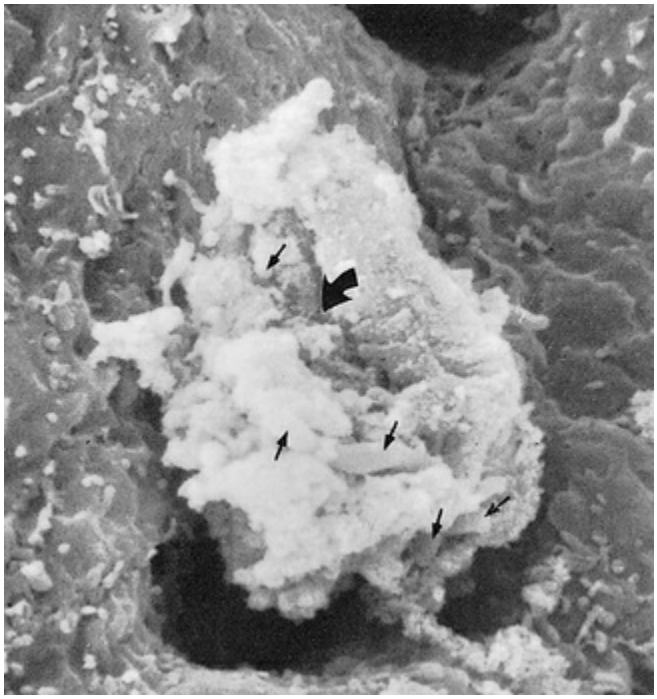

FIG. 16.4 Scanning electron microscope view at higher magnification than shown in Fig. 16.3. A leukocyte emerging from the pocket wall is covered with bacteria *(small arrows)*. The *large curved arrow* points to a phagosomal vacuole through which bacteria are being engulfed.

Leukocytes are present in sulci even when histologic sections of adjacent tissue are free of inflammatory infiltrate.[90] Differential counts of leukocytes from clinically healthy human gingival sulci have shown 91.2% to 91.5% PMNs and 8.5% to 8.8% mononuclear cells.[102,113]

Mononuclear cells were identified as 58% B lymphocytes, 24% T lymphocytes, and 18% mononuclear phagocytes. The ratio of T lymphocytes to B lymphocytes was found to be reversed from the normal ratio of about 3:1 found in peripheral blood to about 1:3 in GCF.[113]

Leukocytes are attracted by different plaque bacteria,[49,112] but they can also be found in the dentogingival region of germ-free adult animals.[67,94] Leukocytes were reported in the gingival sulcus in nonmechanically irritated (resting) healthy gingiva, thereby indicating that their migration may be independent of an increase in vascular permeability.[6] The majority of these cells are viable and have phagocytic and killing capacity.[56,84,91] Therefore leukocytes constitute a major protective mechanism against the extension of plaque into the gingival sulcus.

Live and dead leukocytes are found in saliva; this is discussed later in this chapter. The main port of entry of leukocytes into the oral cavity is the gingival sulcus.[97]

Saliva

Saliva has protective functions and maintains the oral tissues in a physiologic state (Table 16.2). Saliva exerts a major influence on plaque by mechanically cleansing the exposed oral surfaces, buffering acids produced by bacteria, and modulating bacterial activity with immune mediators.[78] Saliva is now considered a main biologic fluid for diagnosis of human health and diseases. Systemic and local disease markers are available through saliva. Available

tests allow the individual to measure multi-omics outputs.[22] Functional and static assays are now available as biosensors of health and disease.

TABLE 16.2
Role of Saliva in Oral Health

Function	Salivary Components	Probable Mechanism
Lubrication	Glycoproteins, mucoids	Coating similar to gastric mucin
Physical protection	Glycoproteins, mucoids	Coating similar to gastric mucin
Cleansing	Physical flow	Clearance of debris and bacteria
Buffering	Bicarbonate and phosphate	Antacids
Tooth integrity maintenance	Minerals	Maturation, remineralization
	Glycoprotein pellicle	Mechanical protection
Antibacterial action	Immunoglobulin A	Control of bacterial colonization
	Lysozyme	Breaking of bacterial cell walls
	Lactoperoxidase	Oxidation of susceptible bacteria

Antibacterial Factors

Saliva carries inorganic and organic factors that influence bacteria and their products in the oral environment. Inorganic factors include ions and gases, bicarbonate, sodium, potassium, phosphates, calcium, fluorides, ammonium, and carbon dioxide. Organic factors include lysozyme, lactoferrin, myeloperoxidase, lactoperoxidase, defensins, peptides, and agglutinins such as glycoproteins, mucins, β2-macroglobulins, fibronectins,[108] and antibodies.

Lysozyme is a hydrolytic enzyme that cleaves the linkage between structural components of the glycopeptide muramic acid–containing region of the cell wall of certain bacteria in vitro. Lysozyme works on both gram-negative and gram-positive organisms[46]; its targets include *Veillonella* species and *Actinobacillus actinomycetemcomitans.* It works on the molecular level, protecting the oral cavity and repelling transient bacterial invaders.[48]

The *lactoperoxidase–thiocyanate system* in saliva has been shown to be bactericidal to some strains of *Lactobacillus* and *Streptococcus*[75,93] by preventing the accumulation of lysine and glutamic acid, both of which are essential for bacterial growth. Another antibacterial finding is lactoferrin, which is effective against *Actinobacillus*

species.[50]

Myeloperoxidase, an enzyme that is similar to salivary peroxidase, is released by leukocytes; it is bactericidal for *Actinobacillus,*[74] but it has the added effect of inhibiting the attachment of *Actinomyces* strains to hydroxyapatite.[21]

Human alpha and beta-defensins (hBD)-1,-2,-3 are a family of low-molecular-weight antimicrobial peptides. Produced by a number of cells, including neutrophils, they amplify and combat bacterial[1] infections important to homeostasis.

Salivary Antibodies

As with GCF, saliva contains antibodies that are reactive with indigenous oral bacterial species. Although immunoglobulins G (IgG) and M (IgM) are present, the preponderant immunoglobulin found in saliva is *immunoglobulin A* (IgA), whereas IgG is more prevalent in GCF.[106] Major and minor salivary glands contribute all of the secretory IgA and lesser amounts of IgG and IgM. GCF contributes most of the IgG, complement, and PMNs that, in conjunction with IgG or IgM, inactivate or opsonize bacteria.

Salivary antibodies appear to be synthesized locally, because they react with bacteria that are indigenous to the mouth but not with organisms that are characteristic of the intestinal tract.[33,35] Bacteria found in saliva are frequently associated with IgA, and the bacterial deposits on teeth contain both IgA and IgG in quantities that are greater than 1% of their dry weight.[34] It has been shown that IgA antibodies present in parotid saliva can inhibit the attachment of oral *Streptococcus* species to epithelial cells.[30,110] Gibbons and colleagues[33-35] suggested that antibodies in secretions may impair the ability of bacteria to attach to mucosal or dental surfaces.

« Flash Back

Saliva was known to have protective actions against infection through immunoglobulins only. Now it is clear that enzymes, cytokines, nucleotides, and live cells are part of the host armamentarium.

Enzymes

The *enzymes* that are normally found in saliva are derived from the salivary glands, bacteria, leukocytes, oral tissues, and ingested substances; the major enzyme is parotid amylase. Certain salivary enzymes have been reported in increased concentrations in periodontal disease: hyaluronidase and lipase,[16] β-glucuronidase and chondroitin sulfatase,[37] aspartate aminotransferase and alkaline phosphatase,[109] amino acid decarboxylases,[37] catalase, peroxidase, and collagenase.[55]

Proteolytic enzymes in the saliva are generated by both the host and oral bacteria. These enzymes have been recognized as contributors to the initiation and progression of periodontal disease.[45,69] To combat these enzymes, saliva contains antiproteases that inhibit cysteine proteases such as cathepsins[47] and antileukoproteases that inhibit elastase.[81] Another antiprotease, which has been identified as a tissue inhibitor of matrix metalloproteinase, has been shown to inhibit the activity of collagen-degrading enzymes.[23]

High-molecular-weight mucinous glycoproteins in saliva bind specifically to many plaque-forming bacteria. The glycoprotein–bacteria interactions facilitate bacterial accumulation on the exposed tooth surface.[30,33-35,112] The specificity of these interactions has been demonstrated. The interbacterial matrix of human plaque appears to contain polymers that are similar to salivary glycoproteins and may aid in maintaining the integrity of plaque. In addition, these glycoproteins selectively adsorb to the hydroxyapatite to make up part of the acquired pellicle. Other salivary glycoproteins inhibit the sorption of some bacteria to the tooth surface and to epithelial cells of the oral mucosa. This activity appears to be associated with the glycoproteins that possess blood group reactivity.[2,30,33,35,110] Another effect of mucin is the deletion of bacterial cells from the oral cavity via aggregation with mucin-rich films.

Glycoproteins and a glycolipid that is present on mammalian cell surfaces appear to serve as receptors for the attachment of some viruses and bacteria. Thus the close similarity between the glycoproteins of salivary secretions and the components of the epithelial cell surface suggests that the secretions can competitively

inhibit antigen sorption and that they therefore may limit pathologic alterations.

Salivary Buffers and Coagulation Factors

The maintenance of physiologic hydrogen ion concentration (pH) at the mucosal epithelial cell surface and tooth surface is an important function of salivary buffers. The primary effect action of buffers has been investigated with relationship to dental caries. In saliva, the most important buffer is the bicarbonate–carbonic acid system.[68]

Saliva also contains coagulation factors (i.e., factors VIII, IX, and X; plasma thromboplastin antecedent; and Hageman factor) that hasten blood coagulation and protect wounds from bacterial invasion.[60] An active fibrinolytic enzyme may also be present.

Leukocytes

In addition to desquamated epithelial cells, saliva contains all forms of leukocytes, of which the principal cells are PMNs. Whole-blood PMNs are naïve and not activated, whereas the cells found in saliva have interacted with multiple antigens from the microbiome. The number of PMNs varies from person to person at different times of the day, and it is increased in the presence of gingivitis. PMNs reach the oral cavity by migrating through the lining of the gingival sulcus. Living PMNs in saliva are sometimes referred to as *orogranulocytes,* and their rate of migration into the oral cavity is termed the *orogranulocytic migratory rate.* Novel investigation presents the positive correlation between rate of PMN migration and the severity of gingival inflammation, and it is therefore a reliable index for the assessment of gingivitis.[102] In a high-throughput methods, distinct subsets of neutrophils were found in oral mucosa, including naïve, parainflammatory, and proinflammatory cells.[76]

Clinician's Corner

What is the clinical importance of saliva?

Saliva has several important properties, including mechanical, chemical, biologic, and immunologic.[22] It is a viscous, clear, watery fluid secreted from salivary glands. It is a major biologic fluid for diagnosis and "omics" research. Diagnosing local and systemic conditions is possible through salivary markers. Low saliva is a risk factor for caries and periodontal disease. Xerostomia is defined as dry mouth resulting from reduced or absent saliva flow. Xerostomia is a symptom of various medical conditions, and it is a side effect of radiation to the head and neck and a wide variety of medications.

Role in Periodontal Pathology

Saliva modulates plaque initiation, maturation, and metabolism. Salivary flow and composition also influence calculus formation, periodontal disease, and caries. The removal of the salivary glands in experimental animals significantly increases the incidence of dental caries[36] and periodontal disease[42] in addition to delaying wound healing.[99]

In humans, increases of inflammatory gingival conditions, dental caries, rapid tooth destruction, and cervical or cemental caries are associated, at least partially, with decreased salivary gland secretion (xerostomia; Box 16.1). Xerostomia may result from sialolithiasis, sarcoidosis, Sjögren syndrome, Mikulicz disease, irradiation, surgical removal of the salivary glands, and other factors (see Chapters 37 and 26).

Box 16.1

Hallmarks of Xerostomia

Features	Healthy	Xerostomia
Flow rate	1–2 mL	< 0.1 mg/mL
Sensation	Normal	Dry mouth
Consistency and texture	Resilient and lubricated	Erythematous, sticky

« Flash Back

- Gingival tissue is constantly challenged by external factors.
- Epithelial surface, crevicular fluid, saliva, epithelial surfaces, immune cells, and mediators provide oral immunity.
- Oral diseases, including caries and periodontal diseases, benefit from oral immune components.

Case Scenario 16.1

Patient:
62-year-old female

Chief Complaint:
"I have trouble going to sleep because my mouth and throat are dry."

Background Information:
The patient is a heavy smoker and has difficulty sleeping. She only sleeps 4 hours per night and drinks minimal alcohol socially. The patient has a history of allergic rhinitis, for which she takes over-the-counter antihistamines and decongestants.

Current Findings:
Probing depths were in the range of 3 to 4 mm, bleeding on probing was 38%, and the patient has poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the most probable etiology for this condition? A. Xerostomia	**Answer: A** **Explanation:** The patient presents with dry mouth, lack of sleep, and poor oral hygiene. Xerostomia is the primary cause of this condition. Lack of normal salivary flow reflects on mucosal inflammation. The

B. Dry mouth syndrome C. Gingivitis D. Aging E. Sjögren syndrome	xerostomia in this case is from Sjögren syndrome.
2. All of the following conditions present xerostomia EXCEPT which one? A. Dry mouth syndrome B. Sjögren syndrome C. Amyloidosis D. Sarcoidosis E. Mucous membrane pemphigoid (MMP)	**Answer: E** **Explanation:** MMP, formerly known as cicatricial pemphigoid, is an autoimmune condition that is immune mediated. Auto-antibodies against basement membrane antigens attack the tissue, causing the disease.
3. All of the following are saliva stimulants EXCEPT which one? A. Pilocarpine B. Cevimeline C. Anethole trithione D. Artificial saliva (Oralube)	**Answer: D** **Explanation:** Artificial saliva (Oralube) is a saliva substitute, not a stimulant. Artificial saliva or saliva substitutes can be used to replace moisture and lubricate the mouth. Saliva stimulants such as pilocarpine act as cholinergic parasympathomimetic agents with predominantly muscarinic M3 action that causes stimulation of residual-functioning exocrine glands.

CHAPTER 17

Gingival Inflammation

Joseph P. Fiorellini, David M. Kim, Marcelo Freire, Panagiota G. Stathopoulou, Hector L. Sarmiento

CHAPTER OUTLINE

Stage I Gingival Inflammation: The Initial Lesion
Stage II Gingival Inflammation: The Early Lesion
Stage III Gingival Inflammation: The Established Lesion
Stage IV Gingival Inflammation: The Advanced Lesion

Local innate and specific immunity will maintain gingival health. Components from the innate immune response include epithelial cells and nonspecific cells within the epithelium, mucins, lysozyme, lactoferrin, lactoperoxidase, and various antimicrobial peptides such as histatins, beta-defensins, and protease inhibitors. Epithelial cells (keratinocytes) themselves are reactive and express a variety of receptors, including Toll-like receptors, and produce a variety of cytokines on activation.

The pathologic changes of gingivitis are initiated by a host

response to oral microorganisms attached to the tooth and perhaps in or near the gingival sulcus. These organisms are capable of synthesizing products (e.g., collagenase, hyaluronidase, protease, chondroitin sulfatase, endotoxin) that cause damage to epithelial and connective tissue cells as well as to intercellular constituents such as collagen, ground substance, and glycocalyx (cell coat). The resultant widening of the spaces between junctional epithelial cells during early gingivitis may permit injurious agents derived from bacteria or bacteria themselves to gain access to the connective tissue.[10,44,48] Microbial products activate cells, including monocytes and macrophages, to produce vasoactive substances such as prostaglandin E2, interferon, tumor necrosis factor, and interleukin-1.[25,38] In addition, interleukin-1β alters the properties of gingival fibroblasts by delaying their death via mechanism-blocking apoptosis. This stabilizes the gingival fibroblast population during inflammation.[54]

Morphologic and functional changes in the gingiva during plaque accumulation have been thoroughly investigated, especially in beagle dogs and humans.[36] A useful framework for the organization and consideration of these data has been devised on the basis of histopathologic, radiographic, and ultrastructural features and biochemical measurements.[37,39] The sequence of events that culminates in clinically apparent gingivitis is categorized as the *initial*, *early*, and *established stages* of disease, with periodontitis designated as the *advanced stage*[38] (Table 17.1). One stage evolves into the next, with no clear-cut dividing lines.

TABLE 17.1

Stages of Gingivitis

Stage	Time (Days)	Blood Vessels	Junctional and Sulcular Epithelia	Predominant Immune Cells	Collagen	Clinical Findings
I. Initial lesion	2 to 4	Vascular dilation Vasculitis	Infiltration by PMNs	PMNs	Perivascular loss	Gingival fluid flow
II. Early lesion	4 to 7	Vascular proliferation	Same as stage I Rete pegs Atrophic areas	Lymphocytes	Increased loss around infiltrate	Erythema Bleeding on probing

III. Established lesion	14 to 21	Same as stage II, plus blood stasis	Same as stage II but more advanced	Plasma cells	Continued loss	Changes in color, size, texture, and so on

PMNs, Polymorphonuclear leukocytes (neutrophils).

Despite extensive research, we still cannot definitively distinguish between normal gingival tissue and the initial stage of gingivitis.[36] Most biopsies of clinically normal human gingiva contain inflammatory cells; these consist predominantly of T cells, with very few B cells or plasma cells.[36,49,50] These cells do not create tissue damage, but they appear to be important in the day-to-day host response to bacteria and other substances to which the gingiva is exposed.[36] Therefore, under normal conditions, a constant stream of neutrophils is migrating from the vessels of the gingival plexus through the junctional epithelium, to the gingival margin, and into the gingival sulcus and the oral cavity.[43]

Stage I Gingival Inflammation: The Initial Lesion

The first manifestations of gingival inflammation are vascular changes that consist of dilated capillaries and increased blood flow. These initial inflammatory changes occur in response to the microbial activation of resident leukocytes and the subsequent stimulation of endothelial cells. Clinically, this initial response of the gingiva to bacterial plaque (i.e., subclinical gingivitis[26]) is not apparent.

Microscopically, some classic features of acute inflammation can be seen in the connective tissue beneath the junctional epithelium. Changes in blood vessel morphologic features (e.g., the widening of small capillaries or venules) and the adherence of neutrophils to vessel walls (margination) occur within 1 week and sometimes as early as 2 days after plaque has been allowed to accumulate[18,41] (Fig. 17.1). The etiopathogenesis of gingival diseases is linked to local or systemic immune response, to innate or adaptive immunity, and to cellular or secretory factors. Leukocytes—mainly

polymorphonuclear neutrophils (PMNs)—leave the capillaries by migrating through the walls via diapedesis and emigration[25,50,51] (Fig. 17.2). They can be seen in increased quantities in the connective tissue, the junctional epithelium, and the gingival sulcus[2,3,24,34,41,45,46] (Figs. 17.3 and 17.4). Exudation of fluid from the gingival sulcus[18] and extravascular proteins is present.[20,21]

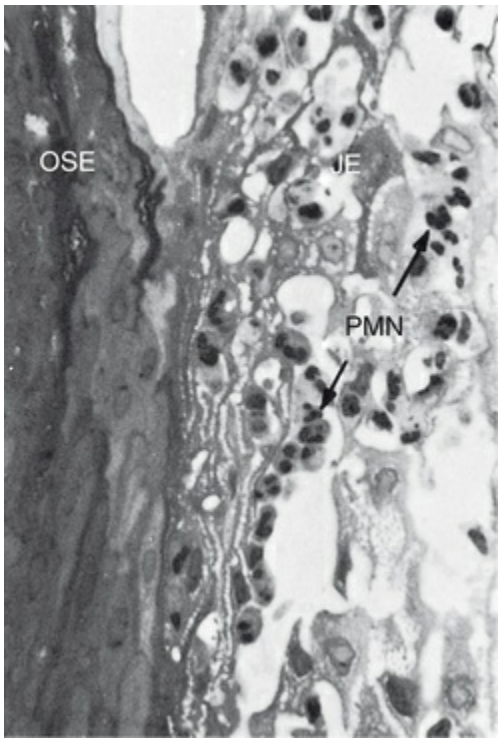

FIG. 17.1 Human biopsy sample, experimental gingivitis. After 4 days of plaque accumulation, the blood vessels immediately adjacent to the junctional epithelium are distended and contain polymorphonuclear leukocytes (neutrophils) (PMNs). Neutrophils have also migrated between the cells of the junctional epithelium (JE). *OSE,* Oral sulcular epithelium (magnification, ×500). (From Payne WA, Page RC, Ogilvie AL, et al: Histopathologic features of the initial and early stages of experimental gingivitis in man. *J Periodontal Res* 10:51, 1975.)

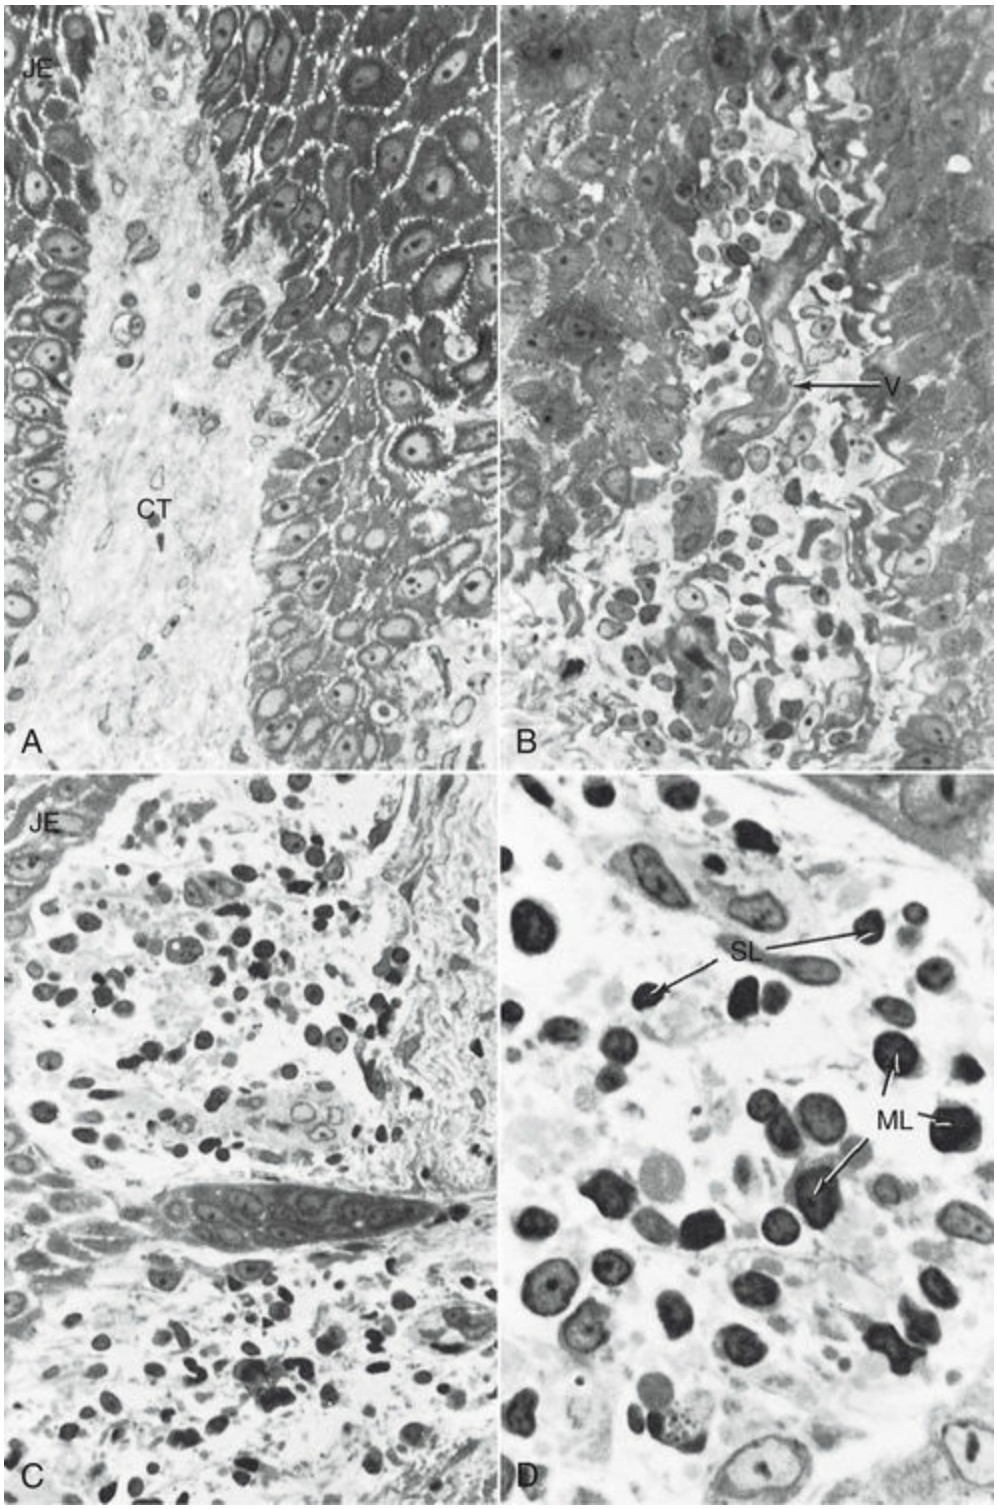

FIG. 17.2 Human biopsy, experimental gingivitis. (A) Control biopsy specimen from a patient with good oral hygiene and no detectable plaque accumulation. The junctional epithelium is on the left. The connective tissue (CT) shows few cells other than fibroblasts, blood vessels, and a dense background of collagen fibers (magnification, ×500.) (B) Biopsy specimen taken after 8 days of plaque accumulation. The

connective tissue is infiltrated with inflammatory cells, which displace the collagen fibers. A distended blood vessel (V) is seen in the center (magnification, ×500). (C) After 8 days of plaque accumulation, the connective tissue next to the junctional epithelium at the base of the sulcus shows a mononuclear cell infiltrate and evidence of collagen degeneration (i.e., clear spaces around the cellular infiltrate (magnification, ×500). (D) The inflammatory cell infiltrate at higher magnification (×1250). After 8 days of plaque accumulation, numerous small (SL) and medium-sized (ML) lymphocytes are seen within the connective tissue. Most of the collagen fibers around these cells have disappeared, presumably as a result of enzymatic digestion. (From Payne WA, Page RC, Ogilvie AL, et al: Histopathologic features of the initial and early stages of experimental gingivitis in man. *J Periodontal Res* 10:51, 1975.)

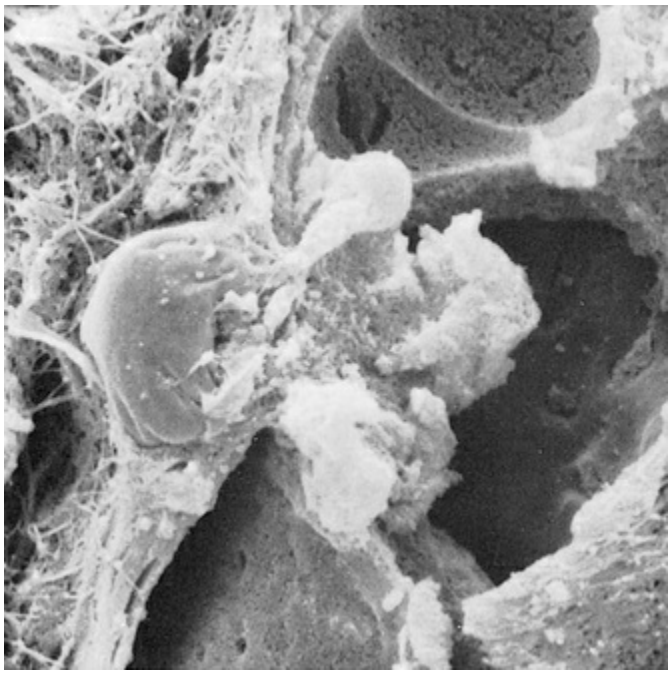

FIG. 17.3 Scanning electron micrograph showing a leukocyte traversing the vessel wall to enter into the gingival connective tissue.

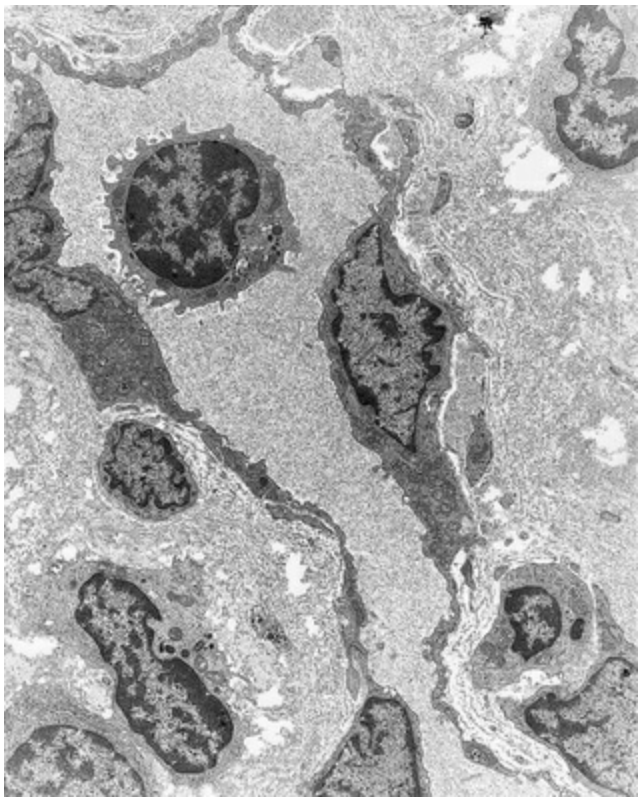

FIG. 17.4 Early human gingivitis lesion. There is an area of lamina propria subjacent to the crevicular epithelium that shows a capillary with several extravascular lymphocytes and one lymphocyte within the lumen. The specimen also exhibits a considerable loss of perivascular collagen density (magnification, ×2500). (Courtesy Dr. Charles Cobb, Kansas City, Missouri.)

However, these findings are not accompanied by manifestations of tissue damage that are perceptible at the light microscopic or ultrastructural level; they do not form an infiltrate, and their presence is not considered to indicate pathologic change.[36]

Subtle changes can also be detected in the junctional epithelium and perivascular connective tissue at this early stage. For example, the perivascular connective tissue matrix becomes altered, and there is exudation and deposition of fibrin in the affected area.[36] In addition, lymphocytes soon begin to accumulate (see Fig. 17.2D). The increased migration of leukocytes and their accumulation within the gingival sulcus may be correlated with an increased flow of gingival fluid into the sulcus.[4]

The character and intensity of the host response determine whether this *initial lesion* resolves rapidly, with restoration of the

tissue to a normal state; alternatively, it may evolve into a chronic inflammatory lesion. If the latter occurs, an infiltrate of macrophages and lymphoid cells appears within a few days.

Stage II Gingival Inflammation: The Early Lesion

The *early lesion* evolves from the *initial lesion* within about 1 week after the beginning of plaque accumulation.[35,41] Clinically, the early lesion may appear as early gingivitis, and it overlaps with and evolves from the initial lesion with no clear-cut dividing line. As time goes on, clinical signs of erythema may appear, mainly because of the proliferation of capillaries and the increased formation of capillary loops between rete pegs or ridges (Fig. 17.5). Bleeding on probing may also be evident.[1] Gingival fluid flow and the numbers of transmigrating leukocytes reach their maximum between 6 and 12 days after the onset of clinical gingivitis.[26]

FIG. 17.5 Marginal gingivitis and irregular gingival contour.

Microscopic examination of the gingiva reveals leukocyte infiltration in the connective tissue beneath the junctional epithelium, which consists mainly of lymphocytes (75%, with the

majority being T cells)[41,47] but also includes some migrating neutrophils as well as macrophages, plasma cells, and mast cells. All of the changes seen in the initial lesion continue to intensify with the early lesion.[15,28,30,35,47] The junctional epithelium becomes densely infiltrated with neutrophils, as does the gingival sulcus, and may begin to show the development of rete pegs or ridges.

The amount of collagen destruction also increases[12,28,47]; 70% of the collagen is destroyed around the cellular infiltrate. The main fiber groups that are affected appear to be the circular and dentogingival fiber assemblies. Alterations in blood vessel morphologic features and vascular bed patterns have also been described.[18,19]

PMNs that have left the blood vessels in response to chemotactic stimuli from plaque components travel to the epithelium and cross the basement lamina; they are found in the epithelium, emerging in the pocket area (see Fig. 17.3). PMNs are attracted to bacteria and engulf them during the process of phagocytosis (Fig. 17.6). PMNs release their lysosomes in association with the ingestion of bacteria.[23] Fibroblasts show cytotoxic alterations,[40] with a decreased capacity for collagen.

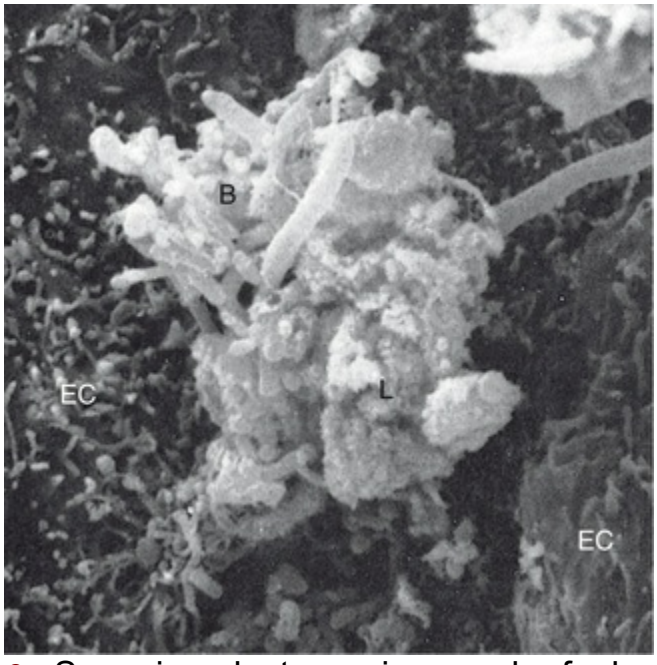

FIG. 17.6 Scanning electron micrograph of a leukocyte emerging to the pocket wall and covered with bacteria

and extracellular lysosomes. *B,* Bacteria; *EC,* epithelial cells; *L,* lysosomes.

Meanwhile, on the opposite side of molecular events, collagen degradation is related to matrix metalolproteinases (MMPs). Different MMPs are responsible for extracellular matrix remodeling within 7 days of inflammation, which is directly related to MMP-2 and MMP-9 production and activation.[54]

Stage III Gingival Inflammation: The Established Lesion

Over time, the *established lesion* evolves. It is characterized by a predominance of plasma cells and B lymphocytes, and it is probably in conjunction with the creation of a small gingival pocket lined with a pocket epithelium.[46] The B cells that are found in the established lesion are predominantly of the immunoglobulin G1 and G3 subclasses.[36]

With chronic gingivitis, which occurs 2 to 3 weeks after the beginning of plaque accumulation, the blood vessels become engorged and congested, venous return is impaired, and the blood flow becomes sluggish (Fig. 17.7). The result is localized gingival *anoxemia,* which superimposes a somewhat bluish hue on the reddened gingiva.[17] The extravasation of erythrocytes into the connective tissue and the breakdown of hemoglobin into its component pigments can also deepen the color of the chronically inflamed gingiva. The established lesion can be described as moderately to severely inflamed gingiva.

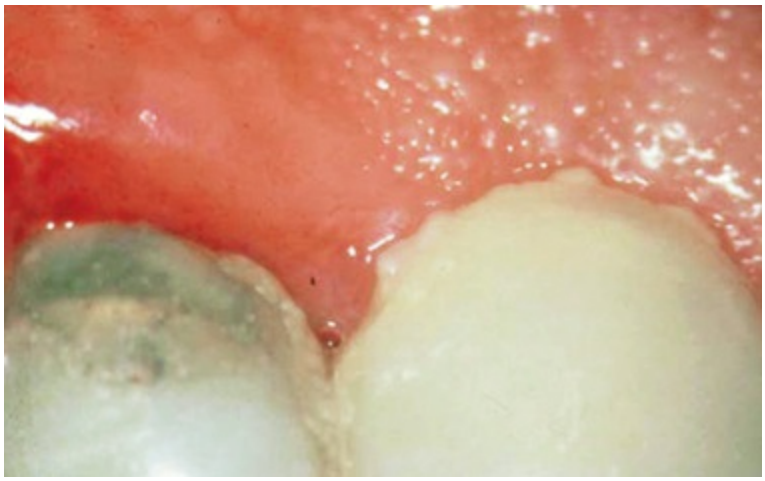

FIG. 17.7 Marginal supragingival plaque and gingivitis.

In histologic sections, an intense and chronic inflammatory reaction is observed. Several detailed cytologic studies have been performed on chronically inflamed gingiva.[13-15,40,46,49,53] A key feature that differentiates established lesions is the increased number of plasma cells, which become the preponderant inflammatory cell type. Plasma cells invade the connective tissue not only immediately below the junctional epithelium but also deep into the connective tissue, around the blood vessels, and between the bundles of collagen fibers.[6] The junctional epithelium reveals widened intercellular spaces that are filled with granular cellular debris, including lysosomes derived from disrupted neutrophils, lymphocytes, and monocytes (Fig. 17.8). The lysosomes contain acid hydrolases that can destroy tissue components. The junctional epithelium develops rete pegs or ridges that protrude into the connective tissue, and the basal lamina is destroyed in some areas. In the connective tissue, collagen fibers are destroyed around the infiltrate of intact and disrupted plasma cells, neutrophils, lymphocytes, monocytes, and mast cells (Fig. 17.9).

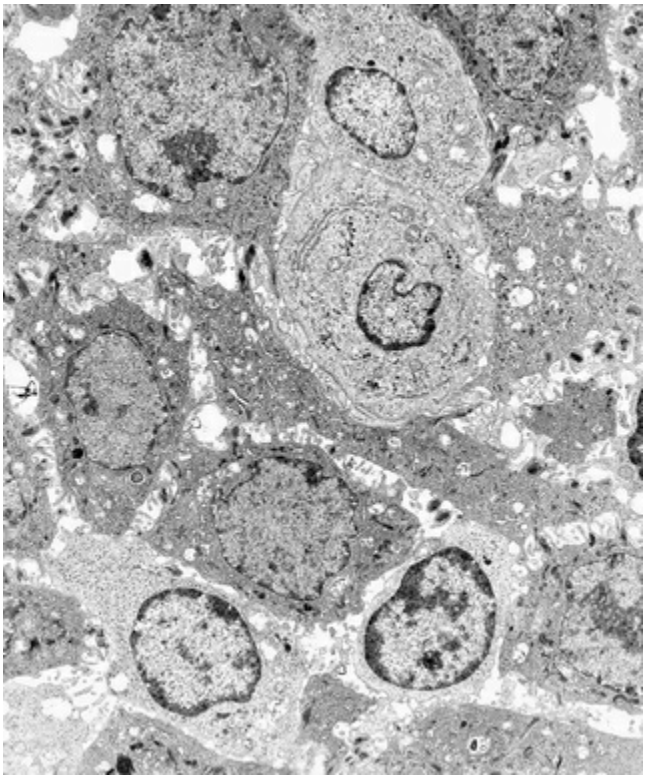

FIG. 17.8 Established gingivitis in a human subject. An area of crevicular epithelium exhibits enlarged intercellular spaces with numerous microvilli and desmosomal junctions. Several lymphocytes, both small and large, are seen migrating through the epithelial layer (magnification, ×3000).

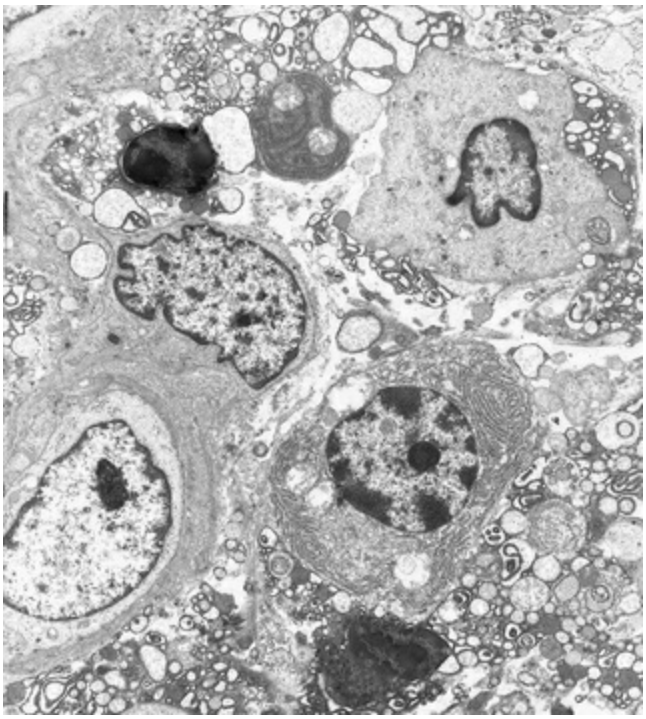

FIG. 17.9 Advanced gingivitis in a human subject. This specimen from the lamina propria exhibits plasma cell degeneration, with abundant cellular debris visible (magnification, ×3000). (Courtesy Dr. Charles Cobb, Kansas City, Missouri.)

The predominance of plasma cells is thought to be a primary characteristic of established lesions. However, several studies of human experimental gingivitis have failed to demonstrate plasma cell predominance in the affected connective tissues,[7,8,49] including one study of 6 months' duration.[1] An increase in the proportion of plasma cells was evident with longstanding gingivitis, but the time for development of classic "established lesions" may exceed 6 months.

An inverse relationship appears to exist between the number of intact collagen bundles and the number of inflammatory cells.[51] Collagenolytic activity is increased in inflamed gingival tissue[16] by the enzyme collagenase. Collagenase is normally present in gingival tissues[5]; it is produced by some oral bacteria and by PMNs.

Enzyme histochemistry studies have shown that chronically inflamed gingivae have elevated levels of acid and alkaline phosphatase,[55] β-glucuronidase, β-glucosidase, β-galactosidase, esterases,[29] aminopeptidase,[33,42] and cytochrome oxidase.[9] Neutral mucopolysaccharide levels are decreased,[53] presumably as a result

of degradation of the ground substance.

Established lesions of two types appear to exist; some remain stable and do not progress for months or years,[32,33,52] and others seem to become more active and convert to progressively destructive lesions. In addition, established lesions appear to be reversible, in that the sequence of events that occurs in the tissues as a result of successful periodontal therapy seems to be essentially the reverse of the sequence of events observed as gingivitis develops. As the flora reverts from that characteristically associated with destructive lesions to that associated with periodontal health, the percentage of plasma cells decreases greatly and the lymphocyte population increases proportionately.[27,31]

Stage IV Gingival Inflammation: The Advanced Lesion

The extension of the lesion into alveolar bone characterizes the fourth stage, which is known as the *advanced lesion*[40] or *phase of periodontal breakdown*.[26] This is described in detail in Chapter 21.

Microscopically, fibrosis of the gingiva is present and there is widespread manifestation of inflammatory and immunopathologic tissue damage.[36] At the advanced stage, the presence of plasma cells dominates the connective tissue, and neutrophils continue dominating the junctional epithelium.

Patients with experimental gingivitis had significantly more plaque accumulation, higher interleukin-1β levels, and lower interleukin-8 concentrations at 28 days.[11]

Gingivitis will progress to periodontitis only in individuals who are susceptible. Patients who had sites with consistent bleeding (gingival index = 2) had 70% more attachment loss as compared with sites that were not consistently inflamed (gingival index = 0). Teeth with noninflamed sites consistently had a 50-year survival rate of 99.5%, whereas teeth with consistently inflamed gingiva had a 63.4% survival rate over 50 years. On the basis of this longitudinal study

of the natural history of periodontitis in a well-maintained male population, persistent gingivitis represents a risk factor for periodontal attachment loss and tooth loss.[22] However, whether periodontitis can occur without a precursor of gingivitis is not known at this time.

CHAPTER 18

Clinical Features of Gingivitis

Joseph P. Fiorellini, Hector L. Sarmiento, David M. Kim, Yu-Cheng Chang

CHAPTER OUTLINE

Course and Duration
Description
Clinical Findings

Experimental gingivitis studies provided the first empiric evidence that the accumulation of microbial biofilm on clean tooth surfaces results in the development of an inflammatory process in gingival tissue.[42,69] Research also shows that local inflammation persists as long as the microbial biofilm is present adjacent to the gingival tissues and that the inflammation resolves after meticulous removal of the biofilm.[69]

The prevalence of gingivitis is evident worldwide. Epidemiologic studies indicate that more than 82% of adolescents in the United States have overt gingivitis and signs of gingival bleeding. A similar or higher prevalence of gingivitis is reported for children and

adolescents in other parts of the world.[4] A significant percentage of adults also show signs of gingivitis; more than half of the US adult population is estimated to exhibit gingival bleeding, and other populations have even higher levels of gingival inflammation.[3,5,6,8,66] Plaque remains the primary etiologic factor that causes gingivitis, but other factors can affect the development of periodontal disease. Experimental gingivitis studies suggest an important role of the host response in the development and degree of gingival inflammation.[82]

Clinical features of gingivitis can be characterized by any of the following clinical signs: redness and sponginess of the gingival tissue, bleeding on provocation, changes in contour, and the presence of calculus or plaque with no radiographic evidence of crestal bone loss.[10] Histologic examination of inflamed gingival tissue reveals ulcerated epithelium. Inflammatory mediators negatively affect epithelial function as a protective barrier. Repair of this ulcerated epithelium depends on the proliferative or regenerative activity of the epithelial cells, and removal of the etiologic agents that triggered gingival breakdown is essential.

Course and Duration

Gingivitis can develop with sudden onset and have a short duration, and it can be painful. A less severe phase of this condition can also occur.

Chronic gingivitis develops slowly and has a long duration. It is painless, unless it is complicated by acute or subacute exacerbations, and it is the type that is most often encountered (Fig. 18.1). Chronic gingivitis is a fluctuating disease in which inflammation persists or resolves and normal areas become inflamed.[30,36]

FIG. 18.1 Chronic gingivitis. The marginal and interdental gingivae are smooth, edematous, and discolored. Isolated areas of acute response are seen.

Recurrent gingivitis reappears after having been eliminated by treatment or after disappearing spontaneously.

Description

Localized gingivitis is confined to the gingiva of a single tooth or group of teeth. *Generalized gingivitis* involves the entire mouth.

Marginal gingivitis involves the gingival margin, and it can include a portion of the contiguous attached gingiva. *Papillary gingivitis* involves the interdental papillae, and it often extends into the adjacent portion of the gingival margin. Papillae are involved more frequently than the gingival margin, and the earliest signs of gingivitis often occur in the papillae. *Diffuse gingivitis* affects the gingival margin, the attached gingiva, and the interdental papillae. Gingival disease in individual cases is described by combining the preceding terms as follows:

- *Localized marginal gingivitis* is confined to one or more areas of the marginal gingiva (Fig. 18.2).

FIG. 18.2 Localized diffuse, intensely red area on the facial surface of tooth #7 and dark pink marginal changes in the remaining anterior teeth.

• *Localized diffuse gingivitis* extends from the margin to the mucobuccal fold in a limited area (Fig. 18.3).

FIG. 18.3 Generalized marginal gingivitis in the lower jaw with areas of diffuse gingivitis.

• *Localized papillary gingivitis* is confined to one or more interdental spaces in a limited area (Fig. 18.4).

FIG. 18.4 Generalized papillary gingivitis.

• *Generalized marginal gingivitis* involves the gingival margins in relation to all the teeth. The interdental papillae are usually affected (Fig. 18.5).

FIG. 18.5 Generalized marginal and papillary gingivitis.

• *Generalized diffuse gingivitis* involves the entire gingiva. Because the alveolar mucosa and attached gingiva are affected, the mucogingival junction is sometimes obliterated (Fig. 18.6). Systemic conditions can be involved in the case of generalized diffuse gingivitis and should be evaluated if they are suspected as an etiologic cofactor.

FIG. 18.6 Generalized diffuse gingivitis involves the marginal, papillary, and attached gingivae.

Hallmarks of Gingivitis

Feature	Healthy Gingiva	Gingivitis
Color	Coral pink	Red
Contour	Knife-edged and scalloped	Rolled with bulbous papillae
Consistency and texture	Firm and resilient with stippling of the attached gingiva	Edematous and with loss of stippling

Clinical Findings

A systematic approach is required for the evaluation of the clinical features of gingivitis. The clinician should focus on subtle tissue alterations because they may have diagnostic significance. A systematic clinical approach requires an orderly examination of the gingiva for color, contour, consistency, position, and ease and severity of bleeding and pain. This section discusses these clinical characteristics and the microscopic changes that are responsible for each.

Gingival Bleeding on Probing

The two earliest signs of gingival inflammation that precede established gingivitis are increased gingival crevicular fluid production and bleeding from the gingival sulcus on gentle probing (Fig. 18.7). Chapter 16 discusses gingival crevicular fluid in detail.

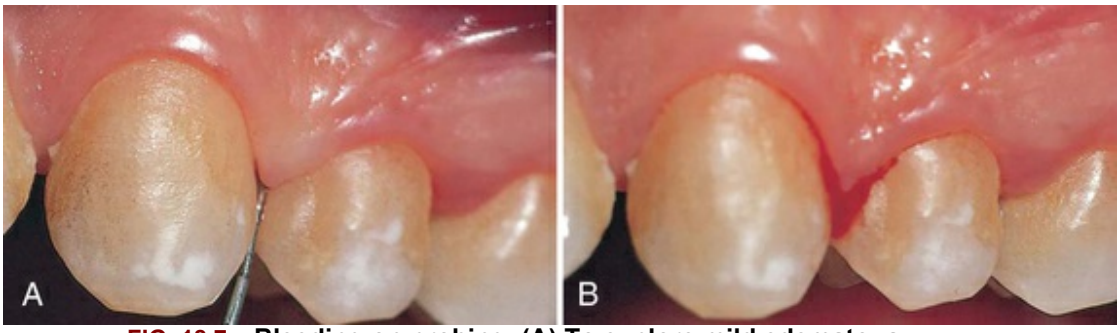

FIG. 18.7 **Bleeding on probing. (A) To explore mild edematous gingivitis, a probe is introduced to the bottom of the gingival sulcus. (B) Bleeding appears after a few seconds.**

Gingival bleeding varies in severity, duration, and ease of provocation. Bleeding on probing (BOP) is easily detected clinically and therefore is of value for early diagnosis and for prevention of more advanced gingivitis. BOP appears earlier than a change in color or other visual signs of inflammation.[36,37,46] The use of bleeding rather than color changes to diagnose early gingival inflammation is advantageous, in that bleeding is a more objective sign that requires less subjective estimation by the examiner.

An estimated 53.2 million (50.3%) US adults who are 30 years of age or older exhibit gingival bleeding.[5] Probing pocket depth measurements by themselves are of limited value in assessing the extent and severity of gingivitis. For example, gingival recession may result in a reduction of probing depth and cause inaccurate assessment of the periodontal status.[7] BOP is widely used by clinicians and epidemiologists to measure disease prevalence and progression, measure outcomes of treatment, and motivate patients to perform necessary home care.[24] See Chapter 6 for several gingival indices that are based on bleeding [2,16,53] and for more information on probing.

Gingival BOP indicates an inflammatory lesion in the epithelium and the connective tissue that exhibits specific histologic differences compared with healthy gingiva.[25] Although gingival BOP may not be a good diagnostic indicator of clinical attachment loss, its absence is an excellent negative predictor of future attachment loss.[34] The absence of gingival BOP is desirable and implies a low risk of future clinical attachment loss. Longitudinal findings revealed that sites with consistent bleeding (gingival index = 2) had 70% more attachment loss than sites that were noninflamed over a

26-year period in 565 male patients. Persistent gingivitis can be considered a risk factor for periodontal attachment loss that may lead to tooth loss.[35]

Numerous studies have shown that current cigarette smoking suppresses the gingival inflammatory response, and smoking was found to exert a strong, chronic, dose-dependent suppressive effect on gingival BOP in the Third National Health and Nutrition Examination Survey (NHANES III).[19] Research has revealed an increase in gingival BOP in patients who quit smoking,[54] and people who are committed to a smoking cessation program should be informed about the possibility of an increase in gingival bleeding associated with smoking cessation.

Gingival Bleeding Caused by Local Factors

Factors that contribute to plaque retention and may lead to gingivitis include anatomic and developmental tooth variations, caries, frenum pull, iatrogenic factors, malpositioned teeth, mouth breathing, overhangs, partial dentures, lack of attached gingiva, and recession. Orthodontic treatment and fixed retainers are associated with increased plaque retention and increased BOP.[38,78]

Chronic and Recurrent Bleeding

The most common cause of abnormal gingival BOP is chronic inflammation.[50] The bleeding is chronic or recurrent, and it is provoked by mechanical trauma (e.g., toothbrushing, toothpicks, food impaction) or by biting into solid foods (e.g., apples).

In gingival inflammation, histopathologic alterations that result in abnormal gingival bleeding include dilation and engorgement of the capillaries and thinning or ulceration of the sulcular epithelium (Fig. 18.8). Because the capillaries are engorged and closer to the surface and because the thinned, degenerated epithelium is less protective, stimuli that are normally innocuous cause rupture of the capillaries, and gingival bleeding occurs. Sites that bleed on probing have a greater area of inflamed connective tissue (i.e., cell-rich, collagen-poor tissue) than sites that do not bleed. In most cases, the cellular infiltrate of sites that bleed on probing is predominantly lymphocytic, which is a characteristic of stage II

(early) gingivitis.[9,17,25]

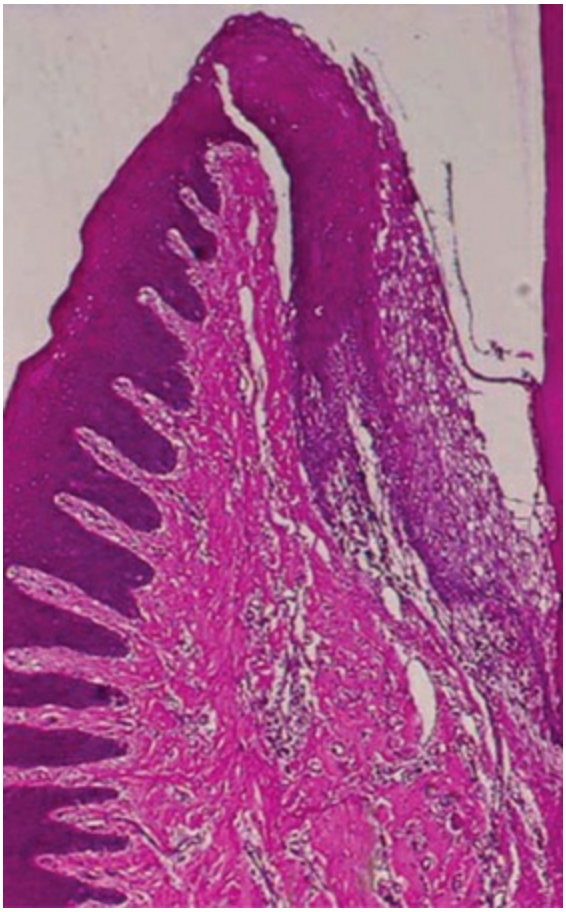

FIG. 18.8 Microscopic view of the interdental space in a human autopsy specimen. Note the inflammatory infiltrate and thinned epithelium in the area adjacent to the tooth and the collagenous tissue in the outer half of the section.

Histologic evaluations of animal specimens have revealed that during the early stages of gingivitis, expression of the cytokines (i.e., matrix metalloproteinases [MMPs]) that are responsible for connective tissue breakdown is ubiquitous. Different MMPs play roles in this breakdown at different stages (e.g., a decrease of MMP-14 activity at day 7 of inflammation; immediate increase in MMP-2, especially with fibroblastic stimulation). MMP-9 expression peaked 5 days after gingivitis occurrence, which was also regulated by macrophages and neutrophils. Extracellular matrix remodeling was regulated with MMP-2 and MMP-9 production and activation by the host inflammatory response.[39]

Clinical Correlation

Medications and Gingival Bleeding

- Drugs such as antiplatelet medications (e.g., aspirin) or anticoagulants (e.g., warfarin) that are prescribed for specific medical indications also increase the bleeding tendencies of gingival tissues.
- Women taking oral contraceptives are significantly more prone to gingivitis and therefore to gingival bleeding.

The severity of bleeding and the ease of its provocation depend on the intensity of inflammation. After the vessels are damaged and ruptured, interrelated mechanisms induce hemostasis.[73] The vessel walls contract, blood flow diminishes, blood platelets adhere to the edges of the tissue, and a fibrous clot is formed that contracts and results in approximation of the edges of the injured area. Bleeding recurs when the area is irritated.

In cases of moderate or advanced periodontitis, BOP is considered a sign of active tissue destruction. Acute episodes of gingival bleeding are caused by injury, and they can occur spontaneously in patients with gingival disease. Laceration of the gingiva by toothbrush bristles during aggressive toothbrushing or by sharp pieces of hard food can cause gingival bleeding, even in the absence of gingival disease. Gingival burns from hot foods or chemicals increase the ease of gingival bleeding.

Spontaneous bleeding or bleeding on slight provocation can occur with acute necrotizing ulcerative gingivitis. With this condition, engorged blood vessels in the inflamed connective tissue are exposed by ulceration of the necrotic surface epithelium.

Gingival Bleeding Associated With Systemic Changes

With some systemic disorders, gingival hemorrhage occurs spontaneously or after irritation (usually generalized), and it is excessive and difficult to control. These hemorrhagic diseases

represent a wide variety of conditions that vary with regard to etiologic factors and clinical manifestations. Such conditions have the common feature of a hemostatic mechanism failure that results in abnormal bleeding in the skin, internal organs, and other tissues, including the oral mucosa.[71]

Hemorrhagic disorders in which abnormal gingival bleeding is encountered include vascular abnormalities (e.g., vitamin C deficiency, allergy such as Henoch–Schönlein purpura), platelet disorders[27] (e.g., thrombocytopenic purpura), hypoprothrombinemia (e.g., vitamin K deficiency), other coagulation defects (e.g., hemophilia, leukemia, Christmas disease), deficient platelet thromboplastic factor as a result of uremia,[47] multiple myeloma,[12] and postrubella purpura.[30] The effects of hormonal replacement therapy, oral contraceptives, pregnancy, and the menstrual cycle are also reported to affect gingival bleeding.[43,65,79,80] In women, long-term depression-related stress exposure may increase concentrations of interleukin-6 in gingival crevicular fluid and worsen periodontal conditions, producing elevated levels of gingival inflammation and increased pocket depths.[32]

Clinical Correlation

Pregnancy Gingivitis

Pregnancy gingivitis affects many pregnant women and is primarily caused by the hormonal imbalances associated with pregnancy. It is characterized by mild to severe gingival inflammation along with pain and, in some cases, significant hyperplasia and bleeding. In most patients, the condition normally resolves by itself after delivery, when the hormonal levels return to normal.

Changes in sex hormones have long been established as significant modifying factors in gingivitis, especially among adolescents. Several reports have shown notable effects of fluctuating estrogen and progesterone levels on the periodontium, starting as early as puberty.[1,55] Diabetes is an endocrine condition

with a well-characterized effect on gingivitis.[78] In diabetes, marked inflammation affects both epithelial and connective tissues, leading to degeneration of the dermal papilla, an increase in the number of inflammatory cells, the destruction of reticulin fibers, and an accumulation of dense collagen fibers that causes fibrosis.[70]

Several medications have also been found to have adverse effects on the gingiva. For example, anticonvulsants, antihypertensive calcium channel blockers, and immunosuppressive drugs cause gingival enlargement (see Chapter 19), which can cause gingival inflammation and bleeding. The American Heart Association has recommended over-the-counter aspirin as a prophylactic and therapeutic agent for cardiovascular disease, and aspirin is often prescribed for other conditions such as rheumatoid arthritis, osteoarthritis, rheumatic fever, and other inflammatory joint diseases.[28] It is important to consider aspirin's effect on bleeding during a routine dental examination to avoid false-positive readings that could result in an inaccurate diagnosis.[67] Chapter 19 discusses periodontal involvement in hematologic disorders.

Color Changes in the Gingiva

The color of the gingiva is determined by several factors, including the number and size of blood vessels, the epithelial thickness, the quantity of keratinization, and the pigments in the epithelium.

Color Changes With Gingivitis

Change in color is an important clinical sign of gingival disease. The normal gingival color is coral pink, and it is produced by the tissue's vascularity and modified by the overlying epithelial layers. The gingiva becomes red when vascularization increases or the degree of epithelial keratinization is reduced or disappears. The color becomes pale when vascularization is reduced (in association with fibrosis of the corium) or epithelial keratinization increases. Chronic inflammation intensifies the red or bluish red color as a result of vascular proliferation and a reduction of keratinization. Venous stasis contributes a bluish hue. The gingival color changes with increasing chronicity of the inflammatory process. The changes start in the interdental papillae and gingival margin and

then spread to the attached gingiva.

Proper diagnosis and treatment depend on understanding the tissue changes that alter the color of the gingiva at the clinical level. Color changes in acute gingival inflammation differ in both nature and distribution from those in patients with chronic gingivitis. The color changes can be marginal, diffuse, or patchlike, depending on the underlying acute condition. With acute necrotizing ulcerative gingivitis, the involvement is marginal; with herpetic gingivostomatitis, it is diffuse; and with acute reactions to chemical irritation, it is patchlike or diffuse.

Clinical Correlation

Mouth Breathing and Gingival Inflammation

Gingivitis in the maxillary buccal area of the oral cavity is a common finding in patients who are mouth breathers. The affected gingiva typically appears red, shiny, and edematous, which is thought to be related to the surface dehydration caused by mouth breathing.

Color changes vary with the intensity of inflammation. Initially, there is an increase in erythema. If the condition does not worsen, this is the only color change until the gingiva reverts to normal. With severe acute inflammation, the red color gradually becomes a dull, whitish gray. The gray discoloration produced by tissue necrosis is demarcated from the adjacent gingiva by a thin, sharply defined erythematous zone. Chapter 14 provides detailed descriptions of the clinical and pathologic features of the various forms of acute gingivitis.

Metallic Pigmentation

Heavy metals (i.e., bismuth, arsenic, mercury, lead, and silver) that are absorbed systemically as a result of therapeutic use or occupational or household exposures can discolor the gingiva and other areas of the oral mucosa.[45] These changes are rare, but they should be ruled out in suspected cases.

Metals typically produce a black or bluish line in the gingiva that follows the contour of the margin (Fig. 18.9). The pigmentation may also appear as isolated black blotches involving the interdental marginal and attached gingiva. This is different from the tattooing produced by the accidental embedding of amalgam or other metal fragments[15] (Fig. 18.10).

FIG. 18.9 **Bismuth gingivitis. Note the linear black discoloration of the gingiva in a patient who is receiving bismuth therapy.**

FIG. 18.10 Discoloration of the gingiva is caused by embedded metal particles (i.e., amalgam).

Gingival pigmentation from systemically absorbed metals results from the perivascular precipitation of metallic sulfides in the subepithelial connective tissue. Gingival pigmentation is not a result of systemic toxicity. It occurs only in areas of inflammation in which the increased permeability of irritated blood vessels permits the seepage of metal into the surrounding tissue. In addition to inflamed gingiva, mucosal areas that are irritated by biting or

abnormal chewing habits (e.g., inner surface of lips, cheek at the level of the occlusal line, lateral border of the tongue) are common sites of pigmentation. Pigmentation can be eliminated by treating the inflammatory changes without necessarily discontinuing the metal-containing medication.

Color Changes Associated With Systemic Factors

Many systemic diseases can cause color changes in the oral mucosa, including the gingiva.[22] In general, these abnormal pigmentations are nonspecific, and they should stimulate further diagnostic efforts or referral to the appropriate specialist.[68]

Endogenous oral pigmentation can be caused by melanin, bilirubin, or iron.[45] *Melanin* oral pigmentation can be normal, and is often found in highly pigmented ethnic groups (see Chapter 18). Diseases that increase melanin pigmentation include the following:

- Addison disease is caused by adrenal dysfunction, and it produces isolated patches of discoloration that vary from bluish black to brown.
- Peutz–Jeghers syndrome produces intestinal polyposis and melanin pigmentation in the oral mucosa and lips.
- Albright syndrome (i.e., polyostotic fibrous dysplasia) and von Recklinghausen disease (i.e., neurofibromatosis) produce areas of oral melanin pigmentation.

The skin and mucous membranes can also be stained by *bile pigments.* Jaundice is best detected by examination of the sclera, but the oral mucosa may also acquire a yellowish color. The deposition of *iron* in hemochromatosis may produce blue-gray pigmentation of the oral mucosa. Several endocrine and metabolic disturbances,

including diabetes and pregnancy, can result in color changes. Blood dyscrasias such as anemia, polycythemia, and leukemia also can induce color changes.

Exogenous factors that are capable of producing color changes in the gingiva include atmospheric irritants, such as coal and metal dust, and coloring agents in food and lozenges. Tobacco causes hyperkeratosis of the gingiva, and it can induce a significant increase in melanin pigmentation of the oral mucosa.[56] Localized bluish black areas of pigment are often caused by amalgam implanted in the mucosa (see Fig. 18.10).

The need for aesthetics in dentistry has increased, with a growing demand for a pleasing smile. This has made many individuals more aware of their gingival pigmentation, which may be apparent when smiling and speaking.[20,21] Traditionally, gingival depigmentation has been carried out with the use of nonsurgical and surgical procedures, including chemical, cryosurgical, and electrosurgical techniques. However, those techniques were met with skepticism because of their various degrees of success.

Lasers have been used to ablate cells that produce the melanin pigment; a nonspecific laser beam destroys the epithelial cells, including those at the basal layer. Selective ablation using a laser beam with a wavelength that is specifically absorbed by melanin effectively destroys the pigmented cells without damaging the nonpigmented cells. In both cases, radiation energy is transformed into ablation energy, resulting in cellular rupture and vaporization with minimal heating of the surrounding tissue.[76]

Changes in Gingival Consistency

Chronic and acute inflammations produce changes in the normal firm and resilient consistency of the gingiva. In patients with chronic gingivitis, destructive (i.e., edematous) and reparative (i.e., fibrotic) changes coexist, and the consistency of the gingiva is determined by their relative predominance (Figs. 18.11 and 18.12). Table 18.1 summarizes the clinical alterations in the consistency of the gingiva and the microscopic changes that produce them.

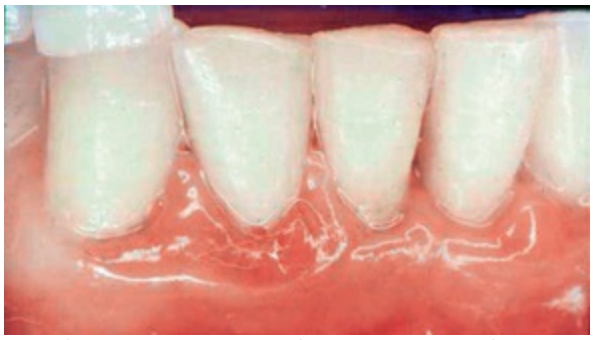

FIG. 18.11 **Chronic gingivitis. Swelling, loss of stippling, and discoloration occur when inflammatory exudate and edema are the predominant microscopic changes. The gingiva is soft and friable and bleeds easily.**

FIG. 18.12 **Chronic gingivitis. Firm gingiva is produced when fibrosis predominates in the inflammatory process.**

TABLE 18.1
Clinical and Histopathologic Changes in Gingival Consistency

Clinical Changes	Underlying Microscopic Features
Chronic Gingivitis	
1. Soggy puffiness that pits on pressure	1. Infiltration by fluid and cells of inflammatory exudate
2. Marked softness and friability, with ready fragmentation on exploration with probe and pinpoint surface areas of redness and desquamation	2. Degeneration of connective tissue and epithelium associated with injurious substances that provoke inflammation and inflammatory exudate; change in the connective tissue–epithelium relationship, with inflamed, engorged connective tissue expanding to within a few epithelial cells of the surface; thinning of epithelium and degeneration associated with edema and leukocyte invasion, separated by areas in which rete pegs are elongated to connective tissue
3. Firm, leathery	3. Fibrosis and epithelial proliferation associated with long-standing

consistency	chronic inflammation
Acute Gingivitis	
1. Diffuse puffiness and softening	1. Diffuse edema of acute inflammatory origin; fatty infiltration in xanthomatosis
2. Sloughing with grayish, flakelike particles of debris adhering to eroded surface	2. Necrosis with formation of pseudomembrane composed of bacteria, polymorphonuclear leukocytes, and degenerated epithelial cells in fibrinous meshwork
3. Vesicle formation	3. Intercellular and intracellular edema with degeneration of nucleus and cytoplasm and rupture of cell wall

Calcified Masses in the Gingiva

Calcified microscopic masses may be found in the gingiva.[14,52] They can occur alone or in groups, and they vary with regard to size, location, shape, and structure. Such masses may be calcified material that was removed from the tooth and traumatically displaced into the gingiva during scaling,[52] root remnants, cementum fragments, or cementicles. Chronic inflammation and fibrosis, an occasional foreign body, and giant-cell activity occur in reaction to the masses, which are sometimes enclosed in an osteoid-like matrix. Crystalline foreign bodies have also been described in the gingiva, but their origin has not been determined.[60]

Toothbrushing

Toothbrushing has various effects on the consistency of the gingiva, such as promoting keratinization of the oral epithelium, enhancing capillary gingival circulation, and thickening alveolar bone.[44,49,77] In animal studies, mechanical stimulation by toothbrushing was found to increase the proliferative activity of the junctional basal cells in dog gingiva by 2.5 times compared with the use of a scaler.[31] These findings may indicate that toothbrushing causes an increased turnover rate and desquamation of the junctional epithelial surfaces. This process may repair small breaks in the junctional epithelium and prevent direct access to the underlying tissue by periodontal pathogens.[81]

Changes in Gingival Surface Texture

The surface of normal gingiva usually exhibits numerous small depressions and elevations that give the tissue an orange-peel

appearance referred to as *stippling*.[13] Stippling is restricted to the attached gingiva and is predominantly localized to the subpapillary area, but it extends to various degrees into the interdental papilla.[61] Although the biologic significance of gingival stippling is not known, some investigators conclude that the loss of stippling is an early sign of gingivitis.[33,61] However, clinicians must take into consideration that its pattern and extent vary in different mouth areas, among patients, and with age.

In patients with chronic inflammation, the gingival surface is smooth and shiny or firm and nodular, depending on whether the dominant changes are exudative or fibrotic. A smooth surface texture is also produced by epithelial atrophy in atrophic gingivitis, and peeling of the surface occurs with chronic desquamative gingivitis. Hyperkeratosis results in a leathery texture, and drug-induced gingival overgrowth produces a nodular surface.

Clinical Correlation

Stippling and Its Clinical Importance

Healthy, attached gingiva has a pitted orange-peel appearance on its surface. This surface feature, called *stippling*, is an external reflection of the underlying connective tissue projections into the overlying epithelium. Presence of stippling in the attached gingiva is indicative of gingival health, and this surface feature is usually lost when the tissue is edematous.

Changes in Gingival Position

Traumatic Lesions

A feature of gingival disease classification is the recognition of non–plaque-induced traumatic gingival lesions as distinct gingival conditions.[11] Traumatic lesions—whether chemical, physical, or thermal—are among the most common lesions in the mouth. Sources of chemical injuries include aspirin, hydrogen peroxide, silver nitrate, phenol, and endodontic materials. Physical injuries can include lip, oral, and tongue piercings, which can result in gingival recession. Thermal injuries can result from hot drinks and

foods.

In acute cases, the appearance of slough (i.e., necrotizing epithelium), erosion, or ulceration and accompanying erythema are common features. In chronic cases, permanent gingival defects usually take the form of gingival recession. Typically, the localized nature of the lesions and lack of symptoms readily eliminate them from the differential diagnosis of systemic conditions that may exist with erosive or ulcerative oral lesions.[64]

Gingival Recession

Gingival recession is a common finding. The prevalence, extent, and severity of gingival recession increase with age, and this condition is more prevalent among males.[5]

Positions of the Gingiva

By clinical definition, recession is exposure of the root surface by an apical shift in the position of the gingiva. To understand recession, it helps to distinguish between the actual and apparent positions of the gingiva. The *actual position* is the level of the coronal end of the epithelial attachment on the tooth, whereas the *apparent position* is the level of the crest of the gingival margin (Fig. 18.13). The severity of recession is usually determined by the apparent position of the gingiva. However, the actual gingival position is used to determine the clinical attachment loss. For example, in periodontal disease, the inflamed pocket wall covers part of the denuded root; some of the recession is hidden, and some maybe visible. The total amount of clinical attachment loss is the sum of the two.

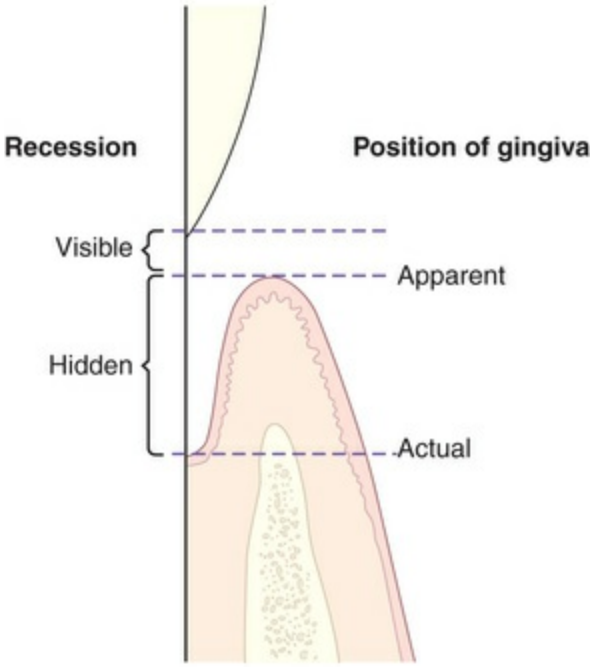

FIG. 18.13 Diagram of apparent and actual positions of the gingiva and visible and hidden recession.

Recession refers to the location of the gingiva rather than to its condition. Receded gingiva can be inflamed, but it may be normal except for its position (Fig. 18.14). Recession can be localized to one tooth or a group of teeth, or it may be generalized throughout the mouth.

FIG. 18.14 **Degrees of recession. Recession is slight in teeth #26 and #29 and marked in teeth #27 and #28. The change in gingival contour and the recession, as seen in tooth #28, are referred to as *Stillman clefts.***

Gingival recession increases with age; the incidence varies from 8% among children to 100% after 50 years of age.[84] This has led

some investigators to assume that recession might be a physiologic process related to aging. However, no convincing evidence has been presented for a physiologic shift of the gingival attachment.[40] The gradual apical shift most likely results from the cumulative effect of minor pathologic involvement and repeated minor direct trauma to the gingiva. In some populations without access to dental care, however, recession can result from increasing periodontal disease.[29,41]

The following etiologic factors have been implicated in gingival recession: faulty toothbrushing technique (i.e., gingival abrasion), tooth malposition, friction from the soft tissues (i.e., gingival ablation),[72] gingival inflammation, abnormal frenum attachment, and iatrogenic dentistry. Trauma from occlusion has been suggested in the past, but its mechanism of action has never been demonstrated. For example, a deep overbite has been associated with gingival inflammation and recession. Excessive incisal overlap may result in a traumatic injury to the gingiva. Orthodontic movement in a labial direction in monkeys has been shown to result in the loss of marginal bone and connective tissue attachment and in gingival recession.[74]

Standard oral hygiene procedures, including toothbrushing and flossing, frequently lead to transient and minimal gingival injury.[18,62] Although toothbrushing is important for gingival health, faulty technique or brushing with hard bristles can cause significant injury. This type of injury can manifest as lacerations, abrasions, keratosis, or recession, with the facial marginal gingiva being affected most often.[57] In these cases, recession tends to be more frequent and more severe in patients with clinically healthy gingiva, little bacterial plaque, and good oral hygiene.[23,58,59]

Clinical Correlation

Biologic Width and Gingival Inflammation

Biologic width is the circumferential rim of space around teeth where the junctional epithelium and the underlying connective tissue of the gingiva attach to the teeth. When restoring teeth, if the margins of the restorations violate the biologic width, gingival

inflammation ensues. If left untreated, it can lead to bone loss. Crown lengthening is a surgical procedure that is performed clinically (i.e., before restoration delivery) to intentionally create space for the biologic width to reestablish.

Susceptibility to recession is influenced by the position of teeth in the arch,[83] the root–bone angle, and the mesiodistal curvature of the tooth surface.[51] On rotated, tilted, or facially displaced teeth, the bony plate is thinned or reduced in height. Pressure from mastication or moderate toothbrushing damages the unsupported gingiva and produces recession. The effect of the angle of the root in the bone with recession is often observed in the maxillary molar area. If the lingual inclination of the palatal root is prominent or the buccal roots flare outward, the bone in the cervical area is thinned or shortened, and recession results from repeated trauma of the thin marginal gingiva.

The health of the gingival tissue also depends on properly designed and placed restorative materials. Pressure from a poorly designed partial denture, such as an ill-fitting denture clasp, can cause gingival trauma and recession.[85] Overhanging dental restorations have long been viewed as a contributing factor to gingivitis because of plaque retention. In addition, there is general agreement that placing restorative margins within the biologic width frequently leads to gingival inflammation, clinical attachment loss, and eventually bone loss. Clinically, the violation of biologic width typically manifests as gingival inflammation, deepened periodontal pockets, and gingival recession.

A relationship may exist between smoking and gingival recession (see Chapter 12). The multifactorial mechanisms probably include reduced gingival blood flow and an altered immune response, but current evidence is not conclusive.[26,63]

Clinical Significance

Several aspects of gingival recession make it clinically significant. Exposed root surfaces are susceptible to caries. Abrasion or erosion of the cementum exposed by recession leaves an underlying dentinal surface that can be sensitive. Hyperemia of the pulp and associated symptoms can result from excessive exposure of the root

surface.[48] Interproximal recession creates oral hygiene problems results in plaque accumulation.

Changes in Gingival Contour

Changes in gingival contour are primarily associated with gingival enlargement (see Chapter 19), but changes may also occur with other conditions. Of historical interest are descriptions of indentations of the gingival margin referred to as Stillman clefts (see Fig. 18.14)[75] and McCall festoons. The term *Stillman cleft* has been used to describe a specific type of gingival recession that consists of a narrow, triangular-shaped gingival recession. As the recession progresses apically, the cleft becomes broader, thereby exposing the cementum of the root surface. When the lesion reaches the mucogingival junction, the apical border of oral mucosa is usually inflamed because of the difficulty in maintaining adequate plaque control at this site.

The term *McCall festoon* has been used to describe a rolled, thickened band of gingiva that is usually seen adjacent to the cuspids when recession approaches the mucogingival junction. Initially, Stillman clefts and McCall festoons were attributed to traumatic occlusion, and the recommended treatment was occlusal adjustment. However, this association was never proved, and the indentations merely represent peculiar inflammatory changes of the marginal gingiva.[14]

Case Scenario 18.1

Patient:

37-year-old female

Background Information

Patient has no underlying medical condition that would affect her oral health. Her last dental cleaning was done 6 years ago. Patient denies flossing and reports brushing once each day. Patient reports sensitivity while brushing.

Current Findings:

Probing depths were in the range of 2 to 3 mm, BOP was 43%, poor oral hygiene

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the most probable cause of this gingival condition? A. Extensive restorations B. Dental plaque C. Chemical injury D. Uncontrolled diabetes	**Answer: B** **Explanation:** In this patient with no known underlying systemic conditions and presenting with extensive plaque and poor oral hygiene, dental plaque seems to be the primary cause.
2. Reddish gingiva is noted in all of the following systemic conditions EXCEPT: A. Leukemia B. Addison disease C. Mouth breathing D. Lichen planus	**Answer: B** **Explanation:** In Addison disease, brown pigmentation of gingiva occurs due to increased melanin production, not reddening of gingiva.
3. What is the likely treatment for addressing this gingival condition? A. Dental prophylaxis/plaque debridement B. Scaling and root planing C. Flap surgery D. Periodontal regeneration	**Answer: A** **Explanation:** Removing plaque and improving the patient's oral hygiene compliance will lead to resolution of gingivitis.

Case Scenario 18.2

Patient:
44-year-old male

Chief Complaint:
"My gums in the lower front area are sore and bleed when I brush."

Background Information
Patient has no underlying medical condition that would affect his oral health. His last dental cleaning was done 3 years ago. Patient reports brushing at least once daily but denies flossing. Patient reports sensitivity and bleeding of the gingiva in the mandibular anterior sextant while brushing.

Current Findings:
Probing depths were in the range of 2 to 3 mm, BOP was 37%, poor oral hygiene

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. The early signs of gingival inflammation that precede established localized gingivitis include which of the following? A. Increased gingival crevicular fluid production B. Bleeding from the	**Answer: D** **Explanation:** Suppuration (i.e., discharge of purulence) on gentle probing is an uncommon early sign of gingivitis. Suppuration indicates active infection and is a common sign of gingival or periodontal abscess.

gingival sulcus on gentle probing C. Suppuration on gentle probing D. A and B only E. All of the above	
2. Localized marginal gingivitis normally A. Extends from the gingival margin to the mucobuccal fold in limited areas B. Extends from the gingival margin to the mucobuccal fold in the entire mouth C. Extends only interpapillary D. Extends on the lingual surfaces only	**Answer: A** **Explanation:** Localized marginal gingivitis is typically restricted to the gingival margin on one side and mucobuccal fold on the other side in localized areas of the dentition.
3. Blood supply to the gingiva in the mandibular anterior buccal sites includes which of the following? A. Supraperiosteal vessels B. Vessels from periodontal ligament C. Blood supply from the alveolar process D. All of the above	**Answer: D** **Explanation:** Buccal gingiva is supplied by all groups of blood vessels.

CHAPTER 19

Gingival Enlargement

Alpdogan Kantarci, Fermin A. Carranza, Eva Hogan

CHAPTER OUTLINE

Terminology and Classification
Diagnosis
Types of Gingival Enlargement
Other Forms of Gingival Enlargement

Enlargement of gingiva has many causes and can manifest with various clinical characteristics. A change in the dimensions of gingival tissue is always a pathologic event. Gingival enlargement can be transient and reversible or can be chronic and irreversible. As in other pathologic processes, inflammation of the periodontal tissues typically results in three outcomes: complete resolution of inflammation and restoration of tissue integrity (i.e., homeostasis), destruction of periodontal tissues and loss of attachment (i.e., chronic periodontitis), or fibrosis.

Fibrosis is a component of the defense mechanism against

progression of periodontal inflammation. During this process, fibroblasts play a major role by generating excessive amounts of collagen and noncollagenous proteins of the extracellular matrix. Increased matrix deposition is not sufficiently balanced by the enzymatic degradation of the matrix composition (e.g., collagen), resulting in fibrotic changes in soft tissues. Fibrosis of gingival tissues is commonly referred to as *gingival hyperplasia*. In contrast to other tissues in which fibrosis is observed, gingival lesions are usually inflamed due to accumulation of bacteria and reduced oral care. Gingival overgrowth lesions are unique in their pathogenetic mechanisms.

Pathologic enlargements of gingival tissues were recognized in ancient civilizations and were linked to systemic conditions as early as the 18th century. Most common forms of gingival enlargement result from systemic use of various medications. The first scientific report on drug-induced gingival overgrowth was published in 1939, when the anticonvulsant diphenylhydantoinate was associated with gingival enlargement.[59] Later studies provided significant insights into the complex molecular and cellular mechanisms underlying gingival enlargement. Because many forms of gingival enlargement are associated with systemic factors and conditions, understanding the exact pathogenesis of lesions is essential for designing better approaches to treatment.

This chapter focuses on the clinical, etiologic, and pathologic aspects of gingival enlargement that are used to develop novel and targeted approaches to therapy. Neoplastic enlargement of gingival tissues associated with benign or malignant oral cancers is not covered in depth because this emerging field of oral pathology has evolved beyond the scope of this chapter and can be found in oral pathology textbooks that provide extensive coverage of oral tumors.

Terminology and Classification

Gingival enlargement and *gingival overgrowth* are terms used interchangeably with *hyperplasia*, *hypertrophy*, and *fibrosis*. *Hyperplasia* is an increase in the number of cells in tissues that results in increased tissue volume. *Hypertrophy* refers to increased

tissue size and volume resulting from increased cell size. Although their pathogenetic mechanisms are different, hyperplasia and hypertrophy usually occur simultaneously when cellular involvement in hyperplasia most likely triggers the overgrowth.

The two processes are closely linked. *Fibrosis* refers to a pathologic process in which disrupted wound healing is associated with defective cell proliferation, cell-to-cell interactions, cell-to-matrix interactions, and matrix deposition and with an impaired immune system response. In this regard, fibrosis can be defined as a pathologic lesion, whereas hyperplasia and hypertrophy can be viewed as pathologic processes.

All of these terms refer to different pathogenetic states. In gingival tissues, they are associated with various phases of inflammation. Hyperplastic, hypertrophic, and fibrotic changes are observed during gingival enlargement and cannot be accurately differentiated. This chapter therefore uses *gingival overgrowth* (GO) or *gingival enlargement* to refer to all pathologic forms in periodontal tissues.

Classification of GO is based on etiologic factors. The most common form results from systemic use of medications and is called *drug-induced gingival overgrowth* (DIGO). Three families of drugs can lead to DIGO: anticonvulsants, calcium channel blockers, and immunosuppressants. GO also is associated with severe systemic diseases such as leukemia and with genetic factors. Any form that cannot be classified among these GO forms is known as *idiopathic GO*. GO can also be the result of inflammatory changes due to gingivitis. GO cases are classified as follows:

- Inflammatory enlargement due to chronic gingivitis
- Drug-induced enlargement
- GO associated with systemic conditions
- GO associated with systemic diseases
- Gingival fibromatosis

Enlargement of the gingiva can be indirectly associated with changes in the dimensions of underlying osseous structures.

Although not covered in depth in this chapter, neoplastic lesions in the oral cavity can manifest with fibrotic lesions and can appear clinically similar to other forms of GO. Regardless of the cause, all forms of gingival enlargement have distinct pathologic characteristics that should be carefully considered during treatment. It is important to identify the cause and confounding etiologic factors that lead to different forms of GO.

Diagnosis

Because GO is frequently associated with systemic conditions, the general health of the patient and his or her drug use should be carefully managed. GO is one of the most serious pathologies in periodontal medicine, and it requires a meticulous differential diagnosis for selecting a therapeutic approach tailored to the patient's systemic status.

Accurate diagnosis requires a thorough review of the medical history of the patient. Gingival enlargement should be distinguished as localized or generalized. Generalized GO can affect marginal gingiva; localized forms can be confined to papillae. Previous classifications also distinguished between diffuse and discrete enlargements, which are sometimes difficult to differentiate. However, these categorizations can be critical for determining the correct cause of the pathology.

In periodontal tissues, indices are important for quantification of the extent and severity of GO. Various indices have been proposed. For example, the degree of gingival enlargement can be scored as follows:

- Grade 0: no signs of gingival enlargement
- Grade I: enlargement confined to interdental papilla
- Grade II: enlargement involves papilla and marginal gingiva
- Grade III: enlargement covers three-fourths or more of the crown

In addition to clinical determination of the degree of severity, a more accurate assessment of GO can be made by models cast on the impressions. A technique developed by Seymour and colleagues has been validated by others and can be a valuable tool for precise determination of the severity and extent of GO, especially for research purposes and long-term follow-up.[23,35,56,95,102] Other indices used to assess the severity of GO include those developed by Angelopoulos and Goaz[4] and Pernu and coworkers.[81] Three-dimensional scanning can be used to measure GO and compare the treatment outcomes with baseline values.[111]

Regardless of the method used for measuring the extent and severity of GO lesions, an accurate assessment is critical for identifying the inflammatory and fibrotic components. Indices should be chosen based on practicality of the data acquired to allow clinicians to select the method of therapy (e.g., gingivectomy and gingivoplasty vs. nonsurgical treatment measures) and plan the maintenance phase.

Types of Gingival Enlargement

Inflammatory Enlargement of Gingiva Due to Gingivitis

Clinical Manifestations

All changes in gingival tissues manifest with some degree of inflammation. In some cases, gingival enlargement is a direct outcome of gingivitis without any complicating factors or involvement of systemic conditions. When a patient with gingival enlargement is seen, the initial assessment is made by careful visual examination of abnormalities of gingival contours, texture, and color, which are compared with normal standards. Visual inspection is accompanied by a detailed medical history to exclude potential systemic factors and conditions. Dental irregularities, dysfunctional habits, and oral care efficiency should be considered in the evaluation, and clinical measurements should be recorded.

Inflammatory GO originates as a slight ballooning of the interdental papilla and marginal gingiva. In the early stages, it

produces swelling around the involved teeth, which can increase in size until it covers part of the crowns. Gingival enlargement may be localized or generalized. It progresses slowly and painlessly unless it is complicated by acute infection or trauma (Figs. 19.1 and 19.2). Occasionally, chronic inflammatory GO occurs as a discrete sessile or pedunculated mass that resembles a tumor. It can be interproximal or located on the marginal or attached gingiva. Painful ulceration sometimes occurs in the fold between the mass and the adjacent gingiva.

FIG. 19.1 Chronic inflammatory gingival enlargement localized to the anterior region.

FIG. 19.2 Chronic inflammatory gingival enlargement.

Etiology

Acute inflammatory enlargement of the gingiva usually is caused by a mechanical, chemical, or physical irritation and can be

resolved by removal of the irritant. Mouth breathing, impacted food items, and poor oral hygiene are usually responsible for acute inflammatory reactions in gingival tissues. Acute lesions are usually localized to marginal or papillary gingiva.

The main etiologic factor for acute inflammatory gingival enlargement is trauma. Traumatic lesions occur when a foreign substance (e.g., toothbrush bristle) is forcefully embedded in the gingiva and complicated by resident microbes. Trauma-induced injuries result in a chronic process characterized by granulation tissue formation and fibrosis. Because nerve tissue does not proliferate, pain is uncommon.

Key Fact

The main etiological factor for acute inflammatory gingival enlargement is trauma. Traumatic lesions occur when a foreign substance (e.g., toothbrush bristle) is forcefully embedded into the gingiva and the situation is complicated by the presence of microbial pathogens. Trauma-induced injuries result in a chronic process characterized by granulation tissue formation and fibrosis. Because nerve tissue does not proliferate, pain is uncommon.

Acute inflammatory enlargement can lead to the formation of gingival abscess. Gingival abscess is a localized, painful, and rapidly expanding lesion (Fig. 19.3). It is typically limited to the marginal gingiva or the interdental papilla. In its early stages, it appears as a red swelling with a smooth, shiny surface. The lesion usually becomes fluctuant and pointed, with a surface orifice and a purulent exudate in 24 to 48 hours. Adjacent teeth may become sensitive to percussion. The lesion usually ruptures spontaneously. Because of an acute inflammatory process, the gingival abscess consists of a purulent exudate of a diffuse infiltration of polymorphonuclear leukocytes, edematous tissue, and vascularization. The surface epithelium has various degrees of intracellular and extracellular edema, invasion by leukocytes, and sometimes ulceration. The lesion is confined to the gingiva, and it should be distinguished from periodontal abscess.

FIG. 19.3 Gingival abscess on the facial gingival surface in the space between the cuspid and the lateral incisor, unrelated to the gingival sulcus.

Chronic inflammatory GO is commonly associated with microbial biofilm. Biofilm can be linked to a lack of proper oral hygiene, orthodontic appliances, faulty restoration margins, misaligned teeth, oral habits, an open bite, or other factors. Factors that favor plaque accumulation and retention include poor oral hygiene, irritation by anatomic abnormalities, and improper restorative and orthodontic appliances. Gingivitis and gingival enlargement are often seen in patients who are mouth breathers. The gingiva appears red and edematous, with a diffuse surface shininess of the exposed area. The maxillary anterior region is commonly involved. In many cases, the altered gingiva is clearly demarcated from the adjacent, unexposed normal gingiva (Fig. 19.4). Irritation from surface dehydration is attributed to mouth breathing. However, comparable changes could not be reproduced by air-drying the gingiva of experimental animals, suggesting that the pathogenesis of mouth breathing–associated gingival changes is far more complex.

FIG. 19.4 Gingival enlargement in a mouth breather. The lesion is sharply circumscribed in the anterior marginal and papillary areas.

Plasma cell gingivitis sometimes manifests as a mild marginal gingival enlargement that extends to the attached gingiva. The gingiva appears red, friable, and sometimes granular, and it bleeds easily; usually, gingivitis does not cause the loss of attachment (Fig. 19.5). The lesion is located on the oral aspect of the attached gingiva and is different from plaque-induced gingivitis.

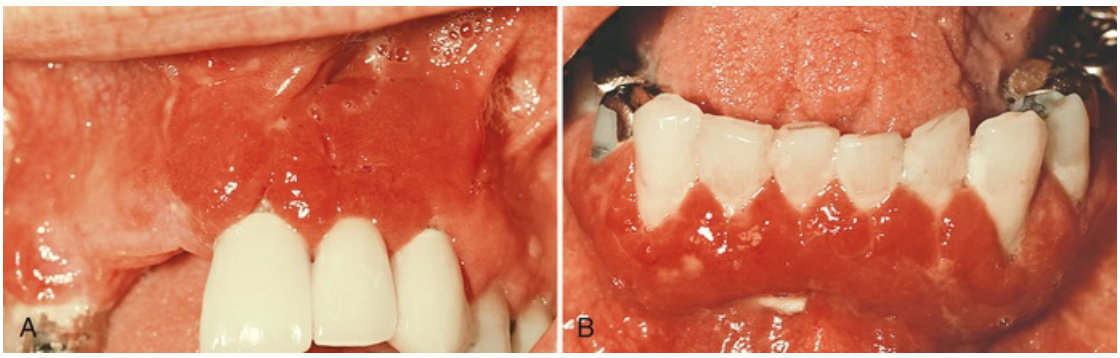

FIG. 19.5 Plasma cell gingivitis. (A) Diffuse lesions on the facial surface of the anterior maxilla. (B) Mandibular lesions. (Courtesy Dr. Kim D. Zussman, Thousand Oaks, CA.)

In addition to the acute and chronic forms of gingival enlargements associated with gingivitis, inflammatory lesions can be observed in other forms of GO. Systemic conditions also cause inflammatory changes in gingiva. The distinction should be made very early in treatment planning, and the involvement of drugs, systemic conditions, and neoplastic lesions should be carefully ruled out.

Histopathology

Inflammatory enlargement of the gingiva typically follows the sequence of the inflammatory process. Chronic inflammatory GO lesions show the exudative and proliferative features of chronic inflammation (Fig. 19.6). Lesions that are deep red or bluish red are soft and friable with a smooth, shiny surface, and they bleed easily. They also have a preponderance of inflammatory cells and fluid, along with vascular engorgement, new capillary formation, and associated degenerative changes. Lesions that are relatively firm, resilient, and pink have a greater fibrotic component, with an abundance of fibroblasts and collagen fibers.

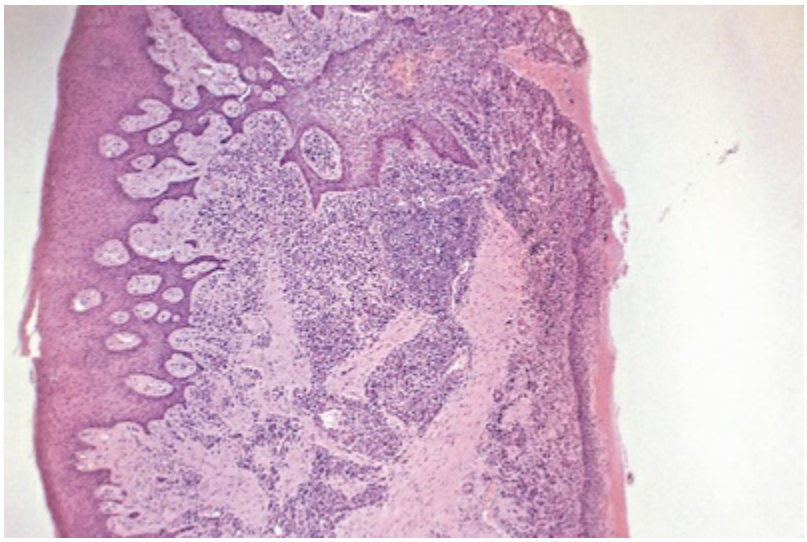

FIG. 19.6 Survey section of chronic inflammatory gingival enlargement shows the inflamed connective tissue core and strands of proliferating epithelium.

In patients with plasma cell gingivitis, the oral epithelium shows spongiosis and infiltration with inflammatory cells. Ultrastructurally, there are signs of damage in the lower spinous layers and the basal layers. The underlying connective tissue contains a dense infiltrate of plasma cells that also extends to the oral epithelium, producing a dissecting type of injury. Associated cheilitis and glossitis have been reported.[91]

Plasma cell gingivitis is thought to be allergic in origin and possibly a reaction to components of chewing gum, dentifrices, or various dietary items. Cessation of exposure to the allergen brings

resolution of the lesion. In rare instances, marked inflammatory gingival enlargements with a predominance of plasma cells can appear; they are associated with aggressive periodontitis.[78] A solitary plasma cell tumor (i.e., plasmocytoma) has been described in the nasopharynx and rarely in the oral mucosa.[10] It is a slow-growing, pedunculated tumor with a pink and smooth surface, and it is composed of normal plasma cells. It is usually benign, but in rare cases it can be an oral manifestation of multiple myeloma, which is a malignant B-cell tumor of the bone marrow.

Treatment

Chronic enlargement of the gingiva due to gingivitis is reversible and can be resolved by removal of the etiologic factors, including the biofilm, and correction of environmental factors. In severe forms of inflammatory enlargement, surgical approaches may be required.

Drug-Induced Overgrowth of Gingiva

Most common forms of DIGO are caused by the use of anticonvulsants, calcium channel blockers, and immunosuppressants prescribed to patients for serious health concerns. The prevalence of DIGO substantially varies for different medications and among studies. Three drugs associated with DIGO are phenytoin, nifedipine, and cyclosporine. About 20 other medications have been linked to DIGO. An estimated 30% to 80% of the patients using these medications are at risk for overgrowth lesions. Genetic factors, drug dosage, and local factors can affect the development and severity of DIGO.[93,105]

DIGO frequently results in impaired oral hygiene, biofilm accumulation, and gingival inflammation. Increased prevalence of gingival infection and inflammation among patients with DIGO poses risk for their general health.[20,24,70] The inciting drugs are being replaced with alternatives, but they remain the drugs of choice in many countries for the treatment of specific conditions. Alternatives have also been linked to DIGO, and GO associated with medication use continues to be a clinical problem in dentistry and medicine.

Clinical Correlation

Anticonvulsants, calcium channel blockers, and immunosuppressants are prescribed to patients with serious health concerns such as epilepsy, hypertension, and solid organ transplantation, respectively. Drug-induced GO is a major dental problem due to impaired oral hygiene, biofilm accumulation, and gingival inflammation, and it poses a risk for the general health of these patients.

DIGO lesions usually develop fast and become chronic over time (Fig. 19.7). The first signs of overgrowth can be observed as early as 3 months of drug use as a localized nodular enlargement of the interdental papilla. Because most of the medications associated with DIGO are prescribed for an extended time, the lesions expand and in some cases cover the crowns of the teeth. Severe forms of DIGO may result in complete coverage of dental surfaces (Fig. 19.8). Clinically, there are subtle differences in how the lesions manifest depending on the type of medication used. Dental biofilm and bacterial infection frequently lead to inflamed tissues characterized by edema and bleeding (Fig. 19.9). The degree of fibrosis and inflammation depend on the dose, duration, and type of drug; oral hygiene; individual susceptibility, including genetic factors; and environmental influences.[104,106]

FIG. 19.9 Combined gingival enlargement resulted from the inflammatory involvement of a phenytoin-induced overgrowth.

Anticonvulsants

Phenytoin (diphenylhydantoinate) is the drug of choice for the treatment of grand mal, temporal lobe, and psychomotor seizures, and it has been linked to GO for more than 70 years.[68] Other anticonvulsant agents such as phenobarbital and valproic acid have been associated with GO less often than phenytoin.[62,87] The estimated prevalence of phenytoin-induced GO is about 50%.[22] Clinical onset occurs as early as 1 month, and increasing severity is seen in 12 to 18 months.[1,14,29]

Phenytoin-induced GO lesions frequently occur on the anterior buccal maxilla and mandible, and the entire dentition can be

covered in severe cases.[19,63] Phenytoin-induced GO is characterized by enlargement of interdental papillae and increased thickening of the marginal tissues,[4] causing aesthetic and functional problems, such as malpositioning of teeth, difficulty in speech, and impaired oral hygiene.[82]

Calcium Channel Blockers

Calcium channel blockers are a group of drugs commonly used to treat hypertension, angina pectoris, coronary artery spasm, and cardiac arrhythmia.[68] Benzothiazepine derivatives (e.g., diltiazem), phenylalkylamine derivatives (e.g., verapamil), and dyhydropyridines (e.g., amlopidine, felodipine, isradipine, nicardipine, nifedipine, nitrendipine, oxodipine, nimodipine, nisoldipine) are different types of calcium channel blockers that have been associated with some degree of DIGO.[13,15,17,28,64,71,94]

The first case of GO associated with the calcium channel blocker nifedipine was reported in 1984.[85] Among patients taking the medication, the prevalence of nifedipine-induced GO is highly variable, ranging from 6% to 83%.[7,36,37,98] Clinically, interdental papillae are affected, and overgrowth is limited to attached and marginal gingiva, which usually is observed on the anterior segments.[92] Nifedipine-induced GO can coexist with periodontitis and attachment loss that is different from other forms of DIGO.

Immunosuppressants

Cyclosporin A has been the immunosuppressant of choice for preventing rejection of solid organ and bone marrow transplants and for treatment of autoimmune conditions.[45] The prevalence of cyclosporin A–induced GO has been reported to be about 30% but it can be much higher, especially for pediatric populations.[58]

The first case of cyclosporin A–induced GO was reported in 1983.[86] Clinically, the lesions are more inflamed and bleed more than other forms of DIGO, and they commonly are limited to buccal surfaces. Severity of the lesions can be similar to those of phenytoin and nifedipine. They affect the entire dentition and interfere with occlusion, mastication, and speech.[38]

Histopathology

Lesions from different types of DIGO demonstrate significant histologic variations.[106] GO biopsies from patients undergoing treatment with phenytoin show a thick, stratified squamous epithelium with long, thin rete pegs extending deep into the connective tissue.[3,19,33] Fibrosis with minimal inflammatory cell infiltration is a common finding.[105] The histologic characteristics of GO induced by calcium channel blockers are similar to phenytoin-induced lesions, including epithelial thickness, rete peg formation, and excessive matrix accumulation (Fig. 19.10).

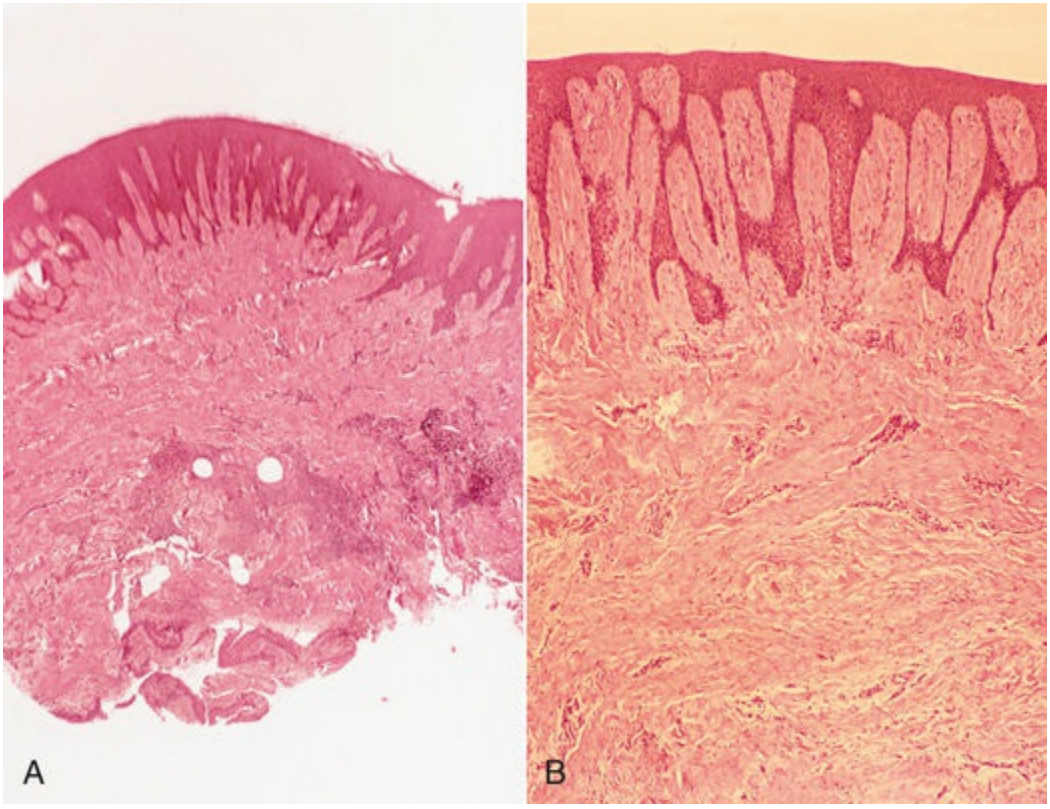

FIG. 19.10 Microscopic view of gingival enlargement associated with phenytoin therapy. (A) Hyperplasia and acanthosis of the epithelium and densely collagenous connective tissue are seen with evidence of inflammation in the area adjacent to the gingival sulcus. (B) High-power view shows extension of deep rete pegs into the connective tissue.

Cyclosporin A induced–GO also manifests with a thickened epithelium, rete peg formation, and irregular collagen fibers. These lesions, however, are characterized with more inflammatory

infiltration and vascularization compared with phenytoin and calcium channel blockers (Fig. 19.11; see Fig. 19.10).[86]

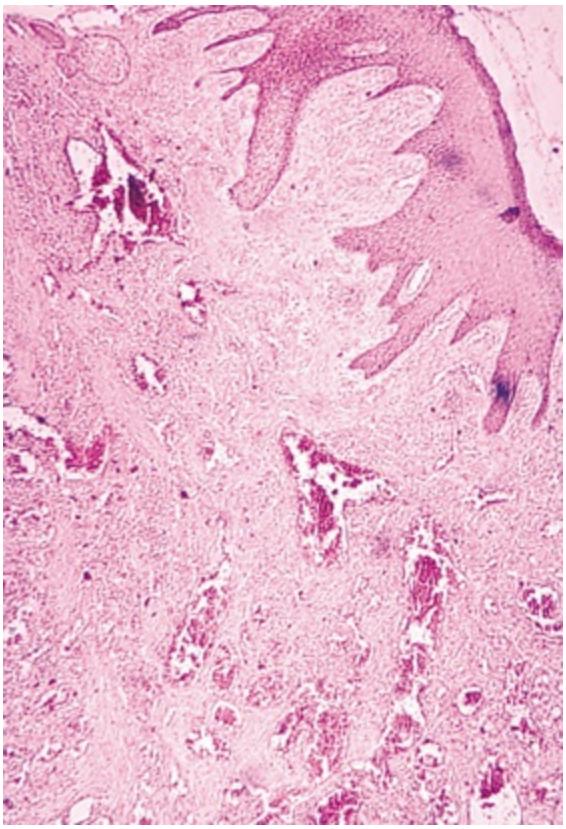

FIG. 19.11 Microscopic view of cyclosporine-associated gingival enlargement.

Key Fact

Different types of DIGO lesions demonstrate a thick, stratified squamous epithelium with long, thin rete pegs extending deep into the connective tissue. Fibrosis is a common finding in patients with phenytoin-induced GO. Histologic characteristics of GO induced by calcium channel blockers are similar to those of phenytoin-induced lesions, including epithelial thickness, rete peg formation, and excessive matrix accumulation. Cyclosporin A–induced GO lesions have more inflammatory infiltration and increased vascularization compared with GO caused by phenytoin or calcium channel blockers.

Pathogenesis of Drug-Induced Gingival Overgrowth

The pathogenesis of DIGO is complex. The main mechanism is mediated through defective function of gingival fibroblasts. Because gingival fibroblasts are responsible for the matrix deposition of gingival tissues, extensive research has focused on these key cells and their function. Study findings vary, some pathways have not been validated in humans, and data are limited to in vitro and animal studies, but collectively the findings suggest that DIGO-associated medications affect the extracellular matrix metabolism by decreasing collagenase activity and increasing the production of matrix proteins.

Gingival fibroblasts from phenytoin-induced GO are characterized by elevated levels of collagen synthesis.[46] It has been suggested that fibroblasts may be susceptible to the development of DIGO.[46] Gingival fibroblasts from nifedipine-induced GO lesions have defective collagen production due to decreased levels of collagenase activity, which can result in collagen deposition.[103] Through interference with calcium metabolism, calcium channel blockers decrease calcium levels in gingival fibroblasts and T cells, thereby affecting T-cell proliferation or activation and collagen biosynthesis.[7,103]

Cyclosporin A directly impairs collagen synthesis by gingival fibroblasts,[67] with a concomitant rise in the levels of type I collagen.[90] Cyclosporin A also decreases expression of matrix metalloproteinase-1 (MMP-1) and MMP-3.[12] In addition to collagen, which is the major extracellular matrix component of gingival tissues, noncollagenous matrix is affected by the medications that result in DIGO. Glycosaminoglycan metabolism is impaired in patients with phenytoin-induced GO[32] and in response to cyclosporin A treatment of gingival fibroblasts.[76]

In addition to fibroblast metabolism and function, inflammatory regulation of tissue turnover is a major factor in DIGO pathogenesis. Fibroblast functions such as proliferation, differentiation, and production of extracellular matrix are affected by levels of cytokines and growth factors. GO lesions are characterized by increased levels of interleukin-6 (IL-6), IL-1β, platelet-derived growth factor subunit B (PDGFB), fibroblast growth factor 2 (FGF2), transforming growth factor-β (TGF-β), and

connective tissue growth factor (CTGF).[6,16,31,48,50,73,75,83,88,89,106,108] Macrophages are the main source of these cytokines.[18,23,30,34,80]

The TGF-β1–CTGF axis has been characterized in detail and is an essential mechanism leading to DIGO. TGF-β1 regulates cell proliferation and differentiation and can activate gene expression for the synthesis of extracellular matrix components, including collagen in cyclosporin A–induced GO.[53,88] TGF-β1 induces CTGF mRNA and protein expression in human gingival fibroblasts; the TGF-β1–CTGF pathway directly regulates fibrosis, gingival fibroblast lysyl oxidase, and collagen generation.[48] CTGF expression is increased in all forms of DIGO, with the highest levels occurring in phenytoin-induced GO, which also has the highest levels of fibrosis.[106]

CTGF expression is not limited to the connective tissue. It also is demonstrated in the gingival epithelium, predominantly in the basal epithelial cells close to the connective tissue border.[55] In vitro studies showed that CTGF could be produced by gingival epithelial cells,[55] illustrating a possible mechanism of fibrosis in gingiva, which may be related to crosstalk between epithelial and connective tissue cells. Studies revealed a unique mechanism for TGF-β1–induced CTGF expression in gingival fibroblasts regulated by prostaglandin E_2, cAMP, mitogen-activated protein kinases (MAPKs), and activation of Jun N-terminal kinases (JNKs).[11]

A key event in the pathogenetic mechanism of DIGO is some degree of epithelial-mesenchymal transition induced by medications. Highly fibrotic tissues are characterized by increased epithelial-mesenchymal transition, through which epithelial cells in the gingiva acquire fibroblast function, and the process is regulated by CTGF.[100] The molecular pathways of DIGO have been reviewed elsewhere.[105]

Treatment

DIGO cannot be prevented by conventional approaches, but it can be ameliorated by elimination of local factors, plaque control, and regular periodontal maintenance. The most effective treatment of DIGO is withdrawal or substitution of medications. A case report showed resolution of gingival lesions in 1 to 8 weeks after discontinuing the medication.[57] For example, changing nifedipine to

another antihypertensive drug, isradipine, caused regression of gingival enlargement.[107] Tacrolimus, used as an alternative for cyclosporin A, resulted in regression of gingival enlargement.[52] However, most alternatives have also been linked to DIGO in recent years.

In addition to withdrawal or substitution of medication, scaling and root planing have given relief to patients with GO.[99] Nonsurgical treatment can eliminate the inflammatory component of DIGO, which can account for 40% of tissue enlargement.[56]

Because the anterior labial gingiva is frequently affected, surgery is commonly performed to solve aesthetic problems. Surgical elimination of DIGO lesions involves gingivectomy and gingivoplasty.[51] However, the recurrence rate is high; the recurrence rate for GO among patients taking cyclosporin A or nifedipine was approximately 40% 18 months after the surgery.[51]

Patients should be given oral hygiene instructions, and periodontal prophylaxis and removal of calculus should be done as needed during recall visits. New pharmacologic strategies, especially using animal models, are being explored.[5]

Clinical Correlation

DIGO cannot be prevented, but it can be ameliorated by elimination of local factors, plaque control, and regular periodontal maintenance. The most effective treatment for drug-induced gingival overgrowth is withdrawal or substitution of the medication. Nonsurgical treatment results in elimination of the inflammatory component of DIGO. Surgical elimination of DIGO lesions involves gingivectomy and gingivoplasty. The recurrence rate is high. Maintenance should include oral hygiene instructions, periodontal prophylaxis, and removal of calculus as needed.

Gingival Overgrowth Associated With Systemic Conditions

Changes in systemic conditions can lead to gingival enlargement. The causes and clinical features of GO associated with systemic

conditions are diverse and usually manifest with amplification of existing inflammation due to bacterial inflammation. These gingival pathologies are referred as *conditioned enlargements* and include lesions associated with hormonal and nutritional etiologic factors. Gingival inflammation due to microbial factors is a prerequisite that hormonal and nutritional changes modify, and some researchers classify these lesions as gingivitis-associated pathologies. However, pregnancy and puberty have been established as causes for hormonal changes. Nutritional factors are rare but have historically included deficits such as vitamin C deficiency. Likewise, allergic reactions may be linked to GO.

Pregnancy-Associated Gingival Overgrowth

Clinical Manifestations

GO is a common pathology in pregnancy. Clinically, it manifests as a single mass or multiple tumor-like masses at the gingival margin. Marginal gingival enlargement during pregnancy results from the aggravation of previous inflammation, and its incidence has been reported as 10% to 70%. Sometimes, the lesions can be observed as single enlargements, which are referred to as *pregnancy tumors*. Pregnancy tumors are not neoplasms; they represent an inflammatory response to microbial plaque modified by the patient's condition. It usually appears after the third month of pregnancy, but it may occur earlier. The reported incidence is 1.8% to 5%.[65]

Overall, pregnancy-associated GO manifests with a highly varied clinical picture. Enlargement is usually generalized, but it tends to be more prominent interproximally than on the facial and lingual surfaces. The enlarged gingiva is bright red or magenta, soft, and friable, and it has a smooth, shiny surface. Bleeding occurs spontaneously or on slight provocation. The lesion appears as a discrete, mushroom-like, flattened spherical mass that protrudes from the gingival margin or, more often, from the interproximal space, and it is attached by a sessile or pedunculated base (Fig. 19.12). It tends to expand laterally, and pressure from the tongue and the cheek perpetuates its flattened appearance. It is dusky red or magenta; it has a smooth, glistening surface that often exhibits

numerous deep red, pinpoint markings.

FIG. 19.12 Localized gingival enlargement in a 27-year-old, pregnant patient.

The superficial lesion of pregnancy-associated GO usually does not invade the underlying bone. The mass is usually firm, but it may have various degrees of softness and friability. It is usually painless unless its size and shape foster the accumulation of debris under its margin or interfere with occlusion, in which case painful ulceration may occur. Although the microscopic findings are characteristic of gingival enlargement during pregnancy, they are not pathognomonic.

Pyogenic granuloma is similar in clinical and microscopic appearance to the gingival enlargement seen during pregnancy. This lesion manifests as a tumor-like gingival enlargement that is considered to be an exaggerated response to minor trauma (Fig. 19.13). The exact nature of the systemic conditioning factor has not been identified. The differential diagnosis is based on the patient's history.[9]

FIG. 19.13 Pyogenic granuloma. (Courtesy Dr. Silvia Oreamuno, San Jose, Costa Rica.)

Etiology

Hormonal changes have always been linked to pathology in periodontal tissues. For example, progesterone and estrogen levels increase 10 to 30 times by the end of the third trimester compared with the menstrual cycle.[2] Although mechanistic evidence is lacking, it is hypothesized that these hormonal changes induce an increased vascular permeability, which leads to gingival edema and an increased inflammatory response to dental plaque. During this process, the impaired vascular response and inflammatory milieu can lead to modification of the subgingival microbiota. Although not specific, an increased presence of *Prevotella intermedia, Prevotella melaninogenica,* and *Porphyromonas gingivalis* has been linked to pregnancy-associated GO in vivo and in vitro,[60,61,84] demonstrating that the lesions have strong infectious associations.

Histopathology

Gingival enlargement in pregnancy is called *angiogranuloma,* referring to its strong clinical presentation with vascular changes and fibrotic process. Marginal and tumor-like enlargements consist of a central mass of connective tissue, with numerous diffusely arranged, newly formed, and engorged capillaries lined by cuboid endothelial cells (Fig. 19.14) and of a moderately fibrous stroma with various degrees of edema and chronic inflammatory infiltrate. The stratified squamous epithelium is thickened, with prominent rete pegs and some degree of intracellular and extracellular edema, prominent intercellular bridges, and leukocytic infiltration.

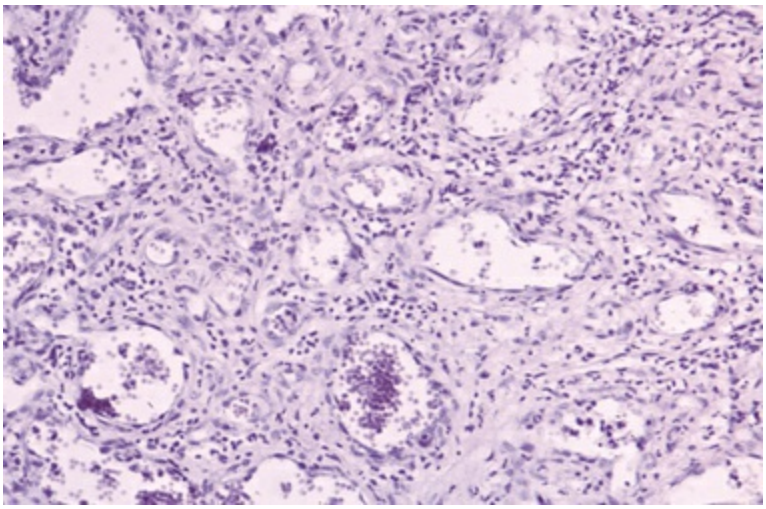

FIG. 19.14 Microscopic view of gingival enlargement in a pregnant patient.

Treatment

Similar to other forms of gingival changes associated with hormonal variations during pregnancy, GO lesions can be prevented by good oral hygiene. Oral care in pregnant women should be meticulous, and patients should be treated by removal of plaque and calculus. Severe cases may require removal during the second trimester; however, removal of the GO lesions without establishment of an optimal oral hygiene regimen ensures recurrence of gingival enlargement. Although spontaneous reduction in the size of gingival enlargement typically follows the termination of pregnancy, complete elimination of the residual inflammatory lesion and GO requires removal of all plaque deposits, elimination of factors that favor its accumulation, and in some fibrotic cases, surgical intervention.

Treatment of pyogenic granuloma consists of the removal of the lesions and the elimination of irritating local factors. The recurrence rate of pyogenic granuloma is about 15%.

Puberty-Associated Gingival Overgrowth

Clinical Manifestations

Enlargement of the gingiva is sometimes seen during puberty. The lesions are not specific to female gender; they occur in male and female adolescents. Clinically, there is a strong association with

plaque accumulation. The lesions are usually marginal and interdental, and they are characterized by prominent bulbous interproximal papillae (Fig. 19.15). Often, only the facial gingivae are enlarged, and the lingual surfaces are relatively unaltered. The mechanical action of the tongue and the excursion of food prevent a heavy accumulation of local irritants on the lingual surface.

FIG. 19.15 Conditioned gingival enlargement during puberty.

Etiology

Gingival enlargement during puberty has all of the clinical features that are associated with chronic inflammatory gingival disease. The degree of enlargement and its tendency to recur in the setting of relatively scant plaque deposits distinguish puberty-associated GO from purely gingivitis-associated lesions, suggesting a profound impact by the hormonal changes. The incidence of puberty-associated GO lesions decline with age,[101] further supporting the role of hormonal changes during puberty.

Studies of the subgingival microbiota of children between the ages of 11 and 14 years and their association with clinical parameters implicated *Capnocytophaga* species in the initiation of pubertal gingivitis.[40,72] Other studies have reported that hormonal changes coincide with an increase in the proportion of *Prevotella intermedia* and *Prevotella nigrescens*.[74,110] The etiologic role of the changes in microbiota, however, is not clear. It is not known whether changes in inflammatory conditions predispose to a shift in microbial species.

Histopathology

The microscopic appearance of gingival enlargement during puberty is one of chronic inflammation with prominent edema. It cannot be distinguished from other forms of gingivitis-associated GO lesions.

Treatment

After puberty, enlargement undergoes spontaneous reduction, but it does not disappear completely until the plaque and calculus are removed.

Nutrition-Associated Gingival Overgrowth

Malnutrition has been historically associated with several oral lesions. GO has been observed in cases of chronic vitamin C deficiency in patients with scurvy. These lesions are no longer common, but GO is still considered a part of the classic description of scurvy.

Clinical Manifestations

Gingival enlargement with vitamin C deficiency is marginal. The gingiva is bluish red, soft, and friable, and it has a smooth, shiny surface. Hemorrhage that occurs spontaneously or on slight provocation and surface necrosis with pseudomembrane formations are common features.

Etiology

Acute vitamin C deficiency alone does not cause gingival inflammation, but it does cause hemorrhage, collagen degeneration, and edema of the gingival connective tissue. These changes modify the response of the gingiva to plaque to the extent that the normal defensive delimiting reaction is inhibited and the extent of the inflammation is exaggerated, thereby resulting in the massive gingival enlargement seen in patients with scurvy (Fig. 19.16).

FIG. 19.16 Gingival enlargement in a patient with vitamin C deficiency. (Courtesy Dr. Gerald Shklar, Boston, MA.)

Histopathology

In patients with vitamin C deficiency, the gingiva has a chronic inflammatory cellular infiltration with a superficial acute response. There are scattered areas of hemorrhage with engorged capillaries. Marked diffuse edema, collagen degeneration, and a scarcity of collagen fibrils and fibroblasts are striking findings.

Treatment

Nutrition-associated GO lesions are rare. Changes in nutrition accompanied by nonsurgical treatment and good oral hygiene usually result in complete resolution of the pathology. In rare cases, surgical removal may be indicated.

Gingival Overgrowth Associated With Systemic Diseases

GO may be linked to various systemic diseases. Although uncommon and occurring with different etiopathogenetic mechanisms, the GO associated with systemic diseases can be linked to serious issues in clinical management. These lesions should be carefully diagnosed.

Leukemia-Associated Gingival Overgrowth

Clinical Manifestations

Leukemic gingival enlargement can be diffuse or marginal and localized or generalized. It can appear as a diffuse enlargement of the gingival mucosa, an oversized extension of the marginal gingiva (Fig. 19.17), or a discrete tumor-like interproximal mass. In patients with leukemic enlargement, the gingiva is bluish red, and it has a shiny surface. The consistency is moderately firm, but there is a tendency toward friability and hemorrhage that occur spontaneously or with slight irritation.

FIG. 19.17 Leukemia-associated gingival enlargement

(Courtesy Dr. Spencer Wolfe, Dublin, Ireland.)

Acute painful necrotizing ulcerative inflammatory involvement can occur in the crevice formed at the junction of the enlarged gingiva and the contiguous tooth surfaces. Patients with leukemia may also have a simple chronic inflammation without the involvement of leukemic cells, and they can have the same clinical and microscopic features seen in patients without the systemic disease. Most cases, however, have features of simple chronic inflammation and leukemic infiltrate. True leukemic enlargement often occurs with acute leukemia, but it may also be seen with subacute leukemia. It seldom occurs with chronic leukemia.

Histopathology

Gingival enlargements in leukemic patients show various degrees of chronic inflammation. Mature leukocytes are seen along with areas of connective tissue that are infiltrated with a dense mass of

immature and proliferating leukocytes, the specific nature of which varies with the type of leukemia. Engorged capillaries, edematous and degenerated connective tissue, and epithelium with various degrees of leukocytic infiltration and edema are found. Isolated surface areas of acute necrotizing inflammation with a pseudomembranous meshwork of fibrin, necrotic epithelial cells, polymorphonuclear leukocytes, and bacteria are often seen.

Wegener Granulomatosis

Clinical Manifestations

Wegener granulomatosis is a rare disease that is characterized by acute granulomatous necrotizing lesions of the respiratory tract, including nasal and oral defects. Renal lesions develop, and acute necrotizing vasculitis affects the blood vessels. The initial manifestations of Wegener granulomatosis can involve the orofacial region and include oral mucosal ulceration, gingival enlargement, abnormal tooth mobility, exfoliation of teeth, and a delayed healing response. The granulomatous papillary enlargement is reddish purple and bleeds easily on stimulation (Fig. 19.18).

FIG. 19.18 Wegener granulomatosis affecting the gingival tissue.

Etiology

The cause of Wegener granulomatosis is unknown, but the condition is considered an immunologically mediated tissue injury. At one time the usual outcome for patients with this condition was

death from kidney failure within a few months, but more recently the use of immunosuppressive drugs has produced prolonged remissions in more than 90% of patients.

Histopathology

Chronic inflammation involves scattered giant cells, foci of acute inflammation, and microabscesses covered by a thin, acanthotic epithelium. Vascular changes have not been described with gingival enlargement in patients with Wegener granulomatosis, probably because of the small size of the gingival blood vessels.

Sarcoidosis

Clinical Manifestations

Sarcoidosis is a granulomatous disease of unknown etiology. It starts in individuals during their 20s or 30s, it predominantly affects blacks, and it can involve almost any organ, including the gingiva, in which a red, smooth, painless enlargement may appear.

Histopathology

Sarcoid granulomas consist of discrete epithelioid cells and multinucleated, foreign body–type giant cells with peripheral mononuclear cells.

Gingival Fibromatosis

Clinical Manifestations

Gingival fibromatosis can be hereditary or idiopathic. These lesions are rare and occur in highly fibrotic forms of GO.[39,109] Hereditary gingival fibromatosis is the most common form, and it has been linked to several genetic loci.[8,26,42,43,96,112,113] Idiopathic gingival enlargement is a rare condition of undetermined cause.

The enlargement affects the attached gingiva, the gingival margin, and the interdental papillae. The facial and lingual surfaces of the mandible and maxilla usually are affected, but the involvement may be limited to either jaw. The enlarged gingiva is pink, firm, and almost leathery in consistency, and it has a

characteristic minutely pebbled surface (Fig. 19.19). In severe cases, the teeth are almost completely covered, and the enlargement projects into the oral vestibule. The jaws appear distorted because of the bulbous enlargement of the gingiva. Secondary inflammatory changes are common at the gingival margin.

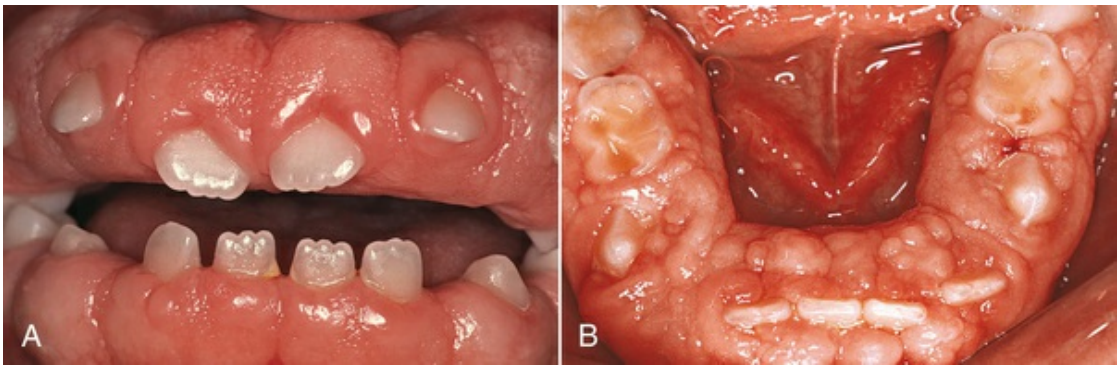

FIG. 19.19 **Idiopathic gingival enlargement. (A) Facial view. (B) Occlusal view of the mandibular arch.**

Etiology

The genetic basis of hereditary gingival fibromatosis is well established, with different populations having different genetic loci and specific genes.[27,41,44,49,69,77,79,97,114,115] In some families, gingival enlargement is linked to the impairment of physical development. Other syndromes are sometimes colocalized with gingival fibromatosis.[47,66] Idiopathic forms of gingival fibromatosis have not been linked to specific genes, and the condition is designated as idiopathic.

Key Fact

The genetic basis of hereditary gingival fibromatosis is well established. In some families, gingival enlargement is linked to impairment of physical development. Other syndromes can coexist with gingival fibromatosis. Idiopathic forms of gingival fibromatosis have not been linked to any specific genes.

Although the genes associated with lesions of hereditary forms

have been identified, the pathogenetic mechanisms linked to these genetic factors are not fully understood. Enlargement usually begins with the eruption of the primary or secondary dentition, and it may regress after extraction, which suggests that the teeth or the plaque attached to them may be initiating factors. The presence of bacterial plaque is a complicating factor. Gingival enlargement has been described in tuberous sclerosis, which is an inherited condition characterized by the triad of epilepsy, mental deficiency, and cutaneous angiofibromas.

Histopathology

In cases of GO with fibromatosis, the lesions are highly fibrotic, with a bulbous increase in connective tissue that is relatively avascular and consists of densely arranged collagen bundles and numerous fibroblasts. The surface epithelium is thickened and acanthotic, with elongated rete pegs.[21,54,55] Histopathology is similar to phenytoin-induced GO with low levels of inflammatory infiltration. However, collagen bundle formation, dominance, and orientation are distinctive in areas where cellular structures are reduced.[21]

Treatment

Treatment of GO lesions manifesting as gingival fibromatosis requires gingivectomy and gingivoplasty. Clinical management is difficult because of the high recurrence rate, and the severity of lesions usually results in extreme crowding and misalignment of teeth. After removal of the fibromatosis lesions, patients may require orthodontic treatment.[25]

Other Forms of Gingival Enlargement

Multiple forms of gingival enlargement have various causes. In addition to the types of GO previously discussed in this chapter, the gingiva can be enlarged due to increases in the size of the underlying osseous and dental tissues. These *false enlargements* usually have no abnormal clinical features except for the massive increase in the size of the area. For example, enlargement of the bone subjacent to the gingival area occurs most often with tori and

exostoses, but it can also occur with Paget disease, fibrous dysplasia, cherubism, central giant cell granuloma, ameloblastoma, osteoma, and osteosarcoma.

The gingival tissue can appear normal, or it can have unrelated inflammatory changes. Likewise, during the various stages of eruption, particularly of the primary dentition, the labial gingiva can have a bulbous marginal distortion caused by superimposition of the bulk of the gingiva on the normal prominence of the enamel in the gingival half of the crown. This enlargement is called *developmental enlargement,* and it often persists until the junctional epithelium has migrated from the enamel to the cementoenamel junction.

In a strict sense, developmental gingival enlargements are physiologic, and they usually present no problems for patients. However, when the enlargement is complicated by marginal inflammation, the composite picture gives the impression of extensive gingival enlargement (Fig. 19.20).

FIG. 19.20 Developmental gingival enlargement.

Neoplastic formations in gingival tissues can be clinically confused with fibrotic enlargements of gingiva. Oral cancer accounts for less than 3% of all malignant tumors in the body, but it is the 6th most common cancer in males and the 12th most common in females. The gingiva is not a common site of oral malignancy, accounting for only 6% of oral cancers.

Epulis is a generic term that is used to clinically designate all discrete tumors and tumor-like masses of the gingiva. It serves to

locate the tumor but does not describe it. Most lesions referred to by this term are inflammatory rather than neoplastic. For example, fibromas arise from the gingival connective tissue or from the periodontal ligament. They are slow-growing, spherical tumors that tend to be firm and nodular but that may be soft and vascular. Fibromas are usually pedunculated. Hard fibromas of the gingiva are rare; most of the lesions that are diagnosed clinically as fibromas are inflammatory enlargements.

Histopathologic review of fibromas demonstrates bundles of well-formed collagen fibers with scattered fibrocytes and various degrees of vascularity. The so-called giant cell fibroma contains multinucleated fibroblasts. In another variant, mineralized tissue (i.e., bone, cementum-like material, and dystrophic calcifications) can be found; this type of fibroma is called *peripheral ossifying fibroma.*

Similar to fibromas, papillomas are benign proliferations of surface epithelium that are in many cases associated with human papillomavirus (HPV) infection. Gingival papillomas appear as solitary wartlike or cauliflower-like protuberances (Fig. 19.21). They can be small and discrete, or they can be broad, hard elevations with minutely irregular surfaces. The lesions consist of finger-like projections of stratified squamous epithelium that are often hyperkeratotic, with central cores of fibrovascular connective tissue.

FIG. 19.21 Papilloma of the gingiva.

Peripheral giant cell granulomas of the gingiva arise interdentally or from the gingival margin. They occur most frequently on the

labial surface, and they can be sessile or pedunculated. They vary in appearance from smooth, regularly outlined masses to irregularly shaped, multilobulated protuberances with surface indentations (Fig. 19.22). Ulceration of the margin is occasionally seen. The lesions are painless, vary in size, and can cover several teeth. They can be firm or spongy, and their color varies from pink to deep red or purplish blue.

FIG. 19.22 Gingival giant cell granuloma.

Clinically, peripheral giant cell granulomas cannot be easily differentiated from other forms of gingival enlargement. Microscopic examination is required for definitive diagnosis. The word *peripheral* is needed to differentiate them from comparable lesions that originate within the jawbone (i.e., central giant cell granulomas). In some cases, the giant cell granuloma of the gingiva is locally invasive and causes destruction of the underlying bone (Fig. 19.23A). Complete removal leads to uneventful recovery. The lesion has numerous foci of multinuclear giant cells and hemosiderin particles in a connective tissue stroma (see Fig. 19.23B). Areas of chronic inflammation are scattered throughout the lesion, with acute involvement occurring at the surface. The overlying epithelium is usually hyperplastic, with ulceration at the base. Bone destruction occasionally occurs within the lesion (Fig. 19.24).

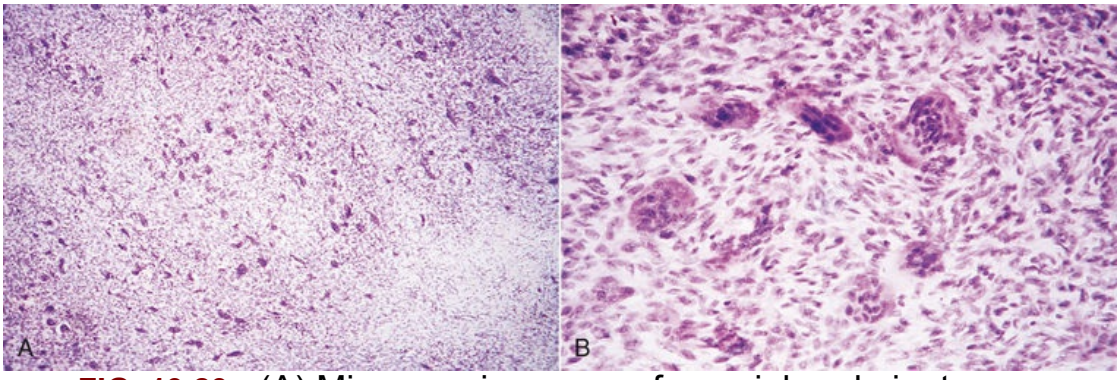

FIG. 19.23 (A) Microscopic survey of a peripheral giant cell granuloma. (B) High-power microscopic study of the lesion demonstrates the giant cells and the intervening stroma.

FIG. 19.24 Bone destruction in the interproximal space between the canine and the lateral incisor is caused by the extension of a peripheral giant cell reparative granuloma of the gingiva. (Courtesy Dr. Sam Toll.)

Gingival cysts of microscopic proportions are common, but they seldom reach a clinically significant size. When they do, they appear as localized enlargements that may involve the marginal and attached gingiva. The cysts occur in the mandibular canine and premolar areas, most often on the lingual surface. They are painless,

but with expansion they can cause erosion of the surface of the alveolar bone. The gingival cyst should be differentiated from the lateral periodontal cyst, which arises within the alveolar bone adjacent to the root and which is developmental in origin. Gingival cysts develop from odontogenic epithelium or from surface or sulcular epithelium traumatically implanted in the area. Removal is followed by uneventful recovery.

A gingival cyst cavity is lined by a thin, flattened epithelium with or without localized areas of thickening. Less frequently, the following types of epithelium can be found: unkeratinized stratified squamous epithelium, keratinized stratified squamous epithelium, and parakeratinized epithelium with palisading basal cells.

Squamous cell carcinoma is the most common malignant tumor of the gingiva. It may be *exophytic*, manifesting as an irregular outgrowth, or *ulcerative*, appearing as a flat, erosive lesion. It is often symptom free, going unnoticed until complicated by inflammatory changes that can mask the neoplasm but cause pain; it sometimes becomes evident after tooth extraction. These masses are locally invasive, and they involve the underlying bone and periodontal ligament of adjoining teeth and the adjacent mucosa (Fig. 19.25). Metastasis is usually confined to the region above the clavicle; however, involvement that is more extensive can include the lung, liver, or bone.

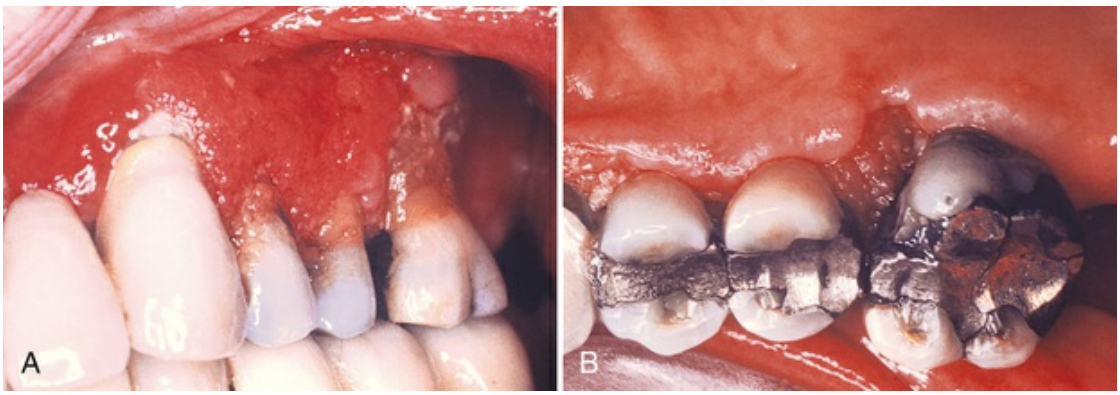

FIG. 19.25 Squamous cell carcinoma of the gingiva. (A) Facial view shows extensive verrucous involvement. (B) Palatal view shows mulberry-like tissue emerging between the second premolar and the first molar.

Malignant melanoma is a rare oral tumor that tends to occur in

the hard palate and maxillary gingiva of older persons. It is usually darkly pigmented, and it is often preceded by localized pigmentation. It can be flat or nodular, and it is characterized by rapid growth and early metastasis. It arises from melanoblasts in the gingiva, cheek, or palate. Infiltration into the underlying bone and metastasis to cervical and axillary lymph nodes are common.

Fibrosarcoma, lymphosarcoma, and reticulum cell sarcoma of the gingiva are rare; only isolated cases have been described in the literature. Kaposi sarcoma often occurs in the oral cavity, particularly in the palate and the gingiva, of patients with acquired immunodeficiency syndrome. Tumor metastasis to the gingiva occurs infrequently.

The low incidence of oral malignancy should not mislead the clinician. Ulcerations that do not respond to therapy in the usual manner and all gingival tumors and tumor-like lesions must be biopsied and submitted for microscopic diagnosis.

In most clinical cases of GO, the clinical appearance is complicated by inflammation, bleeding, and swelling, which further creates difficulty in identifying the cause and pathologic process. A thorough knowledge of GO and the patient's systemic and oral medical histories are critical for designing the treatment and maintaining outcomes. Because some GO forms are linked to systemic and severe diseases, this approach is also essential for securing the patient's safety before treatment is initiated.

Case Scenario 19.1

Patient:
25-year-old female

Chief Complaint:
“My teeth move, and my gums are swollen.”

Background Information
Patient does not receive any antiepileptic, antihypertensive, or immunosuppressive medications known to cause fibrotic changes in the gingiva. Possible systemic diseases such as leukemia were ruled out after consultation with the referring physician and based

on laboratory analyses of peripheral blood. Local factors, such as mouth breathing or overhanging restorations, are not contributory.

Current Findings:

Intraoral examination reveals moderate to severe gingival overgrowth, particularly in the maxillary and mandibular anterior areas. Significant and generalized periodontal probing depths and severe generalized bone loss were observed. Available immediate family members of the patient, her mother and her brother, were examined; both exhibited clinically significant gingival overgrowth. In addition to overgrowth, the patient's brother had significant bone loss around incisors and first molars. A family pedigree is created.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the preliminary diagnosis for gingival overgrowth? A. Drug-induced gingival overgrowth B. Hereditary gingival fibromatosis C. Idiopathic gingival overgrowth	**Answer: B** **Explanation:** Hereditary gingival fibromatosis is a non–drug-induced fibrotic form of gingival overgrowth with strong familial linkage.
2. Considering the age, clinical findings, and extent of bone loss, what is the preliminary diagnosis for periodontitis? A. Aggressive periodontitis B. Chronic periodontitis	**Answer: A** **Explanation:** Extent of bone loss is severe and suggests that periodontal bone loss is aggressive.
3. What would the treatment plan include for long-term maintenance of outcomes?	**Answer: F** **Explanation:** This is a complex case of hereditary gingival fibromatosis and aggressive periodontitis.

A. Surgical removal of overgrowth B. Regenerative treatment C. Anti-infective treatment D. Orthodontic treatment E. Implants F. All of the above	Treatment outcomes should be maintained by a multidisciplinary approach.

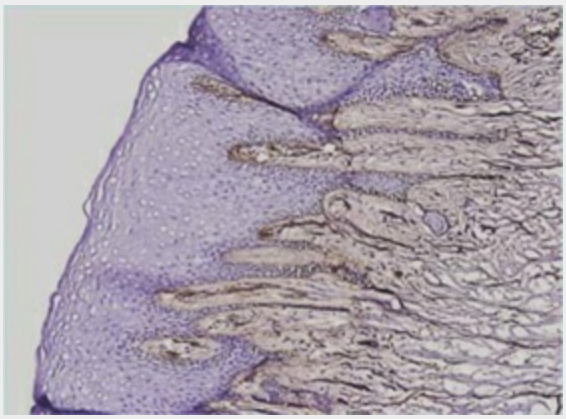
Case Scenario 19.2

Patient:
37-year-old male

Chief Complaint:
"My gums are swollen, and I can't eat anything. I can't see my teeth."

Background Information:
Patient was diagnosed with epilepsy and has been using phenytoin for grand mal seizures. He does not smoke and does not have any other systemic condition. He had minor restorative procedures (i.e., occlusal fillings).

Current Findings:
Intraoral examination revealed extensive gingival overgrowth in the maxillary and mandibular anterior segments. Gingival tissues were minimally inflamed with minimal plaque. There are pseudopockets of 4 to 6 mm with no sign of bone loss. Patient was treated with gingivectomy and gingivoplasty, and tissue biopsies were obtained for histologic analysis. Patient has follow-up visits every 6 months.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Which of the following is the major finding in histopathology? A. Extensive inflammatory cell infiltration B. Collagen fiber bundles and fibroblast	**Answer: B** **Explanation:** Phenytoin-induced gingival overgrowth is characterized by increased fibrosis and a low level of inflammatory cell infiltration.
2. Which of the following is true for the epithelial layer? A. Thick and stratified squamous tissue B. Long and thin rete pegs extending deep into the connective tissue C. All of the above	**Answer: C** **Explanation:** The epithelial layer of the gingiva demonstrates thickening with rete peg extensions, which is thought to be associated with the epithelial-mesenchymal transition.

CHAPTER 20

Acute Gingival Infections

Perry R. Klokkevold, Fermin A. Carranza

CHAPTER OUTLINE

Necrotizing Ulcerative Gingivitis
Primary Herpetic Gingivostomatitis
Pericoronitis
Conclusions

Necrotizing Ulcerative Gingivitis

Necrotizing ulcerative gingivitis (NUG) is a microbial disease of the gingiva that most often occurs in an impaired host. It manifests with the characteristic clinical signs of necrosis and sloughing of the gingival tissues and may be accompanied by systemic symptoms.

Clinical Features

NUG has historically been identified as an acute disease. However, the term *acute* in this case is used as a clinical descriptor and not a

diagnosis because chronic forms of the disease do not exist. Although the acronym *ANUG* is frequently used, it is a misnomer.[60] A summary of acute periodontal lesions advocated the more simplified term, *necrotizing gingivitis,* rather than *necrotizing ulcerative gingivitis*, but the latter term continues to be used in this chapter.[29] Involvement can be limited to a single tooth or group of teeth, or it can be widespread throughout the mouth (Fig. 20.1).

FIG. 20.1 Necrotizing ulcerative gingivitis. (A) Typical punched-out papilla between the mandibular canine and lateral incisor is covered by a grayish white pseudomembrane. (B) More advanced case shows the destruction of the papillae, which results in an irregular marginal contour. (C) Typical lesions with spontaneous hemorrhage. (D) Generalized involvement of the papillae and the marginal gingiva with whitish necrotic lesions.

More advanced forms of necrotizing ulcerative disease can include destruction of the periodontal attachment apparatus, including bone,[41] especially in patients with long-standing disease or severe immunosuppression. When periodontal attachment loss and bone loss occurs, the condition is called *necrotizing ulcerative periodontitis* (NUP) (see Chapter 29).

History

NUG is characterized by a sudden onset of symptoms, sometimes occurring after an episode of debilitating disease or acute respiratory tract infection. A change in living habits, protracted work without adequate rest, poor nutrition, tobacco use, and psychological stress are common features of the patient's history.

Oral Signs

Characteristic lesions are punched-out, craterlike depressions at the crest of the interdental papillae that subsequently extend to the marginal gingiva and rarely to the attached gingiva and oral mucosa. The surface of the gingival crater is covered by a gray, pseudomembranous slough that is demarcated from the remainder of the gingival mucosa by a pronounced linear erythema (see Fig. 20.1A). In some cases, the lesions are denuded of the surface pseudomembrane, thereby exposing the gingival margin, which is red, shiny, and hemorrhagic. The characteristic lesions can progressively destroy the gingiva and the underlying periodontal tissues (see Fig. 20.1B).

Spontaneous gingival hemorrhage and pronounced bleeding after the slightest stimulation are additional characteristic clinical signs (see Fig. 20.1B and C). Other common signs include a fetid odor and increased salivation.

NUG can occur in otherwise disease-free mouths, or it can be superimposed on chronic gingivitis or periodontitis with periodontal pockets. However, NUG does not usually lead to periodontal pocket formation because the necrotic changes involve the gingival and junctional epithelium; healthy epithelium is needed for periodontal pocket deepening (see Chapter 23). Although the numbers are much less, spirochetes and fusiform bacilli are found on normal edentulous mucosa.[59]

Key Fact

Necrotizing ulcerative gingivitis can be superimposed on chronic periodontitis with pockets, but it does not usually lead to pocket formation because the necrotic changes involve the gingival and junctional epithelium.

Oral Symptoms

The lesions are extremely sensitive to touch, and the patient often complains of a constant radiating, gnawing pain that is intensified by eating spicy or hot foods and chewing. There is a metallic foul taste, and the patient is conscious of an excessive amount of pasty saliva.

Extraoral and Systemic Signs and Symptoms

Patients are usually ambulatory and have a minimum of systemic symptoms. Local lymphadenopathy and a slight elevation in temperature are common features of the mild and moderate stages of the disease. In severe cases, patients can have high fever, increased pulse rate, leukocytosis, loss of appetite, and general lassitude. Systemic reactions are more severe in children. Insomnia, constipation, gastrointestinal disorders, headache, and mental depression sometimes accompany the condition.

In rare cases, severe sequelae such as gangrenous stomatitis and noma have been described.[2,3,18,33] These patients are almost exclusively encountered in populations in developing countries, especially children with systemic disease or malnutrition.[18,29,60]

Clinical Course

The clinical course varies among individuals. The severity of NUG often diminishes without treatment, leading to a subacute stage with milder clinical symptoms. Some patients experience repeated remissions and exacerbations, and the condition can recur in previously treated patients. If untreated, especially in an immunocompromised host, NUG can lead to progressive destruction of the periodontium and gingival recession accompanied by an increase in the severity of systemic complications.[31,52]

Histopathology

Microscopically, the NUG lesion is a nonspecific acute necrotizing inflammation of the gingival margin that involves the stratified squamous epithelium and the underlying connective tissue. The

surface epithelium is destroyed and replaced by a meshwork of fibrin, necrotic epithelial cells, polymorphonuclear leukocytes (PMNs, predominantly neutrophils), and various types of microorganisms (Fig. 20.2). This is the zone that appears clinically as the surface pseudomembrane. At the immediate border of the necrotic pseudomembrane, the epithelium is edematous, and the individual cells exhibit various degrees of hydropic degeneration. PMNs infiltrate the intercellular spaces.

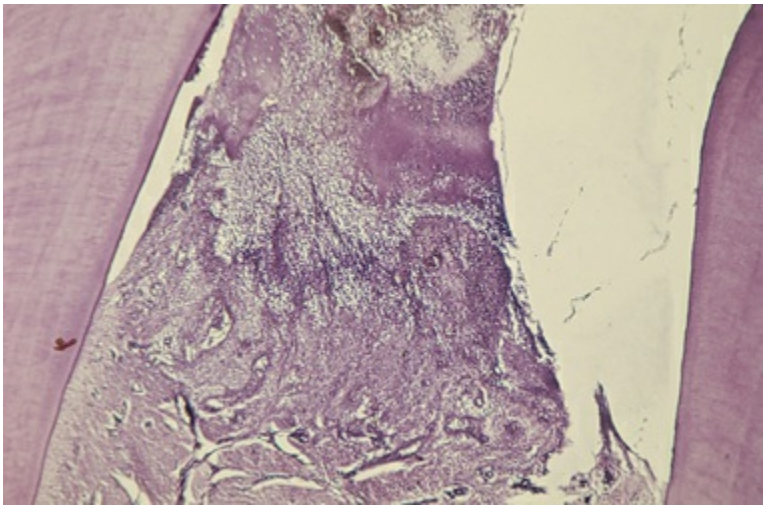

FIG. 20.2 In a survey section of interdental papilla in a patient with necrotizing ulcerative gingivitis, the necrotic tissue forms the gray marginal pseudomembrane *(top)*. Ulceration and the accumulation of leukocytes and fibrin replace normal epithelium *(bottom)*.

The underlying connective tissue is markedly hyperemic, with numerous engorged capillaries and a dense infiltration of PMNs. This acutely inflamed zone appears clinically as the linear erythema beneath the surface pseudomembrane. Numerous plasma cells can appear in the periphery of the infiltrate; this is interpreted as an area of established chronic gingivitis on which the acute lesion became superimposed.[30] The epithelium and connective tissue alterations decrease as the distance from the necrotic gingival margin increases, blending gradually with the uninvolved gingiva.

The microscopic appearance of tissues in a NUG lesion is nonspecific. Comparable changes result from trauma, chemical

irritation, or the application of caustic medications.

Relationship of Bacteria and the Necrotizing Ulcerative Gingivitis Lesion

Light and electron microscopy have been used to study the relationship of bacteria and the characteristic lesion of NUG. Light microscopy shows that the exudate on the surface of the necrotic lesion contains microorganisms that morphologically resemble cocci, fusiform bacilli, and spirochetes.[75] The layer between the necrotic and living tissue contains enormous numbers of fusiform bacilli and spirochetes in addition to leukocytes and fibrin. Spirochetes and other bacteria invade the underlying living tissue.[5,13,17,38]

Spirochetes have been found as deep as 300 μm from the surface. Most spirochetes in the deeper zones are morphologically different from cultivated strains of *Treponema microdentium.* They occur in nonnecrotic tissue before other types of bacteria, and they can achieve high intercellular concentrations in the epithelium and connective tissue adjacent to the ulcerated lesion.[37]

Smears from the lesions (Fig. 20.3) show scattered bacteria (predominantly spirochetes and fusiform bacilli), desquamated epithelial cells, and occasional PMNs. Spirochetes and fusiform bacteria are usually seen with other oral spirochetes, vibrios, and filaments.

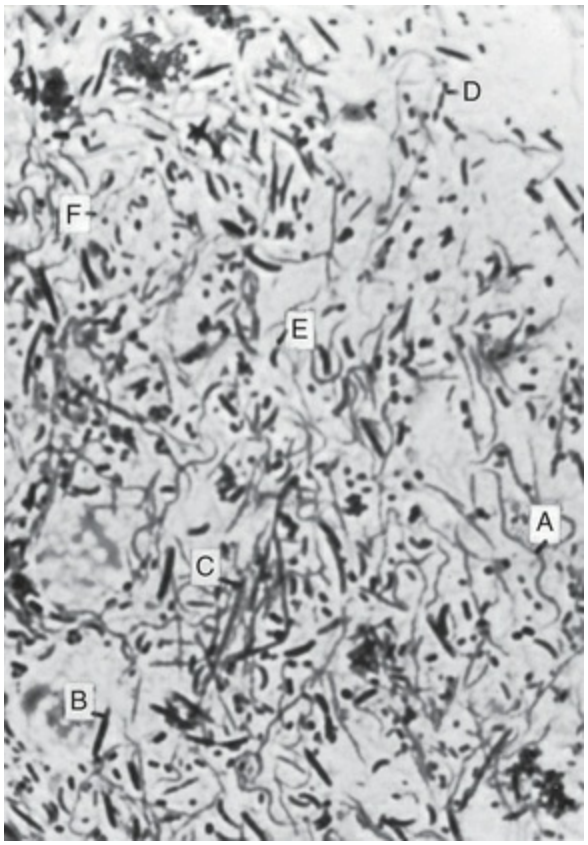

FIG. 20.3 A bacterial smear was obtained from a lesion in a patient with necrotizing ulcerative gingivitis. *A*, Spirochete. *B, Bacillus fusiformis. C*, Filamentous organism (i.e., *Actinomyces* or *Leptotrichia*). *D, Streptococcus. E, Vibrio. F, Treponema microdentium.*

Diagnosis

Diagnosis is based on clinical findings of gingival pain, ulceration, and bleeding. A bacterial smear is not necessary or definitive because the bacterial picture is not appreciably different from that of patients with marginal gingivitis, periodontal pockets, pericoronitis, or primary herpetic gingivostomatitis.[58] However, bacterial studies are useful for the differential diagnosis of NUG and specific infections of the oral cavity (e.g., diphtheria, thrush, actinomycosis, streptococcal stomatitis).

The microscopic examination of a biopsy specimen is not sufficiently specific to be diagnostic. It can be used to differentiate NUG from specific infections (e.g., tuberculosis) or from neoplastic disease, but it does not differentiate NUG from other necrotizing conditions of nonspecific origin, such as those produced by trauma

or caustic medications.

Key Fact

A bacterial smear or culture is not necessary or definitive in the diagnosis of NUG because the bacterial flora is not appreciably different from that of patients with other common inflammatory conditions (e.g., gingivitis, periodontitis). However, bacterial studies are useful for the differential diagnosis of NUG when specific infections of the oral cavity (e.g., diphtheria, thrush, actinomycosis, streptococcal stomatitis) are suspected.

Differential Diagnosis

NUG should be differentiated from other conditions that resemble it in some respects, such as herpetic gingivostomatitis (Table 20.1), chronic periodontitis, desquamative gingivitis (Table 20.2), streptococcal gingivostomatitis, aphthous stomatitis, gonococcal gingivostomatitis, diphtheritic and syphilitic lesions (Table 20.3), tuberculous gingival lesions, candidiasis, agranulocytosis, and dermatoses (e.g., pemphigus, erythema multiforme, lichen planus), and stomatitis venenata (see Chapter 22).

TABLE 20.1

Differentiation of Necrotizing Ulcerative Gingivitis and Primary Herpetic Gingivostomatitis

Necrotizing Ulcerative Gingivitis	Primary Herpetic Gingivostomatitis
Caused by interaction between host and bacteria, most often fusospirochetes	Caused by specific viral infection
Necrotizing condition	Diffuse erythema and vesicular eruption
Punched-out gingival margin; pseudomembrane that peels off and leaves raw areas	Vesicles that rupture and leave slightly depressed oval or spherical ulcer
Marginal gingiva affected; other oral tissues rarely affected	Diffuse involvement of gingiva; may include buccal mucosa and lips
Uncommon in children	Occurs more frequently in children
No definite duration	Duration of 7 to 10 days
No demonstrated immunity	Acute episode results in some degree of immunity
Contagion not demonstrated	Contagion

TABLE 20.2

Differentiation of Necrotizing Ulcerative Gingivitis, Chronic Desquamative Gingivitis, and Chronic Periodontal Disease

Necrotizing Ulcerative Gingivitis	Desquamative Gingivitis	Chronic Destructive Periodontal Disease
Bacterial smears show fusospirochetal complex	Bacterial smears reveal numerous epithelial cells and few bacterial forms	Bacterial smears vary
Marginal gingiva affected	Diffuse involvement of marginal and attached gingivae and other areas of oral mucosa	Marginal gingiva affected
Acute history	Chronic history	Chronic history
Painful	May or may not be painful	Painless if uncomplicated
Pseudomembrane	Patchy desquamation of gingival epithelium	Usually no desquamation, but purulent material may appear from pockets
Papillary and marginal necrotic lesions	Papillae do not undergo necrosis	Papillae do not undergo noticeable necrosis
Affects adults of both genders and occasionally affects children	Affects adults, most often women	Usually found in adults, occasionally found in children
Characteristic fetid odor	No odor	Some odor but not strikingly fetid

TABLE 20.3

Differentiation of Necrotizing Ulcerative Gingivitis, Diphtheria, and Secondary Stage of Syphilis

Necrotizing Ulcerative Gingivitis	Diphtheria	Secondary Stage of Syphilis (Mucous Patch)
Caused by interaction between host and bacteria, typically fusospirochetes	Caused by *Corynebacterium diphtheriae*	Caused by *Treponema pallidum*
Affects marginal gingiva	Rarely affects marginal gingiva	Rarely affects marginal gingiva
Membrane removal easy	Membrane removal difficult	Membrane not detachable
Painful condition	Less painful	Minimal pain
Marginal gingivae affected	Throat, fauces, and tonsils affected	Any part of mouth affected
Serologic findings normal	Serologic findings normal	Serologic findings abnormal[a]
Immunity not conferred	Immunity conferred by an attack	Immunity not conferred
Doubtful contagiousness	Contagious	Only direct contact can communicate disease
Antibiotic therapy relieves symptoms	Antibiotic treatment is effective	Antibiotic therapy has excellent results

[a]Wassermann test, Kahn test, and Venereal Disease Research Laboratories (VDRL)

test.

Treatment options for these diseases vary dramatically, and misdiagnosis and improper treatment can exacerbate the condition. In the case of primary herpetic gingivostomatitis, early diagnosis can result in treatment with antiviral drugs that would be ineffective for NUG, whereas the treatment of a case of herpes with the debridement required for NUG could exacerbate the herpes.

Streptococcal gingivostomatitis is a rare condition that is characterized by a diffuse erythema of the gingiva and other areas of the oral mucosa.[44] In some cases, it is confined as a marginal erythema with marginal hemorrhage. Necrosis of the gingival margin is not a feature of this disease, and there is no fetid odor. Bacterial smears show a preponderance of streptococcal forms, which were identified as *Streptococcus viridans,* but other studies report findings of group A β-hemolytic streptococci.[39]

Agranulocytosis is characterized by a marked decrease in the number of circulating PMNs, lesions of the throat and other mucous membranes, and ulceration and necrosis of the gingiva that can resemble that of NUG and that occurs most commonly after chemotherapy in cancer patients or in patients with leukemia. The oral condition of patients with agranulocytosis is primarily necrotizing, but it lacks the severe inflammatory reaction seen with NUG. Blood studies can differentiate between NUG and the gingival necrosis associated with agranulocytosis.

Vincent angina is a fusospirochetal infection of the oropharynx and throat that is distinguished from NUG, which affects the marginal gingiva. Patients with Vincent angina have a painful membranous ulceration of the throat, with edema and hyperemic patches breaking down to form ulcers that are covered with pseudomembranous material. The process can extend to the larynx and the middle ear.

NUG in leukemia patients results from the reduced host defense mechanisms that occur with the disease. NUG can be superimposed on the gingival tissue alterations caused by leukemia. The differential diagnosis does not require distinguishing between NUG and leukemic gingival changes; instead, it is determined whether leukemia is a predisposing factor in the mouth of a patient with NUG. For example, if a patient with necrotizing involvement of the

gingival margin also has diffuse discoloration and generalized edema of the attached gingiva, the possibility of an underlying systemically induced gingival change should be considered. Leukemia is one of the conditions that would need to be ruled out (see Chapter 14).

NUG in the patient with human immunodeficiency virus (HIV) infection has the same clinical features, although it often follows an extremely destructive course that leads to NUP, with a loss of soft tissue and bone and the formation of bony sequestra[26] (see Chapter 29).

Clinical Correlation

A serious systemic disease or condition such as leukemia or acquired immunodeficiency that renders the host immunocompromised can be the predisposing causative factor leading to acute gingival disease.

Etiology

Role of Bacteria

Plaut[54] in 1894 and Vincent[77] in 1896 postulated that NUG was caused by specific bacteria: fusiform bacilli and spirochetal organisms. Opinions still differ about whether bacteria are the primary causative factors of NUG. Several observations support this concept, including that spirochetal organisms and fusiform bacilli are always found in patients with the disease along with other organisms. Rosebury and colleagues[58] described a fusospirochetal complex that consists of *T. microdentium,* intermediate spirochetes, vibrios, fusiform bacilli, and filamentous organisms in addition to several *Borrelia* species.

Loesche and colleagues[40] described a predominant constant flora and a variable flora associated with NUG. The constant flora is composed of *Prevotella intermedia* in addition to *Fusobacterium, Treponema,* and *Selenomonas* species. The variable flora consists of a heterogeneous array of bacterial types.

Treatment with metronidazole results in a significant reduction

of *Treponema* species, *Prevotella intermedia,* and *Fusobacterium,* with resolution of the clinical symptoms.[16,40] The antibacterial spectrum of this drug provides evidence for the anaerobic members of the flora as etiologic agents. These bacteriologic findings have been supported by immunologic data[9] that demonstrated increased immunoglobulin G and M antibody titers for medium-sized spirochetes and *P. intermedia* in patients with NUG compared with titers in patients with chronic gingivitis and healthy controls.

Role of the Host Response

Regardless of whether specific bacteria are implicated in the cause of NUG, the presence of these organisms without other predisposing factors appears to be insufficient to cause the disease. The fusospirochetal flora is frequently found in patients who do not have NUG. Exudates from NUG lesions produce fusospirochetal abscesses rather than typical NUG lesions when the exudates are inoculated subcutaneously into experimental animals.[57]

The role of an impaired host response in NUG has long been recognized. Even in the early descriptions of the disease, NUG was associated with physical and emotional stress[11,60] and decreased resistance to infection. NUG has not been produced experimentally in humans or animals, only by inoculation of bacterial exudates from the lesions. In the animal model, local or systemic immunosuppression with glucocorticoids (e.g., ketoconazole) results in more characteristic lesions of NUG in infected animals. Swenson and Muhler used scillaren B, an amorphous glucoside, which reduced tissue resistance to create oral fusospirochetal infections in dogs.[71,72]

NUG is not found in well-nourished individuals with a fully functional immune system. All of the predisposing factors for NUG are associated with immunosuppression. Cogen and colleagues[10] described depression of host defense mechanisms, particularly in PMN chemotaxis and phagocytosis, in patients with NUG. Host–bacteria interactions are described in Chapter 9.

It is essential for the clinician to determine the predisposing factors that lead to immunodeficiency in patients with NUG to address the continued susceptibility of the patient and to determine whether an underlying systemic disease exists. Immunodeficiency

may be related to various levels of nutritional deficiency, fatigue caused by chronic sleep deprivation, other health habits (e.g., alcohol, drug abuse), psychosocial factors, or systemic disease. NUG can be the presenting symptom for patients with immunosuppression related to HIV infection.

Local Predisposing Factors

Preexisting gingivitis, injury to the gingiva, and smoking are important predisposing factors. Although NUG can appear in an otherwise disease-free mouth, it most often occurs superimposed on preexisting chronic gingival disease and periodontal pockets. Deep periodontal pockets and pericoronal flaps are particularly vulnerable areas because they offer a favorable environment for the proliferation of anaerobic fusiform bacilli and spirochetes. Areas of the gingiva that are traumatized by opposing teeth in malocclusion (e.g., palatal surface behind the maxillary incisors, labial gingival surface of the mandibular incisors) can predispose an individual to the development of NUG.

The relationship between NUG and smoking has often been mentioned in the literature. Pindborg[52] reported that 98% of his patients with NUG were smokers and that the increasing frequency of this disease correlates with increasing exposure to tobacco smoke. The effect of smoking on periodontal disease in general has been the subject of numerous studies during the past 2 decades,[1a,21a,22a,33a,35a,49a] and smoking has been established as a high-risk factor for disease (see Chapter 12).

Systemic Predisposing Factors

NUG is not found in a well-nourished individual with a fully functional immune system. It is therefore important for the clinician to determine the predisposing factors for immunodeficiency. Immunodeficiency can be related to various levels of nutritional deficiency, psychosocial stress, fatigue caused by chronic sleep deficiency, other health habits (e.g., alcoholism, drug abuse), and systemic disease (e.g., diabetes, debilitating infection).

Nutritional Deficiency

Necrotizing gingivitis has been produced in animals by giving them nutritionally deficient diets.[7,34,47,73,76] Several researchers found an increase in the fusospirochetal flora in the mouths of the experimental animals, but the bacteria were regarded as opportunists that proliferated only when the tissues were altered by the deficiency.

A poor diet has been cited as a predisposing factor for NUG and its sequelae in developing African countries, although the effects appear primarily to diminish the effectiveness of the immune response.[19,20,35] Nutritional deficiencies (e.g., vitamin C, vitamin B_2) accentuate the severity of the pathologic changes induced when the fusospirochetal bacterial complex is injected into animals.[70]

Debilitating Disease

Debilitating systemic disease can predispose patients to NUG. Systemic disturbances include chronic diseases (e.g., syphilis, cancer), severe gastrointestinal disorders (e.g., ulcerative colitis), blood dyscrasias (e.g., leukemia, anemia), and acquired immunodeficiency syndrome. Nutritional deficiency that results from debilitating disease can be an additional predisposing factor. Experimentally induced leukopenia in animals can produce ulcerative gangrenous stomatitis.[47,74,75] Ulceronecrotic lesions appear in the gingival margins of hamsters that are exposed to total body irradiation[43]; these lesions can be prevented with systemic antibiotics.[42]

Psychosomatic Factors

Psychological factors appear to be important in the cause of NUG. The disease often occurs in association with stressful situations (e.g., induction into the armed forces, academic examinations).[24] Psychological disturbances[25] and increased adrenocortical secretion[65] are common in patients with the disease.

A significant correlation between disease incidence and two personality traits—dominance and abasement—suggests a NUG-prone personality.[22] Data from a study evaluating the relationship between personality traits and stress with gingival inflammation and soft tissue pathology in military recruits found that gingival inflammation correlated significantly with personality traits (e.g.,

tolerance to change, anxiety).[48]

The mechanisms by which psychologic factors create or predispose an individual to gingival damage have not been established. However, alterations in digital and gingival capillary responses that suggest increased autonomic nervous activity have been demonstrated in patients with NUG.[23]

It can be concluded that opportunistic bacteria are the primary etiologic agents of NUG in patients who demonstrate immunosuppression. Stress, smoking, and preexisting gingivitis are common predisposing factors.

Epidemiology and Prevalence

The prevalence of NUG appears to have been rather low in the United States and Europe before 1914. During World Wars I and II, numerous epidemics broke out among the Allied troops, but German soldiers did not seem to have been similarly affected. Epidemic-like outbreaks have also occurred among civilian populations. A study at a dental clinic in Prague, Czech Republic, reported the incidence of NUG as 0.08% among patients 15 to 19 years old, 0.05% among those 20 to 24 years old, and 0.02% among those 25 to 29 years old.[68]

NUG occurs in individuals of all ages, with the highest incidence reported for patients between the ages of 15 and 30 years.[15,36,68,70] It is not common among children in the United States, Canada, and Europe, but it has been reported in children from low socioeconomic groups in underdeveloped countries.[33] In India, 54%[46] and 58%[53] of patients in two studies were younger than 10 years of age.

In a random school population in Nigeria, NUG occurred in 11.3% of children between the ages of 2 and 6 years.[66] In a Nigerian hospital population, it affected 23% of children who were younger than 10 years of age.[19] Studies of African populations typically report a higher prevalence of necrotizing periodontal disease among young children than in those older than 10 years.[1] NUG has been reported in several members of the same family in low socioeconomic groups. Twenty percent of households with children 2 to 6 years of age in a rural Nigerian city had one or more children

with NUG.[66] NUG is more common among children with Down syndrome than among other children with mental deficiencies.[4]

Opinions differ with regard to whether NUG is more common during the winter,[36,50] summer, or fall[66] and whether there is a peak seasonal incidence.[14]

Communicability

NUG often occurs in groups in an epidemic pattern. At one time, NUG was considered contagious and required reporting to the community health department, but it was later concluded not to be communicable.[56,62]

A distinction must be made between communicability and transmissibility when referring to the characteristics of disease. The term *transmissible* denotes a capacity for the maintenance of an infectious agent in successive passages through a susceptible animal host.[56] The term *communicable* signifies a capacity for the maintenance of infection by natural modes of spread, such as direct contact through drinking water, food, and eating utensils; by the airborne route; or by arthropod vectors. A disease that is communicable is described as *contagious.* It has been demonstrated that disease associated with the fusospirochetal bacterial complex is transmissible; however, *it is not communicable or contagious.*

Attempts to spread NUG from human to human have been unsuccessful.[63] King[35] traumatized an area in his own gingiva and introduced debris from a patient with a severe case of NUG. There was no response until he happened to fall ill shortly thereafter. After his illness, he observed the characteristic lesion in the experimental area. It can be inferred with reservation from this experiment that systemic debility is a prerequisite for the contagion of NUG.

Because NUG often occurs among groups that use the same kitchen facilities, it is a common impression that the disease is spread by bacteria on eating utensils. However, the growth of fusospirochetal organisms requires carefully controlled conditions and an anaerobic environment; they do not ordinarily survive on eating utensils.[12,28]

The occurrence of NUG in epidemic-like outbreaks does not

necessarily mean that it is contagious. The affected groups may be afflicted by the disease as a result of common predisposing factors rather than because of its spread from person to person. In all likelihood, a predisposed immunocompromised host and the presence of appropriate bacteria are necessary for the production of this disease.

Key Fact

Although certain bacteria (e.g., fusospirochetal complex) are likely responsible for the lesions observed in necrotizing ulcerative gingivitis, immunocompromise appears to be a necessary predisposing condition for the disease.

Primary Herpetic Gingivostomatitis

Primary herpetic gingivostomatitis is an infection of the oral cavity caused by herpes simplex virus (HSV) type 1.[15,44,45,61] It occurs most often among infants and children who are younger than 6 years of age,[6,61,64] but it is also seen in adolescents and adults. It occurs with equal frequency in male and female patients. In most individuals, however, the primary infection is asymptomatic.

As part of the primary infection, the virus ascends through the sensory and autonomic nerves, where it persists as latent HSV in neuronal ganglia that innervate the site. In approximately one-third of the world's population, secondary manifestations result from various stimuli, such as sunlight, trauma, fever, and stress. Secondary manifestations include herpes labialis (Fig. 20.4), herpetic stomatitis, herpes genitalis, ocular herpes, and herpetic encephalitis. Secondary herpetic stomatitis can occur on the palate, on the gingiva (Fig. 20.5), or on the mucosa as a result of dental treatment that traumatizes or stimulates the latent virus in the ganglia that innervate the area. It may manifest as pain away from the site of treatment 2 to 4 days later. Careful inspection for characteristic vesicles can be diagnostic (see Fig. 20.4).

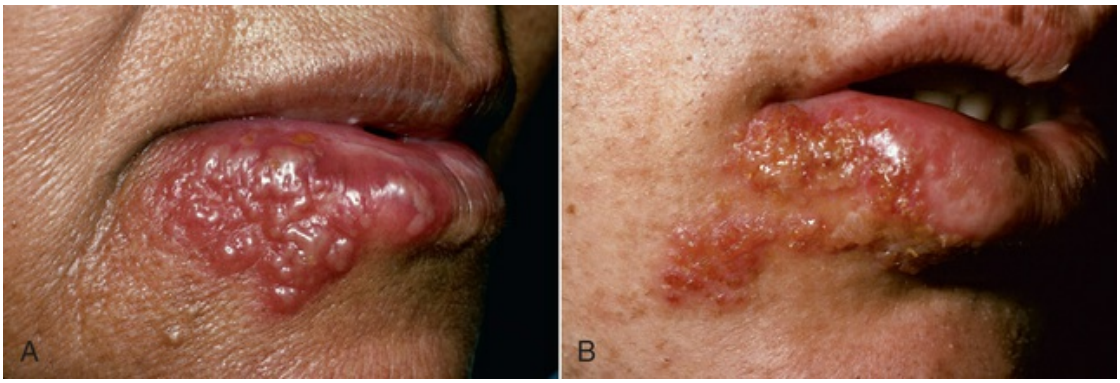

FIG. 20.4 Herpetic vesicles recurred in the lip. (A) Early stage. (B) Late stage, showing brownish, crusted lesions. (From Sapp JP, Eversole LR, Wysocki GP: *Contemporary oral and maxillofacial pathology.* ed 2, St Louis, 2002, Mosby.)

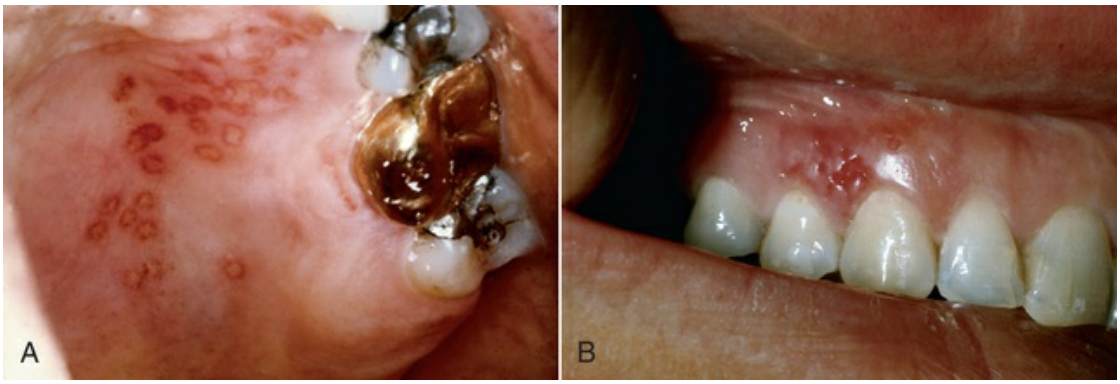

FIG. 20.5 Recurrent intraoral herpetic vesicles are seen (A) in the palate and (B) in the gingiva. The latter location is rare. (From Sapp JP, Eversole LR, Wysocki GP: *Contemporary oral and maxillofacial pathology,* ed 2, St Louis, 2002, Mosby.)

Clinical Features

Oral Signs

Primary herpetic gingivostomatitis appears as a diffuse, erythematous, shiny involvement of the gingiva and the adjacent oral mucosa, with various degrees of edema and gingival bleeding. During its initial stage, it is characterized by discrete, spherical, gray vesicles, which can occur on the gingiva, labial and buccal mucosae, soft palate, pharynx, sublingual mucosa, and tongue (Fig. 20.6). After approximately 24 hours, the vesicles rupture and form

painful small ulcers with red, elevated, halo-like margins and depressed yellowish or grayish white central portions. They occur in widely separated areas or in clusters where confluence occurs (Fig. 20.7).

FIG. 20.6 Primary herpetic gingivostomatitis in a 12-year-old boy, who has diffuse erythematous involvement of the gingiva and a spherical, gray vesicle in the lip. (Courtesy Dr. Heddie Sedano, University of California, Los Angeles, and University of Minnesota.)

FIG. 20.7 Involvement of the lip (A), gingiva (B), and tongue (C) in primary herpetic gingivostomatitis. (From Sapp JP, Eversole LR, Wysocki GP: *Contemporary oral and maxillofacial pathology*. ed 2, St Louis, 2002, Mosby.)

Occasionally, primary herpetic gingivitis occurs without overt vesiculation. The clinical picture consists of diffuse, erythematous, shiny discoloration and edematous enlargement of the gingivae with a tendency to bleed.

The course of the disease is limited to 7 to 10 days. The diffuse gingival erythema and edema that appear early during the course

of the disease persist for several days after the ulcerative lesions have healed. Scarring does not occur in the areas of healed ulcerations.

Oral Symptoms

The disease is accompanied by generalized soreness of the oral cavity, which interferes with eating, drinking, and oral hygiene. The ruptured vesicles are the focal sites of pain; they are particularly sensitive to touch, thermal changes, foods such as condiments and fruit juices, and the action of coarse foods. In infants, the disease is marked by irritability and refusal to take food.

Extraoral and Systemic Signs and Symptoms

Cervical lymphadenitis, fever as high as 101° to 105° F (38° to 40.6° C), and generalized malaise are common.

History

Primary herpetic gingivostomatitis is the result of an acute infection by HSV. There is an acute onset of symptoms.

Histopathology

The virus targets the epithelial cells called *Tzanck cells*, which show ballooning degeneration that consists of acantholysis, nuclear clearing, and nuclear enlargement. Infected cells fuse to form multinucleated cells, and intercellular edema leads to the formation of intraepithelial vesicles that rupture and develop a secondary inflammatory response with a fibropurulent exudate[49] (Fig. 20.8). Discrete ulcerations that result from the rupture of the vesicles have a central portion of acute inflammation, with various degrees of purulent exudate surrounded by engorged blood vessels.

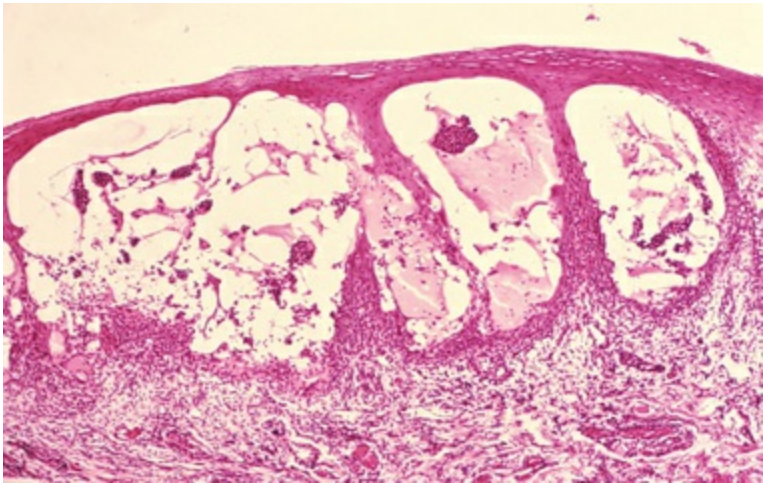

FIG. 20.8 Biopsy showing intraepithelial viral vesicles that contain fluid and debris, with a large number of viruses and virally altered epithelial cells (i.e., Tzanck cells). (Courtesy Dr. Heddie Sedano, University of California, Los Angeles, and University of Minnesota.)

Diagnosis

It is critical to arrive at a diagnosis as early as possible for a patient with a primary herpetic infection. Treatment with antiviral medications can dramatically alter the course of the disease by reducing symptoms and potentially reducing recurrences. The diagnosis is usually established from the patient's history and the clinical findings. Material can be obtained from the lesions and submitted to the laboratory for confirmatory tests, including virus culture and immunologic tests that involve the use of monoclonal antibodies or deoxyribonucleic acid hybridization techniques.[6,55] This should not delay treatment if strong clinical evidence exists for primary gingivostomatitis.

Differential Diagnosis

Primary herpetic gingivostomatitis should be differentiated from several conditions. Lesions of recurrent aphthous stomatitis (RAS)[21] range from occasional small (0.5 to 1 cm in diameter), well-defined, round or ovoid, shallow ulcers with a yellowish gray central area surrounded by an erythematous halo, which heal in 7 to 10 days without scarring, to larger (1 to 3 cm in diameter), oval or irregular

ulcers, which persist for weeks and heal with scarring (Fig. 20.9). The cause is unknown, although immunopathologic mechanisms appear to play a role.

FIG. 20.9 Aphthous lesion in the lip. The depressed gray center is surrounded by an elevated red border. (From Sapp JP, Eversole LR, Wysocki GP: *Contemporary oral and maxillofacial pathology.* ed 2, St Louis, 2002, Mosby.)

RAS is a different clinical entity from primary herpetic gingivostomatitis. The ulcerations may look the same for the two conditions, but diffuse erythematous involvement of the gingiva and acute toxic systemic symptoms do not occur with RAS. A history of previous episodes of painful mucosal ulcerations suggests RAS rather than primary HSV.

Information about erythema multiforme, bullous lichen planus, and desquamative gingivitis can be found in Chapter 22.

Communicability

Primary herpetic gingivostomatitis is contagious.[8,39] Most adults have developed immunity to HSV as a result of infection during childhood, which in most cases is subclinical. For this reason, acute herpetic gingivostomatitis usually occurs in infants and children. Recurrent herpetic gingivostomatitis has been reported,[27] although it is not often clinically significant unless immunity is destroyed by debilitating systemic disease. Studies that have demonstrated HSV in periodontal pockets suggest more recurrence of viral replication than has previously been recognized.[69] Secondary herpetic infection

of the skin, such as herpes labialis, does recur.[67]

Clinical Correlation

Acute herpetic gingivostomatitis usually occurs in infants and children because most adults have developed immunity to herpes simplex virus from childhood exposure, often with mild or no symptoms.

Pericoronitis

The term *pericoronitis* refers to inflammation of the gingiva in relation to the crown of an incompletely erupted tooth (Fig. 20.10). It occurs most often in the mandibular third molar area. Pericoronitis can be acute, subacute, or chronic.

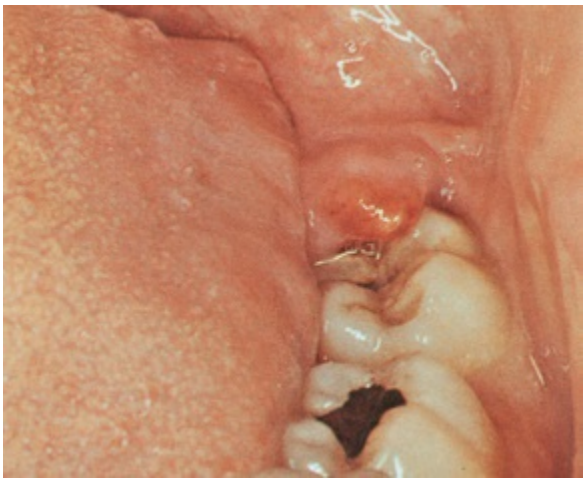

FIG. 20.10 Pericoronitis. An inflamed coronal flap covers the disto-occlusal surface of the impacted mandibular third molar. Note the swelling and redness. (From Glickman I, Smulow J: Periodontal disease: clinical, radiographic and histopathologic features. Philadelphia, 1974, Saunders.)

Clinical Features

The partially erupted or impacted mandibular third molar is the most common site of pericoronitis. The space between the crown of the tooth and the overlying gingival flap (i.e., operculum) is an ideal area for the accumulation of food debris and bacterial growth.

Even in patients with no clinical signs or symptoms, the gingival flap is often chronically inflamed and infected, and it has various degrees of ulceration along its inner surface. Acute inflammatory involvement is a constant possibility; it may be exacerbated by trauma, occlusion, or a foreign body trapped underneath the tissue flap (e.g., popcorn husk, nut fragment).

Acute pericoronitis is identified by various degrees of inflammatory involvement of the pericoronal flap and adjacent structures and by systemic complications. The inflammatory fluid and cellular exudate increase the bulk of the flap, which can interfere with complete closure of the jaws. It also can be traumatized by contact with the opposing dentition, thereby aggravating the inflammatory involvement.

The resultant clinical picture is a red, swollen, suppurating lesion that is exquisitely tender, with radiating pains to the ear, throat, and floor of the mouth. The patient is extremely uncomfortable as a result of pain, a foul taste, and an inability to close the jaws. Swelling of the cheek in the region of the angle of the jaw and lymphadenitis are common findings. Trismus may be a presenting complaint. The patient can have systemic complications such as fever, leukocytosis, and malaise.

Complications

Involvement can be localized in the form of a pericoronal abscess. It may spread posteriorly into the oropharyngeal area and medially to the base of the tongue, making it difficult for the patient to swallow. Depending on the severity and extent of the infection, there may be involvement of the submaxillary, posterior cervical, deep cervical, and retropharyngeal lymph nodes.[32,51] Peritonsillar abscess formation, cellulitis, and Ludwig angina are infrequent but potential sequelae of acute pericoronitis.

Conclusions

Acute gingival diseases are similar in that they typically manifest with painful intraoral or perioral lesions and there is a need for urgent treatment to relieve symptoms. However, each case requires

careful assessment and an accurate diagnosis, including identification of risk factors. In many cases, there are systemic risk factors that increase susceptibility to acute gingival disease.

Case Scenario 20.1

Patient:
38-year-old male

Chief Complaint:
"I have pain in my gums that suddenly got worse."

Background Information:
Patient denies serious illness but reports that he has been under a lot of stress recently. He denies any history of smoking. He brushes daily and flosses sometimes. He has not been to the dentist for years and cannot recall his last professional dental cleaning.

Current Findings:
Tissues were too tender to probe effectively. There is generalized marginal erythema and edema with localized necrosis of interdental tissue between the mandibular central incisors.

CASE-

BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Does this patient have necrotizing ulcerative gingivitis? A. Yes B. No	**Answer: A** **Explanation:** Necrotizing ulcerative gingivitis (NUG) is characterized by a sudden onset of symptoms with typical punched out, craterlike depressions of the interdental papilla.
2. Should this patient be evaluated for other systemic diseases? A. Yes B. No	**Answer: A** **Explanation:** The role of an impaired host response in NUG has long been recognized. All predisposing factors for NUG are associated with immunosuppression. The clinician should determine the predisposing factors that lead to immunodeficiency in patients with NUG to address the continued susceptibility of the patient and to determine whether an underlying systemic disease is present.

CHAPTER 21

Gingival Disease in Childhood

Daniela R. Silva, Clarice S. Law, Donald F. Duperon, Fermin A. Carranza

CHAPTER OUTLINE

Periodontium of the Primary Dentition
Periodontal Changes Associated with Normal Development
Gingival Diseases of Childhood
Periodontal Diseases of Childhood
Gingival Manifestation of Systemic Disease in Children
Oral Mucosa in Childhood Diseases
Therapeutic Considerations for Pediatric Patients
Conclusions

Periodontal disease in adults is partly precipitated by gingival inflammation during the formative years of childhood and early adolescence. Without appropriate intervention, the nondestructive gingival inflammation of childhood may progress to the more

significant periodontal diseases seen in the adult population.

After reviewing anatomic and physiologic changes in the periodontium and dentition, this chapter describes the gingival changes associated with childhood and adolescence. Periodontal diseases during these early periods of life are discussed in Chapters 14, 27, and 28.

Periodontium of the Primary Dentition

In the edentulous infant, the gingival tissues have thick gingival mucosa and segmentations that correspond with the primary buds (Fig. 21.1). A high labial frenum attachment is a normal finding in almost 85% of infants; it may diminish in size with normal development.[58] During the primary dentition stage, the normal gingiva continues to be somewhat different from that found in adults. The tissues are pale pink, but they are pink to a lesser degree than the attached gingiva of adults because the thinness of the keratinized layer allows the underlying vessels in children to be more visible.[42] Stippling appears at about 3 years of age and has been reported for 56% of children between 3 and 10 years of age, with little differences between maxillary and mandibular arches or between boys and girls throughout childhood[11] (Fig. 21.2).

FIG. 21.1 Normal gingiva of an edentulous 1-month-old child shows a high labial frenulum and pink and healthy tissues. (Copyright Dr. Daniela Silva. All rights reserved.)

FIG. 21.2 Normal gingiva of a 4-year-old child shows light stippling and flattened interproximal gingiva in areas of physiologic spacing. (Copyright Dr. Daniela Silva. All rights reserved.)

The *interdental gingiva* is broad buccolingually and narrow mesiodistally, which is consistent with the morphology of the primary dentition. Its structure and composition are similar to those of the adult gingiva.

Gingival sulcular depth is shallower in the primary dentition than in the permanent dentition. Probing depths range from 1 to 2 mm, with increasing depth from anterior to posterior.[8,25,61]

The *attached gingiva* varies in width anteroposteriorly, with a range of 3 to 6 mm. On the buccal surfaces, the width decreases from anterior to posterior, with some data indicating a narrowing over the canines (Fig. 21.3). The lingual attached gingiva shows an inverse relationship, with an increase in width from anterior to posterior.[25] The gingival width normally increases with age as children transition from the primary to the permanent dentition.[5,8,15,61] The junctional epithelium is thicker in the primary dentition than in the permanent dentition,[10] which is thought to reduce the permeability of the tissues to bacterial toxins.

FIG. 21.3 Normal gingiva of a 4-year-old African-American child demonstrates the width of the attached gingiva, as illustrated by the pigmentation that occurs only in the attached area. (Copyright Dr. Daniela Silva. All rights reserved.)

Radiographically, the lamina dura is prominent in the primary dentition, with a wider periodontal space than in the permanent dentition. The marrow spaces of the bone are larger, and the crests of the interdental bony septa are flat, with bony crests within 1 to 2 mm of the cementoenamel junction[26,54] (Fig. 21.4).

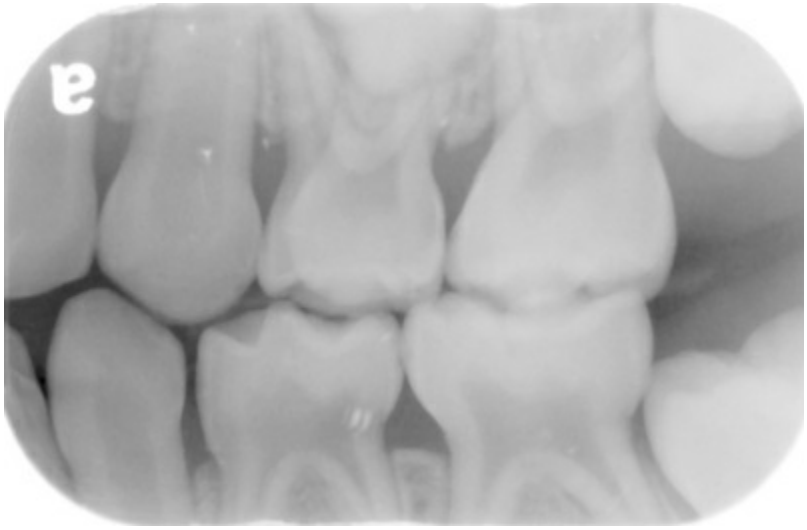

FIG. 21.4 Bitewing radiograph of a 6-year-old child shows the flattened interseptal bone and bony crests within 1 to 2 mm of the cementoenamel junction.

Periodontal Changes Associated With Normal Development

Significant changes occur in the periodontium as the dentition changes from the primary to the permanent teeth. Most of the changes are associated with eruption and are physiologic in nature. These changes should be distinguished from gingival disease, which can occur simultaneously.

Tooth Eruption

Before the eruption of a primary or permanent tooth, the gingiva reveals a bulge that is firm and pink or blanched as a result of the underlying tooth crown. An *eruption cyst* occasionally is evident. This fluctuant mass can be filled with blood, and it usually manifests as a bluish or deep red enlargement of the gingiva over the erupting tooth (Fig. 21.5A). The most common sites of these cysts are the primary first molars and the permanent first molars. Many resolve without treatment, but they can be marsupialized if they are painful or interfere with occlusion (see Fig. 21.5B).[14]

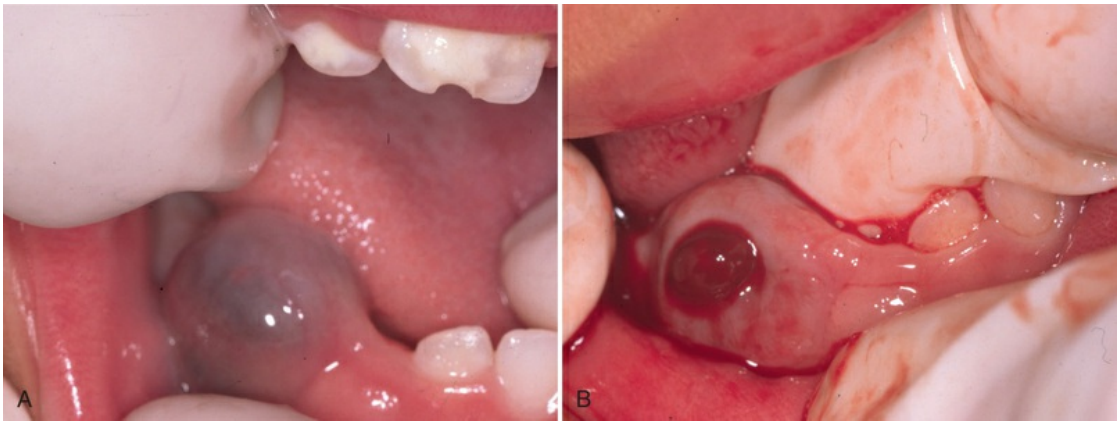

FIG. 21.5 (A) An eruption cyst is seen at the lower right first primary molar area of a 16-month-old child. With this condition, there is transparent, bluish, blue, or blue-black swelling of the alveolar mucosa over a tooth in eruption. (B) An eruption cyst is located at the lower right first primary molar area of a 16-month-old child. After a small incision of the mucosa, the hemorrhagic content was marsupialized. (Copyright Dr. Daniela Silva. All rights

reserved.)

As a tooth erupts, the gingival margin and the sulcus develop. At this point, the margin is rounded, edematous, and reddened. During the period of active tooth eruption, it is normal for the marginal gingiva that surrounds partially erupted teeth to appear prominent; this is most evident in the maxillary anterior region. The prominence is caused by the height of the contour of the erupting tooth and mild inflammation from mastication. Poor oral hygiene can contribute to the development of significant gingivitis in unprotected gingival areas.

Teething

The effect of primary tooth eruption on infant health has been debated for centuries, but there is little scientific evidence regarding the diagnosis and management of the teething child. The period associated with the eruption of the primary teeth in infants can be difficult and stressful for the child and the parents. The timing of primary incisor eruption (i.e., 5 to 12 months of age) coincides with diminution of the passive humoral immunity conferred by the transfer of maternal antibodies through the placenta and establishment of the child's own immunity.[17,29,60] Pain is a common feature of teething as reported by parents and some health care providers. The tooth does not cause the pain; rather, the follicle, which is a rich source of eicosanoids, cytokines, and growth factors, stimulates a localized inflammatory response.[57,60]

Most medical and dental professionals agree that teething does not cause life-threatening illness, but they disagree about which symptoms are associated with tooth eruption. The studies and systematic reviews of symptoms related to teething most commonly include decreased appetite, biting, drooling, gum rubbing, irritability, sucking, and abnormal temperature.[24,28,29,38,39,46,53,57,60,67,68] However, there is no evidence that any of these symptoms can be diagnostic of teething in a child without excluding the possibility of other systemic diseases.

Learning Box 21.1

What are the most common symptoms associated with teething that have been proved or confirmed by scientific studies? They are drooling, irritability, decreased appetite, and gum rubbing.

Primary Tooth Exfoliation

As with tooth eruption, the process of tooth exfoliation involves changes in the periodontium. The depth of the gingival sulcus increases as the junctional epithelium migrates down the resorbing root of an exfoliating tooth.[9,10] Microscopically, minor traumatic changes demonstrate compression, ischemia, and hyalinization of the periodontal ligament.[49] Changes in the permeability and integrity of the junctional epithelium can make the exfoliating tooth more susceptible to inflammation.[10]

During the process of exfoliation, teeth can change position, leading to changes in occlusion. Malalignment caused by spacing and changes in skeletal relationships related to erupting teeth can contribute to significant trauma of the periodontal structures. With more severe injury, crushing and necrosis of the periodontal ligament can occur. In most patients, these injuries spontaneously resolve as the teeth exfoliate, erupt, and align through the normal growth and development processes.

Other Developmental Issues

Relation of Periodontal Status to Malocclusion

Data indicate an association between abnormal tooth position and gingivitis.[20] Crowding in the mixed dentition can often make plaque and food removal more difficult, increasing the likelihood of gingivitis. Severe changes include gingival enlargement, discoloration, occasional ulceration, and formation of deep pockets or pseudopockets. Gingival health usually can be restored with orthodontic correction, but failure to align the teeth does not necessarily have an effect on periodontal disease later in life.[20]

Mucogingival Problems

The prevalence of mucogingival problems and recession in children

ranges from 1% to 19%, depending on the criteria used to assess the condition.[33] Evidence suggests that some mucogingival problems start during the primary dentition as a consequence of developmental aberrations in eruption and deficiencies in the thickness of the periodontium.[42,43] A high frenum attachment may also be a factor in the development of mucogingival problems if there is excess tension at the marginal tissues.[52,62] During the mixed dentition, recession is most often found on the facial aspect of mandibular permanent incisors due to rotations or labial positioning related to space problems. Although erupting permanent lower incisors often show minimal attached gingiva, gingival width often increases as the teeth erupt and stimulate bone development[15] (Fig. 21.6).

FIG. 21.6 Erupting permanent incisors have minimal attached gingiva. (Copyright Dr. Daniela Silva. All rights reserved.)

The maxillary canine region is prone to localized gingival recession. Late-erupting canines in a crowded dentition can be displaced buccally, erupting into or near unattached gingiva or mucosa and increasing the risk of insufficient gingival tissue width and recession. Recession also can be associated with an anterior open bite as a result of the labial inclination of the teeth.[36] Orthodontic treatment and realignment may be necessary to protect the integrity of the attached gingiva.

Mucogingival problems can result from factitious habits, such as self-inflicted trauma from a fingernail (Fig. 21.7) or excessive

toothbrushing by the parent or the child. Because the width of the attached gingiva increases with age, any of these problems may resolve spontaneously, suggesting a cautious approach to treatment with judicious monitoring instead of immediate surgical intervention.[15,54]

FIG. 21.7 Gingival recession on the maxillary and mandibular left primary canine areas is caused by self-inflicted trauma from the patient's fingernail. (Copyright Dr. Daniela Silva. All rights reserved.)

Gingival Diseases of Childhood

Plaque-Induced Gingival Disease

Gingivitis is extremely common among children and adolescents, and it affects up to 70% of children who are more than 7 years old.[16,47] Inflammation is usually limited to the marginal gingiva (Fig. 21.8), with undetectable loss of bone or connective tissue attachment in most cases. Although gingivitis does not always progress to periodontitis, the management of gingival disease in children and adolescents is important, because periodontitis is always preceded by gingivitis.[47]

FIG. 21.8 Plaque-induced gingivitis is limited to the marginal gingiva in a 12-year-old girl. (Copyright Dr. Daniela Silva. All rights reserved.)

In children and adults, the primary cause of gingivitis is dental plaque, which is related to poor oral hygiene. The relationship between plaque and the gingival index, however, is weak and remains unclear.[9,37,38,41] Although gingivitis is highly prevalent among children, its severity usually is less intense than that found in adults.[10] Similar oral hygiene conditions produce less severe forms of disease in children compared with adults.[47]

As children age, their tendency to develop gingivitis increases.[10] The prevalence of disease is lowest during the preschool years and increases throughout childhood, peaking during puberty. However, increases in the degree of gingival inflammation do not fully correlate with the amount of plaque, which suggests the influence of other factors.

Clinical Features

The most prevalent type of gingival disease in childhood is *chronic marginal gingivitis* (see Fig. 21.8). The gingival tissues exhibit changes in color, size, consistency, and surface texture that are similar to those of chronic inflammation in the adult. Red, linear inflammation is accompanied by underlying chronic changes, including swelling, increased vascularization, and hyperplasia. Bleeding and increased pocket depth are not found as often in

children as in adults, but they may be observed if severe gingival hypertrophy or hyperplasia occur.[9,47]

Chronic gingivitis in children is characterized by a loss of collagen in the area around the junctional epithelium and an infiltrate that consists mostly of lymphocytes, with small numbers of polymorphonuclear leukocytes, plasma cells, monocytes, and mast cells. Lesions typically have relatively few plasma cells, and they resemble the early nondestructive, nonprogressive lesions that are seen in adults. Unlike the adult inflammatory response, gingivitis in children is dominated by T lymphocytes, with few B lymphocytes and plasma cells in the infiltrate. This difference may explain why gingivitis in children rarely progresses to periodontitis.[34,35,41,55] Gingival histology in children also demonstrates other unique features that may decrease the tendency to progress to severe gingivitis. The junctional epithelium of the primary dentition tends to be thicker than in the permanent dentition,[10] which is thought to reduce the permeability of the gingival structures to bacterial toxins that initiate the inflammatory response.

Learning Box 21.2

What are the main differences between chronic marginal gingivitis in children compared with adults? Children with a nonsignificant medical history have less severe gingival bleeding and very seldom have increased pocket depth, as seen in healthy adults. Gingivitis in children also is different from that in adults because the response is dominated by T lymphocytes, with few B lymphocytes and plasma cells in the infiltrate, and it rarely progresses to periodontitis.

Calculus

Calculus deposits are uncommon in infants and toddlers, but they can increase with age. About 9% of 4- to 6-year-old children exhibit calculus deposits. By the age of 7 to 9 years, 18% of children have calculus deposits, and by the age of 10 to 15 years, 33% to 43% have some calculus formation.[69] In the category of special needs patients,

children with cystic fibrosis[69] or chronic kidney disease[40] have a higher incidence of calculus deposits, which can be caused by increased calcium and phosphate concentrations in saliva. Children who are fed exclusively with gastric or nasogastric tubes show significant calculus buildup as a result of a lack of function and increased oral pH (Fig. 21.9).[23]

FIG. 21.9 A 5-year-old boy with a history of liver transplantation and gastric tube feeding has a generalized calculus deposit. (Copyright Dr. Daniela Silva. All rights reserved.)

Microbiology of Disease

Because the intensity of gingival disease increases as a child develops into adulthood, it is important to understand the microbiology of disease, which is discussed further in Chapter 8. The composition of the oral microflora changes as the child matures.[10] Yang and colleagues[70] analyzed samples of dental plaque in children and reported that 71% of 18- to 48-month-old children were infected with at least one periodontal pathogen. Sixty-eight percent were infected with *Porphyromonas gingivalis,* and 20% had *Tannerella forsythia* (previously called *Bacteroides forsythus*).[70] A moderate correlation was found between *T. forsythia* in children and

periodontal disease in their mothers. *T. forsythia* also has been associated with gingival bleeding in children.

In a similar study, 60% of children between the ages of 2 and 18 years had detectable levels of *P. gingivalis* in their plaque, and 75% showed similar levels of *Actinobacillus actinomycetemcomitans*. *P. gingivalis* was most strongly associated with the progression of gingivitis and the onset of periodontitis in otherwise healthy children.[45]

Pediatric gingivitis models have demonstrated increased subgingival levels of *Actinomyces, Capnocytophaga, Leptotrichia,* and *Selenomonas*[16]—pathogens usually not seen in adult gingivitis—thereby raising interest in their potential role in the cause of childhood gingivitis.

Eruption Gingivitis

Gingivitis associated with tooth eruption is so common that the term *eruption gingivitis* has come into frequent use. Although tooth eruption does not directly cause gingivitis, inflammation associated with plaque accumulation around erupting teeth, perhaps due to discomfort caused by brushing these friable areas, may contribute to gingivitis.[10] The gingiva around erupting teeth can appear reddened because gingival margins have not yet keratinized fully and sulcus development is incomplete.

Exfoliating and severely carious primary teeth often contribute to gingivitis caused by plaque accumulation as a result of pain during brushing or food impaction in areas of cavitation. As a normal part of exfoliation, the junctional epithelium migrates under the resorbing tooth, thereby increasing pocket depth and potentially creating a niche for pathogenic bacteria.[10] The discomfort of chewing on severely infected teeth often leads to unilateral chewing on the unaffected side.

Puberty Gingivitis

The incidence of marginal gingivitis increases as a child matures, peaking when he or she is 9 to 14 years old and then decreasing slightly after puberty.[10] Gingival disease that behaves in such a manner is often referred to as *pubertal* (or *puberty*) *gingivitis.* Chapters 19 and 41 continue the discussion of this condition.

The most frequent manifestation of puberty gingivitis is bleeding and inflammation in interproximal areas. Inflammatory gingival enlargement may also occur in males and females, but it typically subsides after puberty[44] (see Fig. 21.8). The altered gingival response during this developmental stage is thought to be the result of hormonal changes that magnify the vascular and inflammatory response to dental plaque[10,47] and that modify the reactions of dental plaque microbes.[22]

Drug-Induced Gingival Enlargement

Gingival enlargement (see Chapter 19) can result from the use of certain drugs. Cyclosporine, phenytoin, and calcium channel blockers, which are used to treat conditions that are encountered during childhood (e.g., organ transplantation, epilepsy, cardiac anomalies), increase the prevalence of gingival enlargement (Fig. 21.10). A randomized clinical trial found an interesting and significant decrease in the incidence (21%) of phenytoin-induced gingival hyperplasia in children with epilepsy taking oral folic acid supplementation (0.5 mg/day) compared with the control group (88%).[6] Although complicated by the plaque levels along the gingival margin, this form of gingival disease has features that are not typical of chronic marginal gingivitis.[47]

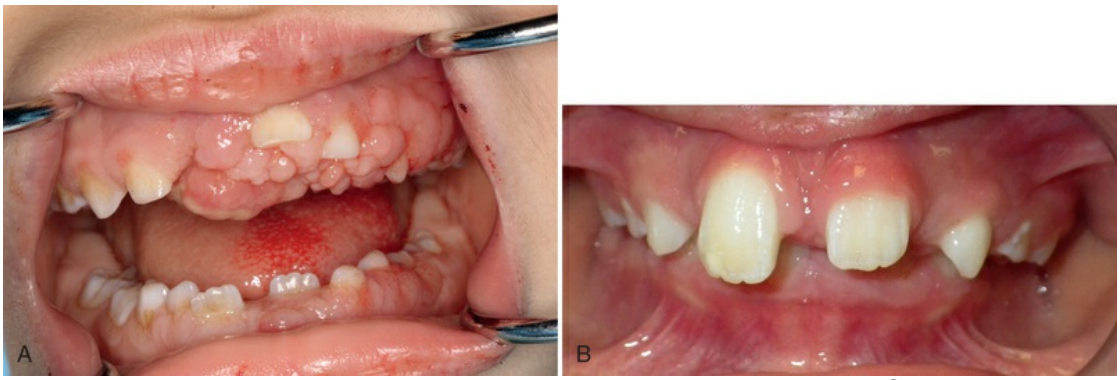

FIG. 21.10 (A) A 7-year-old boy with a history of aplastic anemia and cyclosporine-induced gingival hyperplasia. (B) The same patient 1 year after gingivectomy and 6 months after the dosage of cyclosporine was decreased to one-half of the initial dosage. (Copyright Dr. Daniela Silva. All rights reserved.)

Learning Box 21.3

What are the most common drugs that cause gingival enlargement in children, and what conditions do they treat? Cyclosporine is an immunosuppressant drug used by patients who have undergone organ transplantation. Phenytoin is an antiepileptic medication, and calcium channel blockers are used to treat hypertension, abnormal heart rhythms, and Raynaud phenomenon.

Gingival Changes Related to Orthodontic Appliances

Gingival enlargement can be related to the presence of fixed orthodontic appliances, which complicate plaque removal (Fig. 21.11). Gingival changes can occur within 1 to 2 months of appliance placement. They usually are transient, and they only rarely produce long-term damage to periodontal tissues.[20] The fact that most orthodontic treatment is provided to individuals during puberty, when they are subject to the inflammatory changes associated with puberty gingivitis, may exacerbate the observed effect.

FIG. 21.11 Chronic marginal gingivitis was a result of orthodontic therapy and inadequate oral hygiene.

(Copyright Dr. Daniela Silva. All rights reserved.)

Mouth Breathing

Mouth breathing and lip incompetence, which are together referred to as an *open mouth posture,* are often associated with increased plaque and gingival inflammation.[20] The area of inflammation is often limited to the gingiva of the maxillary incisors. There is usually a clear line of demarcation where the gingiva is uncovered by the lip.

Non–Plaque-Induced Gingival Lesions

Intraoral soft tissue lesions can be encountered in the pediatric population as they are in the adult population. The six most common pediatric intraoral lesions are primary herpetic gingivostomatitis, recurrent herpes simplex, recurrent aphthous stomatitis, candidiasis, angular cheilitis, and geographic tongue.[47] Most of these lesions manifest without significant differences between the pediatric and adult populations, but two do have specific pediatric considerations.

Primary Herpetic Gingivostomatitis

Primary herpetic gingivostomatitis is an acute-onset viral infection that occurs early during childhood, with a heightened incidence between the ages of 1 and 3 years (see Chapter 20). Among children with primary herpetic infections, 99% are symptom free or have symptoms that are attributed to teething. The remaining 1% can develop significant gingival inflammation and ulceration of the attached gingiva, tongue, palate, and lips[28,47] (Fig. 21.12).

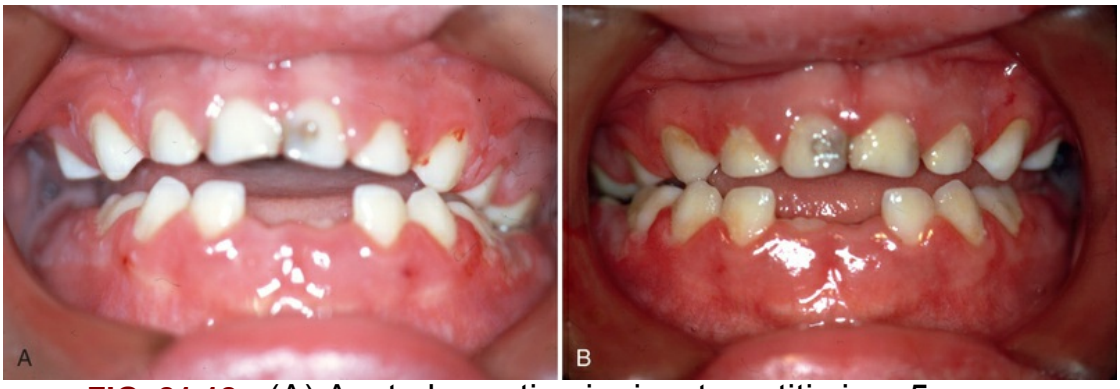

FIG. 21.12 (A) Acute herpetic gingivostomatitis in a 5-

year-old girl produced spontaneous bleeding. The infection is mostly limited to the attached gingiva, tongue, palate, and lips. (B) In the same patient 1 week later, the attached gingiva demonstrates initial healing. (Courtesy Dr. Thomas K. Barber, University of California, Los Angeles Pediatric Dentistry.)

The most important therapeutic measure is to control the child's hydration with bland, nonacetic fluids. Hospitalization may be necessary in some severe cases.

Candidiasis

Candidiasis results from an overgrowth of *Candida albicans*, usually after a course of antibiotics or as a result of congenital or acquired immunodeficiency. It is far less common in children than in adults, and it rarely occurs in a healthy child.[13]

Localized Juvenile Spongiotic Gingival Hyperplasia

Another condition that appears to be unrelated to plaque accumulation is localized juvenile spongiotic gingival hyperplasia. This condition was identified only recently, and its pathogenesis is not well defined. The lesions are localized patches on the attached gingiva that manifest as bright red, raised overgrowths; they are usually painless and associated with easy bleeding. These lesions are most commonly seen on the anterior labial maxillary and mandibular gingiva.[18] Most of the patients with this condition are between 8 and 14 years of age (Fig. 21.13).

FIG. 21.13 Localized juvenile spongiotic gingival hyperplasia is seen in an 11-year-old girl. The papillary gingiva is red, and the gingival overgrowth is prone to easy bleeding. (Courtesy Dr. Chanel McCreedy. All rights reserved.)

Periodontal Diseases of Childhood

Although gingivitis is considered to be almost universal among children who are older than 7 years of age,[16,47] frank periodontal disease with the loss of periodontal attachment and supporting bone is far less common in the pediatric population than in adults.[16] The incidence of disease begins increasing between the ages of 12 and 17 years, but the prevalence of severe attachment loss involving multiple teeth remains low at 0.2% to 0.5%.[16] Of the various manifestations of periodontal disease, chronic periodontitis is more prevalent among adults, and aggressive periodontitis is more common among children and adolescents.[16]

Oral hygiene habits should be imprinted early during life, with instructions about proper technique and directions regarding the frequency of plaque removal procedures. These will form a foundation for a lifetime of dedication to periodontal health. Clinicians should be aware of the specific periodontal needs of children with particular abnormalities, such as gingival hyperplasia associated with immunosuppression protocols used with organ transplantation, antiseizure medications, and increased severity of

periodontal disease in diabetic children. Physically and mentally challenged children deserve special care to ensure that appropriate preventive techniques are available; techniques may include the use of electric toothbrushes and antibacterial mouth rinses. Chapters 27 to 29 describe the different types of periodontal disease.

Aggressive Periodontitis

Aggressive periodontitis is addressed in greater detail in Chapter 28. Because of the relatively early onset of disease, which occurs around the time of puberty, former classifications mention the developmental stage: early-onset periodontitis, prepubertal periodontitis, and juvenile periodontitis.[16,47] The currently accepted designation of aggressive periodontitis may be further broken down into two forms: localized and generalized. Localized aggressive periodontitis has been defined as "interproximal attachment loss on at least two permanent first molars and incisors, with attachment loss on no more than two teeth other than first molars and incisors."[16]

In young individuals, localized aggressive periodontitis is more common than the generalized form. Studies consistently show that among different geographic locations and racial groups, aggressive periodontitis is most prevalent in African populations and their descendants, ranging between 1% and 5%. The prevalence in whites residing in Europe is 0.1% to 0.5%, and in North America, the disease affects approximately 0.1% to 0.2% of whites, 0.5% to 1% of Hispanics, and 2.6% of African Americans.[2,15,56] Some studies suggest a higher prevalence among Asian children.[2,48,64] Of relevance to the pediatric population is the finding that the classic clinical presentation of localized aggressive periodontitis may be preceded by signs of bone loss around the teeth during the primary dentition.[16]

The generalized form of aggressive periodontitis, which is defined as a generalized interproximal attachment loss, including at least three teeth that are not first molars and incisors, is rare among children (Fig. 21.14). The onset of this form of periodontitis usually occurs after the initiation of adolescence. Overall prevalence is 0.13% among 14- to 17-year-old children[16]; however, the prevalence

is higher among individuals with Down syndrome.[4,15,50] A purported genetic influence in the disease process suggests that any signs of disease in a child with a family history of generalized aggressive periodontitis should be investigated further.

FIG. 21.14 (A) In an 8-year-old African-American girl with aggressive periodontitis, the clinical appearance of the mucosa is similar to normal tissue, but the primary canines and molars have mobility, bleeding on probing, and deep pockets. (B) In an 8-year-old

African-American girl with aggressive periodontitis, radiographs show advanced bone loss at the primary canine and molar areas. (Copyright Dr. Daniela Silva. All rights reserved.)

Several studies have suggested the involvement of *A. actinomycetemcomitans*[2,18,32,56,59] and *P. gingivalis*[2] in the pathogenesis of aggressive periodontitis, with the former found at higher levels in children with the localized form and the latter found at higher levels in those with the generalized form. Both of these pathogens are rare in healthy children, with a prevalence of 4.8%, but the rate is elevated for children with periodontitis, with a reported prevalence of 20%.[48] One study found a very strong association between localized aggressive periodontitis and the prevalence and abundance of *A. actinomycetemcomitans.* The study authors also observed *A. actinomycetemcomitans* as being very site specific; it was more prevalent and abundant in diseased sites compared with healthy sites in individuals with localized aggressive periodontitis.[56]

Chronic Periodontitis

Chronic periodontitis, which was formerly known as *adult periodontitis* or *chronic adult periodontitis*, is one of the most prevalent forms of periodontitis. It is characterized by a "slow to moderate rate of progression that may include periods of rapid destruction."[16] Although the disease can appear in children and adolescents as a result of retained plaque and calculus, it is far less prevalent in this population than it is in adults.[16]

Similar to the adult version, which is discussed in greater detail in Chapter 27, chronic periodontitis can occur in children in the localized form, in which less than 30% of the dentition is affected, and in the generalized form, in which more than 30% of the dentition is affected.

The microbiology of this disease is discussed in Chapters 8 and 9. Studies suggest the familial transmission of certain bacteria associated with chronic periodontitis. Strains such as *T. forsythia, Prevotella intermedia*, and *Prevotella nigrescens* are found more often in the children of individuals who harbor these types of bacteria.[66]

Fusobacterium nucleatum and *P. gingivalis* have been identified at significant levels in children of similarly affected parents.[12,30] Levels of these strains increase with age, suggesting that *P. gingivalis* and *T. forsythia* may serve as early markers during screening for periodontal disease.[12,32,63] Although chronic periodontitis may not be highly prevalent among children, early colonization may underscore the importance of early detection, particularly for those at elevated risk for adult forms of the disease.

Gingival Manifestation of Systemic Disease in Children

Systemic diseases that result in periodontitis occur more frequently in children than adults.[2] Chapter 14 discusses some of the systemic diseases and disorders that affect periodontal health. However, many diseases are expressed differently in children than in adults and therefore merit special mention.

Acute necrotizing gingivitis is rarely seen, except in cases of primary or secondary immune suppression, Down syndrome, or severe malnutrition.[19,50] The child's breath is fetid, and he or she complains of pain and discomfort when eating (see Chapter 20).

Endocrine Disorders and Hormonal Changes

Diabetes Mellitus

Type 1 or insulin-dependent diabetes mellitus occurs more frequently in children and young adults than type 2 or non–insulin-dependent diabetes mellitus. As with diabetic adults, gingival inflammation and periodontitis are more prevalent in affected children than in unaffected individuals.[47,51] Clinical consequences include premature tooth loss and impaired immune response to the oral flora. The severity of periodontal disease is worse in children with poor metabolic control.

Although destructive changes are rare in healthy children, periodontal destruction can be observed in diabetic children, usually appearing around the time of puberty and becoming progressively worse as children mature into adulthood. Disease

prevention and fastidious oral hygiene measures should be highly promoted.[31,32]

Hematologic Disorders and Immune Deficiencies

Leukemias

Leukemia is the most common type of cancer in children. Acute lymphocytic leukemia accounts for most cases among children who are younger than 7 years of age. Leukemia must be considered as part of the differential diagnosis for children who present with the hallmark features of acute gingival enlargement, ulceration, bleeding, and infection (Fig. 21.15).[1]

FIG. 21.15 In a 12-year-old boy with acute lymphoblastic leukemia, there is generalized redness of the marginal gingiva with spontaneous bleeding.

(Copyright Dr. Daniela Silva. All rights reserved.)

Neutrophil Disorders

Neutrophil disorders impair defenses against infections, making afflicted individuals susceptible to severe periodontal destruction (see Chapter 14). Many neutrophil disorders are genetic, including some forms of neutropenia, such as familial and cyclic neutropenia, Chédiak–Higashi syndrome, leukocyte adhesion deficiency,

Papillon–Lefèvre syndrome, and Cohen syndrome.[16,27] The diagnosis of the systemic disorder usually occurs before any signs of periodontal destruction appear.

Because periodontal changes are difficult to reverse in children with neutrophil disorders, disease management includes oral hygiene measures, mechanical debridement, antimicrobial therapy, and supportive care for any resultant tissue destruction or tooth loss. Treatment success is unpredictable because of the impact of systemic disease.[16,27]

Congenital Anomalies

Down syndrome is another congenital condition that is diagnosed before the expression of periodontal disease. People with Down syndome experience a high prevalence of severe aggressive periodontitis during early adulthood. The disease process likely reflects a host susceptibility that results in an exaggerated immune and inflammatory response rather than a reaction to a specific causative microbe.[3,4,19,27] Studies of people with Down syndrome uncovered defective neutrophil chemotaxis, which can lead to significant tissue loss and the progression of periodontitis.[27]

Oral Mucosa in Childhood Diseases

Some childhood diseases, such as rubeola (i.e., rubella or measles), varicella (i.e., chickenpox), diphtheria, and scarlatina (i.e., scarlet fever), cause alterations or lesions of the oral mucosa and the underlying tissues. These diseases are explored in textbooks that discuss oral and pediatric pathology.

Therapeutic Considerations for Pediatric Patients

The diagnostic process for pediatric patients follows the general outline described in Chapter 32. Medical and dental histories should be recorded for each child, with parents or legal guardians serving as the primary historians. However, differences between the primary and permanent dentition and aspects related to

development warrant some differences in clinical practices that involve the care of children.

Periodontal indices do not need to be recorded during the primary dentition unless a child exhibits signs of aggressive periodontitis or other unusual disease processes. More explicit periodontal assessments should begin during mixed dentition, when children have permanent incisors and first molars. Rather than recording full-mouth probing depths, clinicians can focus on selected teeth. For example, a rudimentary assessment of teeth #3, #8, #14, #19, #24, and #30 has been suggested,[20] with notes made regarding gingival health, bleeding on probing, and degree of calculus. This quick screening usually is sufficient for children up to the age of 11 years. Between the ages 12 to 19 years, when most individuals have a full permanent dentition, clinicians should also record pocket depths of more than 4 mm. By this stage of dental development, full-mouth pocket-depth probing may be warranted on the basis of general indicators of each patient's gingival health or risk of disease.

In-office professional plaque control procedures can vary in accordance with a patient's stage of development. Calculus deposits are uncommon in infants and toddlers. Supragingival plaque removal with the use of simple rubber-cup coronal polishing or a toothbrush is usually sufficient during the primary dentition.[20] If calculus deposits are evident, selective supragingival scaling can be performed. As the permanent teeth erupt, the prevalence of calculus deposits increases, often necessitating targeted subgingival scaling in addition to supragingival plaque removal.[20]

Chapter 48 discusses plaque control for periodontal patients. In children, however, the dynamic process of developing manual dexterity affects the ability of a child to perform expected procedures. Each child requires an individualized home care program based on his or her ability to perform the requested activities. For young children, plaque control should be a shared responsibility between children and their parents or caregivers. Instruction in plaque control should be delivered to parents and children in language and terms that both understand.

For children who are younger than 7 years of age, parents or caregivers should be asked to assist with toothbrushing.[20] Children

may be encouraged to take a turn brushing their teeth using a simple scrub technique. However, parents should also take a turn to ensure the proper removal of plaque. By 7 years old, children usually possess the manual dexterity to brush their teeth on their own and may require only limited adult supervision.[20] More refined brushing techniques can be introduced during adolescence.

The oral hygiene habits of parents and caregivers have a significant influence on children's oral health behavior. An extensive survey of parents in the United Kingdom found that children and parents place a large emphasis on the cosmetic benefit of toothbrushing. Parents who placed more emphasis on the short-term benefits of toothbrushing were more likely to miss brushing the child's teeth in the evening, but when brushing a child's teeth was habitual, there was a significantly higher chance of brushing twice each day.[64]

Mechanical toothbrushes with rotary heads are effective for plaque removal.[20] The use of these devices can be encouraged as soon as children are able to tolerate the vibrating sensation because many children initially dislike the feeling of the rotary movement. Mechanical toothbrushes are especially recommended for physically challenged children and individuals with fixed orthodontic appliances.[47]

Flossing is usually not indicated for children during the primary dentition stage because most children have interdental spacing throughout most of their arches. However, as interdental contacts develop, flossing should be added to the home care routine. Studies have demonstrated a decrease in gingival bleeding and the quantity of microbes associated with periodontal disease when tooth and tongue brushing are combined with flossing.[7,21] Limitations in manual dexterity may necessitate parental assistance with flossing during the mixed dentition stage. Adolescents with sufficient manual dexterity can be expected to floss on their own.[20]

Antimicrobial mouthrinses for chemical plaque control are not indicated for very young children because of the risk of ingestion of chemical agents.[20] However, rinses may be indicated for older children who demonstrate the ability to expectorate after rinsing.

Conclusions

The periodontium of the primary dentition is different from that of the permanent dentition. Normal development can result in changes to the periodontium. Plaque-induced gingivitis is very common in children, although it may be less intense than in adults. With the exception of localized aggressive periodontitis, children rarely show signs of periodontitis. Some systemic disorders that are commonly associated with periodontal disease manifest initially during childhood.

Recommendations regarding home plaque control routines should be individualized according to each patient's periodontal disease status and developmental stage. Because early diagnosis ensures the greatest chance for successful treatment, it is paramount that children receive a periodontal examination as part of their routine dental visits.

Case Scenario 21.1

Patient:

8-year, 3-month-old male

Chief Complaint:

"My son's gum is purple and swollen."

Background Information:

The child has been a patient since the age of 3 years. He has a noncontributory medical history and no history of drug allergies. Lesions are asymptomatic.

Current Findings:

Lesions are located in the areas of the upper central incisors. They are fluctuant, soft, enlarged, and bluish.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the differential diagnosis for this patient? A. Hematoma due to trauma B. Tooth abscess C. Eruption cyst D. Hemangioma E. Malignant melanoma	**Answer: C** **Explanation:** This clinical presentation is typical of an eruption cyst. It is a well-demarcated, translucent, soft swelling that is directly associated with the crown of the erupting permanent central incisors.
2. Does this patient require surgical therapy to address the chief complaint? A. Yes B. No	**Answer: B** **Explanation:** Most eruption cysts are asymptomatic and resolve without treatment. In a few situations, the cysts interfere with mastication, and the child can benefit from a small incision in the mucosa to allow the hemorrhagic contents to be drained.

Image courtesy Dr. Daniela R. Silva, UCLA School of Dentistry.

Case Scenario 21.2

Patient:

6-year, 5-month-old female

Chief Complaint:

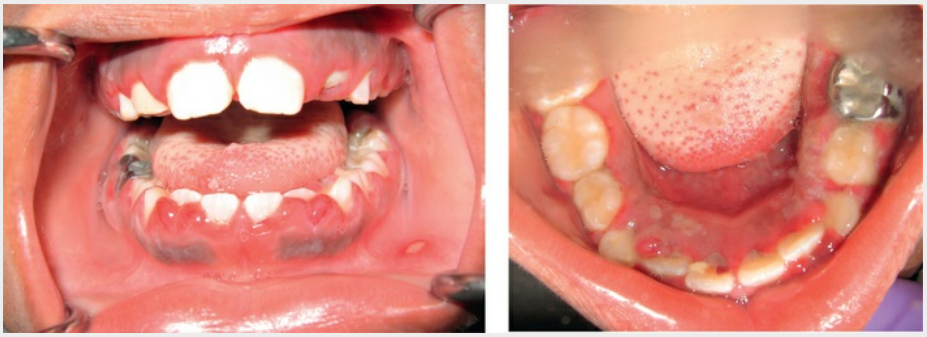
"My daughter has extreme pain in her mouth and cannot eat or drink anything."

Background Information:

Child has a noncontributory medical history and no history of drug allergies. She had comprehensive restorative treatment performed 14 months earlier and is here today for an emergency appointment.

Current Findings:

- Body temperature of 101.8° F and malaise
- Bilateral neck lymphadenopathy
- Swollen, inflamed, and erythematous gingiva
- Multiple ulcers on the marginal gingiva, mucosa, and soft palate
- Tongue is coated solid white with ulcers on the tip



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is the differential diagnosis for this patient? A. Herpetiform ulcers B. Herpangina C. Primary herpetic gingivostomatitis D. Infectious mononucleosis E. ANUG	**Answer: C** **Explanation:** The child has malaise, anorexia, irritability, fever, lymphadenopathy, and halitosis, and the gingival tissues are enlarged, painful, and erythematous. The vesicles occur on movable (i.e., cheeks and soft palate) and attached mucosa.
2. What is the treatment for this child? A. Topical anesthetics and coating agents B. Acyclovir elixir,	**Answer: E** **Explanation:** Treatment should be supportive to eliminate pain and fever and to hydrate the child. Use of the antiviral acyclovir depends on the severity of the condition. For immunocompromised children, systemic acyclovir is recommended; only the topical form is

200 mg/5 mL for 7 to 10 days C. Antipyretics and analgesics D. To drink lots of liquid; eat soft and cold food E. All the above	indicated for immunocompetent children.

Images courtesy Dr. Daniela R. Silva, UCLA School of Dentistry.

CHAPTER 22

Desquamative Gingivitis

Alfredo Aguirre, Jose Luis Tapia Vazquez, Yasmin Mair

CHAPTER OUTLINE

Chronic Desquamative Gingivitis
Diagnosis of Desquamative Gingivitis: A Systematic Approach
Diseases That Can Manifest as Desquamative Gingivitis
Drug-Related Eruptions

Chronic Desquamative Gingivitis

Although the condition was first recognized and reported in 1894,[171] the term *chronic desquamative gingivitis* was not coined by Prinz[131] until 1932. It describes a reaction characterized by intense erythema, desquamation, and ulceration of the free and attached gingiva[54,106] (Fig. 22.1).

FIG. 22.1 In chronic desquamative gingivitis, irregular, conspicuous erythema involves the free and attached gingival tissues.

Patients can be asymptomatic, but when symptomatic, their complaints range from a mild burning sensation to intense pain. Approximately 50% of desquamative gingivitis cases are localized to the gingiva, although patients can have involvement of the gingiva plus other intraoral and extraoral sites.[59,121]

The cause was initially unclear, with a variety of possibilities suggested. Because most cases were diagnosed in women during the fourth and fifth decades of life (although desquamative gingivitis can occur as early as puberty or as late as the seventh or eighth decade), hormonal derangement was suspected. In 1960, McCarthy and colleagues[102] suggested that desquamative gingivitis was not a specific disease entity but was instead a *gingival response associated with a variety of conditions*. This concept has been supported by numerous immunopathologic studies.[82,90,123,142,162,172]

The use of clinical and laboratory parameters has revealed that approximately 75% of desquamative gingivitis cases have a dermatologic genesis. Lichen planus and cicatricial pemphigoid account for 84% of the desquamative gingivitis cases.[83,119] However, many other mucocutaneous autoimmune conditions (e.g., bullous pemphigoid, pemphigus vulgaris, linear immunoglobulin A [IgA] disease, dermatitis herpetiformis, lupus erythematosus, chronic ulcerative stomatitis, dermatomyositis, mixed connective tissue disease) can manifest as desquamative gingivitis.[83,152]

Other conditions that must be considered in the differential diagnosis of desquamative gingivitis include chronic bacterial,

fungal, and viral infections and reactions to medications, mouthwashes, and chewing gum. Although less common, Crohn disease, sarcoidosis, some leukemias, and factitious lesions have also been reported to manifest clinically as desquamative gingivitis.[135,152,178]

It is important to ascertain the disease responsible for desquamative gingivitis to establish the appropriate therapeutic approach. To achieve this goal, a clinical examination is coupled with a thorough history and routine histologic and immunofluorescence studies.[24,90,166,178] Despite a systematic diagnostic approach, the cause of desquamative gingivitis cannot be elucidated in up to one-third of cases.[136]

Diagnosis of Desquamative Gingivitis: A Systematic Approach

Desquamative gingivitis is a clinical term and not a diagnosis. After the condition is identified, a series of laboratory procedures should be used to arrive at a final diagnosis. The success of any therapeutic approach depends on the establishment of an accurate final diagnosis. The following sections describe a systematic approach to determining the disease that is triggering desquamative gingivitis (Fig. 22.2).

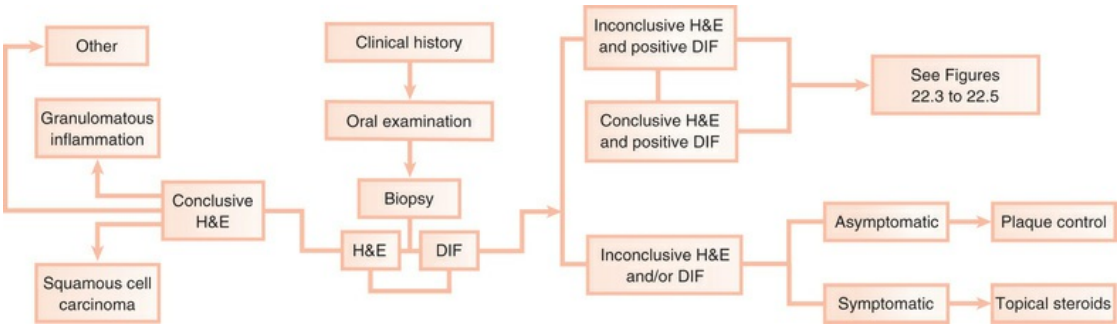

FIG. 22.2 The diagnostic approach for desquamative gingivitis includes hematoxylin and eosin (H&E) and direct immunofluorescence (DIF) evaluation of biopsy specimens.

Clinical History

A thorough clinical history is mandatory to begin the assessment of desquamative gingivitis.[90,122] Data regarding the symptoms associated with this condition and its historical aspects (e.g., lesion onset, whether it has worsened, habits that exacerbate it) provide the foundation for a thorough examination. Information about previous therapy to alleviate the condition should be documented.

Clinical Examination

The distribution pattern of the lesions (e.g., focal or multifocal, with or without confinement to gingival tissues) provides information that can begin to narrow the differential diagnosis.[24,90] A simple clinical maneuver such as the Nikolsky sign offers insight into the plausibility of a vesiculobullous disorder.[107]

Clinical Correlation

The Nikolsky sign is characterized by blister formation or peeling of skin or mucosa when horizontal tangential pressure is applied to the skin or mucosa in patients with vesiculobullous disorders.

Biopsy

Given the extent and number of lesions that may be present in an individual, an incisional biopsy is the best strategy for beginning the microscopic and immunologic evaluation.[24] An important consideration is the selection of the biopsy site. A perilesional incisional biopsy should avoid areas of ulceration because necrosis and epithelial denudation severely hamper the diagnostic process.[169]

After the tissue is excised from the oral cavity, the specimen can be bisected and then submitted for microscopic examination. Buffered formalin (10%) should be used to fix the tissue for conventional hematoxylin and eosin (H&E) evaluation. Michel's buffer (i.e., ammonium sulfate buffer, pH 7.0) is used as the transport solution for immunofluorescence assessment. An

incisional biopsy of uninvolved (normal) mucosa typically shows the same immunofluorescent findings as the biopsy of the perilesional tissue. However, there are notable exceptions, such as lichen planus and chronic cutaneous lupus erythematosus, in which only the lesional tissue exhibits the corresponding immunologic markers (Table 22.1).[169]

TABLE 22.1

Diagnostic Findings for Conditions That Can Manifest as Desquamative Gingivitis

Disease	Histopathology	DIRECT IMMUNOFLUORESCENCE		INDIRECT IMMUNOFLUORESCEN
		Biopsy of Perilesional Mucosa	Biopsy of Uninvolved Mucosa	Serum
Pemphigus	Intraepithelial clefting above the basal cell layer; basal cells have a characteristic tombstone appearance; acantholysis	Intercellular deposits in epithelium; IgG in all cases and C3 in most cases	Same as for perilesional mucosa	Intercellular antibodies (IgG ≥90% of cases
Cicatricial pemphigoid	Subepithelial clefting with epithelial separation from the underlying lamina propria, leaving an intact basal layer	Linear deposits of C3 with or without IgG at the basement membrane zone in most cases	Same as for perilesional mucosa	Basement membrane zone antibodies (IgG) in 10% of cases
Bullous pemphigoid	Subepithelial clefting with epithelial separation from the underlying lamina propria, leaving an intact basal layer	Linear deposits of C3 with or without IgG at the basement membrane zone in most cases	Same as for perilesional mucosa	Basement membrane zone i 40%–70% of cases
Epidermolysis bullosa acquisita	Similar to bullous and cicatricial pemphigoid	Linear deposits of IgG and C3 at the basement membrane zone in most cases	Same as for perilesional mucosa	Basement membrane zone antibodies (IgG) in 25% of cases
Lichen planus	Hyperkeratosis, hydropic degeneration of the basal layer, and sawtooth rete pegs; lamina	Fibrillar deposits of fibrin at the dermal–epidermal junction	Negative	Negative

	propria exhibits dense, bandlike infiltrate, primarily of T lymphocytes; colloid bodies			
Chronic ulcerative stomatitis	Similar to erosive lichen planus; hyperkeratosis, acanthosis, basal cell layer liquefaction, subepithelial clefting, and lymphohistiocytic chronic infiltrate in a bandlike configuration	IgG deposits in the nuclei of the basal layer of epithelial cells	Same as for perilesional mucosa	ANA specific for basal cells stratified squamous epithel
Linear IgA disease	Similar to erosive lichen planus	Linear deposits of IgA at the basement membrane zone	Same as for perilesional mucosa	IgA basement membrane zo antibodies (IgA) in 30% of cases
Dermatitis herpetiformis	Collection of neutrophils, eosinophils, and fibrin in the connective tissue papillae	IgA deposits in the dermal papillae in 85% of cases	IgA deposits in dermal papillae in 100% of cases	IgA endomysial antibodies 70% of cases; gliadin antibo in 30% of cases
Systemic lupus erythematosus	Hyperkeratosis, basal cell degeneration, epithelial atrophy, and perivascular inflammation	IgG or IgM with or without C3 deposits at the dermal–epidermal junction	Same as for perilesional mucosa	ANA in >95% of cases; DNA and ENA antibodies in >50% cases
Chronic cutaneous erythematosus	Hyperkeratosis, basal cell degeneration, epithelial atrophy, and perivascular inflammation	IgG or IgM with or without C3 deposits at the dermal–epidermal junction	Negative	Usually negative
Subacute lupus erythematosus	Less inflammatory cell infiltrate than systemic and chronic cutaneous forms but with similar microscopic features	IgG or IgM with or without C3 deposits at the dermal-epidermal junction in 60% of cases; granular IgG deposits in basal cell cytoplasm in 30% of cases	Same as for perilesional mucosa	ANA in 60% to 90% of cases Ro (SSA) in 80% of cases; RI 30% of cases; anti-RNP in 1(of cases

ANA, Antinuclear antibodies; *C3,* complement 3; *DNA*, deoxyribonucleic acid; *ENA*, extractable nuclear antigens; *IgA*, immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *RF*, rheumatoid factor; *RNP*, ribonucleoprotein.

Adapted from Rinaggio J, Neiders ME, Aguirre A, Kumar V: Using immunofluorescence in the diagnosis of chronic ulcerative lesions of the oral mucosa. *Compend Contin Educ Dent* 20:943–944, 947–948, 950 passim, 1999.

Microscopic Examination

Sections of approximately 5 μm of formalin-fixed, paraffin-embedded tissue stained with conventional H&E are obtained for light microscopy examination.[169]

Immunofluorescence

For *direct* immunofluorescence, unfixed frozen sections are incubated with a variety of fluorescein-labeled, antihuman serum (i.e., anti-IgG, anti-IgA, anti-IgM, antifibrin, and anti-C3). For *indirect* immunofluorescence, unfixed frozen sections of oral or esophageal mucosa from an animal such as a monkey are first incubated with the patient's serum to enable attachment of serum antibodies to the mucosal tissue. The tissue is then incubated with fluorescein-labeled antihuman serum. Immunofluorescence tests are positive if a fluorescent signal is observed in the epithelium, its associated basement membrane, or the underlying connective tissue (see Table 22.1).[169]

Management

After the diagnosis is established, the dentist must choose the optimal management strategy. The choice depends on the practitioner's experience, the systemic impact of the disease, and the systemic complications of the medications. A detailed consideration of these factors dictates three scenarios.

In the first scenario, the dental practitioner takes direct and exclusive responsibility for the treatment of the patient. This occurs with conditions such as erosive lichen planus, which is responsive to topical steroids (Fig. 22.3).

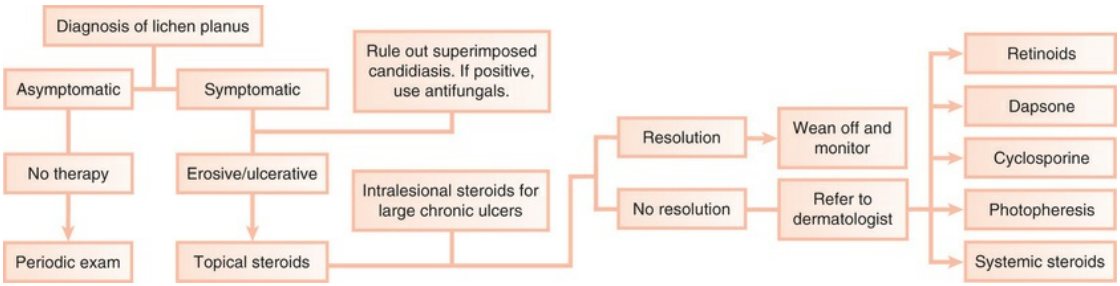

FIG. 22.3 Algorithm for the treatment of lichen planus.

In the second scenario, the dentist collaborates with another health care provider to evaluate and treat a patient concurrently. The classic example is seen with cicatricial pemphigoid, in which dentists and ophthalmologists work together to provide treatment (Fig. 22.4). Although the dentist addresses the oral lesions, the ophthalmologist monitors the integrity of the ocular conjunctiva.

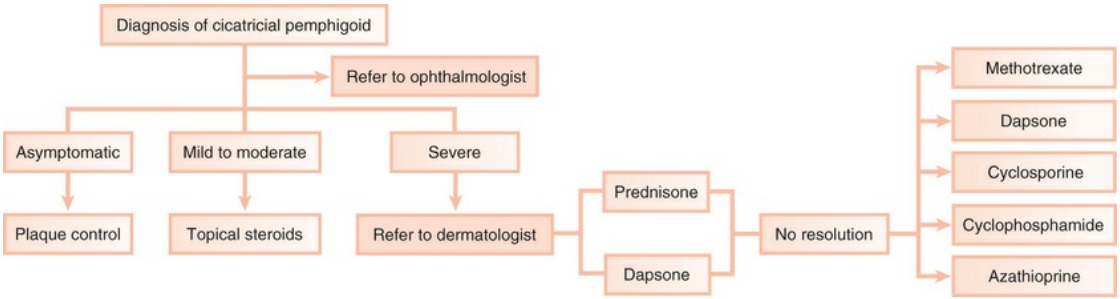

FIG. 22.4 Algorithm for the treatment of cicatricial pemphigoid.

In the third scenario, the patient is immediately referred to a dermatologist for further evaluation and treatment. This occurs with conditions for which the systemic impact of the disease transcends the boundaries of the oral cavity and results in significant morbidity or mortality. Pemphigus vulgaris is an example of a condition that, after diagnosis by the dentist, requires immediate referral to a dermatologist (Fig. 22.5). The complications (e.g., diabetes mellitus, osteoporosis, methemoglobinemia) of chronically administered systemic medications that are indicated for the management of diseases such as pemphigus vulgaris or nonresponsive mucous membrane pemphigoid (MMP) warrant referral to a dermatologist or a specialist in internal medicine.

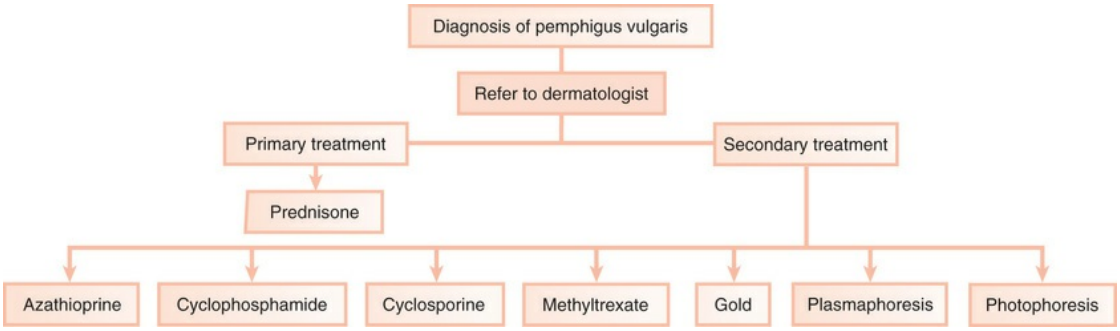

FIG. 22.5 Algorithm for the treatment of pemphigus vulgaris.

When oral treatment is provided, periodic evaluation is needed to monitor the response of the patient to therapy. Initially, the patient should be evaluated at 2 to 4 weeks after beginning treatment to ensure that the condition is under control. Observation should continue until the patient is free of discomfort. Appointments every 3 to 6 months are then appropriate. Medication dosages are usually adjusted during this interval.

Table 22.2 summarizes suggested contemporary therapeutic approaches that can be used to treat selected conditions that can manifest as desquamative gingivitis. Dentists play an important role in the diagnosis and management of desquamative gingivitis. The importance of recognizing and properly diagnosing this condition is accentuated by the fact that a serious and life-threatening disease (i.e., squamous cell carcinoma) can mimic desquamative gingivitis.[138]

TABLE 22.2

Therapeutic Approaches for Treating Selected Conditions That Manifest as Desquamative Gingivitis

Disease	THERAPY		
	Mild Cases	**Recalcitrant Cases**	**Severe or Refractory Cases**
Erosive lichen planus	Delivery of therapeutic agent is enhanced with use of vacuum-formed custom trays **Rx:** Lidex (0.05% fluocinonide) gel **Disp:** One tube (15 g) **Sig:** Apply to affected area pc and hs Monitoring of patient's oral	**Rx:** Protopic (0.1% tacrolimus) ointment **Disp:** One tube (15 g) **Sig:** Apply to affected	Refer to dermatologist for management with systemic corticosteroids

	cavity warranted because candidiasis may develop after a few weeks of topical steroid use; concomitant use of antifungal may be necessary **Rx:** Clotrimazole 10-mg troches **Disp:** 90 **Sig:** Dissolve in mouth tid, then expectorate for 30 consecutive days	area bid	
Cicatricial pemphigoid	**Rx:** Lidex (0.05% fluocinonide) gel **Disp:** One tube (15 g) **Sig:** Apply to affected area pc and hs **Rx:** Temovate (0.05% clobetasol propionate) **Disp:** One tube (15 g) **Sig:** Apply to affected area qid		Refer to dermatologist for management with prednisone (20–30 mg/day); concomitant use of azathioprine may be needed; dapsone, sulfonamide, and tetracycline are other alternatives
Pemphigus	Refer to dermatologist for management with prednisone (20 to 30 mg/day); concomitant use of azathioprine may be needed		
Chronic ulcerative stomatitis	**Rx:** Lidex (0.05% fluocinonide) gel		
	Disp: One tube (15 g)		
	Sig: Apply to affected area qid		
	Rx: Temovate (0.05% clobetasol propionate)		
	Disp: One tube (15 g)		
	Sig: Apply to affected area qid

Diseases That Can Manifest as Desquamative Gingivitis

Lichen Planus

Lichen planus is an inflammatory mucocutaneous disorder that can involve the mucosal surfaces (e.g., oral cavity, genital tract, other mucosae) and the skin, including the scalp and the nails.[141] Evidence suggests that lichen planus is an immunologically mediated mucocutaneous disorder in which host T lymphocytes play a central role.[11,68,76,100] Although the oral cavity can have lichen

planus lesions with a distinct clinical configuration and distribution, the clinical presentation can simulate other mucocutaneous disorders. Oral lichen planus has a broad differential diagnosis.

Numerous epidemiologic studies have found that oral lichen planus occurs in 0.1% to 4% of the population.[146,153] Most patients with oral lichen planus are middle-aged or older women; the disorder occurs with a 2 : 1 ratio of women to men. Children are rarely affected. In a dental setting, cutaneous lichen planus is observed in about one-third of patients diagnosed with oral lichen planus.[97] Two-thirds of patients seen in dermatologic clinics exhibit oral lichen planus.[149]

Key Fact

Lichen planus is a mucocutaneous disorder that classically manifests with bilateral, white striae on the buccal mucosae. The classic reticular subtype is asymptomatic, and no treatment is needed. Atrophic and erosive forms of oral lichen planus are associated with pain and a burning sensation, and topical corticosteroids are the mainstay of treatment. One percent of oral lichen planus cases may develop squamous cell carcinoma.

Oral Lesions

Although there are several clinical forms of oral lichen planus (i.e., reticular, patch, atrophic, erosive, and bullous), the most common are the reticular and erosive subtypes. The typical reticular lesions are asymptomatic and bilateral, and they consist of interlacing white lines on the posterior region of the buccal mucosa. The lateral border and dorsum of the tongue, the hard palate, the alveolar ridge, and the gingiva may also be affected.[26] The reticular lesions can have an erythematous background, which is a feature associated with coexisting candidiasis. Oral lichen planus lesions follow a chronic course and have alternating, unpredictable periods of quiescence and flare-ups.

The erosive subtype of lichen planus is often associated with pain. It manifests as atrophic, erythematous, and often ulcerated

areas. Fine, white radiating striations are observed bordering the atrophic and ulcerated zones. These areas may be sensitive to heat, acid, and spicy foods (Fig. 22.6).

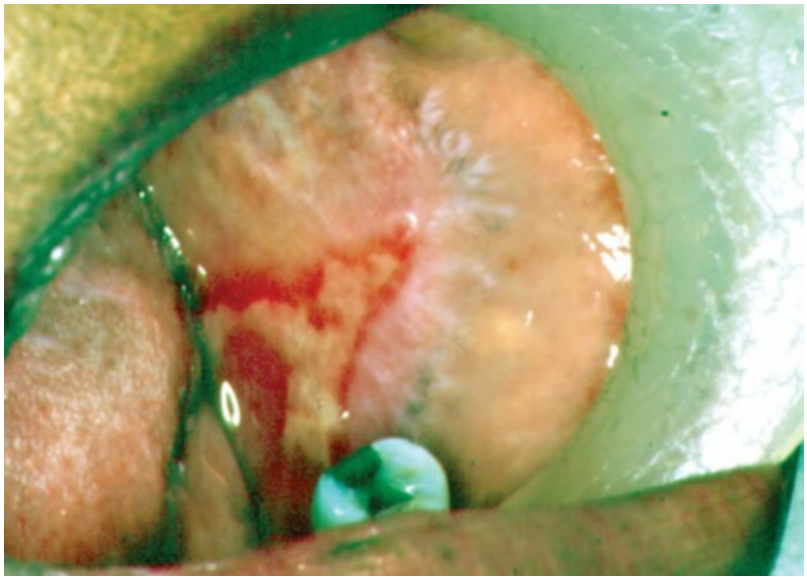

FIG. 22.6 In a case of erosive lichen planus, the large ulcerative lesion on the left buccal mucosa exhibits bordering erythema. The typical white striations of lichen planus are evident in the periphery of the ulcer.

Gingival Lesions

Approximately 7% to 10% of patients with oral lichen planus have lesions restricted to the gingival tissue.[109,149] They may occur as one or more types of the following four distinctive patterns:

1. *Keratotic lesions.* The raised, white lesions can manifest as groups of individual papules, linear or reticular lesions, or plaquelike configurations.
2. *Erosive or ulcerative lesions.* The extensive erythematous areas with a patchy distribution can manifest as focal or diffuse hemorrhagic areas. The lesions are exacerbated by slight trauma (e.g., toothbrushing) (Fig. 22.7).

FIG. 22.7 Erosive lichen planus can manifest as desquamative gingivitis. The gingival tissues are erythematous, ulcerated, and painful. (Courtesy Dr. Luis Gaitan, Oral Pathology Laboratory, Faculty of Odontology, National Autonomous University of Mexico, Mexico City, Mexico.)

3. *Vesicular or bullous lesions.* The raised, fluid-filled lesions are uncommon and short lived on the gingiva, quickly rupturing and leaving ulcerations.
4. *Atrophic lesions.* Atrophy of the gingival tissues with ensuing epithelial thinning results in erythema that is confined to the gingiva.

Histopathology

Microscopically, three main features characterize oral lichen planus: (1) hyperkeratosis or parakeratosis, (2) hydropic degeneration of the basal layer, and (3) a dense, bandlike infiltrate, consisting primarily of T lymphocytes, in the lamina propria (Fig. 22.8). Classically, the epithelial rete ridges have a sawtooth configuration. Hydropic degeneration of the basal layer of the epithelium can be sufficiently extensive that the epithelium becomes thin and atrophic or detaches from the underlying connective tissue and produces a subepithelial vesicle or an ulcer. Colloid bodies (i.e., Civatte bodies) are often seen at the epithelium–connective tissue interface.

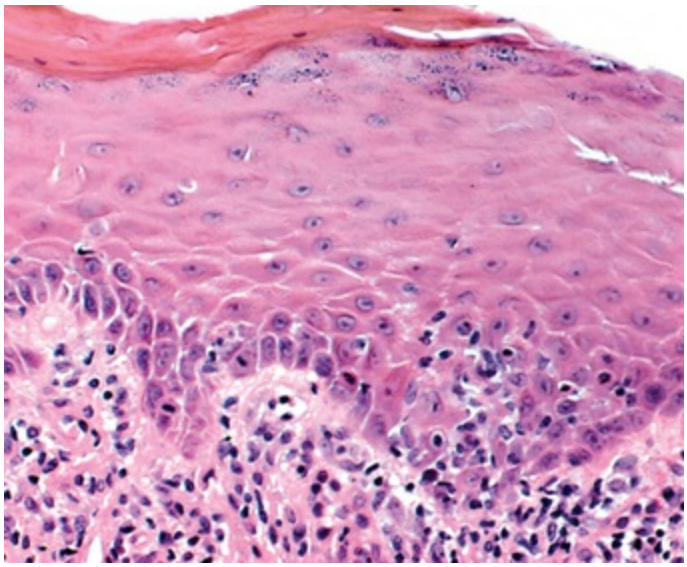

FIG. 22.8 **Microscopic appearance of lichen planus. The biopsy specimen from a gingival lesion shows hyperkeratosis and mild hypergranulosis, along with focal basal cell degeneration, lymphocytic exocytosis, and thickening of the basement membrane. The rete pegs exhibit a slight serrated configuration. The papillary lamina propria shows a bandlike infiltrate of lymphohistiocytic chronic inflammatory cells. Hematoxylin and eosin stain; original magnification ×100.**

The microscopic diagnosis of oral lichen planus is straightforward for the keratotic lesions, and biopsy specimens should be obtained from these areas if possible. However, classic histologic features may be obscured in areas of ulceration, making a conclusive diagnosis of oral lichen planus difficult if it is based solely on conventional microscopy. Electron microscopy studies indicate that separation of the basal lamina from the basal cell layer is an early manifestation of lichen planus.[65]

Key Fact

Civatte bodies are eosinophilic globules typically seen at the junction of epithelium and connective tissue in lichen planus. They are derived from keratinocytes that are undergoing apoptosis.

The pattern of oral lesions of lichen planus can change, and in unusual cases a second or third biopsy may be necessary to arrive at a definitive diagnosis. Controversy exists regarding the malignant potential of oral lichen planus. Some researchers posit that oral cancer emerges in up to 2% of patients with oral lichen

planus.[45,66,67,91,161] Other researchers reject or question the connection between oral lichen planus and oral cancer.[46,70,95,133] Despite this controversy, biopsy and close follow-up are warranted for these patients.

Immunopathology

Direct immunofluorescence of lesional and perilesional oral lichen planus biopsy specimens reveals linear fibrillar (i.e., shaggy) deposits of fibrin in the basement membrane zone (Fig. 22.9), along with scattered immunoglobulin-staining cytoid bodies in the upper areas of the lamina propria (Fig. 22.10). Results of serum tests involving the use of indirect immunofluorescence are negative for patients with lichen planus (see Table 22.1).

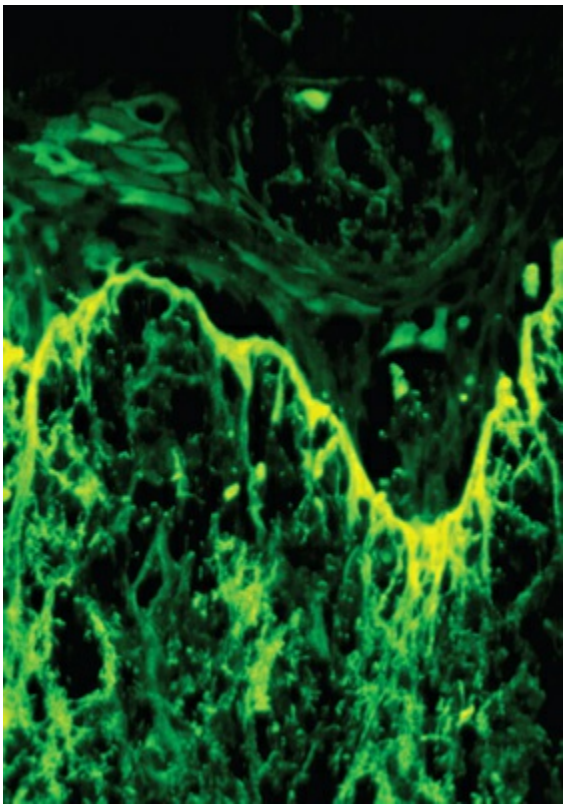

FIG. 22.9 **Direct immunofluorescence staining of lichen planus. Fibrin deposits along the basement membrane of the epithelium exhibit a shaggy configuration.**

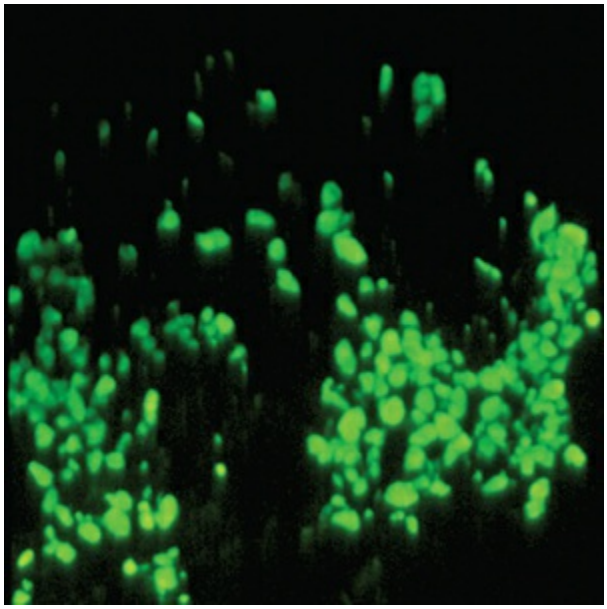

FIG. 22.10 **Direct immunofluorescence staining of lichen planus. Clusters of cytoid bodies exhibit immunoglobulin M deposits in the lamina propria.**

Differential Diagnosis

The classic clinical presentation of oral lichen planus can be simulated by other conditions, mainly by lichenoid mucositis. If oral lichen planus is confined to the gingival tissues (i.e., erosive oral lichen planus), the identification of fine, white radiating striations bordering the erosive areas support a diagnosis of oral lichen planus. If the white striations are absent, the differential diagnosis should primarily include MMP and pemphigus vulgaris. Less common possibilities include linear immunoglobulin A disease (LAD), lichen planus pemphigoides, and chronic ulcerative stomatitis.

Treatment

The keratotic lesions of oral lichen planus are asymptomatic and do not require treatment after the microscopic diagnosis has been established. However, evaluation of the patient every 6 to 12 months is warranted to monitor suspicious clinical changes and to look for the emergence of an erosive component.

The erosive, bullous, or ulcerative lesions of oral lichen planus are treated with high-potency topical steroids, such as 0.05% fluocinonide gel (Lidex, three times daily). Lidex can also be mixed

1 : 1 with carboxymethylcellulose (Orabase) paste or another adhesive ointment. A gingival tray can be used to deliver 0.05% fluocinonide ointment or gel or 0.05% clobetasol propionate with 100,000 IU/ml of nystatin in Orabase (Fig. 22.11).

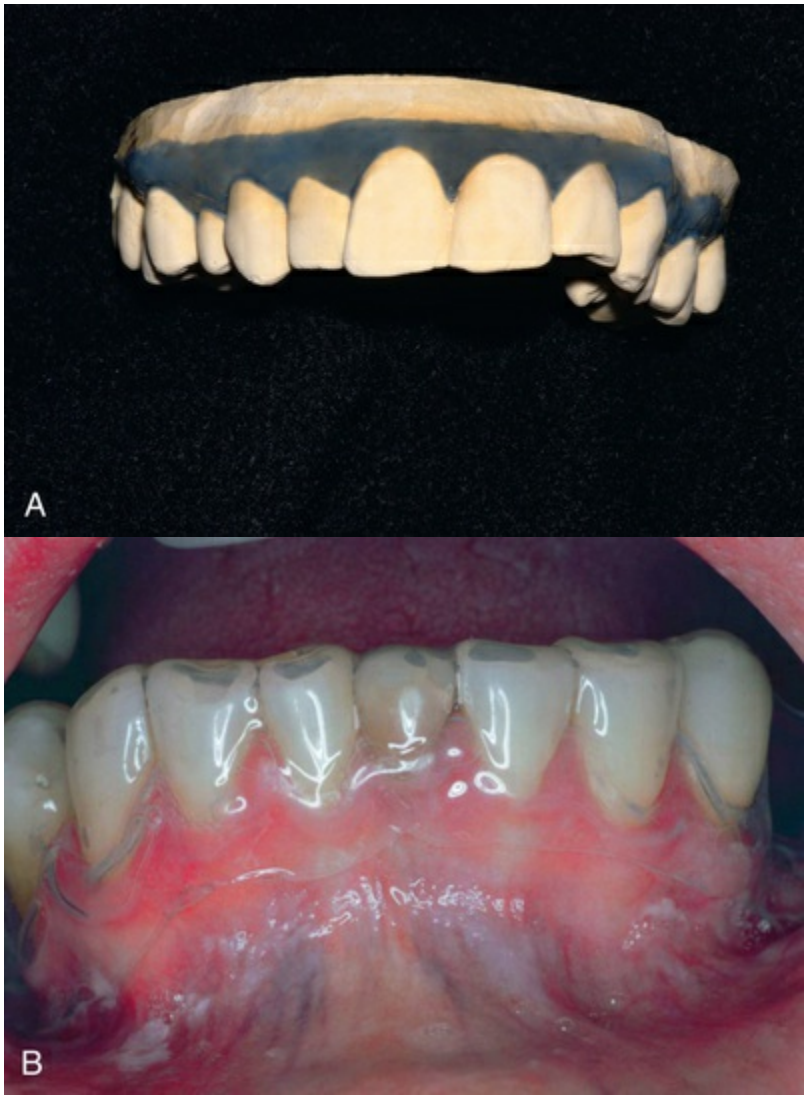

FIG. 22.11 (A) An alginate impression is obtained to create a stone model. A thin layer of block-out resin is applied on the gingival and alveolar mucosal areas with desquamative gingivitis to create a space to carry the medication. A trimmed maxillary stone model shows the block-out resin in place *(blue area)*. (B) A mandibular gingival tray is in place. Soft sheet material for vacuum-forming trays is prepared and trimmed to conform to the local anatomy.

Three 5-minute applications daily of the mixture appear to be effective for controlling erosive lichen planus.[60] Intralesional injections of triamcinolone acetonide (10 to 20 mg) or short-term regimens of 40 mg of prednisone daily for 5 days, followed by 10 to 20 mg daily for an additional 2 weeks, have also been used in more severe cases.[121] Because of the potential side effects, systemic steroids should be administered and monitored by a dermatologist.

Other treatment modalities (e.g., retinoids, hydroxychloroquine, cyclosporine, azathioprine, cyclophosphamide, free gingival grafts) have been used.[121,128] A promising therapeutic agent, tacrolimus (0.1% Protopic ointment, twice daily), is an immunosuppressant that is effective for controlling the lesions of erosive lichen planus.[77,99,113,155]

Because candidiasis is often associated with symptomatic oral lichen planus and because topical steroid therapy promotes fungal growth, treatment should also include a topical antifungal agent.[16,56,71]

Pemphigoid

The term *pemphigoid* applies to several cutaneous, immune-mediated, subepithelial bullous diseases that are characterized by a separation of the basement membrane zone, including bullous pemphigoid, MMP, and pemphigoid (herpes) gestationis.[127,147] Among these conditions, bullous pemphigoid and MMP (i.e., benign MMP or cicatricial pemphigoid) have received considerable attention. Molecular findings for these two diseases indicate that they are separate entities.[147] However, considerable histologic and immunopathologic overlap exists between them, and differentiation may be impossible on the basis of the two criteria.[127]

In many cases, the clinical findings are probably the best way to discriminate between them. Accordingly, the term *bullous pemphigoid* is preferred when the disease is nonscarring and mainly affects the skin. The term *cicatricial pemphigoid* is favored when scarring occurs, and the disease is mainly confined to mucous membranes, although scarring may be absent with some subtypes of MMP.[174] Until more research allows a better understanding of this family of diseases, bullous pemphigoid and MMP are discussed

separately.

Bullous Pemphigoid

Bullous pemphigoid is a chronic, autoimmune, subepidermal bullous disease with tense cutaneous bullae that rupture and become flaccid (Fig. 22.12). Oral involvement occurs in about a third of affected patients.[159] Although the skin lesions of bullous pemphigoid clinically resemble those of pemphigus, the microscopic picture is quite distinct.

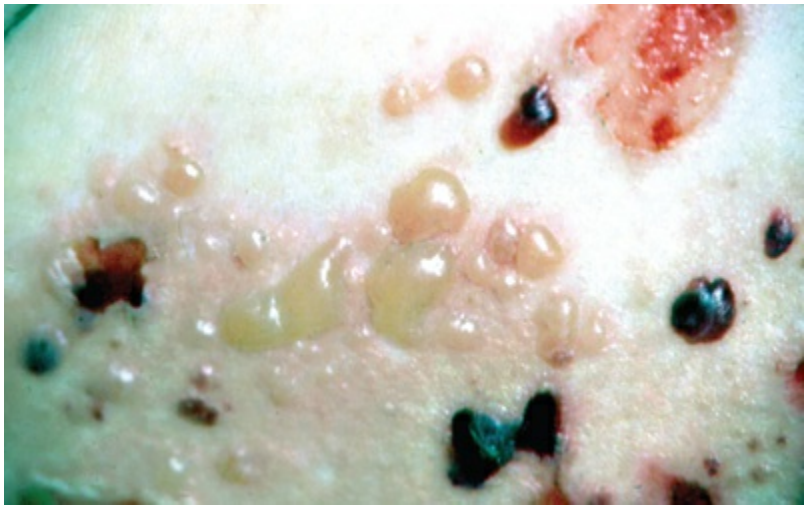

FIG. 22.12 Coalescing cutaneous bullae are seen in a case of bullous pemphigoid, and some of them are hemorrhagic. Rupture of the bullae leads to the formation of serpiginous ulcers.

Histopathology

There is no evidence of acantholysis in bullous pemphigoid, and the developing vesicles are subepithelial rather than intraepithelial. The epithelium separates from the underlying connective tissue at the basement membrane zone. Electron microscopic studies show horizontal splitting or replication of the basal lamina. The separating epithelium remains relatively intact, and the basal layer appears to be regular. The two major antigenic determinants of bullous pemphigoid are the 230-kDa protein plaque known as *bullous pemphigoid 1 (BP1)* and the 180-kDa collagen-like transmembrane protein known as *bullous pemphigoid 2 (BP2)*.[114,130,140]

Immunofluorescence

Immunologically, bullous pemphigoid is characterized by immunoglobulin G (IgG) and complement 3 (C3) immune deposits along the epithelial basement membranes and circulating IgG antibodies to the epithelial basement membrane.[75,118] Direct immunofluorescence studies are positive for 90% to 100% of these patients, whereas indirect immunofluorescence studies are positive for 40% to 70% of affected patients[119] (see Table 22.1).

Oral Lesions

Oral lesions of bullous pemphigoid have been reported to occur secondarily in up to 40% of cases. The clinical presentation includes an erosive or desquamative gingivitis and occasional vesicular or bullous lesions.[159]

Treatment

Because the etiologic factors of bullous pemphigoid are unknown, treatment is designed to control its signs and symptoms.[75,118] The primary treatment is a moderate dose of systemic prednisone. Steroid-sparing strategies (i.e., prednisone plus other immunomodulatory drugs) are used when high doses of steroids are needed or when the steroid alone fails to control the disease.[40] For localized lesions of bullous pemphigoid, high-potency topical steroids or tetracycline with or without nicotinamide can be effective.[121]

Mucous Membrane Pemphigoid

MMP (i.e., cicatricial pemphigoid) is a chronic vesiculobullous autoimmune disorder of unknown cause that predominantly affects women during the fifth decade of life. It has rarely been reported in young children.[22,115,147]

Cicatricial pemphigoid involves the oral cavity, the conjunctiva, and the mucosa of the nose, vagina, rectum, esophagus, and urethra. In about 20% of patients the skin may also be involved.

Investigations suggest that cicatricial pemphigoid encompasses a group of heterogeneous conditions with distinct clinical and molecular features.[38,110,144] An elaborate cascade of events is

involved in the pathogenesis of cicatricial pemphigoid. Initially, antigen–antibody complexing occurs at the basement membrane zone, which is followed by complement activation and subsequent leukocyte recruitment. Proteolytic enzymes are then released and dissolve or cleave the basement membrane zone, usually at the level of the lamina lucida.[49]

The two major antigenic determinants for cicatricial pemphigoid are BP1 and BP2. Most cases of cicatricial pemphigoid are the result of an immune response directed against BP2; less often, this response is mounted against BP1, epiligrin (i.e., laminin 5, a lamina lucida protein in the basement membrane of stratified epithelium), and β_4 integrins.[8,21,38]

Key Fact

Mucous membrane pemphigoid (MMP) is an autoimmune disorder characterized by ocular and oral lesions. Symblepharon (i.e., scarring resulting in adhesion of the eyelid to the eyeball) is a significant complication of MMP. The diagnosis is made by using hematoxylin and eosin (H&E) and direct immunofluorescence studies, and the mainstay of treatment is corticosteroids.

There is strong evidence for the existence of at least five subtypes of cicatricial pemphigoid: oral pemphigoid, anti-epiligrin pemphigoid, anti-BP antigen mucosal pemphigoid, ocular pemphigoid, and multiple-antigen pemphigoid.[147] The sera of ocular pemphigoid patients recognize the β_4 integrin subunit, whereas the sera of patients with oral pemphigoid recognize the α_6 unit.[134]

Ocular Lesions

Among patients (mainly those with desquamative gingivitis) who first see a dentist, the eyes are affected in approximately 25%.[119] In contrast, among patients who first see a dermatologist, 66% have conjunctival lesions; in ophthalmic studies, 100% of patients have ocular involvement.[55,87,111,112]

The initial lesion is characterized by unilateral conjunctivitis that

becomes bilateral within 2 years. Subsequently, adhesions of the eyelid to the eyeball (i.e. symblepharon) may form (Fig. 22.13). Adhesions at the edges of the eyelids (i.e., ankyloblepharon) may lead to a narrowing of the palpebral fissure. Small vesicular lesions may develop on the conjunctiva, which can eventually produce scarring, corneal damage, and blindness.

FIG. 22.13 In a patient with mucous membrane pemphigoid (i.e., cicatricial pemphigoid), the characteristic ocular lesion is a symblepharon, an adhesion of the eyelid to the eyeball. (Courtesy Dr. Carl Allen, The Ohio State University, Columbus, OH.)

Oral Lesions

The most characteristic feature of oral involvement is desquamative gingivitis, typically with areas of erythema, desquamation, ulceration, and vesiculation of the attached gingiva[57,158] (Fig. 22.14). Vesiculobullous lesions can occur elsewhere in the mouth.[57] The bullae tend to have a relatively thick roof and rupture in 2 to 3 days after formation, leaving irregularly shaped areas of ulceration. Healing of these lesions can take 3 weeks or more.

FIG. 22.14 In gingival mucous membrane pemphigoid, lesions are confined to the gingival tissues, where they produce the typical desquamative gingivitis appearance. (Courtesy Dr. Stuart L. Fischman, State University of New York at Buffalo, Buffalo, NY.)

Histopathology

The microscopic appearance of the oral lesions, although not completely diagnostic of MMP, is sufficiently distinctive that a tentative diagnosis can be considered. A striking subepithelial vesiculation with the epithelium separated from the underlying lamina propria leaves an intact basal layer (Fig. 22.15). Separation of the epithelium and the connective tissue occurs at the basement membrane zone. Electron microscopic studies demonstrate a split in the basal lamina.[167] A mixed inflammatory infiltrate (i.e., lymphocytes, plasma cells, neutrophils, and scarce eosinophils) is observed in the underlying fibrous connective tissue.

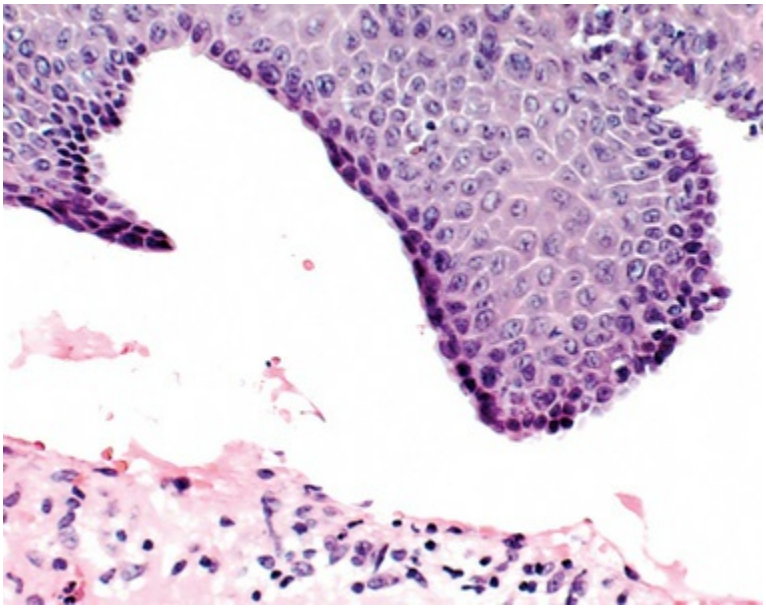

FIG. 22.15 Microscopic features of oral mucous membrane pemphigoid show a separation of the epithelium from the subjacent connective tissue (i.e., subepithelial clefting). An intact basal cell layer remains attached to the epithelium. Hematoxylin and eosin stain; original magnification ×100.

Immunofluorescence

Positive findings along the basement membrane area have been reported with the use of direct and indirect immunofluorescence.[39,74,81] In biopsy tests using direct immunofluorescence, the main immunoreactants are IgG and C3, which are confined to the basement membrane (Fig. 22.16). Some studies indicate that a positive indirect immunofluorescence result is rare (<25%) for these patients.[104] The lack of indirect immunofluorescence findings may reflect an earlier diagnosis of MMP, thereby resulting in the identification of patients with less extensive disease.[2,85] In any event, circulating autoantibodies do not appear to play a role in the pathogenesis of the disease.

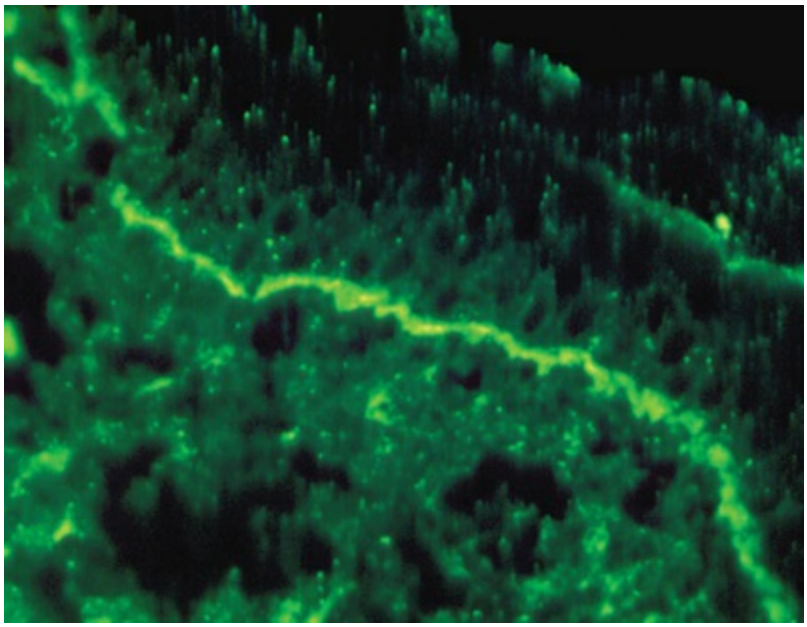

FIG. 22.16 Direct immunofluorescence staining of mucous membrane pemphigoid shows C3 deposits confined along the basement membrane.

Differential Diagnosis

Several disease entities manifest with similar clinical and histologic (i.e., subepithelial bulla) features.[44] They include bullous pemphigoid, bullous lichen planus, dermatitis herpetiformis, LAD, erythema multiforme, herpes gestationis, and epidermolysis bullosa acquisita.

Pemphigus may be confined to the oral cavity during its early stage, and the vesicular and ulcerative lesions may resemble those of MMP. An erosive or desquamative gingivitis also can be seen in pemphigus as a rare manifestation. Biopsy studies can quickly rule out pemphigus by revealing the absence or presence of acantholytic changes.

In erythema multiforme, there are obvious vesiculobullous lesions. However, the onset is usually acute rather than chronic, labial involvement is severe, and the gingivae are usually not affected. Desquamative gingivitis is an unusual finding in erythema multiforme, although occasional vesicular lesions can develop. A biopsy study of an oral lesion reveals an unusual degeneration of the upper stratum spinosum that is characteristically seen in oral erythema multiforme lesions.

Cicatricial pemphigoid must be differentiated from epidermolysis bullosa acquisita, which can manifest with similar histopathologic and immunopathologic features. When the biopsy is treated with salt to separate the dermis from the epidermis, basement membrane immunodeposits occur on the epidermal side with pemphigoid and on the dermal side with epidermolysis bullosa acquisita.[48]

Treatment

Topical steroids are the mainstay of treatment for MMP, particularly when lesions are localized. Fluocinonide (0.05%) and clobetasol propionate (0.05%) in an adhesive vehicle can be used three times daily for up to 6 months. When the oral lesions of MMP are confined to the gingival tissues, topical corticosteroids are effectively delivered with vacuum-formed custom trays or veneers.[147] Optimal oral hygiene is essential because local irritants on the tooth surface result in an exaggerated gingival inflammatory response. Gingival irritation from a dental prosthesis should be minimized.

If the disease is not severe and symptoms are mild, systemic corticosteroids may be omitted. If ocular involvement exists, systemic corticosteroids are indicated.

When lesions do not respond to steroids, systemic dapsone (4-4'-diaminodiphenylsulfone) has proved to be effective.[32,53,110,116] Because of the systemic side effects of dapsone, including hemolysis and methemoglobinemia (particularly in patients with glucose-6-phosphate dehydrogenase deficiency), referral to a dermatologist is often indicated.[124] Systemic steroids can be combined with azathioprine or cyclophosphamide.[7,150]

Biologic agents such as Rituximab (i.e., anti-CD20 monoclonal antibody) combined with an immunosuppressant (i.e., dapsone and/or sulfasalazine) have shown promising results in severe, refractory cases.[170] Some investigators advocate sulfonamides and tetracycline. Although surgery is not a treatment for MMP, it is used for some patients to prevent blindness and for esophageal and upper airways stenosis.[147] Connective tissue grafting to alleviate root surface sensitivity and to improve aesthetics has been used with success to manage gingival recession in a patient with

cicatricial pemphigoid.[93]

Pemphigus Vulgaris

The pemphigus diseases are a group of autoimmune bullous disorders that produce cutaneous and mucous membranes blisters (Figs. 22.17 and 22.18). Pemphigus vulgaris is the most common of the pemphigus diseases, which also include pemphigus foliaceus, pemphigus vegetans, and pemphigus erythematosus.[139] Pemphigus vulgaris is a potentially lethal chronic condition with a 10% mortality rate and a worldwide annual incidence of 0.1 to 0.5 cases per 100,000 individuals.[12,139,148] A predilection for women, usually after the fourth decade of life, has been observed.[121] However, pemphigus vulgaris has also been reported in unusually young children and even in newborns.[30,139,154,176]

FIG. 22.17 A patient with pemphigus vulgaris has a large bulla on the flexor surface of the wrist.

FIG. 22.18 In a patient with pemphigus vulgaris of the oral cavity, multiple and coalescent areas of ulceration are covered by pseudomembranes of necrotic epithelium. The patient had large ulcers on the labial mucosa, tongue, and soft palate.

The epidermal and mucous membrane blisters occur when the cell-to-cell adhesion structures are damaged by the action of circulating autoantibodies and by the in vivo binding of the autoantibodies to the pemphigus vulgaris antigens, which are cell surface glycoproteins on keratinocytes. The pemphigus vulgaris glycoproteins are members of the desmoglein (DSG) subfamily of the cadherin superfamily of cell–cell adhesion molecules, which occur in desmosomes.[84] Whereas high levels of desmoglein 3 (DSG3) autoantibodies correlate with the severity of oral disease in patients with pemphigus vulgaris, elevated levels of desmoglein 1 (DSG1) autoantibodies are associated with severity of cutaneous disease.[64] Evidence suggests that *DSG3*, which is the gene that codes for pemphigus vulgaris, is located on chromosome 18.[175]

Key Fact

Pemphigus vulgaris (PV) is a severe autoimmune mucocutaneous disease that warrants immediate referral to a dermatologist or rheumatologist. This condition is potentially lethal if left untreated. Direct and indirect immunofluorescence studies along with H&E staining of biopsy specimens are used to diagnose PV. Systemic steroids are indicated to treat it.

Most cases of pemphigus vulgaris are idiopathic. However, medications such as penicillamine and captopril can produce drug-induced pemphigus, which is usually reversible after withdrawal of the causative drug. Paraneoplastic pemphigus is antigenically distinct from pemphigus vulgaris, and it is associated with underlying malignancies.[117]

In approximately 60% of patients with pemphigus vulgaris, the oral lesions are the first sign of the disease. The lesions may herald the dermatologic involvement by a year or more.[108,160]

Oral Lesions

Oral lesions can range from small vesicles to large bullae. When the bullae rupture, they leave extensive areas of ulceration (Fig. 22.19). Virtually any region of the oral cavity can be involved, but multiple lesions often develop at sites of irritation or trauma. The soft palate is most often involved (80%), followed by the buccal mucosa (46%), the ventral aspect or dorsum of the tongue (20%), and the lower labial mucosa (10%). Oral lesions of pemphigus vulgaris are confined less often to the gingival tissues.[80] In these patients, erosive gingivitis or desquamative gingivitis is the sole manifestation of oral pemphigus.

FIG. 22.19 In a patient with pemphigus vulgaris of the gingiva, oral lesions were confined to the gingivae and were clinically diagnosed as consistent with desquamative gingivitis. (Courtesy Dr. Beatriz Aldape, Faculty of Odontology, National Autonomous University of Mexico, Mexico City, Mexico.)

Histopathology

The lesions of pemphigus demonstrate a characteristic intraepithelial separation that occurs above the basal cell layer. The intraepithelial vesiculation begins as a microscopic alteration (Fig. 22.20) and gradually results in a grossly visible, fluid-filled bulla. Occasionally the entire superficial layers of epithelium are lost, leaving behind only the basal cells attached to the underlying lamina propria and conferring a characteristic tombstone appearance to the epithelial cells.

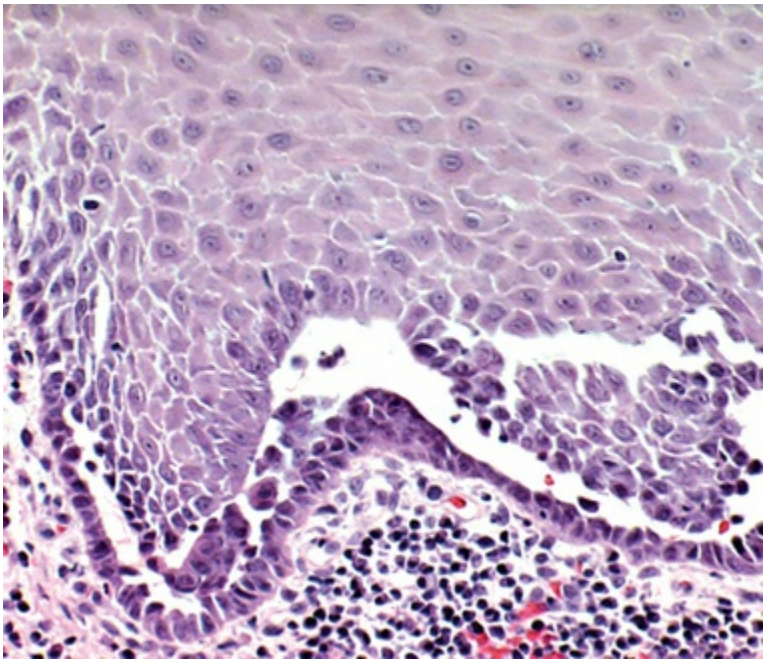

FIG. 22.20 Microscopic features of pemphigus vulgaris include typical intraepithelial clefting with a tombstone appearance of the basal cells, which remain attached to the subjacent basement membrane and fibrous connective tissue. Acantholysis of epithelial cells with the formation of Tzanck cells is seen in the intraepithelial cleft. (Hematoxylin and eosin stain; original magnification ×100.)

Acantholysis, which involves the separation of the epithelial cells of the lower stratum spinosum, takes place. It is characterized by round rather than polyhedral epithelial cells. The intercellular bridges are lost, and the nuclei are large and hyperchromatic.[36,86,179] The underlying connective tissue usually has a mild to moderate,

chronic inflammatory cell infiltrate. As the vesicle or bulla ruptures, the ulcerated lesion becomes infiltrated with polymorphonuclear leukocytes, and the surface may show suppuration.

Immunofluorescence

Autoantibodies can be demonstrated in the oral mucosa of patients with oral pemphigus with the use of immunofluorescence techniques. For direct immunofluorescence, perilesional unfixed frozen sections are incubated with fluorescein-labeled human anti-IgG. For indirect immunofluorescence, unfixed frozen sections of oral or esophageal mucosa from an animal such as a monkey are first incubated with the patient's serum to allow attachment of serum antibodies to the mucosal tissue. The tissue is then incubated with fluorescein-labeled antihuman IgG serum. The test result is positive if immunofluorescence is observed in the intercellular spaces of the stratified squamous epithelium of the mucosa (Fig. 22.21).

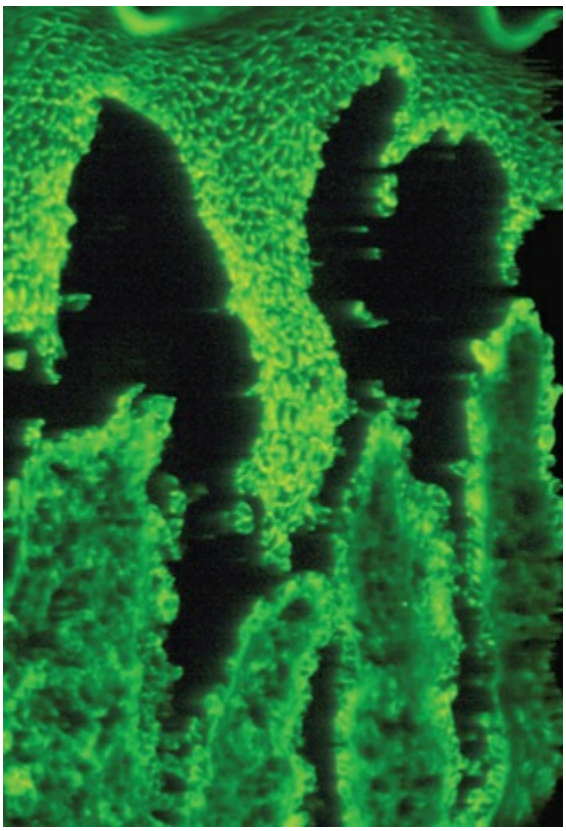

FIG. 22.21 Direct immunofluorescence staining of an oral pemphigus specimen shows the positive

intercellular signal for immunoglobulin G deposits in keratinocytes of the stratified squamous epithelium.

The indirect technique is less sensitive than the direct technique, and it may be negative during the early stages of the disease, particularly in its localized forms (see Table 22.1). In most cases, however, the indirect immunofluorescence titers are helpful for monitoring of disease activity, and they have prognostic value.

Differential Diagnosis

The oral lesions of pemphigus vulgaris may be similar to those seen in erythema multiforme. In patients with erythema multiforme, however, recurrent active episodes of comparatively short duration are followed by long intervals that are free of skin and oral lesions. Erythema multiforme affects the lips with considerable severity. Microscopic examination with conventional H&E and direct immunofluorescence can discriminate between the oral lesions of pemphigus and those of erythema multiforme. Pemphigus vulgaris shows characteristic intraepithelial clefting at the basal–spinous cell layers and interface with acantholysis, whereas erythema multiforme shows microvesiculation of the superficial epithelial layers and numerous necrotic keratinocytes. Pemphigus vulgaris shows an intercellular and intraepithelial signal with direct immunofluorescence; erythema multiforme exhibits negative immunofluorescence.

Pemphigoid may clinically resemble pemphigus. Microscopic examination and direct immunofluorescence studies are needed to establish a correct diagnosis. Bullous pemphigoid and MMP exhibit detachment of the epithelium from the underlying connective tissue (i.e., lifting off) rather than the acantholytic lesion characteristic of pemphigus.

Bullous lichen planus must also be considered during the differential diagnosis. The primary lesion of pemphigus may have a bullous character, and this may be followed by erosion, with its associated pain and discomfort. In patients with lichen planus, the characteristic reticular lesions are invariably associated with the bullae. Microscopic examination and direct immunofluorescence studies are necessary to differentiate this condition from

pemphigus. Bullous lichen planus shows separation of the epithelium from the underlying fibrous connective tissue, sawtooth rete pegs, and a bandlike chronic inflammatory infiltrate in the lamina propria. Direct immunofluorescence reveals linear fibrillar deposits of fibrin in the basement membrane of bullous lichen planus, whereas pemphigus vulgaris has intercellular immunoglobulin deposition in the epithelium.

If the oral lesions of pemphigus vulgaris are restricted to the gingival tissues, erosive lichen planus, pemphigoid, LAD, and chronic ulcerative stomatitis should be ruled out.

Treatment

Guidelines for the treatment of pemphigus vulgaris are available.[105] The main therapy for pemphigus vulgaris is systemic corticosteroids with or without the addition of other immunosuppressive agents.[160] If the patient responds well to corticosteroids, the dosage can be gradually reduced, but a low maintenance dosage is usually necessary to prevent or minimize the recurrence of lesions. Many dermatologists monitor the dose of steroids by periodic evaluation of the titers of DSG3 and DSG1 antibodies. Increasing titers are often associated with an impending exacerbation and warrant an increase of the steroid dose. A decrease in titer justifies a reduction of the steroid dose.[25]

In patients who are not responsive to corticosteroids or who gradually adapt to them, steroid-sparing therapies are used. They are combinations of steroids plus other medications (e.g., azathioprine, cyclophosphamide, cyclosporine, dapsone, gold, methotrexate) and photoplasmapheresis and plasmapheresis.[121] The biologic Rituximab is used as an adjunct to treat pemphigus vulgaris.[27,47,151] However, when used in early stages of the disease, it may induce complete remission.[63]

The maintenance phase aims to control the disease with the lowest dose of medication. To minimize the risk of morbidity associated with the long-term use of steroids, alternate-day steroid therapy, steroid-sparing drugs, and topical steroids can be combined. Because topical steroids may promote the development of candidiasis, topical antifungal medication may also be needed.[98]

Minimization of oral irritation is important for patients with oral

pemphigus vulgaris. Optimal oral hygiene is essential because there is usually widespread involvement of the marginal and attached gingivae and of other areas of the mouth, which can be exacerbated by plaque-associated gingivitis and periodontitis. Periodontal care is an important issue in the overall management of patients with pemphigus vulgaris. To prevent flare-ups, patients in the maintenance phase should receive prednisone before professional oral prophylaxis and periodontal surgery.[139] The fit and design of removable prosthetic appliances should receive special attention because even slight irritation from these prostheses can cause severe inflammation with vesiculation and ulceration.

Chronic Ulcerative Stomatitis

Chronic ulcerative stomatitis, which was first reported in 1990,[72] manifests with chronic oral ulcerations and has a predilection for women during the fourth decade of life. The erosions and ulcerations occur predominantly in the oral cavity, with only a few cases exhibiting cutaneous lesions.[29,88,177] Circulating specific IgG autoantibodies to ΔNp63α, an epithelial nuclear transcription factor that modulates epithelial cell growth, have been demonstrated.[20]

Oral Lesions

Painful solitary small blisters and erosions with surrounding erythema occur mainly on the gingiva and the lateral border of the tongue. Because of the magnitude and clinical features of the gingival lesions, a diagnosis of desquamative gingivitis is considered (Fig. 22.22). The buccal mucosae and hard palate also can have similar lesions.[163]

FIG. 22.22 Erythema and ulceration of the gingiva are consistent with a clinical diagnosis of chronic desquamative gingivitis. Direct and indirect immunofluorescence studies demonstrate stratified epithelium–specific antinuclear antibodies. (Courtesy Dr. Douglas Damm, University of Kentucky, Lexington, KY.)

Histopathology

The microscopic features of chronic ulcerative stomatitis are similar to those observed in erosive lichen planus. Hyperkeratosis, acanthosis, and liquefaction of the basal cell layer with areas of subepithelial clefting are prominent features of the epithelium. The underlying lamina propria exhibits a lymphohistiocytic chronic infiltrate in a bandlike configuration.

Immunofluorescence

Direct immunofluorescence of normal and perilesional tissues reveals typical stratified epithelium–specific antinuclear antibodies. They are nuclear deposits of IgG with a speckled pattern, and they are found mainly in the basal cell layer of the normal epithelium (Fig. 22.23). Fibrin deposits are visualized at the epithelial tissue–connective tissue interface. Indirect immunofluorescence studies involving the use of an esophageal substrate also reveal stratified epithelium–specific antinuclear antibodies.[164]

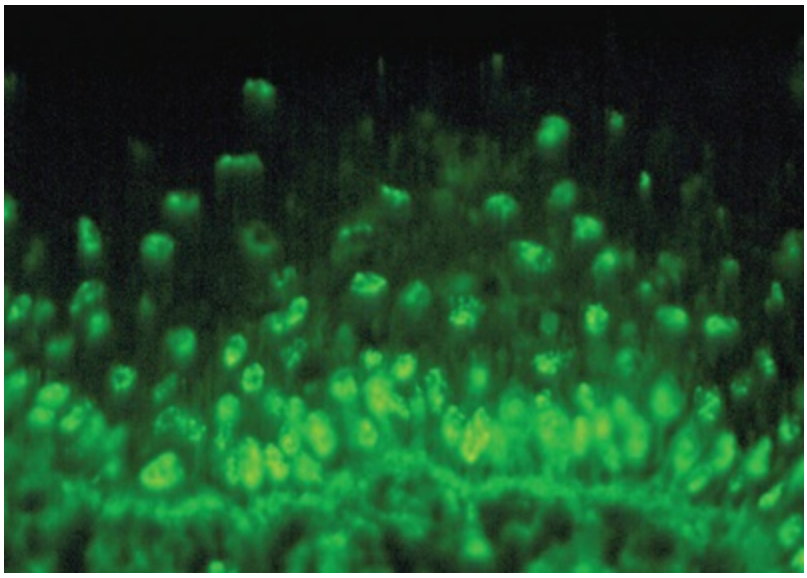

FIG. 22.23 Direct immunofluorescence study of chronic ulcerative stomatitis shows nuclear deposits of immunoglobulin G that are prominent in the basal cell layer and fade toward the superficial layers. (Courtesy Dr. Douglas Damm, University of Kentucky, Lexington, KY.)

Diagnosis

Chronic ulcerative stomatitis is clinically similar to erosive lichen planus. Pemphigus vulgaris, MMP, LAD, bullous pemphigoid, and lupus erythematosus also have to be included in the differential diagnosis. Microscopic examination usually reduces the number of possibilities to chronic ulcerative stomatitis, LAD, and erosive lichen planus. Direct and indirect immunofluorescence studies are needed to arrive at the correct diagnosis.[132] An enzyme-linked immunosorbent assay (ELISA) has been developed that may allow correlation of antibody titers with treatment response.[165]

Key Fact

Chronic ulcerative stomatitis is an autoimmune condition that mainly affects oral mucosa. Its clinical and histologic features are similar to those of oral lichen planus. Despite the similarities, severe cases of chronic ulcerative stomatitis do not respond to corticosteroid treatment, but they are responsive to hydroxychloroquine.

Treatment

For mild cases, topical steroids (e.g., fluocinonide, clobetasol propionate) and topical tetracycline can produce clinical improvement, but recurrences are common.[92] For severe cases, a high dose of a systemic corticosteroid is needed to achieve remission. Unfortunately, reduction of the corticosteroid dose results in relapse of the lesions. Hydroxychloroquine sulfate at a dosage of 200 to 400 mg per day seems to be the treatment of choice to produce complete, long-lasting remission.[13,31,69,72] However, a long-term follow-up study demonstrated that combined therapy (i.e., small doses of corticosteroids and chloroquine) might be required because the initial good response to chloroquine ceases after several months or years of treatment.[29]

Linear Immunoglobulin A Disease

LAD (i.e., linear IgA dermatosis) is an uncommon mucocutaneous disorder with a predilection for women. The etiopathogenic aspects of LAD are not fully understood, although drug-induced LAD triggered by angiotensin-converting enzyme inhibitors has been reported.[52]

LAD manifests as a pruritic vesiculobullous rash, usually during middle age or later, although younger individuals may be affected. Characteristic plaques or crops with an annular manifestation surrounded by a peripheral rim of blisters affect the skin of the upper and lower trunk, the shoulders, the groin, and the lower limbs. The face and perineum may also be affected. Mucosal involvement, including that of the oral mucosa, ranges from 50% to 100% of the cases published.[23,33,73]

LAD can mimic lichen planus clinically and histologically. Immunofluorescence studies are needed to establish the correct diagnosis.

Oral Lesions

Oral manifestations of LAD consist of vesicles, painful ulcerations or erosions, and erosive gingivitis or cheilitis. The hard and soft palates are affected more often; the tonsillar pillars, buccal mucosa, tongue, and gingiva follow in frequency. Rarely, oral lesions may

be the only manifestation of LAD for several years before cutaneous lesions occur.[19] The oral lesions of LAD have been clinically reported as desquamative gingivitis[41,125,129,130] (Fig. 22.24).

FIG. 22.24 In a patient with linear immunoglobulin A disease, intense erythema and ulceration of the gingiva are consistent with a diagnosis of desquamative gingivitis.

Histopathology

The microscopic features of LAD are similar to those observed with erosive lichen planus.

Immunofluorescence

Linear deposits of IgA are observed at the epithelial tissue–connective tissue interface.[173] They are different from the granular pattern that is observed with dermatitis herpetiformis.

Differential Diagnosis

The differential diagnosis of LAD includes erosive lichen planus, chronic ulcerative stomatitis, pemphigus vulgaris, bullous pemphigoid, and lupus erythematosus. Microscopic examination and immunofluorescence studies are necessary to establish the correct diagnosis.

Treatment

The primary treatment of LAD involves a combination of sulfones and dapsone. Small amounts of prednisone (10 to 30 mg/day) can

be added if the initial response is inadequate.[28] Alternatively, tetracycline (2 g/day) in combination with nicotinamide (1.5 g/day) has shown promising results.[126] Mycophenolate (1 g twice daily) in combination with prednisolone (30 mg/day) resulted in the resolution of the refractory ulcerations associated with LAD.[89]

Dermatitis Herpetiformis

Dermatitis herpetiformis is a chronic condition that usually develops in young adults between the ages of 20 and 30 years, and it has a slight predilection for men.[43] Evidence indicates that dermatitis herpetiformis is a cutaneous manifestation of celiac disease. Approximately 25% of patients with celiac disease have dermatitis herpetiformis. The cause of celiac disease is obscure, but tissue transglutaminase seems to be the predominant autoantigen in the intestine, the skin, and sometimes the mucosae.[35] Gluten enteropathy can be severe in about two-thirds of patients, and it is mild or subclinical in the remaining one-third. In severe cases, patients may complain of dysphagia, weakness, diarrhea, and weight loss.[101]

Clinically, dermatitis herpetiformis manifests with bilateral and symmetric pruritic papules or vesicles that are primarily restricted to the extensor surfaces of the extremities. The sacrum, the buttocks, and occasionally the face and oral cavity can be affected.[15,43]

The term *herpetic* is derived from the initial manifestation of the disease, in which clusters of vesicles or papules arise on the skin. These vesicles or papules eventually resolve and are followed by hyperpigmentation of the skin, which ultimately wanes. The oral lesions of dermatitis herpetiformis range from painful ulcerations preceded by the collapse of ephemeral vesicles or bullae to erythematous lesions.[120]

Histopathology

Microscopic examination of the initial lesions of dermatitis herpetiformis reveals focal aggregates of neutrophils and eosinophils among deposits of fibrin at the apices of the dermal pegs.[180]

Immunofluorescence

Direct immunofluorescence demonstrates IgA and C3 at the dermal papillary apices in both perilesional tissue and normal, uninvolved tissue. In contrast, biopsies taken from lesional sites may fail to exhibit IgA or C3, producing false-negative results.[180] Although no circulating autoantibodies to epithelial basement membrane occur in dermatitis herpetiformis, almost 80% of patients have anti-endomysial and gliadin antibodies.[14]

Treatment

A gluten-free diet is essential for the treatment of celiac disease and dermatitis herpetiformis. Oral dapsone is usually needed for patients with newly detected dermatitis herpetiformis to alleviate symptoms promptly.[19,35]

Lupus Erythematosus

Lupus erythematosus is an autoimmune disease with three clinical presentations: systemic, chronic cutaneous, and subacute cutaneous.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a severe disease with a 10 : 1 predilection for women compared with men. SLE can affect the kidneys, heart, skin, and mucosa. The classic cutaneous lesions characterized by a rash on the malar area with a butterfly distribution are uncommon[37] (Fig. 22.25). The oral lesions of SLE are usually ulcerative or similar to those of lichen planus. Oral ulcerations occur in 36% of patients with SLE. In about 4% of patients, hyperkeratotic plaques reminiscent of lichen planus appear on the buccal mucosa and palate.[17]

FIG. 22.25 Systemic lupus erythematosus produces erythema on the bridge of the nose with a butterfly pattern. (Courtesy Department of Dermatology, Hospital General Manuel Gea González, Mexico City, Mexico.)

Direct immunofluorescence of the perilesional and normal tissue reveals immunoglobulins and C3 deposits at the dermal-epidermal interface. Antinuclear antibodies are detected in more than 95% of cases, whereas deoxyribonucleic acid and extractable nuclear antigen antibodies are found in more than 50% of patients (see Table 22.1).

Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous lupus erythematosus usually has no systemic signs or symptoms; lesions are limited to the skin or the mucosal surfaces. The skin lesions are referred to as *discoid lupus erythematosus* (DLE). DLE describes the chronic scarring, atrophy-producing lesion that may develop into hyperpigmentation or hypopigmentation of the healing area (Fig. 22.26). In the oral cavity, about 9% of patients with chronic cutaneous lupus erythematosus have lichen-planus–like plaques on the palate and the buccal mucosa.[5,17] The gingiva may be affected, and the condition can manifest as desquamative gingivitis (Fig. 22.27).

FIG. 22.26 In a patient with chronic cutaneous lupus erythematosus, there are multiple facial lesions with irregular hyperpigmented borders, some of which exhibit central scarring with cutaneous atrophy. Other lesions consist of hyperpigmented cutaneous patches.

FIG. 22.27 Lupus erythematosus of the oral cavity can manifest as desquamative gingivitis. Intense erythema with ulceration is bordered by white radial lines. (Courtesy Dr. Stuart L. Fischman, State University of New York at Buffalo, NY.)

Histopathology

The histopathology of the oral lesions of chronic cutaneous lupus erythematosus consists of hyperkeratosis, alternating acanthosis

and atrophy, and hydropic degeneration of the basal layer of the epithelium. The lamina propria exhibits a chronic inflammatory cell infiltrate similar to that observed with lichen planus. However, a more diffuse and deeper inflammatory infiltrate with a perivascular pattern is typically observed.[157]

Immunofluorescence

Direct immunofluorescence study of lesional tissue reveals immunoglobulins and C3 deposits at the dermal-epidermal junction of the lesional or perilesional tissue but not in normal tissue. This seems to differentiate SLE from DLE. The indirect immunofluorescence method reveals antinuclear antibodies in more than 95% of patients, whereas deoxyribonucleic acid and extractable nuclear antigen circulating antibodies are found in more than 50% of patients.

Subacute Cutaneous Lupus Erythematosus

Patients with subacute cutaneous lupus erythematosus have cutaneous lesions that are similar to those of DLE but that lack the development of scarring and atrophy.[18] Arthritis and arthralgia, low-grade fever, malaise, and myalgia can occur in up to 50% of patients with subacute cutaneous lupus erythematosus.[18,168]

Direct immunofluorescence reveals immunoglobulins and C3 deposits at the dermal-epidermal junction in 60% of cases and granular IgG deposits in the cytoplasm of basal cells in 30% of cases. About 80% of patients with subacute cutaneous lupus erythematosus have Ro (SSA) antibodies to nuclear antigens, whereas 25% to 30% have La (SSB) antibodies to nuclear antigens. The test result for rheumatoid factor is positive in about 30% of these patients, positive for antinuclear antibodies in 60% to 90%, and positive for anti-ribonucleoprotein antibodies to nuclear antigens in 10% (see Table 22.1).

Differential Diagnosis

Erosive lichen planus, erythema multiforme, and pemphigus vulgaris can simulate the lesions observed in patients with lupus erythematosus. The diagnosis of DLE confined to the oral cavity is

difficult to make, but microscopic studies may suggest the characteristic histopathology.[4] Biopsy studies (i.e., H&E and direct immunofluorescence) help to differentiate lupus erythematosus from other erosive diseases.

Treatment

The therapy for SLE depends on the severity and extent of the disease. It can range from topical steroids to nonsteroidal antiinflammatory drugs to moderate to high doses of prednisone for severe systemic organ involvement. Immunosuppressive drugs (e.g., cytotoxic agents such as cyclophosphamide and azathioprine) and plasmapheresis alone or with steroids can be useful.[121] Rituximab has produced dramatic, long-term remissions.[37] For chronic cutaneous lupus erythematosus, topical steroids are effective to manage the cutaneous and oral lesions. For patients whose disease is resistant to topical therapy, systemic antimalarial drugs can be used with good results.[119]

Erythema Multiforme

Erythema multiforme is an acute bullous and macular inflammatory mucocutaneous disease that affects mainly young adults between the ages of 20 and 40 years; it is rarely seen in children (≤20%).[145] The genesis of the mucocutaneous lesions is thought to reside in the development of immune complex vasculitis. This is followed by complement fixation that leads to the leukocytoclastic destruction of vascular walls and small vessel occlusion. The culmination of these events produces ischemic necrosis of the epithelium and underlying connective tissue.[49]

Target (i.e., iris) lesions with central clearing are the hallmark of erythema multiforme. It can be a mild condition (i.e., erythema multiforme minor) or a severe and possibly life-threatening condition (i.e., erythema multiforme major or Stevens–Johnson syndrome). An underdiagnosed type of erythema multiforme is the oral form, with which most patients have chronic or recurrent oral lesions only.[6]

Erythema multiforme minor lasts approximately 4 weeks and exhibits moderate cutaneous and mucosal involvement. Stevens–

Johnson syndrome can last a month or longer. It involves the skin, conjunctiva, oral mucosa, and genitalia, and it requires more aggressive therapy than erythema multiforme minor. Some researchers consider toxic epidermal necrolysis to be the most severe form of erythema multiforme, but other investigators think they are unrelated entities.[10]

The two most common etiologic factors for the development of erythema multiforme are herpes simplex infection and drug reactions. The most common causative drugs are sulfonamides, penicillins, quinolones, chlormezanone, barbiturates, oxicam nonsteroidal antiinflammatory drugs, anticonvulsant drugs, protease inhibitors, and allopurinol.[50]

Oral lesions in patients with erythema multiforme are common, and they occur in more than 70% of patients with skin involvement.[51,96,103] In rare instances, erythema multiforme is confined to the mouth.[6,94,152] The oral lesions consist of multiple, large, shallow, painful ulcers with an erythematous border. They affect the entire oral mucosa in approximately 20% of patients with erythema multiforme. The lesions are so painful that chewing and swallowing are impaired (Fig. 22.28). The buccal mucosa and the tongue are the most frequently affected sites, followed by the labial mucosa. Areas that are less often affected include the floor of the mouth, the hard and soft palates, and the gingiva.[51] Erythema multiforme is rarely confined exclusively to the gingival tissues, prompting a clinical diagnosis of desquamative gingivitis.[9] Hemorrhagic crusting of the vermilion border of the lips may occur, which is helpful for arriving at a clinical diagnosis of erythema multiforme.

FIG. 22.28 In a patient with erythema multiforme, large, shallow, and painful ulcers involve the labial and buccal mucosae. Hemorrhagic crusting of the mandibular vermilion border of the lips is observed.
(Courtesy Dr. Stuart L. Fischman, State University of New York at Buffalo, NY.)

Histopathology

Common microscopic findings of erythema multiforme include the liquefaction degeneration of the upper epithelium and development of intraepithelial microvesicles without the acantholysis that occurs with pemphigus.[156] Acanthosis, pseudoepitheliomatous hyperplasia, and necrotic keratinocytes are observed in the epithelium. Degenerative changes also occur in the basement membrane. In some cases, the junction between the epithelium and the lamina propria is indistinct because of a dense inflammatory cell infiltrate. Edema of the lamina propria, vascular dilation, and congestion also occur. Deeper layers of the connective tissue stroma exhibit a perivascular chronic inflammatory cell infiltrate. However, neutrophils and eosinophils may also be seen.

Immunofluorescence

The immunofluorescence examination result is negative for patients with erythema multiforme. Its value resides in ruling out other vesiculobullous and ulcerative disorders.

Treatment

There is no specific treatment for erythema multiforme. For mild symptoms, systemic and local antihistamines, topical anesthetics, and debridement of lesions with an oxygenating agent are adequate. In patients with bullous or ulcerative lesions and severe symptoms, corticosteroids are considered the drug of choice, although their use is controversial and not completely accepted.[50]

Drug-Related Eruptions

An increase in the incidence of skin and oral manifestations of hypersensitivity to drugs occurred with the advent of sulfonamides, barbiturates, and various antibiotics. The cutaneous and oral lesions are attributed to the drug acting as an allergen that sensitizes the tissues.

Eruptions in the oral cavity that result from sensitivity to drugs that have been taken orally or parenterally are called *stomatitis medicamentosa.* The local reaction from the use of a medicament in the oral cavity (e.g., stomatitis resulting from topical penicillin use) is referred to as *stomatitis venenata* or *contact stomatitis.* In many cases, skin eruptions accompany the oral lesions.

Most drug eruptions in the oral cavity are multiform. Vesicular and bullous lesions occur most often, but pigmented or nonpigmented macular lesions are also frequently observed. Erosions, which are often followed by deep ulceration with purpuric lesions, can occur. The lesions are seen in different areas of the oral cavity, with the gingiva often being affected.[1,58]

The development of gingival lesions caused by contact allergy to the mercurial compounds in dental amalgam has been documented.[78] Because of financial considerations, biopsy and patch testing may be indicated before the indiscriminate replacement of dental amalgam restorations. Similarly, desquamative gingivitis has been reported with the use of tartar control toothpaste. Pyrophosphates and flavoring agents have been identified as the main causative agents of this unusual condition.[42] Oral reactions to cinnamon compounds (i.e., cinnamon oil, cinnamic acid, or cinnamic aldehyde) that are used to mask the taste of pyrophosphates in tartar control toothpaste include an intense erythema of the attached gingival tissues that is

characteristic of plasma cell gingivitis[3,79] (Fig. 22.29).

FIG. 22.29 Plasma cell gingivitis. The gingiva presents a band of moderate to severe inflammation that is reminiscent of desquamative gingivitis.

A thorough clinical history usually discloses the source of gingival disturbance. Elimination of the offending agent (i.e., tartar control toothpaste) leads to resolution of the gingival lesions within a week, and challenge with the offending agent leads to recurrence of the oral lesions. If removal of the offending medication is not possible, topical corticosteroids and topical tacrolimus can be used to treat the lesions.[70]

Clinical Correlation

Diseases That Mimic Desquamative Gingivitis

- Squamous cell carcinoma
- Wegener granulomatosis (strawberry gingivitis)
- Candidiasis
- Graft-versus-host disease
- Crohn disease
- Foreign body gingivitis

Miscellaneous Conditions That Mimic Desquamative Gingivitis

Another group of heterogeneous conditions may masquerade as desquamative gingivitis. Factitious lesions, candidiasis, graft-versus-host disease, Wegener granulomatosis, foreign body gingivitis, Kindler syndrome, and squamous cell carcinoma can divert the attention of the clinician and provide a diagnostic challenge.

Factitious lesions are injuries that are consciously and intentionally produced without a clear motive, although guilt, seeking sympathy, or monetary compensation can be the driving forces for this abnormal behavior. Factitious desquamative gingivitis has been reported in the literature; it may be difficult to diagnose, and it may become apparent only after extensive and costly laboratory tests fail to reveal the genesis of the lesions.[104]

Candidiasis rarely is limited to the gingival tissues and can simulate desquamative gingivitis. Linear gingival erythema is a *Candida*-associated lesion in individuals who are infected with human immunodeficiency virus. It manifests as a ribbon-like red band of the gingival margins and is reminiscent of desquamative gingivitis.[143]

Graft-versus-host disease can occur in recipients of allogenic bone marrow transplants. The associated oral lesions occasionally resemble desquamative gingivitis (eFig. 22.1).

EFIG. 22.1 Graft-versus-host disease developed in a recipient of an allogeneic bone marrow transplant. The maxillary gingiva exhibits features that are consistent with desquamative gingivitis. (Courtesy Dr. Linda Lee, University of

Toronto, Toronto, Ontario, Canada.)

Wegener granulomatosis is a systemic disease that can manifest with striking alterations that are confined to the gingival tissues. Classically, the gingival tissues exhibit erythema and enlargement, and they are typically described as *strawberry gums*[34] (eFig. 22.2).

EFIG. 22.2 Wegener granulomatosis affects the gingival tissues. The classic strawberry gums appearance of the mandibular gingiva is seen in this patient. A slight resemblance to desquamative gingivitis is also evident.

Foreign body gingivitis is clinically characterized by red or red and white chronic lesions that can be painful and that are reminiscent of desquamative gingivitis. This condition is more common among women approaching the fifth decade of life. Microscopic analysis reveals small (<5 μm in diameter) foreign bodies associated with a chronic inflammatory cell response that can exhibit granulomatous and lichenoid characteristics. Energy-dispersive radiographic microanalysis revealed that most of these foreign bodies originate from dental materials (i.e., abrasives, and restorative materials).[61,62]

Kindler syndrome, which involves cutaneous neonatal bullae, poikiloderma, photosensitivity, and acral atrophy, can manifest with oral lesions that are clinically consistent with desquamative gingivitis.[137]

A clinical diagnosis of desquamative gingivitis requires a series of diagnostic steps before a precise diagnosis can be obtained. The steps include a comprehensive clinical history, clinical-pathologic

correlation, microscopic examination (e.g., H&E), and direct immunofluorescence studies.[167] The failure to systematically evaluate a patient with a clinical condition that is consistent with desquamative gingivitis can produce poor outcomes. This is particularly true when therapy for a putative desquamative gingivitis is established before a biopsy of the lesional tissue is obtained. Every year, we see in our laboratory at least two examples of clinically diagnosed desquamative gingivitis for which microscopic and immunofluorescence studies were not performed to rule out the cause of the gingival lesions. The patients were monitored or prescribed topical steroids for several months before the lack of response of the gingival lesions impelled the clinician to obtain a biopsy, which revealed squamous cell carcinoma.[169] Clinicians should be alert to the possibility of squamous cell carcinoma of the gingival tissues with lesions that initially manifest as desquamative gingivitis.

Case Scenario 22.1

Patient:
65-year-old white female

Chief Complaint:
"I have canker sores in my mouth. I can't brush my teeth."

Background Information
Patient has a significant medical history of hypertension, hypercholesterolemia, anxiety, and lower back pain. These conditions are controlled with appropriate pharmacologic therapy. Her oral lesions began 12 months earlier, and symptoms continued to worsen. The patient consulted several dentists and specialists to no avail.

Current Findings:
The patient has prominent painful erythema and erosion of the gingiva and attached mucosa in the maxillary and mandibular soft tissues.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Is the next step in treating this patient prescribing antibiotics? A. Yes B. No	**Answer: B** **Explanation:** Establishing a definitive diagnosis is the next step. Because the clinical presentation is consistent with desquamative gingivitis, a biopsy for hematoxylin and eosin (H&E) and direct immunofluorescence (DIF) staining is warranted.
2. The H&E examination showed hyperkeratosis, basal cell degeneration of the epithelium, serrated rete ridges, and a superficial bandlike infiltrate in the lamina propria. DIF studies revealed a shaggy, linear signal of fibrin at the epithelial–connective tissue interface. What is the diagnosis? A. Pemphigus vulgaris B. Mucous membrane pemphigoid C. Chronic ulcerative stomatitis D. Erosive lichen planus E. Squamous cell carcinoma	**Answer: D** **Explanation:** The clinical, histopathologic, and DIF findings support a diagnosis of erosive lichen planus
3. After removal of calculus, what is the mainstay of treatment for this patient? A. Systemic steroids B. Topical steroids C. Steroid-sparing medications D. Antibiotics	**Answer: B** **Explanation:** After the diagnosis is established, the mainstay of treatment is the use of topical steroids such as 0.05% fluocinonide gel or ointment applied four times daily.

CHAPTER OUTLINE

Classification
Clinical Features
Pathogenesis
Histopathology
Periodontal Disease Activity
Site Specificity
Pulp Changes Associated With Periodontal Pockets
Relationship of Attachment Loss and Bone Loss to Pocket Depth
Area Between Base of Pocket and Alveolar Bone
Relationship of Pocket to Bone
Periodontal Abscess
Lateral Periodontal Cyst

The periodontal pocket, which is defined as a pathologically deepened gingival sulcus, is one of the most important clinical features of periodontal disease. All types of periodontitis, as outlined in Chapter 5, share histopathologic features, such as tissue changes in the periodontal pocket, mechanisms of tissue destruction, and healing mechanisms. However, they differ with regard to their etiology, natural history, progression, and response to therapy.[32]

Classification

Deepening of the gingival sulcus may occur as a result of coronal movement of the gingival margin, apical displacement of the gingival attachment, or a combination of the two processes (Fig. 23.1). Pockets can be classified as follows:

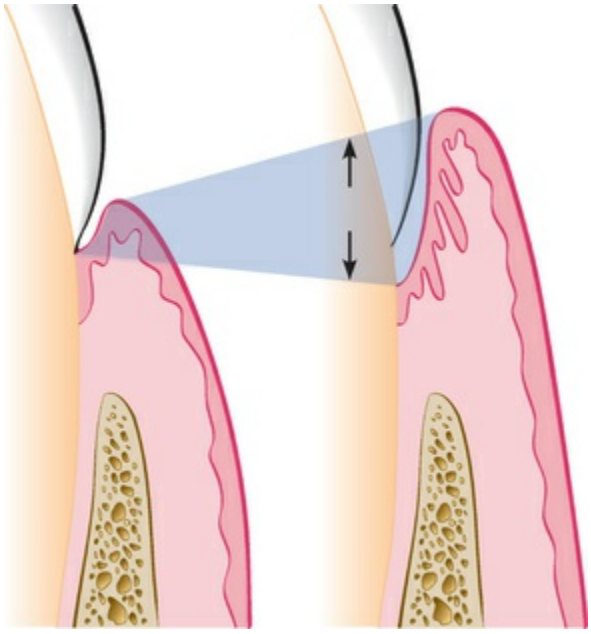

FIG. 23.1 Illustration of pocket formation that indicates expansion in two directions *(arrows)* from the normal gingival sulcus *(left)* to the periodontal pocket *(right)*.

• *Gingival pocket* (also called "peudo-pocket") is formed by gingival enlargement without

destruction of the underlying periodontal tissues. The sulcus is deepened because of the increased bulk of the gingiva (Fig. 23.2A).

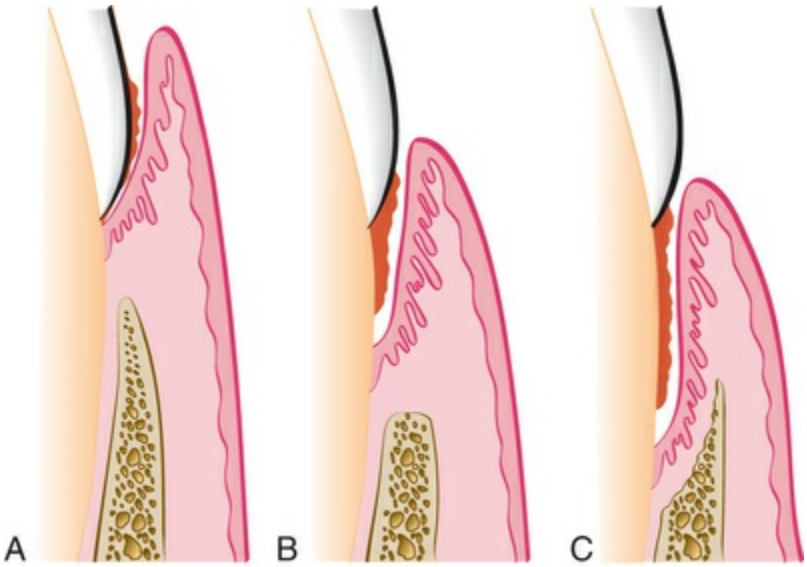

FIG. 23.2 Different types of periodontal pockets. (A) Gingival pocket. There is no destruction of the supporting periodontal tissues. (B) Suprabony pocket. The base of the pocket is coronal to the level of the underlying bone. Bone loss is horizontal. (C) Intrabony pocket. The base of the pocket is apical to the level of the adjacent bone. Bone loss is vertical.

- *Periodontal pocket* produces destruction of the supporting periodontal tissues, leading to the loosening and exfoliation of the teeth. The remainder of this chapter refers to this type of pocket. Based on the location of the base of the pocket in relation to the underlying bone, periodontal pockets can be classified into the following types:
    - *Suprabony* (*supracrestal* or *supraalveolar*) occurs when the bottom of the pocket is

coronal to the underlying alveolar bone (Fig. 23.2B).

- *Intrabony* (*infrabony, subcrestal,* or *intraalveolar*) occurs when the bottom of the pocket is apical to the level of the adjacent alveolar bone. With this second type, the lateral pocket wall lies between the tooth surface and the alveolar bone (Fig. 23.2C).

Pockets can involve one, two, or more tooth surfaces, and they can be of different depths and types on different surfaces of the same tooth and on approximal surfaces of the same interdental space.[30,38] Pockets can also be spiral (i.e., originating on one tooth surface and twisting around the tooth to involve one or more additional surfaces) (Fig. 23.3). These types of pockets are most common in furcation areas.

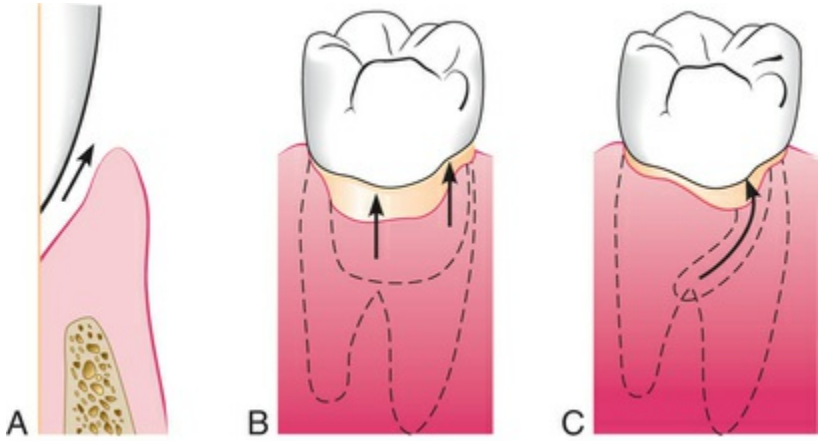

FIG. 23.3 Classification of pockets according to involved tooth surfaces. (A) Simple pocket. (B) Compound pocket. (C) Complex pocket.

Clinical Features

Clinical signs that suggest the presence of periodontal pockets

include a bluish red thickened marginal gingiva, a bluish red vertical zone from the gingival margin to the alveolar mucosa, gingival bleeding and suppuration, tooth mobility, diastema formation, and symptoms such as localized pain or pain "deep in the bone." The only reliable method of locating periodontal pockets and determining their extent is careful probing of the gingival margin along each tooth surface (Fig. 23.4 and Table 23.1). On the basis of depth alone, however, it is sometimes difficult to differentiate between a deep normal sulcus and a shallow periodontal pocket. In such borderline cases, pathologic changes in the gingiva distinguish the two conditions.

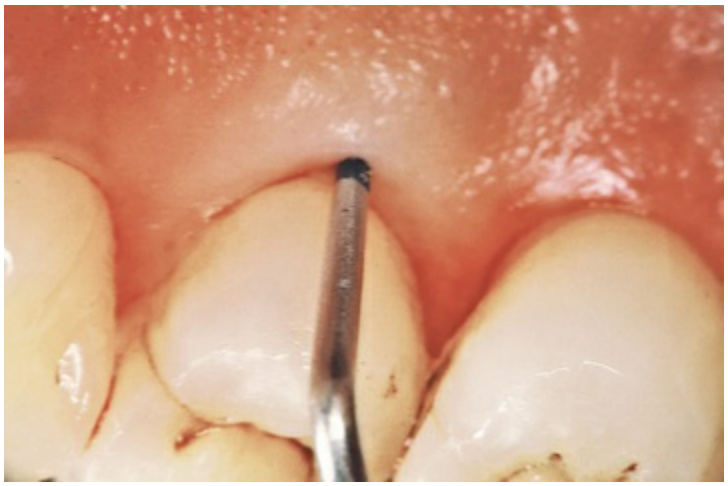

FIG. 23.4 Probing of a deep periodontal pocket. The entire length of the periodontal probe has been inserted to the base of the pocket in the palatal surface of the first premolar.

TABLE 23.1

Correlation of Clinical and Histopathologic Features of the Periodontal Pocket

Clinical Features	Histopathologic Features
1. The gingival wall of the pocket presents various degrees of bluish red discoloration; flaccidity; a smooth, shiny surface; and pitting on pressure.	1. The discoloration is caused by circulatory stagnation; the flaccidity by the destruction of gingival fibers and surrounding tissues; the smooth, shiny surface by atrophy of the epithelium and edema; and the pitting on pressure by edema and degeneration.
2. Less frequently, the	2. In such cases, fibrotic changes predominate over exudation

gingival wall may be pink and firm.	and degeneration, particularly in relation to the outer surface of the pocket wall. However, despite the external appearance of health, the inner wall of the pocket invariably presents some degeneration and is often ulcerated (see Fig. 23.15).
3. Bleeding is elicited by gently probing the soft-tissue wall of the pocket.	3. Ease of bleeding results from increased vascularity, the thinning and degeneration of the epithelium, and the proximity of engorged vessels to the inner surface.
4. When explored with a probe, the inner aspect of the pocket is generally painful.	4. Pain on tactile stimulation is caused by the ulceration of the inner aspect of the pocket wall.
5. In many cases, pus may be expressed with the application of digital pressure.	5. Pus occurs in pockets with suppurative inflammation of the inner wall.

For a more detailed discussion of the clinical aspects of periodontal pockets, see Chapter 32.

Key Fact

Sulcus Versus Periodontal Pocket

Gingival sulcus is the space between the neck of the tooth and the circumferential gingival tissue. Sulcus, when it deepens (as in periodontal disease) due to the apical migration of junctional epithelium, accompanied by attachment loss, it is referred to as a *periodontal pocket*.

Pathogenesis

The initial lesion in the development of periodontitis is the inflammation of the gingiva in response to a bacterial challenge. Changes involved in the transition from the normal gingival sulcus to the pathologic periodontal pocket are associated with different proportions of bacterial cells in dental plaque. Healthy gingiva is associated with few microorganisms, mostly coccoid cells and straight rods. Diseased gingiva is associated with increased numbers of spirochetes and motile rods.[40,41,43] However, the microbiota of diseased sites cannot be used as a predictor of future attachment or bone loss, because their presence alone is not sufficient for disease to start or progress.[35]

Pocket formation starts as an inflammatory change in the connective tissue wall of the gingival sulcus. The cellular and fluid inflammatory exudate causes degeneration of the surrounding connective tissue, including the gingival fibers. Just apical to the junctional epithelium, collagen fibers are destroyed,[20,61] and the area is occupied by inflammatory cells and edema (Fig. 23.5).

FIG. 23.5 Interdental papilla with suprabony pockets on proximal tooth surfaces. Note the densely inflamed connective tissue, with the infiltrate extending between the collagen fibers and the proliferating and ulcerated pocket epithelium.

Early concepts assumed that after the initial bacterial attack, periodontal tissue destruction continued to be linked to bacterial action. More recently it was established that the host's immunoinflammatory response to the initial and persistent bacterial attack unleashes mechanisms that lead to collagen and

bone destruction. These mechanisms are related to various cytokines, some of which are produced normally by cells in noninflamed tissue and others by cells that are involved in the inflammatory process, such as polymorphonuclear leukocytes (PMNs), monocytes, and other cells, thereby leading to collagen and bone destruction. This chapter describes the histologic aspects of gingival inflammation and tissue destruction. For further information about the molecular biology aspects of these mechanisms of tissue destruction, please see Chapter 9 and www.expertconsult.com.

Key Fact

Cytokines are proteins secreted by cells that interact with other cells and eventually lead to a specific cellular response. Cytokines can be proinflammatory or antiinflammatory in nature. Proinflammatory cytokines such as interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF-α) are implicated strongly in the pathogenesis of periodontal disease progression. Antiinflammatory cytokines such as IL-4 and IL-10 counteract the effects of proinflammatory cytokines.

The two mechanisms associated with collagen loss are as follows: (1) collagenases and other enzymes secreted by various cells in healthy and inflamed tissue, such as fibroblasts,[74] PMNs,[73] and macrophages,[53] become extracellular and destroy collagen (enzymes that degrade collagen and other matrix macromolecules into small peptides are called *matrix metalloproteinases*[75]); and (2) fibroblasts phagocytize collagen fibers by extending cytoplasmic processes to the ligament–cementum interface and degrading the inserted collagen fibrils and the fibrils of the cementum matrix.[20,21]

As a consequence of the loss of collagen, the apical cells of the junctional epithelium proliferate along the root surface and extend finger-like projections that are two or three cells in thickness (Fig. 23.6).

Key Fact

Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases

Matrix metalloproteinases (MMPs) are a group of proteases that play an important role in several biologic processes. Like any protease, they are involved in the degradation of proteins. Specifically, they are important players in extracellular matrix (ECM) degradation and are inhibited by tissue inhibitors of metalloproteinases (TIMPs). The balance between MMPs and TIMPs is critical for the maintenance of ECM remodeling in tissues, including the periodontium.

As a result of inflammation, PMNs invade the coronal end of the junctional epithelium in increasing numbers (Fig. 23.7). The PMNs are not joined to one another or to the epithelial cells by desmosomes. When the relative volume of PMNs reaches approximately 60% or more of the junctional epithelium, the tissue loses cohesiveness and detaches from the tooth surface. Thus the coronal portion of the junctional epithelium detaches from the root as the apical portion migrates, resulting in its apical shift; the oral sulcular epithelium gradually occupies an increasing portion of the sulcus (then a pocket) lining.[63]

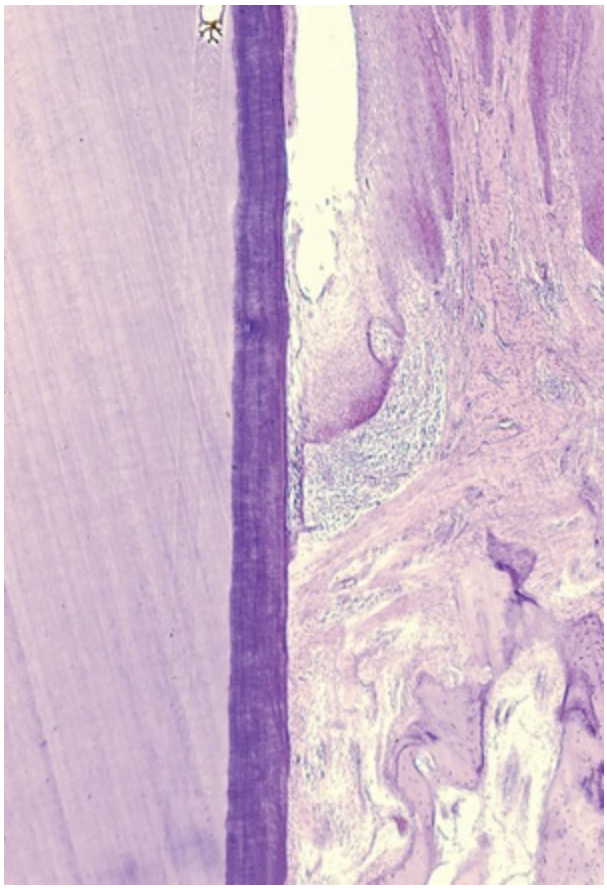

FIG. 23.6 Low-power view of the base of the periodontal pocket and apical area. Note the dense inflammatory infiltrate on the area of destroyed collagen fibers and the thin, finger-like extension of epithelium covering the cementum, which has been denuded of fibers.

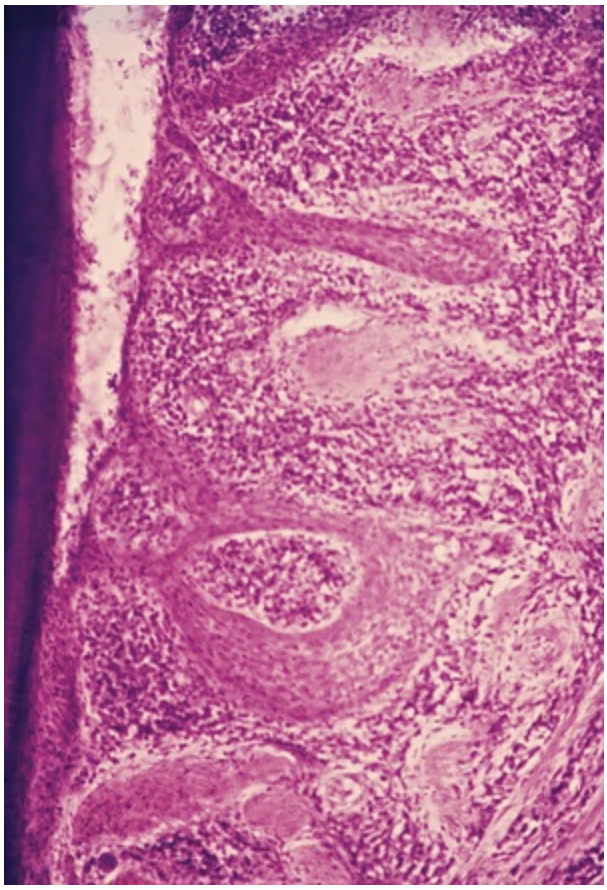

FIG. 23.7 Base of periodontal pocket showing extensive proliferation of lateral epithelium next to atrophic areas, dense inflammatory infiltrate, remnants of destroyed collagen fibers, and the junctional epithelium, which is apparently in a less altered state than the lateral pocket epithelium.

Extension of the junctional epithelium along the root requires the presence of healthy epithelial cells. Marked degeneration or necrosis of the junctional epithelium impairs rather than accelerates pocket formation. (This occurs in necrotizing ulcerative gingivitis, which results in an ulcer rather than pocket formation.)

Degenerative changes seen in the junctional epithelium at the base of periodontal pockets are usually less severe than those in the epithelium of the lateral pocket wall (see Fig. 23.7). Because the migration of the junctional epithelium requires healthy, viable cells, it is reasonable to assume that the degenerative changes seen in this area occur after the junctional epithelium reaches its position on the cementum.

The degree of leukocyte infiltration of the junctional epithelium is independent of the volume of inflamed connective tissue; thus this process may occur in gingiva with only slight signs of clinical inflammation.[61]

With continued inflammation, the gingiva increases in bulk, and the crest of the gingival margin extends coronally. The apical cells of the junctional epithelium continue to migrate along the root, and its coronal cells continue to separate from it. The epithelium of the lateral wall of the pocket proliferates to form bulbous, cordlike extensions into the inflamed connective tissue. Leukocytes and edema from the inflamed connective tissue infiltrate the epithelium that lines the pocket, resulting in various degrees of degeneration and necrosis.

The transformation of a gingival sulcus into a periodontal pocket creates an area in which plaque removal becomes impossible, and a feedback mechanism is established. The rationale for pocket reduction is based on the need to eliminate areas of plaque accumulation.

Histopathology

Changes that occur during the initial stages of gingival inflammation are presented in Chapter 17. After the pocket is formed, several microscopic features are present, which are discussed in this section.

Soft-Tissue Wall

The connective tissue is edematous and densely infiltrated with plasma cells (approximately 80%), lymphocytes, and a scattering of PMNs.[82] The blood vessels are increased in number, dilated, and engorged, particularly in the subepithelial connective tissue layer.[10] The connective tissue exhibits varying degrees of degeneration. Single or multiple necrotic foci are occasionally present.[52] In addition to exudative and degenerative changes, the connective

tissue shows proliferation of the endothelial cells, with newly formed capillaries, fibroblasts, and collagen fibers (see Fig. 23.5).

The junctional epithelium at the base of the pocket is usually much shorter than that of a normal sulcus. Although marked variations are found with regard to the length, width, and condition of the epithelial cells,[62] usually the coronoapical length of the junctional epithelium is reduced to only 50 to 100 μm.[14] The cells may be well formed and in good condition, or they may exhibit slight to marked degeneration (see Figs. 23.6 and 23.7).

The most severe degenerative changes in the periodontal pocket occur along the lateral wall (Fig. 23.8). The epithelium of the lateral wall of the pocket presents striking proliferative and degenerative changes. Epithelial buds or interlacing cords of epithelial cells project from the lateral wall into the adjacent inflamed connective tissue, and they may extend farther apically than the junctional epithelium (Figs. 23.7 and 23.9A). These epithelial projections, as well as the remainder of the lateral epithelium, are densely infiltrated by leukocytes and edema from the inflamed connective tissue. The cells undergo vacuolar degeneration and rupture to form vesicles. Progressive degeneration and necrosis of the epithelium lead to ulceration of the lateral wall, exposure of the underlying inflamed connective tissue, and suppuration. In some cases, acute inflammation is superimposed on the underlying chronic changes.

A comparative study of gingival changes in aggressive and chronic periodontitis revealed more pronounced degenerative changes in the epithelium of aggressive cases with more open intercellular spaces, including microclefts and necrotic areas.[35] The severity of the degenerative changes is not necessarily related to pocket depth. Ulceration of the lateral wall may occur in shallow pockets, and deep pockets are occasionally observed in which the lateral epithelium is relatively intact or shows only slight degeneration. The epithelium at the gingival crest of a periodontal pocket is generally intact and thickened, with prominent rete pegs.

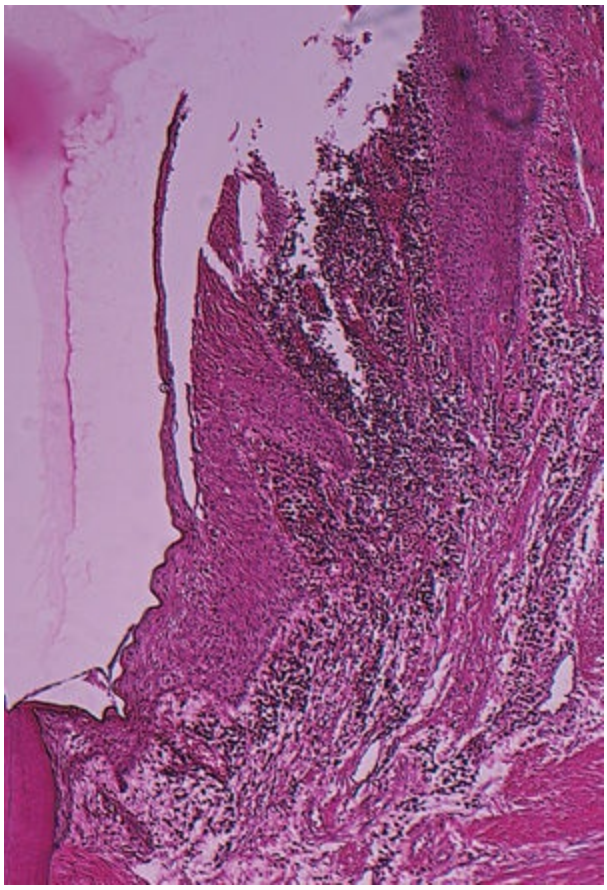

FIG. 23.8 View of the ulcerated lateral pocket wall of a periodontal pocket. Note the extension of epithelial cells and the dense accumulation of leukocytes within the epithelium and in the connective tissue.

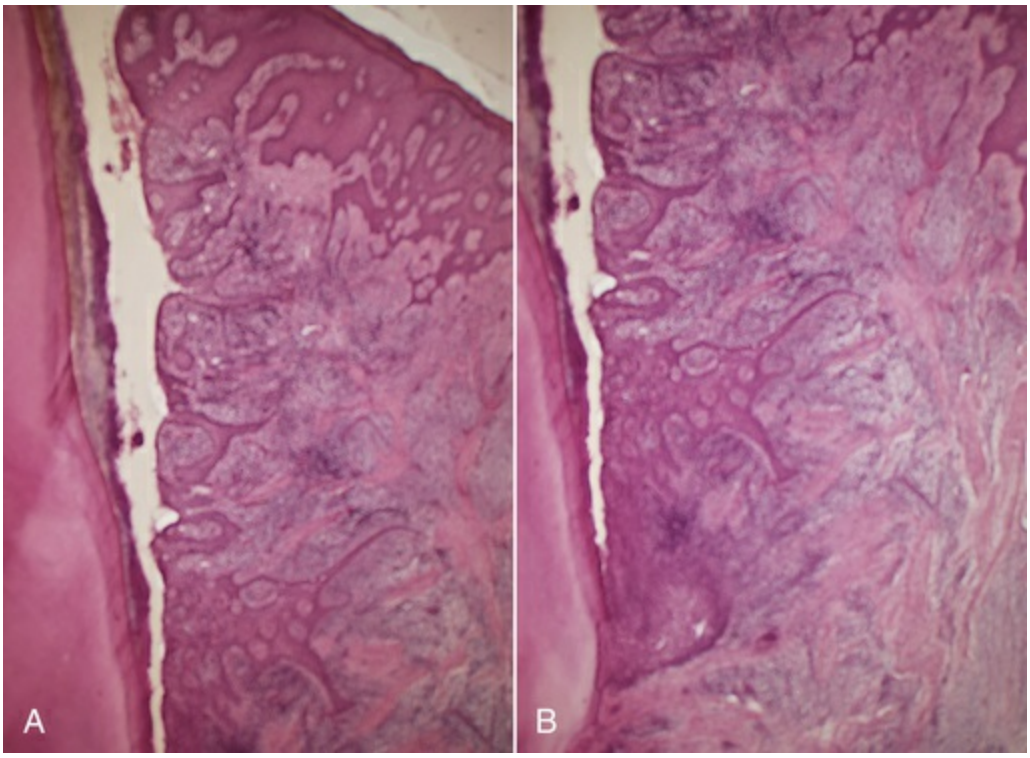

FIG. 23.9 (A) Lateral wall of a periodontal pocket showing epithelial proliferative and atrophic changes as well as marked inflammatory infiltrate and the destruction of collagen fibers. (B) Slightly apical view of the same patient showing the shortened junctional epithelium.

For a detailed electron microscopic study of the pocket epithelium in experimentally induced pockets in dogs, see the article by Müller-Glauser and Schröder.[49]

Key Facts

Features of Junctional Epithelium

- It acts as a physical barrier against plaque bacteria.
- It is stratified squamous nonkeratinized in nature, which develops by the union of oral epithelium and reduced enamel epithelium during tooth eruption.
- It is attached to the tooth by internal basal lamina and to the connective tissue by external basal lamina.
- It exhibits higher permeability to cells, gingival fluid, and host-

defense molecules to flow through.
- It has higher rate of cellular proliferation and turnover.

Bacterial Invasion

Bacterial invasion of the apical and lateral areas of the pocket wall has been described in human chronic periodontitis. Filaments, rods, and coccoid organisms with predominant gram-negative cell walls have been found in intercellular spaces of the epithelium.[25,26] Hillmann and colleagues[35] have reported the presence of *Porphyromonas gingivalis* and *Prevotella intermedia* in the gingiva of aggressive periodontitis cases. *Aggregatibacter actinomycetemcomitans* has also been found in the tissues.[16,47,59]

Bacteria may invade the intercellular space under exfoliating epithelial cells, but they are also found between deeper epithelial cells as well as accumulating on the basement lamina. Some bacteria traverse the basement lamina and invade the subepithelial connective tissue[60] (Fig. 23.10 and 23.11).

FIG. 23.10 Scanning electron micrograph of a section of pocket wall in advanced periodontitis in a human

specimen showing bacterial penetration into the epithelium and connective tissue. Scanning electron microscope view of the surface of the pocket wall (A), sectioned epithelium (B), and sectioned connective tissue (C). Curved arrows point to areas of bacterial penetration into the epithelium. Thick white arrows point to bacterial penetration into the connective tissue through a break in the continuity of the basal lamina. *CF,* Connective tissue fibers; *D,* accumulation of bacteria (rods, cocci, and filaments) on the basal lamina; *F,* filamentous organism on the surface of the epithelium. The asterisk points to coccobacillus in the connective tissue.

FIG. 23.11 Transmission electron micrograph of the epithelium in the periodontal pocket wall showing bacteria in the intercellular spaces. *B,* Bacteria; *EC,* epithelial cell; *IS,* intercellular space; *L,* leukocyte about to engulf bacteria. (×8000.)

The presence of bacteria in the gingival tissues has been interpreted by different investigators as bacterial invasion or as the "passive translocation" of plaque bacteria.[42] This important point

has significant clinicopathologic implications and has not yet been clarified.[17,39,43]

Mechanisms of Tissue Destruction

The inflammatory response triggered by bacterial plaque unleashes a complex cascade of events aimed at destroying and removing bacteria, necrotic cells, and deleterious agents. However, this process is nonspecific; in an attempt to restore health, the host's cells (e.g., neutrophils, macrophages, fibroblasts, epithelial cells) produce proteinases, cytokines, and prostaglandins that can damage or destroy the tissues.

Chapter 9 describes in detail these aspects of inflammation and the mechanisms of tissue destruction at the molecular level.

Microtopography of the Gingival Wall

Scanning electron microscopy has permitted the description of several areas in the soft-tissue (gingival) wall of the periodontal pocket in which different types of activity take place.[56] These areas are irregularly oval or elongated and adjacent to one another, and they measure about 50 to 200 μm. These findings suggest that the pocket wall is constantly changing as a result of the interaction between the host and the bacteria. The following areas have been noted:

1. *Areas of relative quiescence,* showing a relatively flat surface with minor depressions and mounds and occasional shedding of cells (Fig. 23.12A).

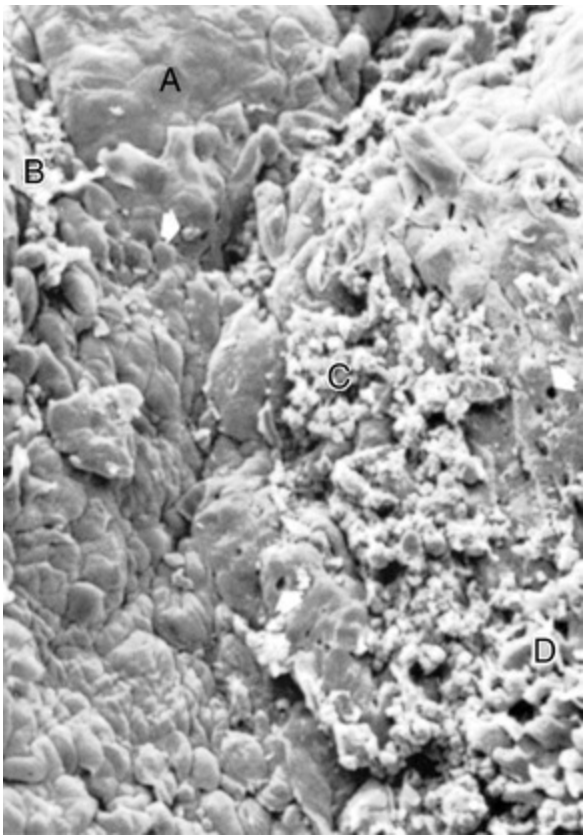

FIG. 23.12 Scanning electron frontal micrograph of the periodontal pocket wall. Different areas can be seen in the pocket wall surface. (A) Area of quiescence. (B) Bacterial accumulation. (C) Bacterial–leukocyte interaction. (D) Intense cellular desquamation. Arrows point to emerging leukocytes and holes left by leukocytes in the pocket wall. (Magnification ×800.)

2. *Areas of bacterial accumulation,* which appear as depressions on the epithelial surface, with abundant debris and bacterial clumps penetrating into the enlarged intercellular spaces. These bacteria are mainly cocci, rods, and filaments, with a few spirochetes (Fig. 23.12B).
3. *Areas of emergence of leukocytes,* in which leukocytes appear in the pocket wall through holes located in the intercellular spaces (Fig. 23.13).

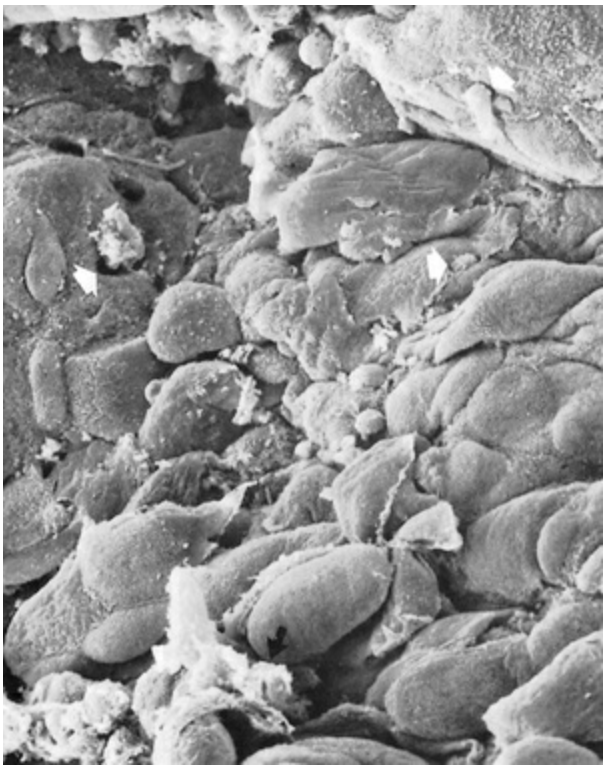

FIG. 23.13 Scanning electron micrograph of the periodontal pocket wall, frontal view, in a patient with advanced periodontitis. Note the desquamating epithelial cells and leukocytes *(white arrows)* emerging onto the pocket space. Scattered bacteria can also be seen *(black arrow).* (Magnification ×1500.)

4. *Areas of leukocyte–bacteria interaction,* in which numerous leukocytes are present and covered with bacteria in an apparent process of phagocytosis. Bacterial plaque associated with the epithelium is seen either as an organized matrix covered by a fibrin-like material in contact with the surface of cells or as bacteria penetrating into the intercellular spaces (Fig. 23.12C).
5. *Areas of intense epithelial desquamation,* consisting of semiattached and folded epithelial squames, which are sometimes partially covered with bacteria (Fig. 23.12D).
6. *Areas of ulceration,* with exposed connective tissue (Fig. 23.14).

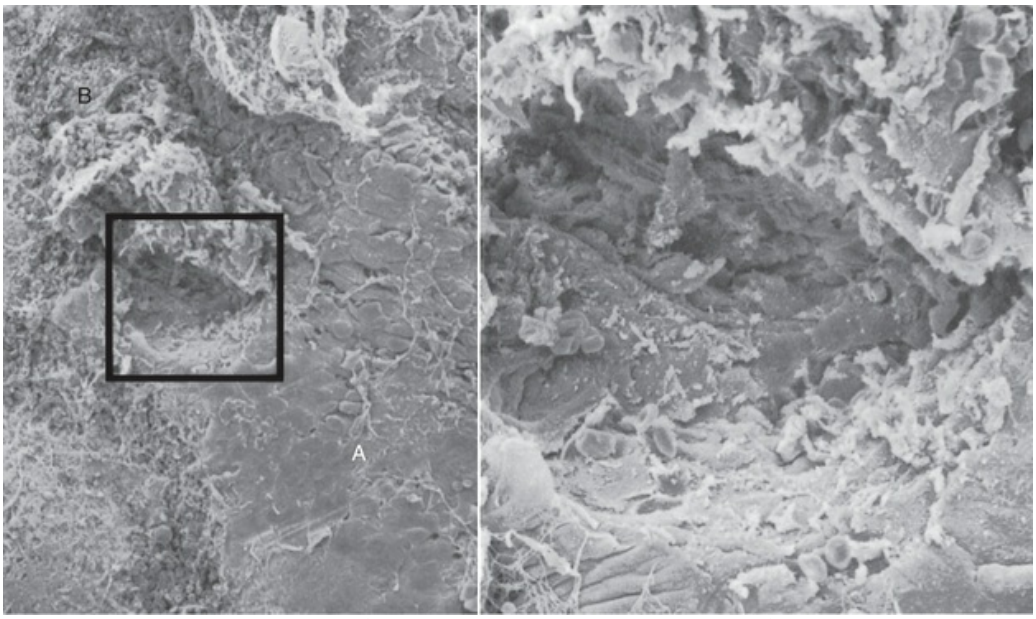

FIG. 23.14 Area of ulceration in the lateral wall of a deep periodontal pocket in a human specimen (magnification ×800) *(left). A,* Surface of pocket epithelium in a quiescent state. *B,* Area of hemorrhage. Scanning electron microscopy (magnification ×3000) of the square on the left *(right).* Connective tissue fibers and cells can be seen in the bottom of the ulcer.

7. *Areas of hemorrhage,* with numerous erythrocytes.

The transition from one area to another could result from bacteria accumulating in previously quiescent areas and triggering the emergence of leukocytes and the leukocyte–bacteria interaction. This would lead to intense epithelial desquamation and finally to ulceration and hemorrhage.

Periodontal Pockets as Healing Lesions

Periodontal pockets are chronic inflammatory lesions and thus are constantly undergoing repair. Complete healing does not occur because of the persistence of the bacterial attack, which continues to stimulate an inflammatory response, thereby causing degeneration of the new tissue elements formed during the continuous effort at repair.

The condition of the soft-tissue wall of the periodontal pocket results from the interplay of the destructive and constructive tissue changes. Their balance determines clinical features such as color, consistency, and surface texture of the pocket wall. If the

inflammatory fluid and cellular exudate predominate, the pocket wall is bluish red, soft, spongy, and friable, with a smooth, shiny surface; at the clinical level, this is generally referred to as an *edematous pocket wall.* If there is a relative predominance of newly formed connective tissue cells and fibers, the pocket wall is more firm and pink and clinically referred to as a *fibrotic pocket wall* (see Table 23.1).

Edematous and fibrotic pockets represent opposite extremes of the same pathologic process rather than different disease entities. They are subject to constant modification, depending on the relative predominance of exudative and constructive changes.

Fibrotic pocket walls may be misleading, because they do not necessarily reflect what is taking place throughout the pocket wall. The most severe degenerative changes in periodontal tissues occur adjacent to the tooth surface and the subgingival plaque. In some cases, inflammation and ulceration on the inside of the pocket are walled off by fibrous tissue on the outer aspect (Fig. 23.15). Externally the pocket appears pink and fibrotic, despite the inflammatory changes occurring internally.

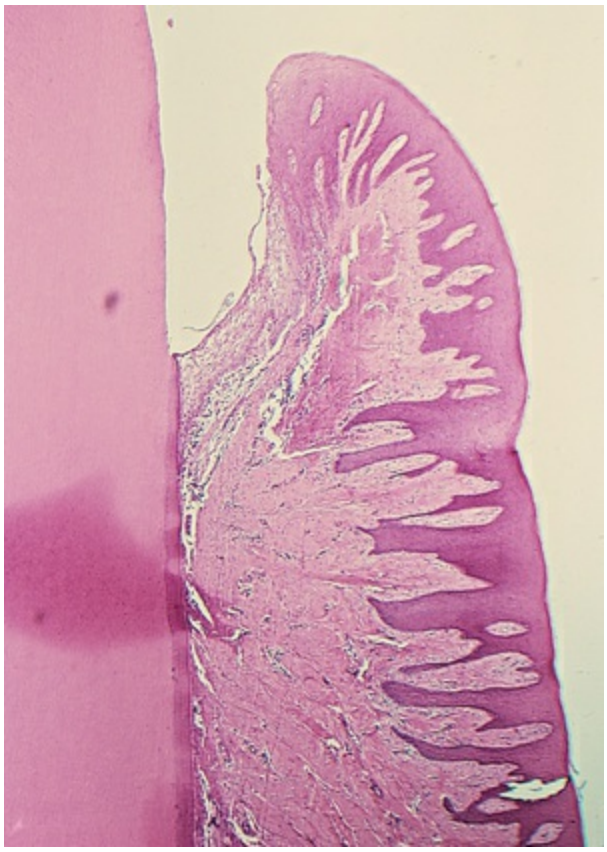

FIG. 23.15 Periodontal pocket wall. The inner half is inflamed and ulcerated; the outer half is densely collagenous.

Pocket Contents

Periodontal pockets contain debris that consists principally of microorganisms and their products (enzymes, endotoxins, and other metabolic products), gingival fluid, food remnants, salivary mucin, desquamated epithelial cells, and leukocytes. Plaque-covered calculus usually projects from the tooth surface (Fig. 23.16). Purulent exudate, if present in the patient, consists of living, degenerated, and necrotic leukocytes; living and dead bacteria; serum; and a scant amount of fibrin.[46] The contents of periodontal pockets, when filtered free of organisms and debris, have been demonstrated to be toxic when injected subcutaneously into experimental animals.[31]

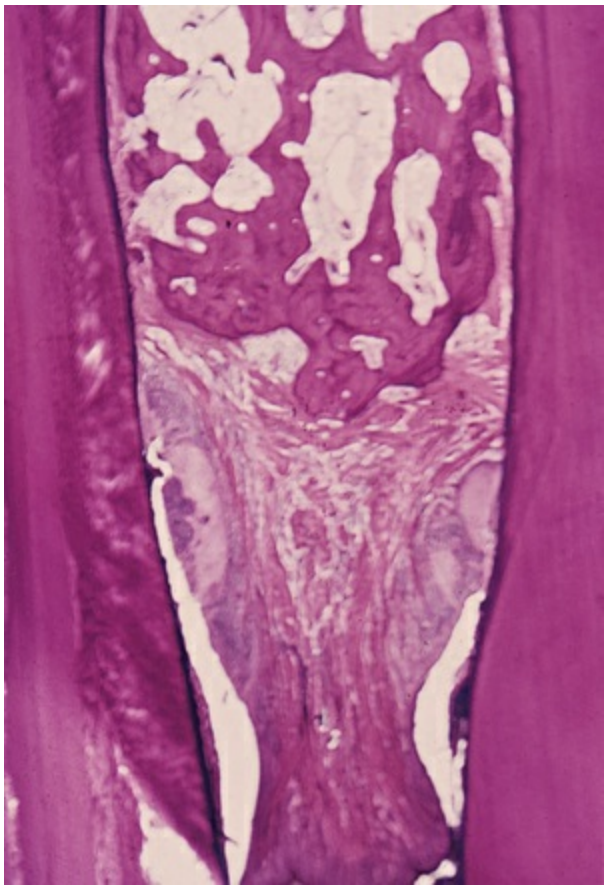

FIG. 23.16 Interdental papilla with ulcerated suprabony periodontal pockets on its mesial and distal aspects. Calculus is present on the approximal tooth surfaces and within the gingiva.

Pus is a common feature of periodontal disease, but it is only a secondary sign. The presence of pus or the ease with which it can be expressed from the pocket merely reflects the nature of the inflammatory changes in the pocket wall. It is not an indication of the depth of the pocket or the severity of the destruction of the supporting tissues. Extensive pus formation may occur in shallow pockets, whereas deep pockets may exhibit little or no pus. The localized accumulation of pus constitutes an abscess, which is discussed later in this chapter.

Key Fact

Gingival Crevicular Fluid

Gingival crevicular fluid (GCF) is an ultrafiltrate of blood, present

in the gingival sulcus space, that contains several molecular components like bacterial degradation products, host tissue degradation products, and inflammatory mediators. Due to the location and ease of collection, several human clinical studies have been and are currently exploring and validating biomarkers of periodontal disease in GCF. The implant equivalent of GCF is commonly referred to as periimplant sulcular fluid (PISF).

Root Surface Walls

The root surface wall of periodontal pockets often undergoes changes that are significant because they may perpetuate the periodontal infection, cause pain, and complicate periodontal treatment.[11]

As the pocket deepens, collagen fibers embedded in the cementum are destroyed, and cementum becomes exposed to the oral environment. Collagenous remnants of Sharpey fibers in the cementum undergo degeneration, creating an environment favorable to the penetration of bacteria. Viable bacteria have been found in the roots of 87% of periodontally diseased noncarious teeth.[2] Bacterial penetration into the cementum can be found as deep as the cementodentinal junction,[1,19] and it may also enter the dentinal tubules.[29,31] Penetration and the growth of bacteria lead to fragmentation and breakdown of the cementum surface and result in areas of necrotic cementum that are separated from the tooth by masses of bacteria.

Pathologic granules[9] have been observed with light and electron microscopy,[6,7] and they may represent areas of collagen degeneration or areas in which collagen fibrils have not been fully mineralized initially.

In addition, bacterial products (e.g., endotoxins[4,5]) have also been detected in the cementum wall of periodontal pockets. When root fragments from teeth with periodontal disease are placed in tissue culture, they induce irreversible morphologic changes in the cells of the culture. Such changes are not produced by normal roots.[33]

Diseased root fragments also prevent the in vitro attachment of human gingival fibroblasts, whereas normal root surfaces allow the cells to attach freely.[3] When placed in the oral mucosa of the patient, diseased root fragments induce an inflammatory response, even if they have been autoclaved.[44]

Key Fact

Bacterial Endotoxin

Endotoxins are lipopolysaccharide (LPS) in nature and are associated with the cell walls of gram-negative bacteria. LPS is highly immunogenic, which the innate immune system recognizes via Toll-like receptors (TLRs), leading to an immune response. LPS from *Porphyromonas gingivalis,* a key pathogen in periodontal disease, plays an important role in both triggering and sustaining inflammation in the periodontium.

These changes manifest clinically as softening of the cementum surface; this is usually asymptomatic, but it can be painful when a probe or explorer penetrates the area. They also constitute a possible reservoir for reinfection of the area after treatment. During the course of treatment, these necrotic areas are removed by root planing until a hard, smooth surface is reached. Cementum is very thin in the cervical areas, and scaling and root planing often remove it entirely, exposing the underlying dentin. Sensitivity to cold may result until the pulp tissue forms secondary dentin.

Decalcification and Remineralization of Cementum

Areas of *increased mineralization*[65] are probably a result of an exchange of minerals and organic components at the cementum–saliva interface after exposure to the oral cavity. The mineral content of exposed cementum increases,[64] and the minerals that are increased in diseased root surfaces include calcium,[67] magnesium,[50,67] phosphorus,[50] and fluoride.[50] Microhardness, however, remains unchanged.[55,81] The development of a highly mineralized superficial layer may increase the tooth's resistance to

decay.[3]

The hypermineralized zones are detectable by electron microscopy, and they are associated with increased perfection of the crystal structure and organic changes that are suggestive of a subsurface cuticle.[64,65] These zones have also been seen in microradiographic studies[66] as a layer that is generally 10 to 20 mm thick, with areas as thick as 50 mm. No decrease in mineralization was found in deeper areas, indicating that increased mineralization does not come from adjacent areas. A loss of or reduction in the crossbanding of collagen near the cementum surface[27,28] and a subsurface condensation of organic material of exogenous origin[64] have also been reported.

Areas of demineralization are often related to root caries. Exposure to oral fluid and bacterial plaque results in proteolysis of the embedded remnants of Sharpey fibers; the cementum may be softened, and it may undergo fragmentation and cavitation.[34] Unlike enamel caries, root surface caries tend to progress around rather than into the tooth.[48] Active root caries lesions appear as well-defined yellowish or light brown areas; they are frequently covered by plaque, and they have a softened or leathery consistency on probing. Inactive lesions are well-defined darker lesions with a smooth surface and a harder consistency on probing.[24]

The dominant microorganism in root surface caries is *Actinomyces viscosus,*[72] although its specific role in the development of the lesion has not been established.[24] Other bacteria, such as *Actinomyces naeslundii, Streptococcus mutans, Streptococcus salivarius, Streptococcus sanguinis,* and *Bacillus cereus,* have been found to produce root caries in animal models. Quirynen and colleagues[54] reported that when plaque levels and pocket depths decrease after periodontal therapy (both nonsurgical and surgical), a shift in oral bacteria occurs, leading to a reduction in periodontal pathogens, an increase in *S. mutans,* and the development of root caries.

A prevalence rate study of root caries among 20- to 64-year-old individuals revealed that 42% had one or more root caries lesions and that these lesions tended to increase with age.[37]

The tooth may not be painful, but exploration of the root surface reveals the presence of a defect, and penetration of the involved area with a probe causes pain. Caries of the root may lead to

pulpitis, sensitivity to sweets and thermal changes, or severe pain. Pathologic exposure of the pulp occurs in severe cases. Root caries may be the cause of toothache in patients with periodontal disease and no evidence of coronal decay.

Caries of the cementum requires special attention when the pocket is treated. The necrotic cementum must be removed by scaling and root planing until firm tooth surface is reached, even if this entails extension into the dentin.

Areas of cellular resorption of cementum and dentin are common in roots that are unexposed by periodontal disease.[68] These areas are of no particular significance because they are symptom free, and, as long as the root is covered by the periodontal ligament, they are likely to undergo repair. However, if the root is exposed by progressive pocket formation before repair occurs, these areas appear as isolated cavitations that penetrate into the dentin. These areas can be differentiated from caries of the cementum by their clear-cut outline and hard surface. They may be sources of considerable pain that require the placement of a restoration.

Surface Morphology of Tooth Wall[78]

The following zones can be found in the bottom of a periodontal pocket (Fig. 23.17):

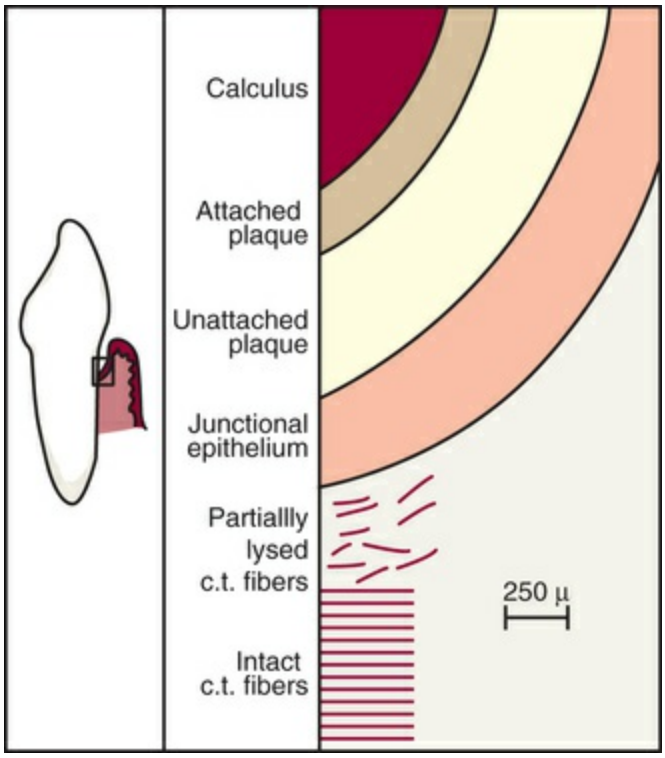

FIG. 23.17 Diagram of the area at the bottom of a pocket. *c.t.*, Connective tissue.

1. *Cementum covered by calculus,* in which all of the changes described in the preceding paragraphs can be found.
2. *Attached plaque,* which covers calculus and extends apically from it to a variable degree (typically 100 to 500 µm).
3. The zone of *unattached plaque* that surrounds attached plaque and extends apically to it.
4. The zone of *attachment of the junctional epithelium to the tooth.* The extension of this zone, which in normal sulci is more than 500 µm, is usually reduced in periodontal pockets to less than 100 µm.
5. A zone of *semidestroyed connective tissue fibers* may be apical to the junctional epithelium[60] (see the Pathogenesis section earlier in this chapter).

Zones 3, 4, and 5 make up the "plaque-free zone" seen in extracted teeth.[8,12,36,58,78] The total width of the plaque-free zone varies according to the type of tooth (i.e., it is wider in the molars than in the incisors) and the depth of the pocket (i.e., it is narrower in deeper pockets).[57] It is important to remember that the term

plaque-free zone refers only to attached plaque, because unattached plaque contains a variety of gram-positive and gram-negative morphotypes, including cocci, rods, filaments, fusiforms, and spirochetes. The most apical zone contains predominantly gram-negative rods and cocci.[76]

Periodontal Disease Activity

For many years the loss of attachment produced by periodontal disease was thought to be a slow but continuously progressive phenomenon. More recently, as a result of studies of the specificity of plaque bacteria, the concept of periodontal disease activity has evolved.

According to this concept, periodontal pockets go through periods of exacerbation and quiescence as a result of episodic bursts of activity followed by periods of remission. *Periods of quiescence* are characterized by a reduced inflammatory response and little or no loss of bone and connective tissue attachment. A buildup of unattached plaque, with its gram-negative, motile, and anaerobic bacteria (see Chapter 8), starts a *period of exacerbation* during which bone and connective tissue attachment are lost and the pocket deepens. This period may last for days, weeks, or months, and it is eventually followed by a period of remission or quiescence during which gram-positive bacteria proliferate and a more stable condition is established. On the basis of a study of radioiodine ^{125}I absorptiometry, McHenry and colleagues[45] confirmed that bone loss in patients with untreated periodontal disease occurs in an episodic manner.

These periods of quiescence and exacerbation are also known as *periods of inactivity* and *periods of activity.* Clinically, active periods show bleeding, either spontaneously or with probing, and greater amounts of gingival exudate. Histologically, the pocket epithelium appears thin and ulcerated, and an infiltrate composed predominantly of plasma cells,[19] PMNs,[53] or both is seen. Bacterial samples from the pocket lumen that are analyzed with dark-field microscopy show high proportions of motile organisms and spirochetes.[43]

Methods to detect periods of activity or inactivity are currently

being investigated (see www.expertconsult.com).

Site Specificity

Periodontal destruction does not occur in all parts of the mouth at the same time; rather it occurs on a few teeth at a time or even only on some aspects of some teeth at any given time. This is referred to as the *site specificity* of periodontal disease. Sites of periodontal destruction are often found next to sites with little or no destruction. Therefore the severity of periodontitis increases with the development of new disease sites and with the increased breakdown of existing sites.

Pulp Changes Associated With Periodontal Pockets

The spread of infection from periodontal pockets may cause pathologic changes in the pulp. Such changes may give rise to painful symptoms, or they may adversely affect the response of the pulp to restorative procedures. Involvement of the pulp in periodontal disease occurs through either the apical foramen or the lateral pulp canals after pocket infection reaches them. Atrophic and inflammatory pulpal changes occur in such cases (see Chapter 46).

Relationship of Attachment Loss and Bone Loss to Pocket Depth

The severity of the attachment loss in pocket formation is generally but not always correlated with the depth of the pocket. This is because the degree of attachment loss depends on the location of the base of the pocket on the root surface, whereas pocket depth is the distance between the base of the pocket and the crest of the gingival margin. Pockets of the same depth may be associated with different degrees of attachment loss (Fig. 23.18), and pockets of different depths may be associated with the same amount of

attachment loss (Fig. 23.19).

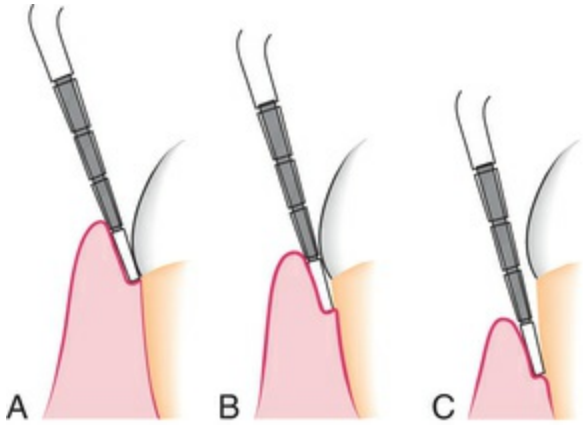

FIG. 23.18 Same pocket depth with different amounts of recession. (A) Gingival pocket with no recession. (B) Periodontal pocket of similar depth as shown in part A but with some degree of recession. (C) Pocket depth the same as shown in parts A and B but with still more recession.

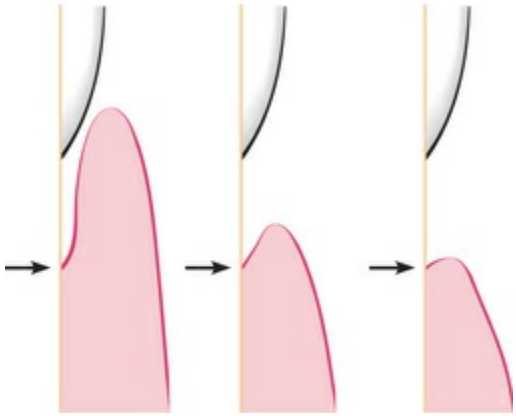

FIG. 23.19 Different pocket depths with the same amount of attachment loss. Arrows point to the bottom of the pocket. The distance between the arrow and the cementoenamel junction remains the same despite different pocket depths.

The severity of bone loss is generally but not always correlated with pocket depth. Extensive attachment and bone loss may be associated with shallow pockets if the attachment loss is accompanied by recession of the gingival margin, and slight bone

loss can occur with deep pockets.

Area Between Base of Pocket and Alveolar Bone

Normally, the distance between the apical end of the junctional epithelium and the alveolar bone is relatively constant. The distance between the apical extent of calculus and the alveolar crest in human periodontal pockets is most constant, having a mean length of 1.97 mm (±33.16%).[71,77]

The distance from attached plaque to bone is never less than 0.5 mm and never more than 2.7 mm.[78-80] These findings suggest that the bone-resorbing activity induced by the bacteria is exerted within these distances. However, the finding of isolated bacteria or clumps of bacteria in the connective tissue[60] and on the bone surface[26] may modify these considerations.

Relationship of Pocket to Bone

In infrabony pockets, the base of the pocket is apical to the crest of the alveolar bone, and the pocket wall lies between the tooth and the bone. The bone loss is in most cases vertical. Alternatively, in suprabony pockets, the base is coronal to the crest of the alveolar bone, and the pocket wall lies coronal to the bone. The type of bone loss is always horizontal.

This creates some microscopic differences that have some therapeutic importance. They are the relationship of the soft-tissue wall of the pocket to the alveolar bone, the pattern of bone destruction, and the direction of the transseptal fibers of the periodontal ligament[15] (Figs. 23.20, 23.21, and 23.22).

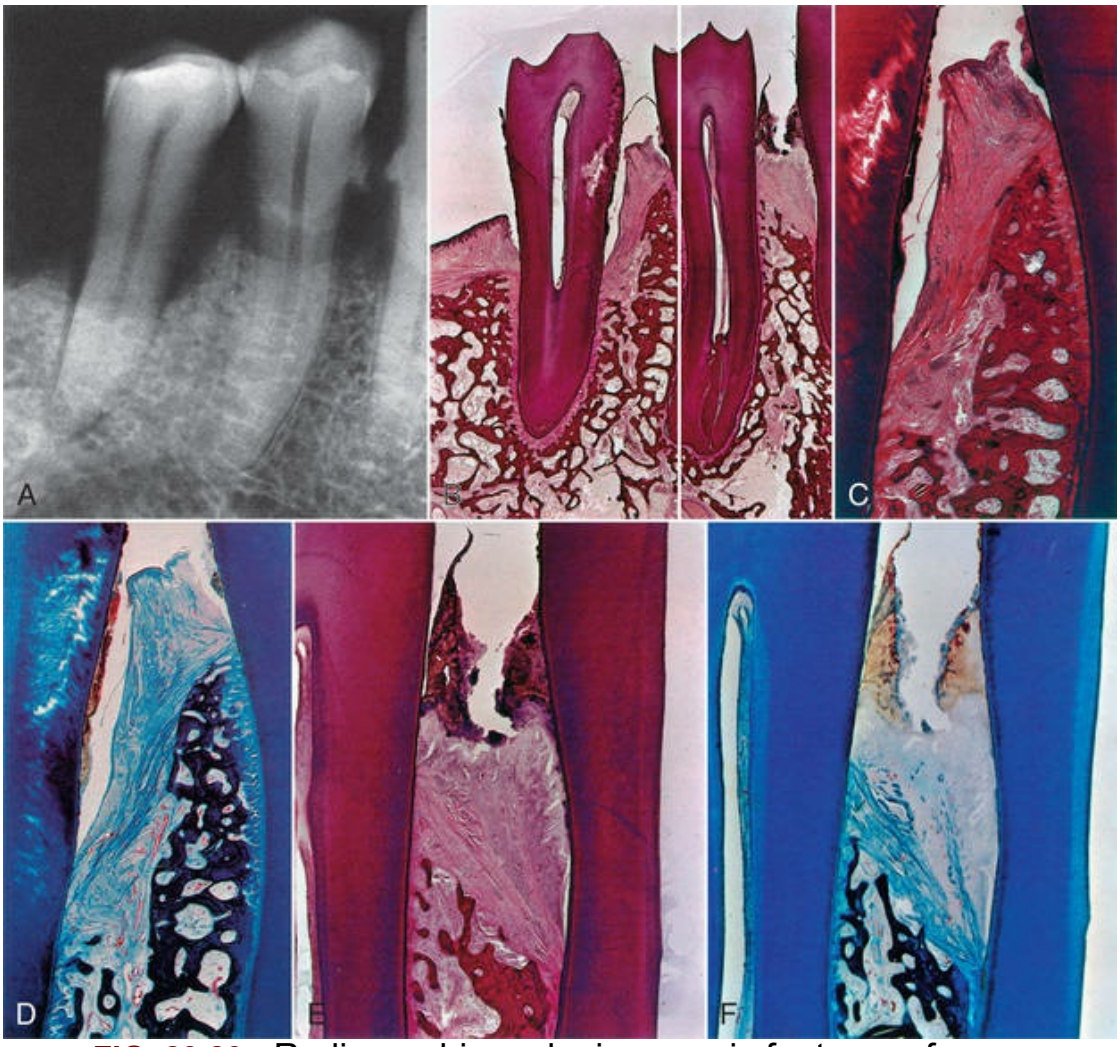

FIG. 23.20 Radiographic and microscopic features of intrabony pockets. (A) Radiograph of a mandibular canine and premolar area showing angular bone loss mesial to the second premolar. The type of bone loss between the first premolar and the canine is not radiographically apparent. (B) Mesiodistal histologic section of the teeth seen in A showing an intrabony pocket mesial to the second premolar as well as suprabony pockets distal to the second premolar and mesial and distal to the first premolar. The mesial suprabony pocket of the first premolar appears to be coronal to a vertical bone loss. (C) Higher-power view of the area between the premolars. Note the angular bone loss and the transseptal fibers that cover the bone. (D) Higher-power view of the area between the premolars stained with Mallory connective tissue stain, clearly showing the direction of transseptal fibers. (E) Higher-power view of the area between the first premolar and the canine. Note the abundant calculus,

the dense leukocytic infiltration of the gingiva, and the angulation of the transseptal fibers and bone. The pocket is still suprabony. (F) Mallory stain of a similar area to the one shown in part E. Note the destruction of the gingival fibers caused by inflammation and the angular fibers formed over angular bone loss and less affected by the inflammation. Transseptal fibers extend from the distal surface of the premolar over the crest of the alveolar bone into the intrabony pocket. Note the leukocytic infiltration of the transseptal fibers. (From Glickman I, Smulow J: *Periodontal disease: clinical, radiographic and histopathologic features*, Philadelphia, 1974, Saunders.)

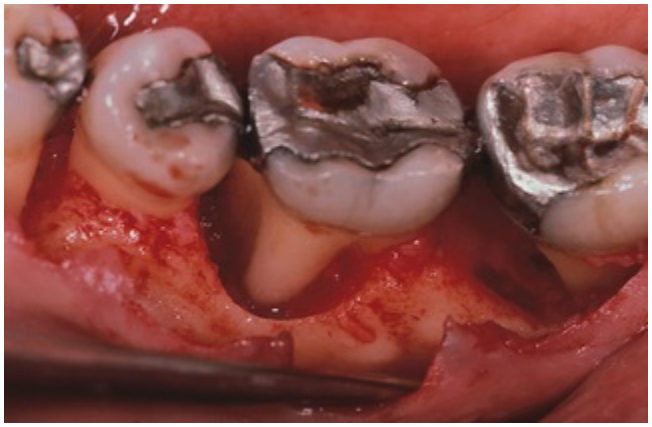

FIG. 23.21 After raising a flap for the treatment of the infrabony pockets, the vertical bone loss around the mesial roots of the mandibular first and second molars can be seen.

FIG. 23.22 Two suprabony pockets in an interdental space. Note the normal horizontal arrangement of the transseptal fibers.

In suprabony pockets, the alveolar crest gradually attains a more apical position in relation to the tooth, but it retains its general morphology and architecture. The interdental fibers that run over the bone from one tooth to the other maintain their usual horizontal direction. In infrabony pockets, the morphology of the alveolar crest changes completely, with the formation of an angular bony defect. The interdental fibers in this case run over the bone in an oblique direction between the two teeth of the interdental space.[15,80] This may affect the function of the area and also necessitate a modification in treatment techniques (see Chapters 59 and 60).[13,15] Table 23.2 summarizes the distinguishing features of suprabony and infrabony pockets. The classification of infrabony pockets is discussed in Chapter 24.

TABLE 23.2

Distinguishing Features of Suprabony and Intrabony Periodontal Pockets

Suprabony Pocket	Intrabony Pocket
1. The base of the pocket is coronal to the level of the alveolar bone.	1. The base of the pocket is apical to the crest of the alveolar bone so that the bone is adjacent to the soft-tissue wall (see Fig. 23.2).

2. The pattern of destruction of the underlying bone is horizontal.	2. The pattern of bone destruction is vertical (angular) (see Figs. 23.20 and 23.21).
3. Interproximally, transseptal fibers that are restored during progressive periodontal disease are arranged horizontally in the space between the base of the pocket and the alveolar bone (see Fig. 23.22).	3. Interproximally, transseptal fibers are oblique rather than horizontal. They extend from the cementum beneath the base of the pocket along the alveolar bone and over the crest to the cementum of the adjacent tooth (see Fig. 23.20).
4. On the facial and lingual surfaces, periodontal ligament fibers beneath the pocket follow their normal horizontal–oblique course between the tooth and the bone.	4. On the facial and lingual surfaces, periodontal ligament fibers follow the angular pattern of the adjacent bone. They extend from the cementum beneath the base of the pocket along the alveolar bone and over the crest to join with the outer periosteum.

Clinical Correlation

Pocket reduction surgeries

Pocket reduction surgeries are aimed at reducing the probing pocket depths in patients with periodontitis. Depending on the disease presentation, one can take a resective or regenerative approach. Suprabony pockets are primarily treated by resective procedures such as gingivectomy or osseous surgery, whereas infrabony defects with multiple walls (that are contained) are generally treated using regenerative approaches.

Periodontal Abscess

A periodontal abscess is a localized purulent inflammation in the periodontal tissues (Fig. 23.23). It is also known as a *lateral abscess* or a *parietal abscess.* Abscesses that are localized in the gingiva, that are caused by injury to the outer surface of the gingiva, and that do not involve the supporting structures are called *gingival abscesses.* Gingival abscesses may occur in the presence or absence of a periodontal pocket.

FIG. 23.23 Periodontal abscess on an upper right central incisor.

Periodontal abscess formation may occur in the following ways:

1. Extension of infection from a periodontal pocket deep into the supporting periodontal tissues and localization of the suppurative inflammatory process along the lateral aspect of the root.
2. Lateral extension of inflammation from the inner surface of a periodontal pocket into the connective tissue of the pocket wall. Formation of the abscess results when drainage into the pocket space is impaired.
3. Formation in a pocket with a tortuous course around the root. A periodontal abscess may form in the cul-de-sac, the deep end of which is shut off from the surface.
4. Incomplete removal of calculus during treatment of a periodontal pocket. The gingival wall shrinks, thereby occluding the pocket orifice, and a periodontal abscess occurs in the sealed-off portion of the pocket.
5. After trauma to the tooth or with perforation of the lateral wall of the root in endodontic therapy. In these situations, a periodontal abscess may occur in the absence of periodontal disease.

Periodontal abscesses are classified according to location as follows:

1. *Abscess in the supporting periodontal tissues along the lateral aspect of the root.* With this condition, a sinus generally

occurs in the bone that extends laterally from the abscess to the external surface.

2. *Abscess in the soft-tissue wall of a deep periodontal pocket.*

Microscopically, an abscess is a localized accumulation of viable and nonviable PMNs within the periodontal pocket wall. The PMNs liberate enzymes that digest the cells and other tissue structures, thereby forming the liquid product known as *pus*, which constitutes the center of the abscess. An acute inflammatory reaction surrounds the purulent area, and the overlying epithelium exhibits intracellular and extracellular edema and the invasion of leukocytes (Fig. 23.24).

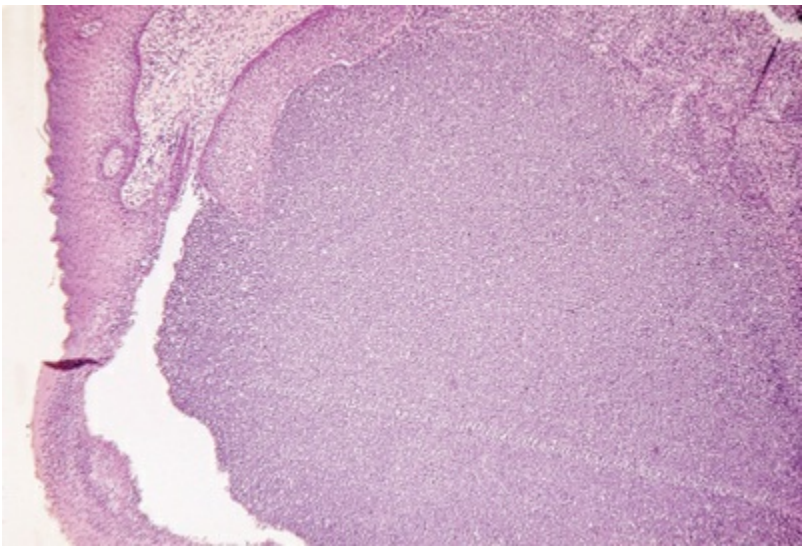

FIG. 23.24 Microscopic view of a periodontal abscess showing the dense accumulation of polymorphonuclear leukocytes covered by squamous epithelium.

The localized acute abscess becomes a chronic abscess when its purulent content drains through a fistula into the outer gingival surface or into the periodontal pocket and the infection that is causing the abscess is not resolved.

The bacterial invasion of tissues has been reported in abscesses; the invading organisms were identified as gram-negative cocci, diplococci, fusiforms, and spirochetes. Invasive fungi were also found and were interpreted as being "opportunistic invaders."[22]

Microorganisms that colonize the periodontal abscess have been reported to be primarily gram-negative anaerobic rods.[51]

Lateral Periodontal Cyst

The periodontal cyst, which is also called *lateral periodontal cyst*, is an uncommon lesion that produces localized destruction of the periodontal tissues along a lateral root surface, most often in the mandibular canine–premolar area.[23,70] It is considered to be derived from the rests of Malassez or other proliferating odontogenic rests.[69]

A periodontal cyst is usually asymptomatic, without grossly detectable changes, but it may present as a localized, tender swelling. Radiographically, an interproximal periodontal cyst appears on the side of the root as a radiolucent area bordered by a radiopaque line. Its radiographic appearance cannot be differentiated from that of a periodontal abscess.

Microscopically, the cystic lining may be (1) a loosely arranged, thin, nonkeratinized epithelium, sometimes with thicker proliferating areas, or (2) an odontogenic keratocyst.[23]

Case Scenario 23.1

Patient:
37-year-old male

Chief Complaint:
"I have swollen gums, and they bleed when I brush."

Background Information
Patient is a nonsmoker and is hypertensive, which he reports to be controlled with amlodipine that he has been taking for the past 5 years. Other than hypertension, the patient did not report any other systemic condition and reports no known drug allergies. His last dental cleaning was done 2 years ago, and he denies flossing but reports brushing twice a day.

Current Findings:
Probing depths were in the range of 3 to 7 mm. Bleeding on

probing % was 55 with moderate oral hygiene. Radiographs revealed normal alveolar bone levels.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Based on the presented information, what kind of a pocket is this? A. Gingival B. Periodontal	**Answer: A** **Explanation:** Gingival pocketing occurs when the gingival margin migrates coronally toward the incisal edges, increasing the probing depths but with no noticeable changes in the bone level. Severe inflammation of the gingiva or drug-induced gingival hyperplasia can lead to such gingival pocketing.
2. Which drugs commonly lead to gingival hyperplasia? A. Calcium channel blockers B. Cyclosporine C. Anticonvulsants D. All of the above	**Answer: D** **Explanation:** All of the mentioned classes of medications can cause gingival hyperplasia. Because this condition is medication induced, recurrence after surgical treatment is common, if the patient continues to take them.
3. What will be the appropriate surgical treatment for this condition? A. Gingivectomy B. Guided tissue regeneration C. Flap-osseous resective	**Answer: A** **Explanation:** Gingivectomy is the surgical excision of excess gingiva. Options B and C are used to treat periodontal pockets associated with bony defects and therefore are not applicable in this situation.

surgery D. All of the above

CHAPTER 24

Bone Loss and Patterns of Bone Destruction

Paulo M. Camargo, Henry H. Takei, Fermin A. Carranza

CHAPTER OUTLINE

Bone Destruction Caused by the Extension of Gingival Inflammation
Bone Destruction Caused by Trauma From Occlusion
Bone Destruction Caused by Systemic Disorders
Factors Determining Bone Morphology in Periodontal Disease
Bone Destruction Patterns in Periodontal Disease
Conclusion

Editors' Note: An animation (slide show) has been added by the editors as a supplement to the chapter. It was produced by My

Dental Hub as a patient education tool and covers the basic elements in a conceptual manner. It is not intended to be a procedural guide for dental professionals.

Periodontitis is an inflammatory condition of the teeth and their supporting structures. The inflammatory process, which occurs as a response to the bacterial biofilm insult, has detrimental effects on the periodontal unit, which results in the destruction of periodontal ligament fibers and bone loss.

The height and density of the alveolar bone are normally maintained by an equilibrium, which is regulated by local and systemic influences, between bone formation and bone resorption.[12,14] When resorption exceeds formation, both bone height and bone density may be reduced (Video 24.1: Vertical Bone Loss).

Bone loss is the ultimate and last consequence of the inflammatory process observed in periodontitis. Therefore the existing bone level is the consequence of past pathologic episodes, whereas changes present in the soft tissue of the pocket wall reflect the presence of the inflammatory condition. Thus the degree of bone loss does not necessarily correlate with the depth of periodontal pockets, the severity of ulceration of the pocket wall, or the presence or absence of suppuration. As an example, a reduced periodontium may exist in areas where bone loss occurred in the past but that currently present with periodontal health (i.e., following periodontal treatment; Fig. 24.1).

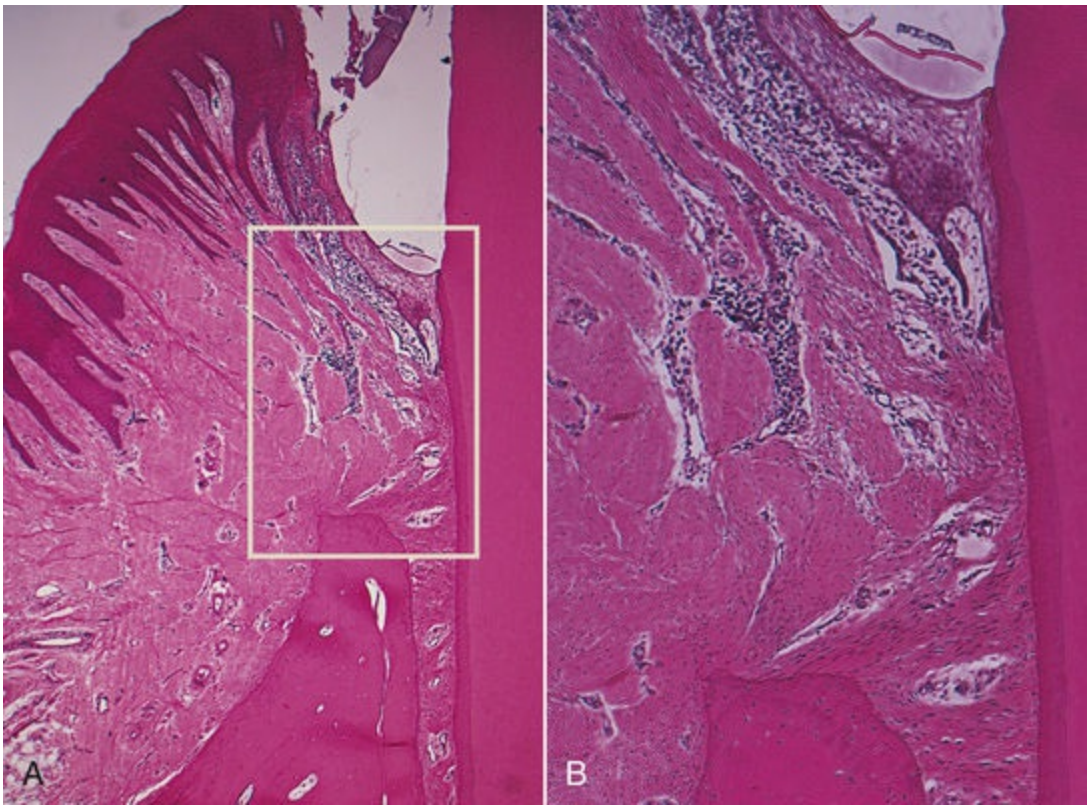

FIG. 24.1 (A) An area of inflammation extending from the gingiva into the suprabony area. (B) Extension of inflammation along the blood vessels and between collagen bundles.

Bone Destruction Caused by the Extension of Gingival Inflammation

The most common cause of bone destruction in periodontitis is the extension of inflammation from the marginal gingiva into the supporting periodontal tissues. The inflammatory migration of the bone surface and the initial bone loss that follows mark the transition from gingivitis to periodontitis.

Periodontitis is always preceded by gingivitis, but not all gingivitis progresses to periodontitis. Some cases of gingivitis apparently never become periodontitis, and other cases go through a brief gingivitis phase and rapidly develop into periodontitis. The factors responsible for the extension of inflammation to the supporting structures, thereby initiating the conversion of gingivitis to periodontitis, are not clearly understood and are likely to be related

to individual susceptibility to the insult presented by the bacterial biofilm or microbiologic changes that occur in the pocket environment and surrounding tissues.

Learning Box 24.1

In periodontitis, the loss of bone is the ultimate and last event of the inflammatory process. The existing bone level is the result of past episodes of bone loss from the effects of periodontitis, but the changes present in the soft tissue of the pocket wall during periodontitis is the result of the ongoing inflammatory process. The degree of bone loss does not necessarily correlate with the depth of the periodontal pockets, the severity of ulceration of the pocket wall, or the presence or absence of exudate.

As stated previously, the transition from gingivitis to periodontitis is associated with changes in the composition of the bacterial biofilm. In advanced stages of disease, the number of motile organisms and spirochetes increases, whereas the number of coccoid rods and straight rods decreases.[34] The cellular composition of the infiltrated connective tissue also changes with increasing severity of the lesion (see Chapter 7). Fibroblasts and lymphocytes predominate in stage 1 gingivitis, whereas the number of plasma cells and blast cells increases gradually as the disease progresses. Seymour and colleagues[58,59] have postulated a stage of "contained" gingivitis, in which T lymphocytes are preponderant; they suggest that, as the lesion becomes a B-lymphocyte lesion, it becomes progressively destructive.

Heijl and coworkers[22] were able to convert, in experimental animals, a confined, naturally occurring state of chronic gingivitis into progressive periodontitis by placing a silk ligature into the sulcus and tying it around the neck of the teeth. Placement of the ligature induced ulceration of the sulcular epithelium, a shift in the inflammatory infiltrate from predominantly plasma cells to polymorphonuclear leukocytes, and osteoclastic resorption of the alveolar crest. The recurrence of episodes of acute destruction over time may be one mechanism that leads to progressive bone loss in

individuals with chronic periodontitis.

The extension of the inflammatory process into the supporting structures of a tooth may be modified by the pathogenic potential of biofilm and the susceptibility/resistance of the host. The latter includes immunologic activity and other tissue-related mechanisms, such as the degree of fibrosis of the gingiva, probably the width of the attached gingiva, and the reactive fibrogenesis and osteogenesis that occur peripheral to the inflammatory lesion.[52] Some studies suggest that the quality of the host response to a similar bacterial insult varies, resulting in some individuals being more susceptible to the destructive aspects of periodontitis than others.

Histopathology

Gingival inflammation extends along the collagen fiber bundles and follows the course of the blood vessels through the loosely arranged tissues around them into the alveolar bone[67] (see Fig. 24.1). Although the inflammatory infiltrate is concentrated in the marginal periodontium, the reaction is a much more diffuse one, often reaching the bone and eliciting a response before evidence of crestal resorption or loss of attachment exists.[41] In the upper molar region, inflammation can extend to the maxillary sinus, resulting in thickening of the sinus mucosa.[40]

Interproximally, inflammation spreads to the loose connective tissue around the blood vessels, through the fibers, and then into the bone through vessel channels that perforate the crest of the interdental septum at the center of the crest (Fig. 24.2), toward the side of the crest (Fig. 24.3), or at the angle of the septum. In addition, inflammation may enter the bone through more than one channel. Less frequently, the inflammation spreads from the gingiva directly into the periodontal ligament and from there into the interdental septum[1] (Fig. 24.4).

FIG. 24.2 Inflammation that extends from the pocket area *(top)* between the collagen fibers, which are partially destroyed.

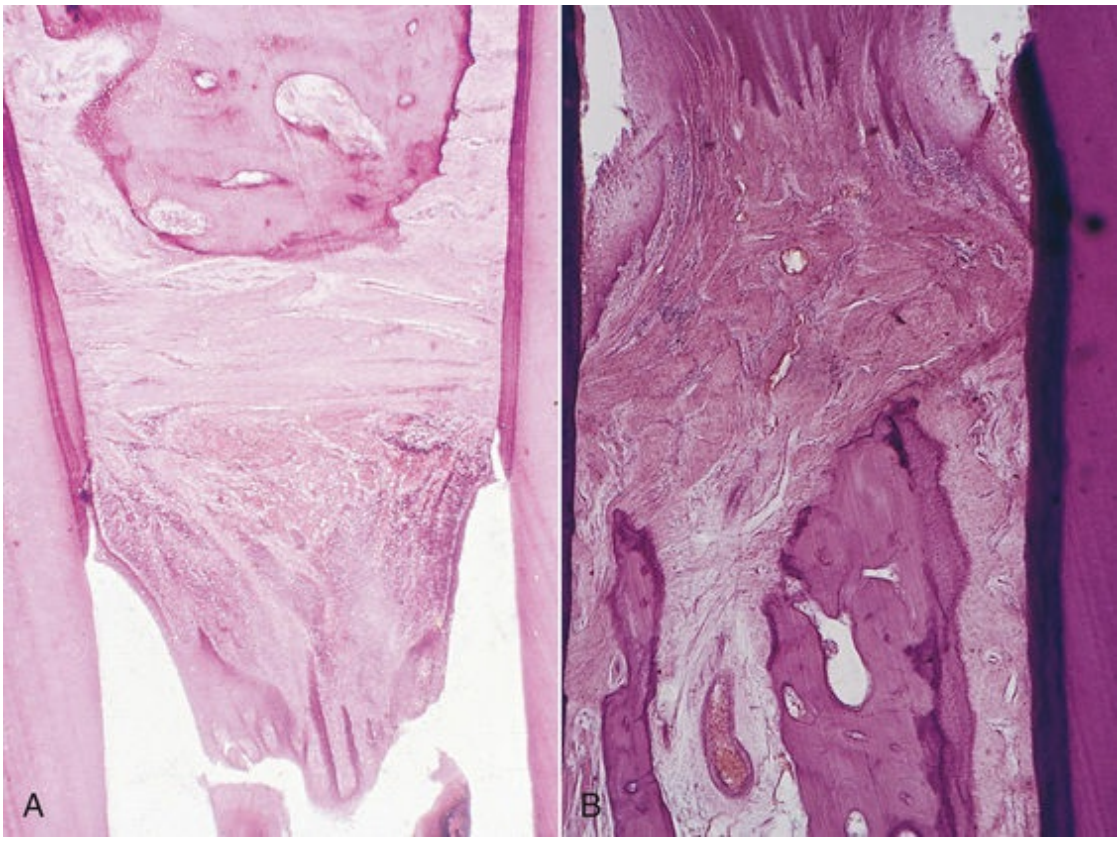

FIG. 24.3 (A) Extension of inflammation into the center of the interdental septum. Inflammation from the gingiva penetrates the transseptal fibers and enters the bone around the blood vessel in the center of the septum. (B) The cortical layer at the top of the septum has been destroyed, and the inflammation penetrates into the marrow spaces.

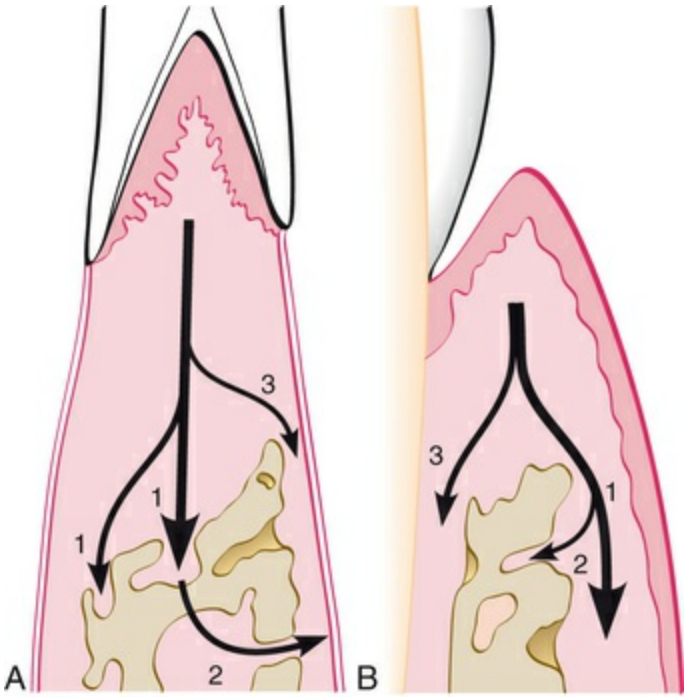

FIG. 24.4 Pathways of inflammation from the gingiva into the supporting periodontal tissues in a patient with periodontitis. (A) Interproximally, from the gingiva into the bone *(1)*, from the bone into the periodontal ligament *(2)*, and from the gingiva into the periodontal ligament *(3)*. (B) Facially and lingually, from the gingiva along the outer periosteum *(1)*, from the periosteum into the bone *(2)*, and from the gingiva into the periodontal ligament *(3)*.

Facially and lingually, inflammation from the gingiva spreads along the outer periosteal surface of the bone (see Fig. 24.4) and penetrates into the marrow spaces through vessel channels in the outer cortex.

Along its course from the gingiva to the bone, the inflammation destroys the gingival and transeptal fibers, reducing them to disorganized granular fragments interspersed among the inflammatory cells and edema.[45] However, there is a continuous tendency to recreate transeptal fibers across the crest of the interdental septum farther along the root as the bone destruction progresses (Fig. 24.5). As a result, transeptal fibers are present, even in cases of extreme periodontal bone loss. The dense transeptal fibers form a firm covering over the bone that is encountered during periodontal flap surgery after the superficial granulation tissue is removed.[50]

FIG. 24.5 Reformation of transseptal fibers. A mesiodistal section through the interdental septum shows gingival inflammation and bone loss. Recreated transseptal fibers can be seen above the bone margin, where they have been partially infiltrated by the inflammatory process.

After inflammation reaches the bone via extension from the gingiva (Fig. 24.6), it spreads into the marrow spaces and replaces the marrow with a leukocytic and fluid exudate, new blood vessels, and proliferating fibroblasts (Fig. 24.7). Multinuclear osteoclasts and mononuclear phagocytes increase in number, and the bone surfaces appear to be lined with Howship lacunae (Fig. 24.8).

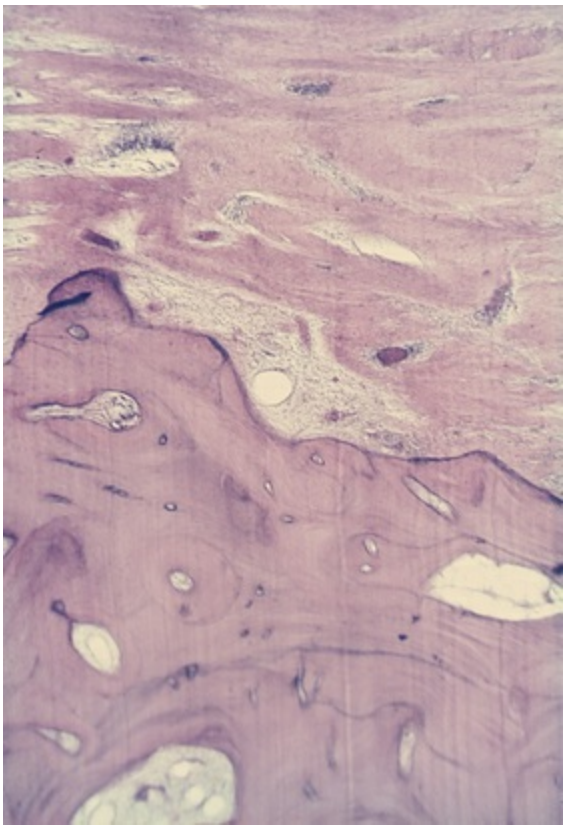

FIG. 24.6 Extension of inflammation has reached the crestal bone surface.

FIG. 24.7 Interdental septum in a human autopsy section. Extensive inflammatory infiltrate has invaded the marrow spaces, entering from both the mesial and distal aspects. Fatty bone marrow has been replaced by inflammatory cells and fibrous marrow.

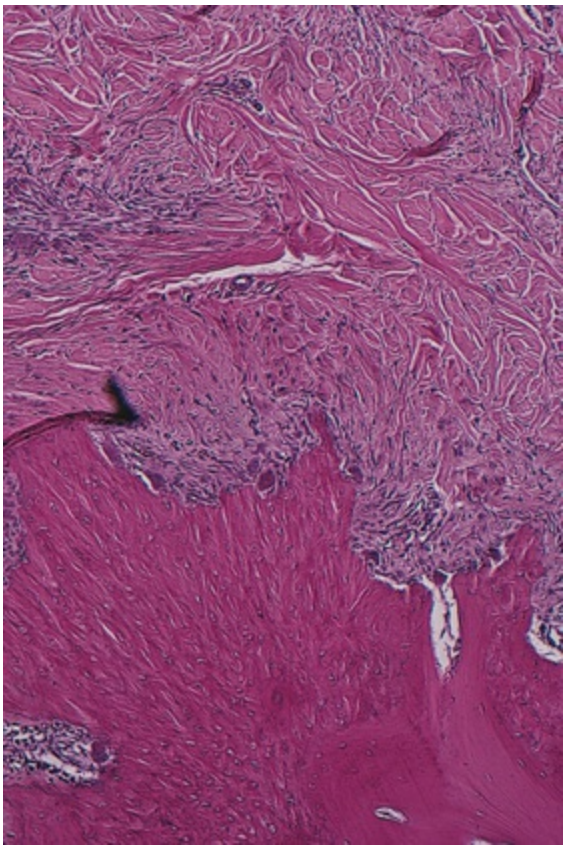

FIG. 24.8 Osteoclasts and Howship lacunae in the resorption of crestal bone.

In the marrow spaces, resorption proceeds from within and causes a thinning of the surrounding bony trabeculae and an enlargement of the marrow spaces; this is followed by the destruction of the bone and a reduction in bone height. Normally, fatty bone marrow is partially or totally replaced by a fibrous type of marrow in the vicinity of the resorption.

Bone destruction in periodontal disease is not a process of bone necrosis.[27] It involves the activity of living cells along viable bone. With the exception of necrotic bone that is visible in distinct pathogenic processes such as necrotizing ulcerative periodontitis and bisphosphonate-related osteonecrosis of the jaws, all bone present in areas with periodontitis is viable, live bone. In periodontitis, bone resorption may be related to the analogy of the bone attempting to run away from the infectious/inflammatory process; this may be seen as a host protection mechanism.

The amount of inflammatory infiltrate correlates with the degree of bone loss but not with the number of osteoclasts. However, the distance from the apical border of the inflammatory infiltrate to the

alveolar bone crest correlates with both the number of osteoclasts on the alveolar crest and the total number of osteoclasts.[51] Similar findings have been reported in experimentally induced periodontitis in animals.[32]

Radius of Action

Garant and Cho[10] suggested that locally produced bone resorption factors may need to be present in the proximity of the bone surface to exert their action. Page and Schroeder,[49] on the basis of Waerhaug's measurements made on human autopsy specimens,[64,65] postulated a range of effectiveness of about 1.5 mm to 2.5 mm in which bacterial biofilm can induce loss of bone. Beyond 2.5 mm, there is little or no effect; interproximal angular defects can appear only in spaces that are wider than 2.5 mm, because narrower spaces would end up with horizontal bone loss. Tal[61] corroborated this concept with measurements in human patients.

Large defects that greatly exceed a distance of 2.5 mm from the tooth surface (as described in aggressive types of periodontitis) may be caused by the presence of bacteria in the tissues.[6,10,54]

Rate of Bone Loss

In a study of Sri Lankan tea laborers with no oral hygiene and no dental care, Löe and colleagues[36] found the rate of bone loss averages about 0.2 mm per year for facial surfaces and about 0.3 mm per year for proximal surfaces when periodontal disease was allowed to progress untreated.

However, the rate of bone loss may vary, depending on the type of disease present. Löe and colleagues[35] also identified the following three subgroups of patients with periodontal disease on the basis of the interproximal loss of attachment and tooth mortality (loss of attachment can be equated with loss of bone, although attachment loss precedes bone loss by about 6 to 8 months[17]):

1. Approximately 8% of persons had a rapid progression of periodontal disease that was characterized by a yearly loss of attachment of 0.1 mm to 1 mm.
2. Approximately 81% of individuals had moderately

progressive periodontal disease with a yearly loss of attachment of 0.05 mm to 0.5 mm.

3. The remaining 11% of persons had minimal or no progression of destructive disease with a yearly loss of attachment of 0.05 mm to 0.09 mm.

Periods of Destruction

Periodontal destruction occurs in an episodic, intermittent manner, with periods of inactivity or quiescence that alternate with destructive periods that result in the loss of collagen and alveolar bone and the deepening of the periodontal pocket.

Periods of destructive activity are associated with subgingival ulceration and an acute inflammatory reaction that results in the rapid loss of alveolar bone[49,56]; it has been hypothesized that this coincides with the conversion of a predominantly T-lymphocyte lesion to one with a predominantly B-lymphocyte–plasma cell infiltrate.[59] Microbiologically, these lesions are associated with an increase in the loose, unattached, motile, gram-negative, anaerobic pocket flora, whereas periods of remission coincide with the formation of a dense, unattached, nonmotile, gram-positive flora with a tendency to mineralize.[43]

It has also been suggested that the onset of periods of destruction coincide with tissue invasion by one or several bacterial species and that this is followed by an advanced local host defense that controls the attack.[54]

Learning Box 24.2

The dense network transseptal fiber that is attached interdentally from tooth to tooth is one of the barriers that protects the interdental bone from the inflammatory process. Even after these fibers are initially destroyed, they continually re-form and are the fibers found during periodontal flap surgery.

Mechanisms of Bone Destruction

The factors involved in bone destruction in periodontal disease are

bacterial and host mediated. The bacterial biofilm products induce the differentiation of bone progenitor cells into osteoclasts and stimulate gingival cells to release mediators that have the same effect.[21,57] Bacterial biofilm products and inflammatory mediators can also act directly on osteoblasts or their progenitors, thereby inhibiting their action and reducing their numbers.

In addition, in patients with rapidly progressing diseases (e.g., aggressive periodontitis), bacterial microcolonies or single bacterial cells have been found between collagen fibers and over the bone surface, suggesting a direct effect.[6,9,57]

Several host factors released by inflammatory cells are capable of inducing bone resorption in vitro, and they play a role in periodontal disease. These include host-produced prostaglandins and their precursors, interleukin-1α, interleukin-β, and tumor necrosis factor alpha.

When injected intradermally, prostaglandin E_2 induces the vascular changes that are seen with inflammation; when injected over a bone surface, prostaglandin E_2 induces bone resorption in the absence of inflammatory cells, with few multinucleated osteoclasts.[18,26] In addition, nonsteroidal antiinflammatory drugs (e.g., flurbiprofen, ibuprofen) inhibit prostaglandin E_2 production, thereby slowing bone loss in naturally occurring periodontal disease in beagle dogs and humans. This effect disappears 6 months after the cessation of drug administration.[25,68] (For more information about the host-mediated mechanisms of bone destruction, see Chapters 7 and 14.)

Bone Formation in Periodontal Disease

Areas of bone formation are also found immediately adjacent to sites of active bone resorption and along trabecular surfaces at a distance from the inflammation in an apparent effort to reinforce the remaining bone (i.e., buttressing bone formation). This estrogenic response is clearly found in experimentally produced periodontal bone loss in animals.[7] In humans, it is less obvious, but it has been confirmed by histometric[4,5] and histologic studies.[13]

Autopsy specimens from individuals with untreated disease occasionally show areas in which bone resorption has ceased and

new bone is being formed on previously eroded bone margins. This confirms the intermittent character of bone resorption in periodontitis, and it is consistent with the varied rates of progression observed clinically in individuals with untreated periodontal disease.

The periods of remission and exacerbation (or inactivity and activity, respectively) appear to coincide with the quiescence or exacerbation of gingival inflammation as manifested by changes in the extent of bleeding, the amount of exudate, and the composition of bacterial biofilm (see Chapters 17 and 18).

The presence of bone formation in response to inflammation, even in those with active periodontal disease, has an effect on the outcome of treatment. The basic aim of periodontal therapy is the elimination of inflammation to inhibit the stimulus for bone resorption and therefore to allow the inherent constructive tendencies to predominate.

Bone Destruction Caused by Trauma From Occlusion

Another cause of periodontal bone destruction is trauma from occlusion, which can occur in the absence or presence of inflammation (see Chapter 25).

In the absence of inflammation, the changes caused by trauma from occlusion vary from increased compression and tension of the periodontal ligament and increased osteoclasis of alveolar bone to necrosis of the periodontal ligament and bone and the resorption of bone and tooth structure. These changes are reversible in that they can be repaired if the offending forces are removed. However, persistent trauma from occlusion results in funnel-shaped widening of the crestal portion of the periodontal ligament with resorption of the adjacent bone.[33] These changes, which may cause the bony crest to have an angular shape, represent adaptation of the periodontal tissues aimed at "cushioning" increased occlusal forces; however, the modified bone shape may weaken tooth support and cause tooth mobility.

When it is combined with inflammation, trauma from occlusion

may aggravate the bone destruction caused by the inflammation[33] and results in bizarre bone patterns.

Bone Destruction Caused by Systemic Disorders

Local and systemic factors regulate the physiologic equilibrium of bone. When a generalized tendency toward bone resorption exists, bone loss initiated by local inflammatory processes may be magnified.

This systemic influence on the response of alveolar bone, as envisioned by Glickman[12] during the early 1950s, considers a systemic regulatory influence in all cases of periodontal disease. In addition to the virulence of biofilm bacteria, the nature of the systemic component rather than its presence or absence influences the severity of the periodontal destruction. This concept of a role played by systemic defense mechanisms has been validated by the studies of immune deficiencies and host modulation in severely destructive types of periodontitis.

Interest has increased concerning the possible relationship between periodontal bone loss and osteoporosis.[11] Osteoporosis is a physiologic condition of postmenopausal women that results in the loss of bone mineral content as well as structural bone changes. Periodontitis and osteoporosis share a number of risk factors (e.g., aging, smoking, certain diseases, medications that interfere with healing). Some studies show a relationship between skeletal density and oral bone density; between crestal height and residual ridge resorption; and among osteopenia and periodontitis, tooth mobility, and tooth loss.[19,23,24,55,63]

Periodontal bone loss may also occur with generalized skeletal disturbances (e.g., hyperparathyroidism, leukemia, histiocytosis X) via mechanisms that may be totally unrelated to the more common biofilm-induced, inflammatory periodontal lesion.

Learning Box 24.3

In the absence of inflammation, the localized bone loss caused by

trauma from occlusion is reversible (can be repaired) if the offending forces are removed.

Factors Determining Bone Morphology in Periodontal Disease

Normal Variation in Alveolar Bone

Considerable normal variation exists within the morphologic features of alveolar bone, and this affects the osseous contours produced by periodontal disease. The anatomic features that substantially affect the bone-destructive pattern of periodontal disease include the following:

- Thickness, width, and crestal angulation of the interdental septa
- Thickness of the facial and lingual alveolar plates
- Presence of fenestrations and dehiscences
- Alignment of the teeth
- Root and root trunk anatomy
- Root position within the alveolar process
- Proximity with another tooth surface

For example, angular osseous defects cannot form in thin facial or lingual alveolar plates, which have little or no cancellous bone between the outer and inner cortical layers. In such cases, the entire crest of the plate is destroyed, and the height of the bone is reduced in a horizontal fashion (Fig. 24.9).

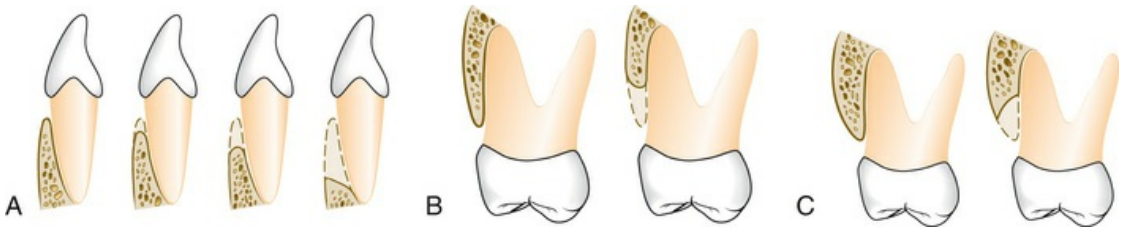

FIG. 24.9 (A) Lower incisor with thin labial bone. Bone loss can become vertical only when it reaches thicker bone in apical areas. (B) Upper molars with thin facial bone, where only horizontal bone loss can occur. (C) Upper molar with a thick facial bone that allows for vertical bone loss.

Exostoses

Exostoses are outgrowths of bone of varied size and shape. Palatal exostoses have been found in 40% of human skulls.[46] They can occur as small nodules, large nodules, sharp ridges, spikelike projections, or any combination of these examples (Fig. 24.10).[42] Exostoses have been described in rare cases as developing after the placement of free gingival grafts.[46]

FIG. 24.10 Occlusal (A) and palatal (B) views of exostosis on the first and second molars.

Trauma From Occlusion

Trauma from occlusion may be a factor in determining the dimension and shape of bone deformities. It may cause a thickening of the cervical margin of alveolar bone or a change in bone morphology (e.g., funnel-like crestal bone, buttressing bone) on which inflammatory changes may later be superimposed.

Learning Box 24.4

Angular osseous defects—as often seen in the interdental areas of the posterior dentition—cannot form in thin radicular, facial, or lingual alveolar bone. These areas have little or no cancellous bone between the outer and inner cortical layers. In these anatomic areas, the entire crest of the plate is destroyed, and the height of the bone is reduced in a horizontal fashion.

Buttressing Bone Formation

Bone formation sometimes occurs in an attempt to buttress bony trabeculae that are weakened by resorption. When this occurs within the jaw, it is termed *central buttressing bone formation.* When it occurs on the external surface, it is referred to as *peripheral*

buttressing bone formation.[13] The latter may cause bulging of the bone contour, which sometimes accompanies the production of osseous craters and angular defects (Fig. 24.11).

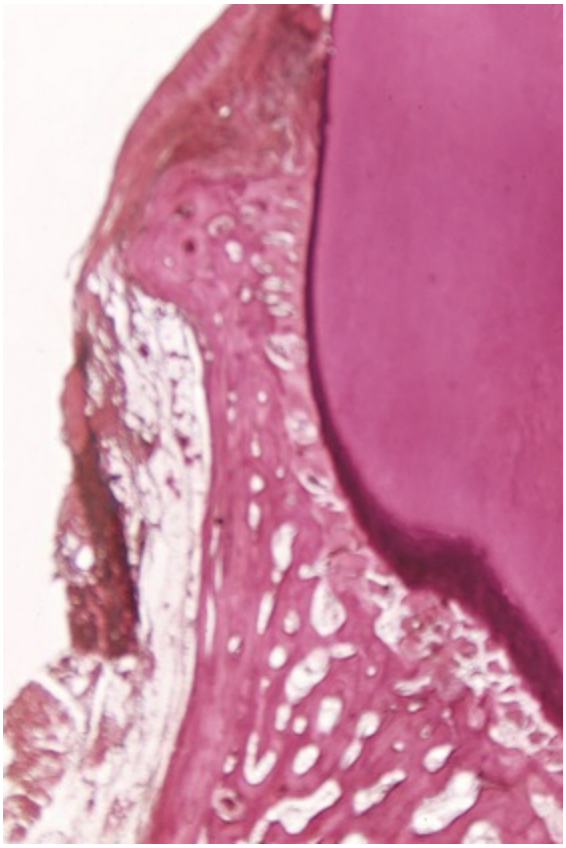

FIG. 24.11 Lipping of facial bone. There is a peripheral buttressing bone formation along the external surface of the facial bony plate and at the crest. Note the deformity in the bone produced by the buttressing bone formation and the bulging of the mucosa.

Food Impaction

Interdental bone defects often occur where the proximal contact is light or absent. Physical pressure and the additional collection of bacteria from food impaction contribute to interproximal resorption and the development of reverse bone architecture. In some cases, the poor proximal relationship may result from a shift in tooth position as a result of extensive bone destruction that precedes food impaction. In patients with this condition, food impaction is a

complicating factor rather than the cause of the bone defect.

Aggressive Periodontitis

Aggressive periodontitis usually results in attachment and bone loss around incisors and first molars, particularly in cases where the disease is observed in teenagers. Although such bone loss is usually horizontal in nature around incisors, a vertical or angular pattern of alveolar bone destruction is found around the first molars in aggressive periodontitis. The cause of the localized bone destruction associated with this type of periodontal disease is unknown (see Chapter 28).

Bone Destruction Patterns in Periodontal Disease

Periodontal disease alters the morphologic features of the bone in addition to reducing bone height. An understanding of the nature and pathogenesis of these alterations is essential for effective diagnosis and treatment.[48]

Horizontal Bone Loss

Horizontal bone loss is the most common pattern of bone loss in periodontal disease (Fig. 24.12A–B). The bone is reduced in height, but the bone margin remains approximately perpendicular to the tooth surface. The interdental septa and the facial and lingual plates are affected but not necessarily to an equal degree around the same tooth.

FIG. 24.12 Horizontal bone loss in the anterior (A) and posterior (B) areas. Notice the increased distance between the marginal bone and the cementoenamel junction; yet the overall bone contour is scalloped, indicating that bone resorption has affected the buccal and interproximal surfaces to a similar degree.

Vertical or Angular Defects

Different types of bone deformities can result from periodontal disease. These usually occur in adults, but they have also been reported in human skulls with deciduous dentitions.[28] Their presence may be suggested on radiographs, but careful probing and surgical exposure of the areas are required to determine their exact conformation and dimensions.

Vertical or angular defects are those that occur in an oblique direction, leaving a hollowed-out trough in the bone alongside the root; the base of the defect is located apical to the surrounding bone (Figs. 24.13A–B and 24.14). In most instances, angular defects have

accompanying infrabony periodontal pockets; infrabony pockets, on the other hand, must always have an underlying angular defect.

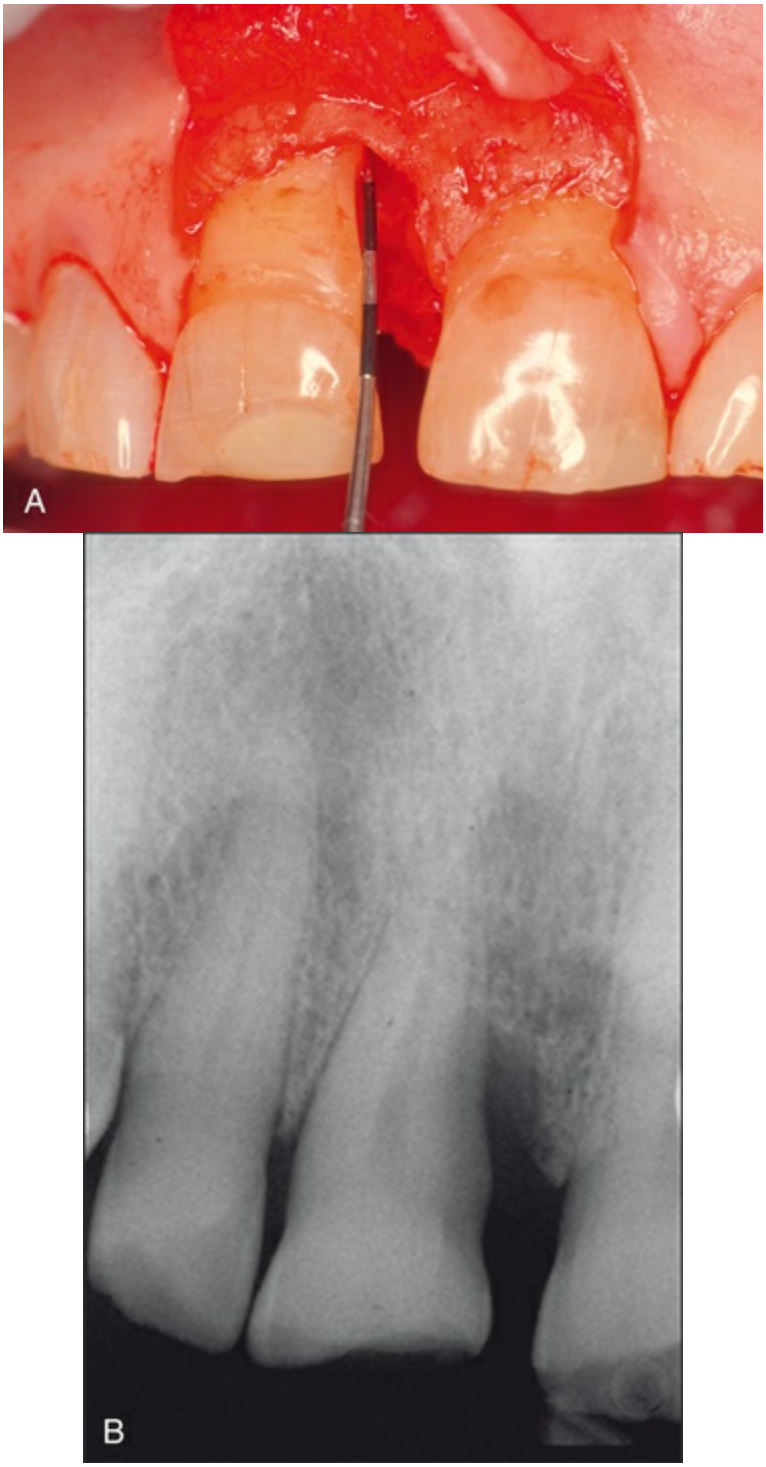

FIG. 24.13 Clinical (A) and radiographic (B) views of a vertical (angular) defect mesial of the upper right central incisor. Note the periodontal probe in a more apical position than the surrounding walls of the bony

defect.

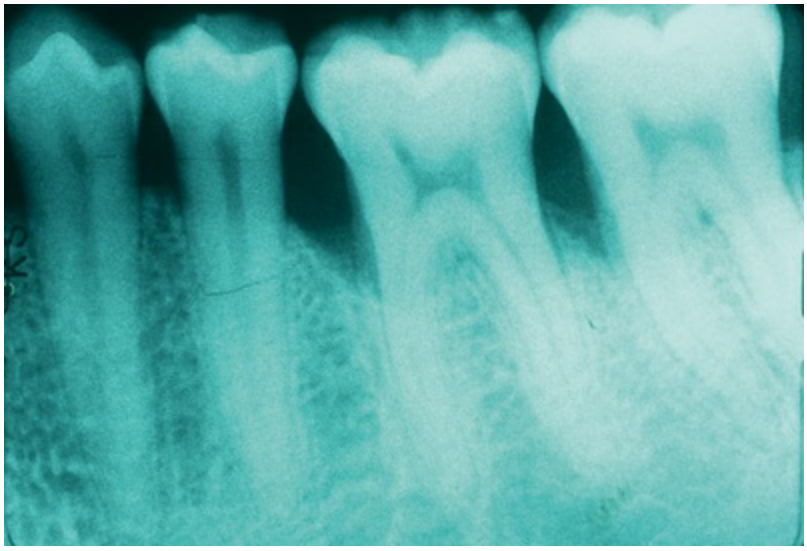

FIG. 24.14 Vertical (angular) defects mesial of the first and second molars.

Goldman and Cohen classified angular defects on the basis of the number of osseous walls.[16] Angular defects may have one, two, or three walls (Figs. 24.15 and 24.16). Continuous defects that involved more than one surface of a tooth, in a shape that is similar to a trough, are called *circumferential defects* (Fig. 24.17). The number of walls in the apical portion of the defect is often greater than that in its occlusal portion, in which case the term *combined osseous defect* is used (Fig. 24.18).

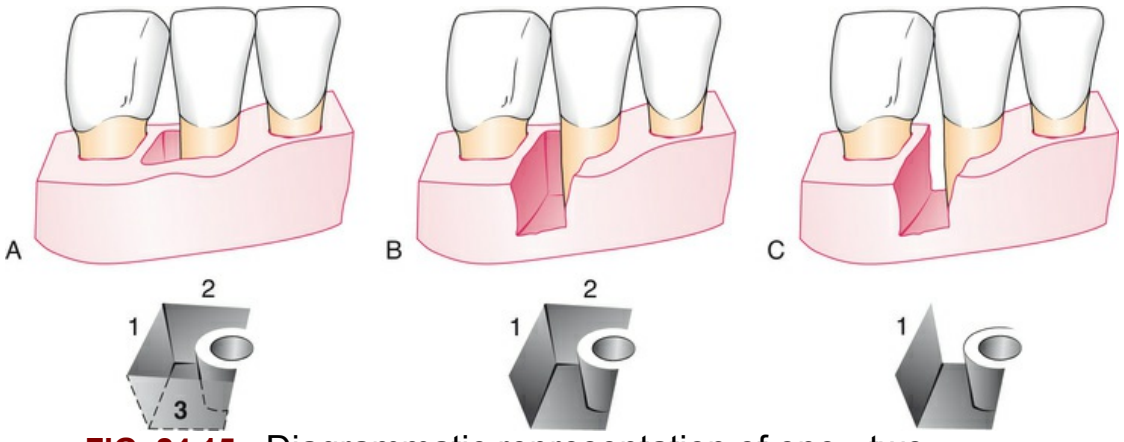

FIG. 24.15 Diagrammatic representation of one-, two-,

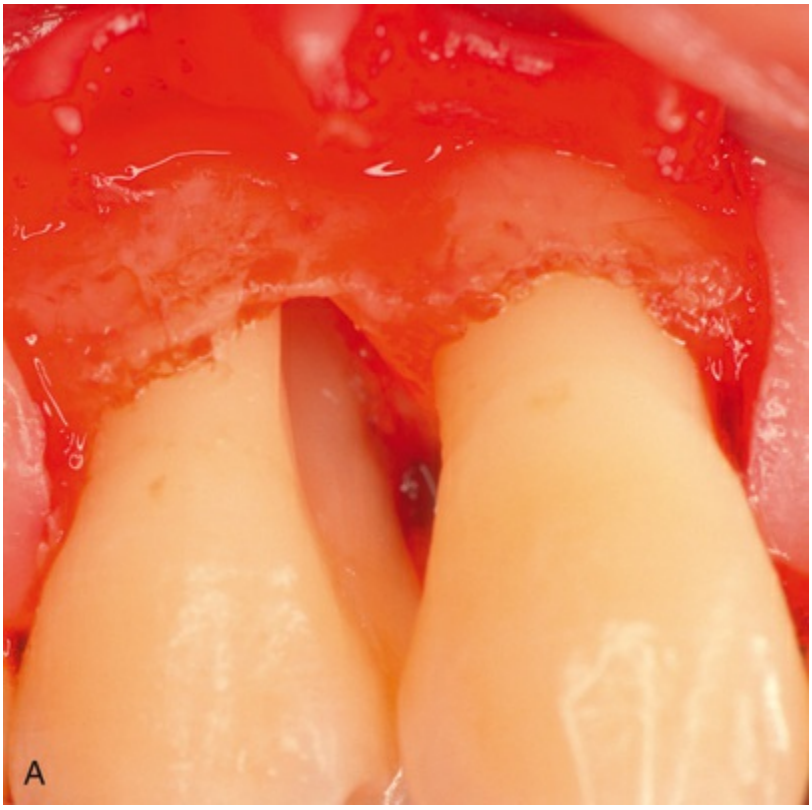
and three-walled vertical defects on the right lateral incisor. (A) Three bony walls: distal *(1),* lingual *(2),* and facial *(3).* (B) Two-wall defect: distal *(1)* and lingual *(2).* (C) One-wall defect: distal wall only *(1).*



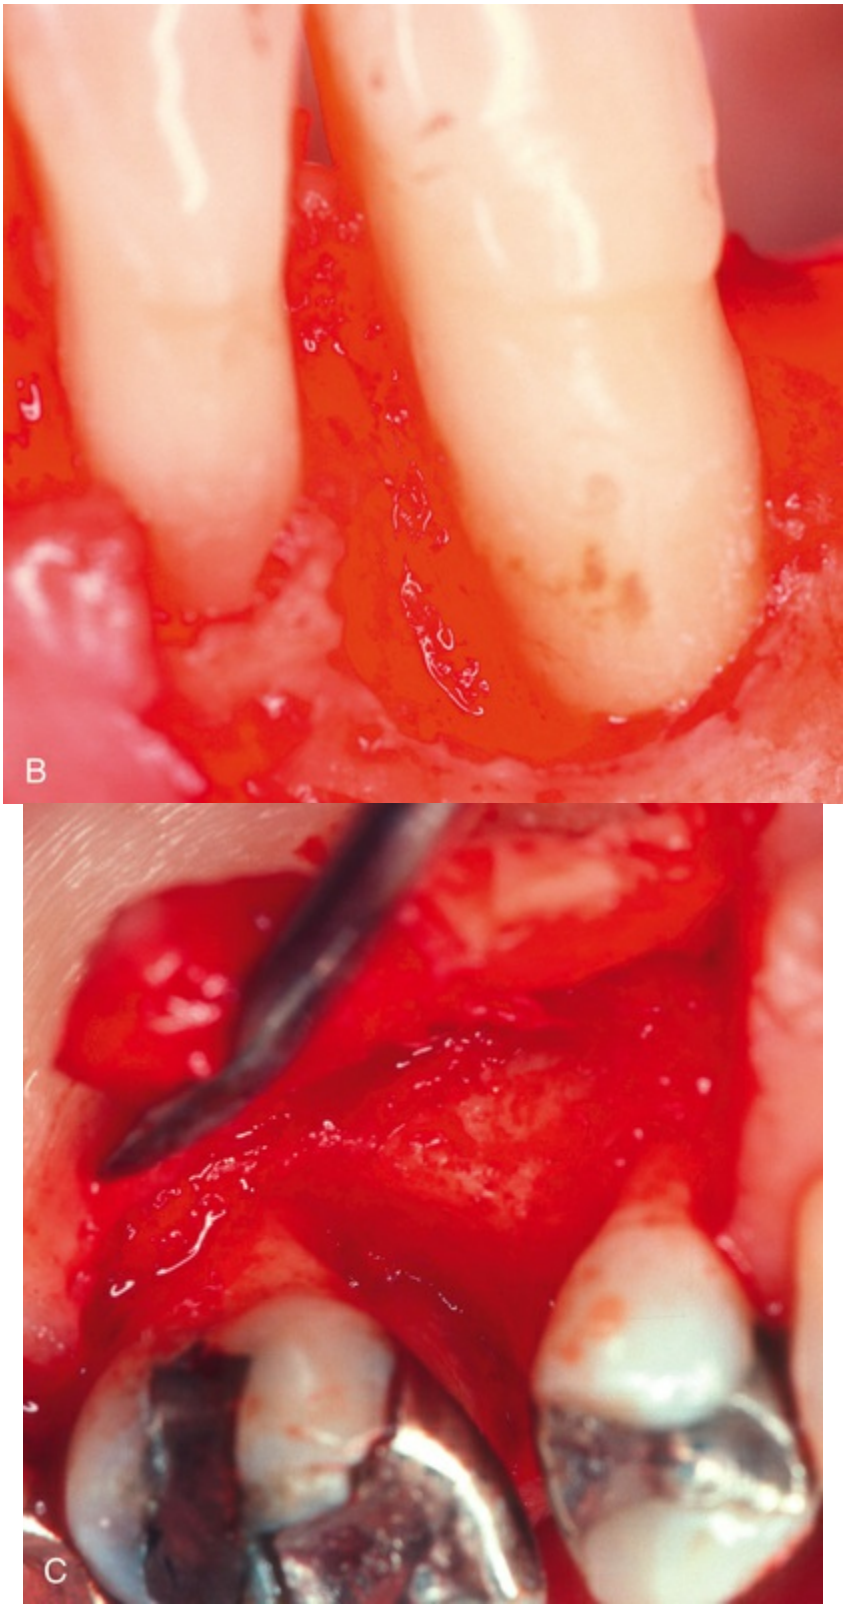


FIG. 24.16 Clinical examples of a three-wall defect mesial of the first bicuspid (A), two-wall defect mesial of the lower canine (buccal wall is missing) (B), and one-wall defect mesial of the first molar (buccal and lingual walls are missing) (C).

FIG. 24.17 Circumferential (troughlike) defect on the buccal and distal aspects of the first molar. Notice that the defect extends into the buccal furcation.

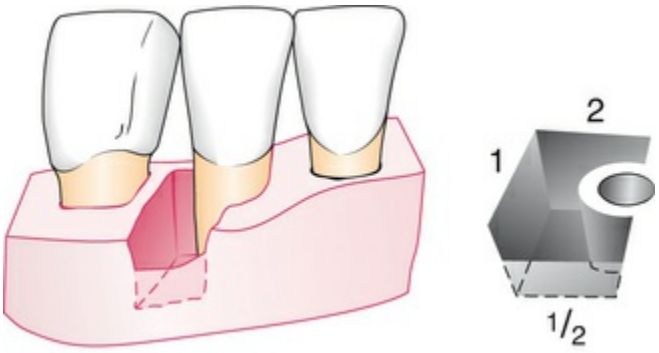

FIG. 24.18 Combined type of osseous defect. Because the facial wall is half the height of the distal *(1)* and lingual *(2)* walls, this is an osseous defect with three walls in its apical half and two walls in its occlusal half.

Vertical defects that occur interdentally can generally be seen on the radiograph, although thick, bony plates may sometimes obscure them. Angular defects can also appear on facial and lingual or palatal surfaces, but these defects are more difficult to visualize on radiographs. Surgical exposure is the only sure way to determine the presence and configuration of vertical osseous defects.

Vertical defects increase with age.[44,47,69] Approximately 60% of people with interdental angular defects have only a single defect.[44] Vertical defects detected radiographically have been reported to

appear most often on the distal[44] and mesial surfaces.[47] However, three-wall defects are more frequently found on the mesial surfaces of the upper and lower molars.[29]

Learning Box 24.5

The localized angular bone loss in aggressive periodontitis is usually located around the first molars and the incisors. These osseous lesions may be present in teenagers.

Osseous Craters

Osseous craters are a specific type of two-wall defect; they present as concavities in the crest of the interdental bone that is confined within the facial and lingual walls (Fig. 24.19). Craters have been found to make up about one-third (35.2%) of all defects and about two-thirds (62%) of all mandibular defects; they occur twice as often in posterior segments as in anterior segments.[37,38]

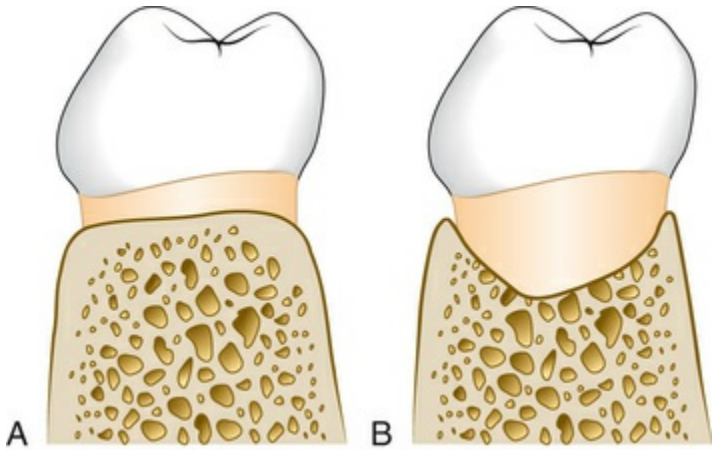

FIG. 24.19 (A) Diagrammatic representation of an osseous crater in a buccolingual section between two lower teeth. *Left*, Normal bone contour. *Right*, Osseous crater. (B) Clinical aspect of an osseous crater between the two bicuspids—notice the buccal and lingual bone walls.

The heights of the facial and lingual crests of a crater have been found to be identical in 85% of cases, with the remaining 15% being

almost equally divided between higher facial crests and higher lingual crests.[53]

The following reasons for the high frequency of interdental craters have been suggested[37,38,53]:

- The interdental area collects biofilm and is difficult to clean.
- The normal flat or even slightly concave buccolingual shape of the interdental septum in the lower molars may favor crater formation.
- Vascular patterns from the gingiva to the center of the crest may provide a pathway for inflammation.

Bulbous Bone Contours

Bulbous bone contours are bony enlargements that are caused by exostoses (see Fig. 24.10), adaptation to function, or buttressing bone formation. They are found more frequently in the maxilla than in the mandible.

Reversed Architecture

Reverse (or negative) alveolar bone architecture is the result of a loss of interdental bone, without a concomitant loss of radicular (buccal or lingual/palatal) bone, thereby reversing the normal (or positive) architecture (Fig. 24.20). Negative architecture is more common in the maxilla of patients with periodontitis.[44]

FIG. 24.20 Examples of positive (normal) and negative (reverse) osseous architecture on the lower left posterior segment. The interproximal bone level in the interdental space between the two bicuspids is more coronal than on the buccal aspect of both teeth, whereas the interproximal bone level in the interdental space between the second bicuspid and the first molar shows the bone level to be apical to the buccal bone.

Ledges

Ledges are plateau-like bone margins that are caused by the resorption of thickened bony plates (Fig. 24.21).

FIG. 24.21 Example of bone ledge on the lingual aspect of the bicuspid and molar.

Furcation Involvement

The term *furcation involvement* refers to the invasion of the bifurcation and trifurcation of multirooted teeth by periodontitis. The prevalence of furcation-involved molars is not clear.[8,47] Although some reports indicate that the mandibular first molars are the most common sites and that the maxillary premolars are the least common,[30] other studies have found a higher prevalence in the upper molars.[69] The number of furcation involvements increases with age.[30,31]

The denuded furcation may be visible clinically or covered by the wall of the pocket. The extent of the involvement is determined by exploration with a periodontal or Nabers probe (Fig. 24.22A–B).

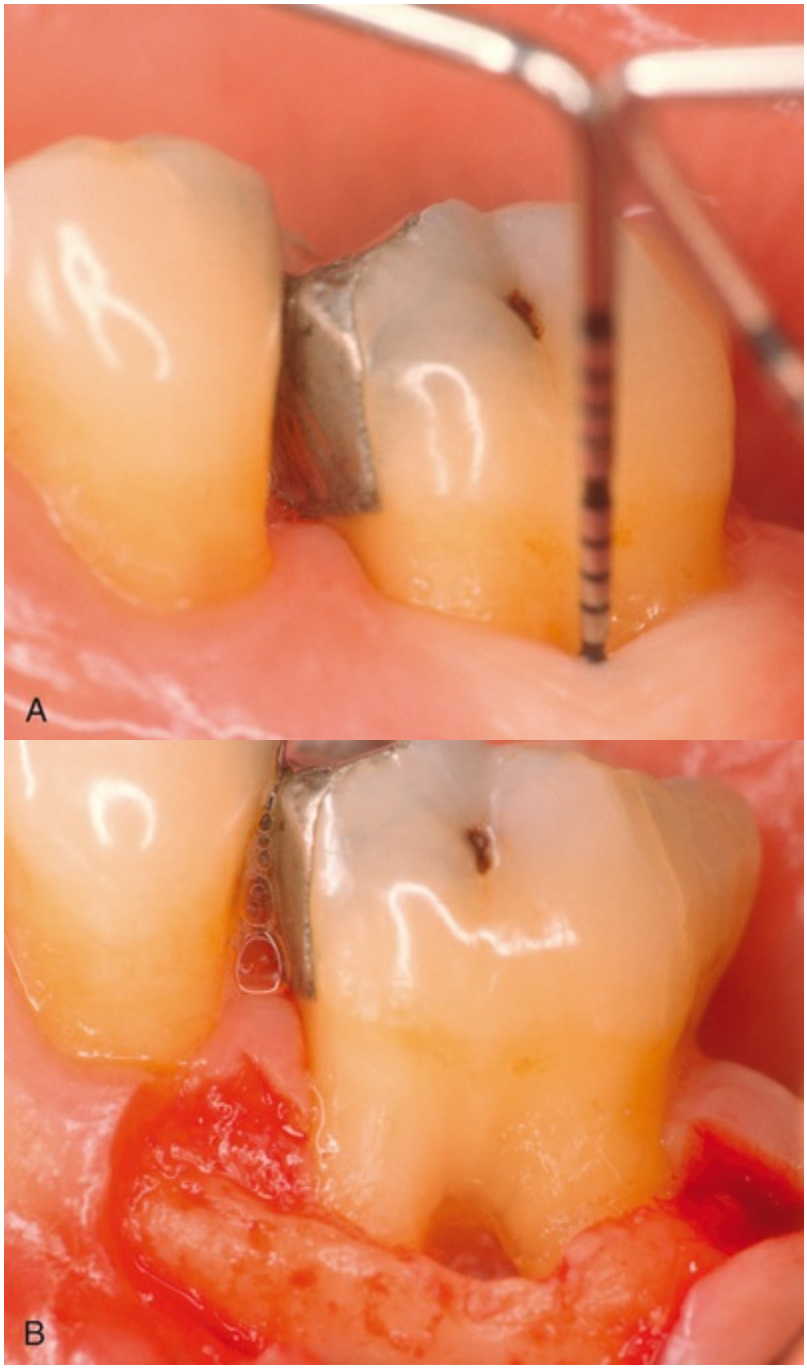

FIG. 24.22 Grade II furcation on the buccal aspect of the lower first molar. (A) Periodontal probe in place showing a 5-mm pocket. (B) After the flap was elevated, it revealed horizontal bone loss.

Furcation involvements have been classified as grades I through IV according to the amount of tissue destruction. Grade I involves incipient bone loss; grade II involves partial bone loss (cul-de-sac); and grade III involves total bone loss with a through-and-through opening of the furcation, but the opening of the furcation is not

visible due to the gingiva, which covers the orifice. Grade IV is similar to grade III but includes gingival recession that exposes the furcation to view. (See Chapter 64 for further discussion on furcation classification.)

Microscopically, furcation involvement presents no unique pathologic features. It is simply the apical extension of the periodontal pocket along a multirooted tooth. During its early stages, widening of the periodontal space occurs with cellular and fluid inflammatory exudation, and this is followed by epithelial proliferation into the furcation area from an adjoining periodontal pocket. Extension of the inflammation into the bone leads to resorption and a reduction in bone height. The bone-destructive pattern may produce horizontal loss, but angular osseous defects associated with intrabony pockets may also exist (Fig. 24.23). Biofilm, calculus, and bacterial debris occupy the denuded furcation space.

FIG. 24.23 Different degrees of furcation involvement in a human autopsy specimen. Furcation involvement is found in all three molars, with an advanced lesion in the second molar and an extremely severe lesion in the first molar that is combined with the exposure of the entire mesial root.

The destructive pattern of a furcation involvement varies in different cases and with the degree of involvement. Bone loss around each individual root may be horizontal or angular, and frequently a crater develops in the interradicular area (Fig. 24.24A–

B). Probing to determine the presence of these destructive patterns must be done horizontally and vertically around each involved root and in the crater area to establish the depth of the vertical component.

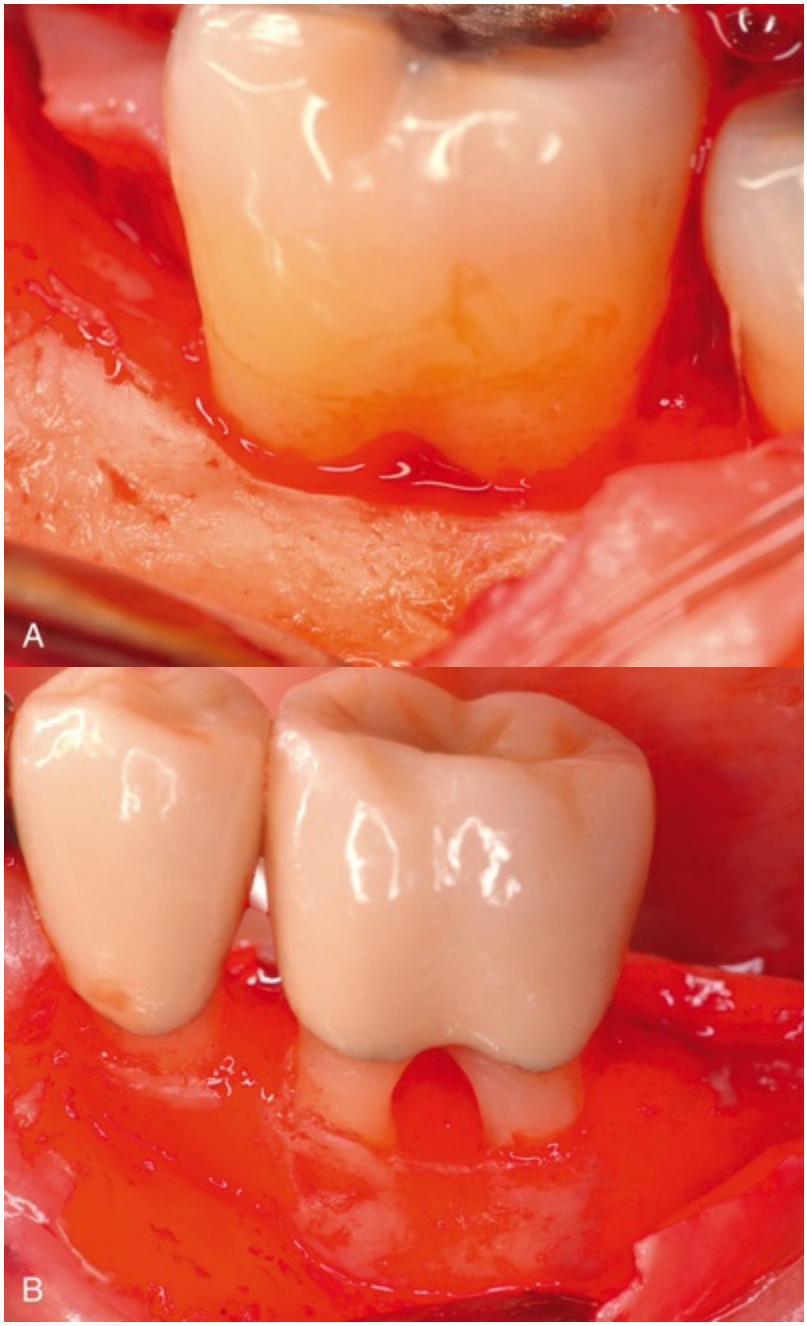

FIG. 24.24 Clinical examples of grade I furcation involvement (A) and grade II furcation involvement (B).

Furcation involvement is a stage of progressive periodontal disease, and it has its same etiology. The difficulty and sometimes

the impossibility[2,3] of controlling biofilm in furcations are responsible for the presence of extensive lesions in this area.[66]

The role of trauma from occlusion in the etiology of furcation lesions is controversial. Some assign a key role to trauma, thinking that furcation areas are most sensitive to injury from excessive occlusal forces.[15] Others deny the initiating effect of trauma and consider that inflammation and edema caused by biofilm in the furcation area tend to extrude the tooth, which then becomes traumatized and sensitive.[60,66]

Other factors that may play a role are the presence of enamel projections into the furcation,[39] which occurs in about 13% of multirooted teeth, and the proximity of the furcation to the cementoenamel junction, which occurs in about 75% of cases of furcation involvement.[31]

The presence of accessory pulpal canals in the furcation area may extend pulpal inflammation to the furcation.[20] This possibility should be carefully explored, particularly when mesial and distal bone retains its normal height. Accessory canals that connect the pulp chamber floor to the furcation have been found in 36% of maxillary first molars, 12% of maxillary second molars, 32% of mandibular first molars, and 24% of mandibular second molars.[62]

The diagnosis of furcation involvement is made by clinical examination and careful probing with a specially designed probe (see Chapters 32 and 64). Radiographic examination of the area is helpful, but lesions can be obscured by the angulation of the beam and the radiopacity of neighboring structures (see Chapter 33).

For more detailed clinical considerations involved with the diagnosis and treatment of furcation involvement, see Chapters 32, 33, and 64.

Conclusion

The understanding of the anatomy, histology, and pattern of bone loss for the diagnosis of and prognosis for periodontal disease is of major importance in determining the therapy that must be rendered. In the final analysis, it is the loss of bone that will determine the retention, maintenance, or loss of the dentition in periodontal disease.

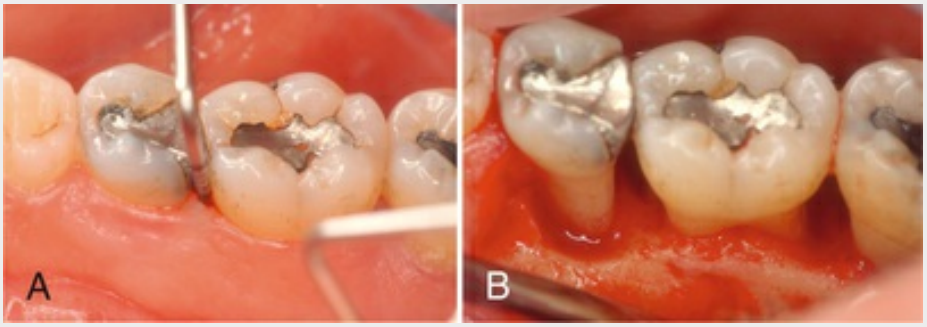
Case Scenario 24.1

Patient:
54-year-old male

Chief Complaint:
"My gums bleed and I have bad breath."

Background Information
The patient has neglected oral care for about 10 years, a period during which he only received treatment for symptomatic teeth. For several years he has noticed blood on the toothbrush when brushing his teeth. More recently, his wife has noticed a foul odor from his mouth. The patient describes himself as an "intense" person who cannot help his clenching habit.

Current Findings:
The patient presents with moderate to advanced chronic periodontitis. He received Phase I periodontal therapy consisting of oral hygiene instructions and scaling and root planing. At reevaluation, the gingival tissues of the lower left segment presented with increased pocket depths and bleeding upon probing. The area was treated surgically, and the osseous profile upon flap elevation is shown below.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the effect of trauma from occlusion in the rate of bone loss and development of intrabony defects as shown in this case?	**Answer: C** **Explanation:** Trauma from occlusion does not initiate clinical attachment loss. In the presence of inflammation induced by the bacterial biofilm,

A. None B. Primary C. Secondary	trauma from occlusion may accelerate the rate of clinical attachment and bone loss and induce the formation of vertical/angular defects.
2. The first molar and second bicuspid present with premature contacts on excursive mandibular movements. If performed as single therapy, what effect should occlusal adjustment have on the progression of clinical attachment and bone loss? A. None B. Mild C. Significant	**Answer: B** **Explanation:** Mild at best, if any. The primary factor in the progression of clinical attachment and bone loss is inflammation caused by the bacterial biofilm. Therefore therapy should focus on eliminating local factors and controlling biofilm formation; without local therapy, occlusal treatment is likely to have little effect on disease progression.
3. Trauma from occlusion may alter the course of bone destruction by redirecting the trajectory of the inflammatory process to the periodontal ligament space as opposed to supraperiosteally. A. True B. False	**Answer: A** **Explanation:** By widening the periodontal ligament space, large blood vessels travel toward the cancellous bone instead of running over the cortical plate. Because inflammation follows the course of larger blood vessels, it can contribute to the formation of vertical/angular defects.

Case Scenario 24.2

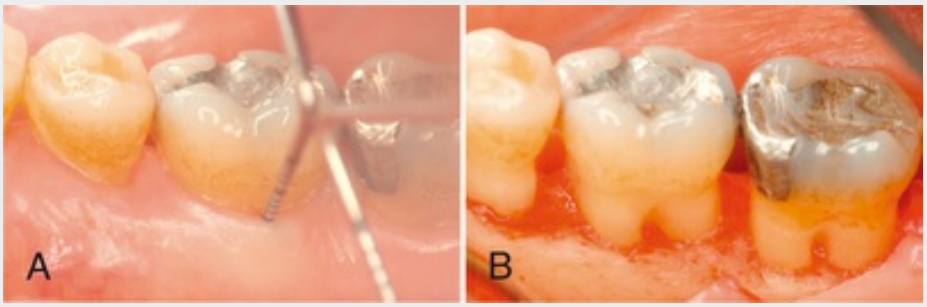
Patient:
45-year-old female

Chief Complaint:
"I don't have any complaints, but during a routine cleaning my new dentist noticed that I had pockets."

Background Information
The patient has been under the care of a family dentist for more than 10 years. She relocated and was referred to a new local dentist, whose dental hygienist delivered Phase I periodontal therapy but was not satisfied with the results and referred the patient to a periodontist.

Current Findings:
The patient smokes 5 to 10 cigarettes per day and has adequate, although not great, oral hygiene. The gingival tissue is mostly fibrotic, with postphase pocket depths ranging from 3 to 6 mm. Bleeding on probing of the posterior teeth on the lower right sextant is 50%. Incipient furcation involvements were detected

with the periodontal probe. The right photograph shows the bone profile during periodontal surgery.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. How can the bone loss observed on the lower right second bicuspid and molars be described? A. Horizontal B. Vertical C. Angular	**Answer: A** **Explanation:** The average distance between the cementoenamel junction is 2 mm, although substantial variation exists. The photograph on the right shows that distance to be around 4 to 5 mm, observed evenly around the teeth. This is a typical presentation of horizontal bone loss. No infrabony defect is present. Vertical or angular bone loss would imply the presence of areas where the base of the bony defect would be apical to the surrounding bony walls.
2. The furcation defects on the lingual aspect of the molars are of what degree? A. I B. II C. III	**Answer: A** **Explanation:** The photograph on the left shows a pocket depth of 5 mm in the lingual furcation of the first molar. Upon surgical exposure, the furcation areas of both molars show incipient bone loss, which is classified as grade I. Notice also that the incipient bone loss in the furcation areas is horizontal in nature, whereby no buccal wall of bone is present.
3. Furcation involvements are best diagnosed by which of the following? A. Radiographic images B. Exploration with a periodontal or Nabers probe C. Surgical exposure	**Answer: B** **Explanation:** The insertion of a periodontal or a Nabers probe into the furcation area is the correct way to diagnose a furcation involvement, which is graded by evaluating the destruction of the hard tissue and clinical attachment in the horizontal direction, using the entrance of the furcation as reference. Most of the time, furcation involvements of degree I will not show on radiographs; additionally, interproximal furcation involvements can be difficult to visualize on two-dimensional radiographs because of the superimposure of images. Surgical exposure is a treatment modality for furcation involvements, but it should not be used as a means to diagnose attachment and bone loss in furcation areas.

CHAPTER OUTLINE

Adaptive Capacity of the Periodontium to Occlusal Forces
Trauma From Occlusion
Stages of Tissue Response to Increased Occlusal Forces
Effects of Insufficient Occlusal Force
Reversibility of Traumatic Lesions
Effects of Excessive Occlusal Forces on Dental Pulp
Relationship Between Plaque-Induced Periodontal Diseases and Trauma From Occlusion
Pathologic Tooth Migration

Adaptive Capacity of the Periodontium to Occlusal Forces

The periodontal ligament has a cushioning effect on forces applied to teeth as means to accommodate forces exerted on the crown. Due to the elastic nature of the periodontal ligament, all teeth with normal bone support present with physiologic mobility in all directions. Physiologic tooth mobility varies among individuals and within the dentition of the same individual. In the absence of excessive occlusal forces or the absence of reduced bone support induced by inflammatory periodontal disease, tooth mobility remains unchanged due to the fact that physiologic forces are not able to induce changes to the periodontal tissues.[3]

When there is an increase in occlusal forces, changes occur in the periodontium in order to accommodate for such forces. Changes in the periodontium depend on the magnitude, direction, duration, and frequency of increased occlusal forces.

When the *magnitude* of occlusal forces is increased, the periodontium responds with a widening of the periodontal ligament space, an increase in the number and width of periodontal ligament fibers, and an increase in the density of alveolar bone.

Changing the *direction* of occlusal forces causes a reorientation of the stresses and strains within the periodontium (Fig. 25.1).[23] The principal fibers of the periodontal ligament are arranged so that they best accommodate occlusal forces along the long axis of the tooth. *Lateral* (horizontal) and *torque* (rotational) forces are more likely to injure the periodontium.

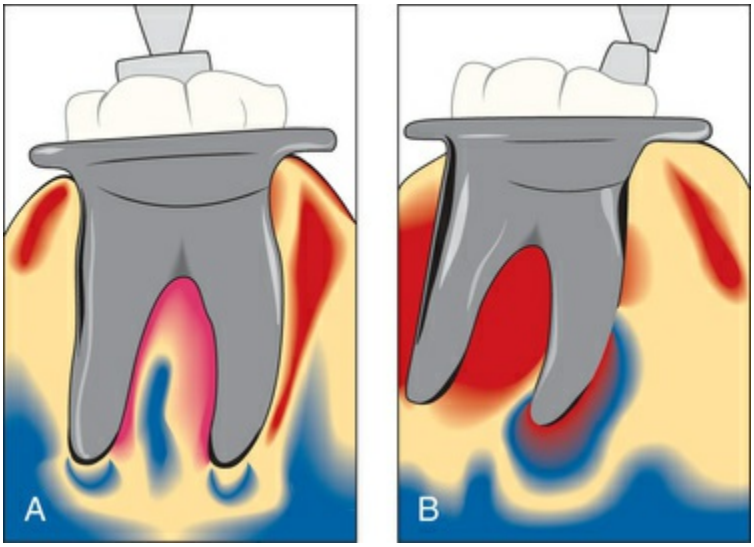

FIG. 25.1 Stress patterns around the roots changed by

shifting the direction of occlusal forces (experimental model using photoelastic analysis). (A) Buccal view of an Ivorine molar subjected to an axial force. The shaded fringes indicate that the internal stresses are at the root apices. (B) Buccal view of an Ivorine molar subjected to a mesial tilting force. The shaded fringes indicate that the internal stresses are along the mesial surface and at the apex of the mesial root.

The response of alveolar bone is also affected by the *duration* and *frequency* of occlusal forces. Constant pressure on the bone is more injurious than intermittent forces. The more frequent the application of an intermittent force, the more injurious the force is to the periodontium.

Learning Box 25.1

When there is an increase in occlusal forces, changes occur in the periodontium in order to accommodate for such forces. Changes in the periodontium depend on the magnitude, direction, duration, and frequency of increased occlusal forces.

Trauma From Occlusion

Trauma from occlusion is defined as microscopic alterations of periodontal structures in the area of the periodontal ligament that become manifest clinically in the elevation of tooth mobility. As mentioned earlier, an inherent "margin of safety" that is common to all tissues permits some variation in occlusion without adversely affecting the periodontium. However, when occlusal forces exceed the adaptive capacity of the tissues, tissue injury results.[43,44] The resultant injury is termed *trauma from occlusion,* which is also known as *occlusal trauma.*

Thus trauma from occlusion refers to the *tissue injury* rather than the *occlusal force.* An occlusion that produces such an injury is called a *traumatic occlusion.*[2] Excessive occlusal forces may also disrupt the function of the masticatory musculature and cause painful spasms, injure the temporomandibular joints, or produce excessive tooth

wear. However, the term *trauma from occlusion* is generally used in connection with injury in the periodontium.

Learning Box 25.2

Trauma from occlusion refers to the *tissue injury* rather than the *occlusal force.* An occlusion that produces such an injury is called a *traumatic occlusion.*

Classification of Trauma From Occlusion

Trauma from occlusion can be classified according to the injurious occlusal force(s) mode of onset (acute and chronic) or according to the capacity of the periodontium to resist to occlusal forces (primary and secondary).

Acute and Chronic Trauma From Occlusion

Acute trauma from occlusion refers to periodontal changes associated with an abrupt occlusal impact such as that produced by biting on a hard object (e.g., an olive pit). In addition, restorations or prosthetic appliances that interfere with or alter the direction of occlusal forces on the teeth may also induce acute trauma. Acute trauma results in tooth pain, sensitivity to percussion, and increased tooth mobility. If the force is dissipated by a shift in the position of the tooth or by the wearing away or correction of the restoration, then the injury heals, and the symptoms subside. Otherwise, periodontal injury may worsen and develop into necrosis accompanied by periodontal abscess formation, or it may persist as a symptom-free chronic condition. Acute trauma can also produce cementum tears (Fig. 25.2).

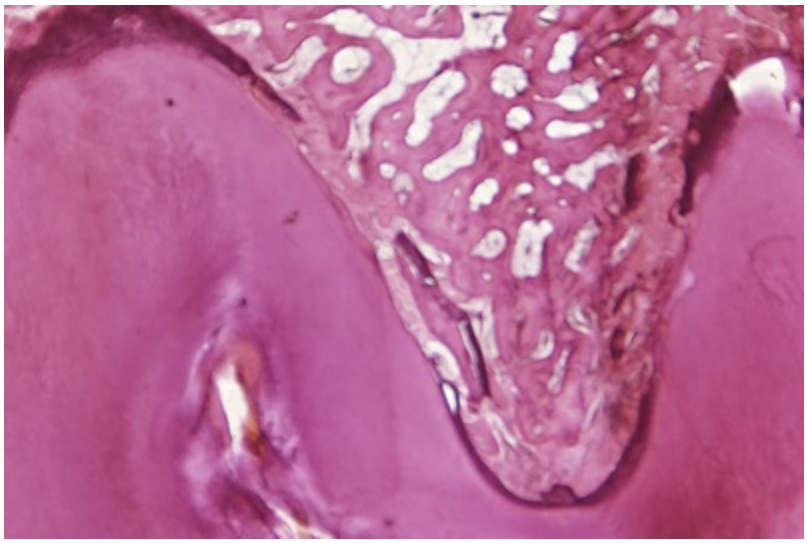

FIG. 25.2 Cemental tear, presumably caused by acute trauma from occlusion in a human autopsy specimen. Note the repair process depositing bone on the displaced, torn cementum and recreating a periodontal ligament.

Learning Box 25.3

Acute trauma from occlusion refers to periodontal changes associated with an abrupt occlusal impact such as that produced by biting on a hard object (e.g., an olive pit). In addition, restorations or prosthetic appliances that interfere with or alter the direction of occlusal forces on the teeth may also induce acute trauma. Acute trauma results in tooth pain, sensitivity to percussion, and increased tooth mobility.

Chronic trauma from occlusion refers to periodontal changes associated with gradual changes in occlusion produced by tooth wear, drifting movement, and extrusion of the teeth in combination with parafunctional habits (e.g., bruxism, clenching) rather than as a sequela of acute periodontal trauma. Chronic trauma from occlusion is more common than the acute form and of greater clinical significance. The features of chronic trauma from occlusion and their significance are discussed in the following sections.

The criterion that determines if an occlusion is traumatic is whether it produces periodontal injury; the criterion is *not* based on

how the teeth occlude. Any occlusion that produces periodontal injury is traumatic. Malocclusion is not necessary to produce trauma; periodontal injury may occur when the occlusion appears normal. The dentition may be anatomically and aesthetically acceptable but functionally injurious. Similarly, not all malocclusions are necessarily injurious to the periodontium. Traumatic occlusal relationships are referred to by such terms as *occlusal disharmony, functional imbalance,* and *occlusal dystrophy.* These terms refer to the effect of the occlusion on the periodontium rather than to the position of the teeth. Because trauma from occlusion refers to the tissue injury rather than the occlusion, an increased occlusal force is not traumatic if the periodontium can accommodate it.

Learning Box 25.4

Chronic trauma from occlusion refers to periodontal changes associated with gradual changes in occlusion produced by tooth wear, drifting movement, and extrusion of the teeth in combination with parafunctional habits (e.g., bruxism, clenching) rather than as a sequela of acute periodontal trauma. Chronic trauma from occlusion is more common than the acute form and of greater clinical significance.

Primary and Secondary Trauma From Occlusion

As mentioned previously, trauma from occlusion can also be classified according to the capacity of the periodontium to resist occlusal forces into primary and secondary trauma from occlusion. In other words, trauma from occlusion may be caused by alterations in occlusal forces, a reduced capacity of the periodontium to withstand occlusal forces, or both. When trauma from occlusion is the result of alterations in occlusal forces, it is called *primary trauma from occlusion.* When it results from the reduced ability of the tissues to resist the occlusal forces, it is known as *secondary trauma from occlusion.*

Primary trauma from occlusion occurs if trauma from occlusion is considered the primary etiologic factor in periodontal destruction and if the only local alteration to which a tooth is subjected is a result of occlusion. Examples include periodontal injury produced around teeth with a previously healthy periodontium after the following: (1) the insertion of a "high filling"; (2) the insertion of a prosthetic replacement that creates excessive forces on abutment and antagonistic teeth; (3) the drifting movement or extrusion of the teeth into spaces created by unreplaced missing teeth; or (4) the orthodontic movement of teeth into functionally unacceptable positions. Most studies of the effect of trauma from occlusion involving experimental animals have examined the primary type of trauma. Changes produced by primary trauma do not alter the level of connective tissue attachment and do not initiate pocket formation. This is probably because the supracrestal gingival fibers are not affected and therefore prevent the apical migration of the junctional epithelium.[48]

Learning Box 25.5

Primary trauma from occlusion occurs if trauma from occlusion is considered the primary etiologic factor in periodontal destruction and if the only local alteration to which a tooth is subjected is a result of occlusion.

Secondary trauma from occlusion occurs when the adaptive capacity of the tissues to withstand occlusal forces is impaired by bone loss that results from marginal inflammation. This reduces the periodontal attachment area and alters the leverage on the remaining tissues. The periodontium becomes more vulnerable to injury, and previously well-tolerated occlusal forces become traumatic.

Fig. 25.3 depicts three situations on which excessive occlusal forces can be superimposed:

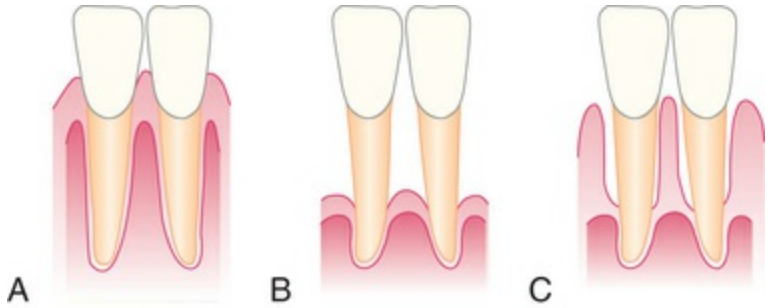

FIG. 25.3 Traumatic forces can occur on (A) normal periodontium with normal height of bone, (B) normal periodontium with reduced height of bone, or (C) marginal periodontitis with reduced height of bone.

1. Normal periodontium with normal height of bone
2. Normal periodontium with reduced height of bone
3. Marginal periodontitis with reduced height of bone

The first case is an example of primary trauma from occlusion, whereas the last two represent secondary trauma from occlusion. The effects of trauma from occlusion in these different situations are analyzed in the following discussion.

It has been found in experimental animals that systemic disorders can reduce tissue resistance and that previously tolerable forces may become excessive.[21,51,61] This could theoretically represent another mechanism by which tissue resistance to increased forces is lowered, thereby resulting in secondary trauma from occlusion.

Stages of Tissue Response to Increased Occlusal Forces

Tissue response occurs in three stages[4,8]: injury, repair, and adaptive remodeling of the periodontium.

Stage I: Injury

Tissue injury is produced by excessive occlusal forces. The body then attempts to repair the injury and restore the periodontium. This can occur if the forces are diminished or if the tooth drifts

away from them. If the offending force is chronic, however, the periodontium is remodeled to cushion its impact. The ligament is widened at the expense of the bone, which results in angular bone defects without periodontal pockets, and the tooth becomes loose.

Under the forces of occlusion, a tooth rotates around a fulcrum or axis of rotation, which in single-rooted teeth is located in the junction between the middle third and the apical third of the clinical root and in multirooted teeth in the middle of the interradicular bone (Fig. 25.4). This creates areas of pressure and tension on opposite sides of the fulcrum. Different lesions are produced by different degrees of pressure and tension. If jiggling forces are exerted, these different lesions may coexist in the same area.

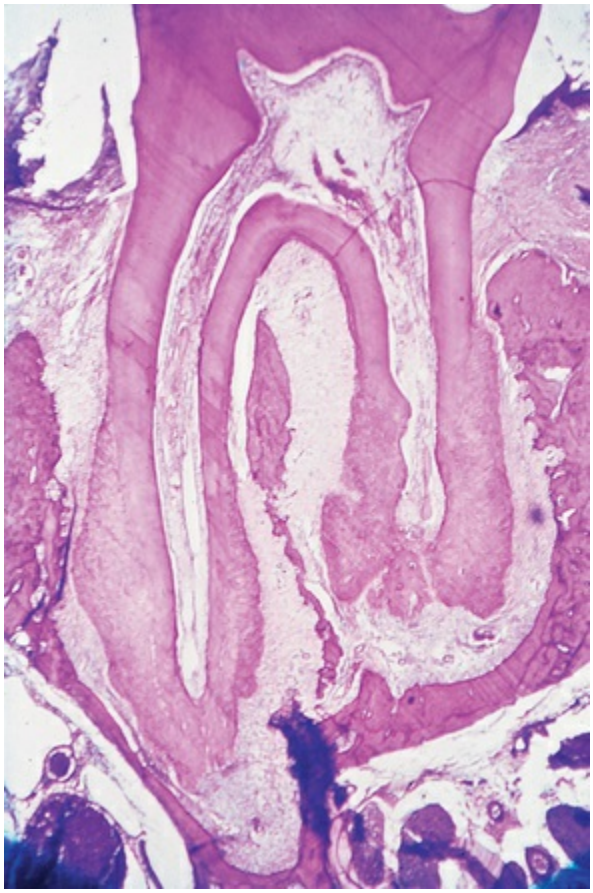

FIG. 25.4 Areas of tension and pressure in opposite sites of the periodontal ligament caused by experimentally induced orthodontic movement in a rat molar.

Slightly excessive pressure stimulates resorption of the alveolar bone, with a resultant widening of the periodontal ligament space. *Slightly excessive tension* causes elongation of the periodontal ligament fibers and the apposition of alveolar bone. In areas of increased pressure, the blood vessels are numerous and reduced in size; in areas of increased tension, they are enlarged.[67]

Greater pressure produces a gradation of changes in the periodontal ligament, starting with compression of the fibers, which produces areas of hyalinization.[54-56] Subsequent injury to the fibroblasts and other connective tissue cells leads to necrosis of areas of the ligament.[52,56] Vascular changes are also produced: within 30 minutes, impairment and stasis of blood flow occur; at 2 to 3 hours, blood vessels appear to be packed with erythrocytes, which start to fragment; and between 1 and 7 days, disintegration of the blood vessel walls and release of the contents into the surrounding tissue occur.[53,63] In addition, increased resorption of alveolar bone and resorption of the tooth surface occur.[29,34]

Severe tension causes widening of the periodontal ligament, thrombosis, hemorrhage, tearing of the periodontal ligament, and resorption of alveolar bone.

Pressure severe enough to force the root against bone causes necrosis of the periodontal ligament and bone. The bone is resorbed from viable periodontal ligament adjacent to necrotic areas and from marrow spaces; this process is called *undermining resorption*.[25,43]

The areas of the periodontium that are most susceptible to injury from excessive occlusal forces are the furcations.[22]

Injury to the periodontium produces a temporary depression in mitotic activity, in the rate of proliferation and differentiation of fibroblasts,[62] in collagen formation, and in bone formation.[29,58,60,62] These return to normal levels after the dissipation of the forces.

Stage II: Repair

Repair occurs constantly in the normal periodontium, and trauma from occlusion stimulates increased reparative activity. The damaged tissues are removed, and new connective tissue cells and

fibers, bone, and cementum are formed in an attempt to restore the injured periodontium (Fig. 25.5). Forces remain traumatic only as long as the damage produced exceeds the reparative capacity of the tissues.

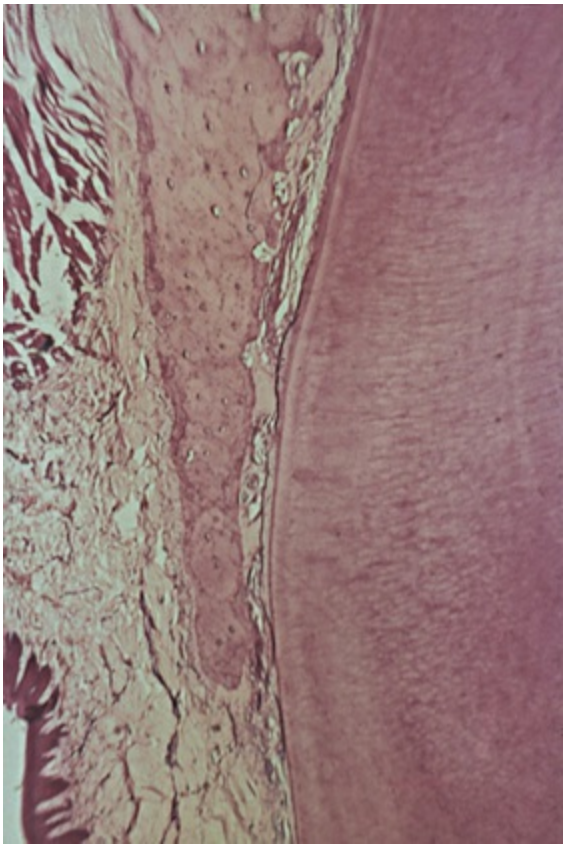

FIG. 25.5 Experimental occlusal trauma in rats. Note the area of necrosis of the marginal periodontal ligament and resorption and remodeling in the more apical periodontal sites.

When bone is resorbed by excessive occlusal forces, the body attempts to reinforce the thinned bony trabeculae with new bone (Fig. 25.6). This attempt to compensate for lost bone is called *buttressing bone formation,* and it is an important feature of the reparative process associated with trauma from occlusion.[16] It also occurs when bone is destroyed by inflammation or osteolytic tumors.

Buttressing bone formation occurs within the jaw (central

buttressing) and on the bone surface (peripheral buttressing). During *central buttressing,* the endosteal cells deposit new bone, which restores the bony trabeculae and reduces the size of the marrow spaces. *Peripheral buttressing* occurs on the facial and lingual surfaces of the alveolar plate. Depending on its severity, peripheral buttressing may produce a shelflike thickening of the alveolar margin, which is referred to as *lipping* (Fig. 25.7), or a pronounced bulge in the contour of the facial and lingual bone.[8,16]

Cartilage-like material sometimes develops in the periodontal ligament space as an aftermath of the trauma.[13] The formation of crystals from erythrocytes has also been demonstrated.[57]

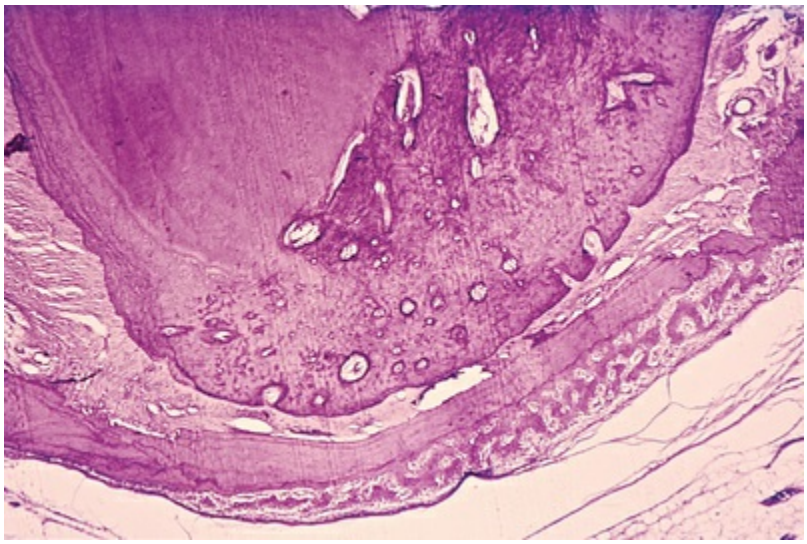

FIG. 25.6 Apical area of a premolar subjected to experimental occlusal trauma in a dog causing intrusion of the tooth and areas of necrosis in the periodontal ligament. Note the active bone formation on the outer aspect of the bone and the resorptive activity in the periphery of the necrotic site.

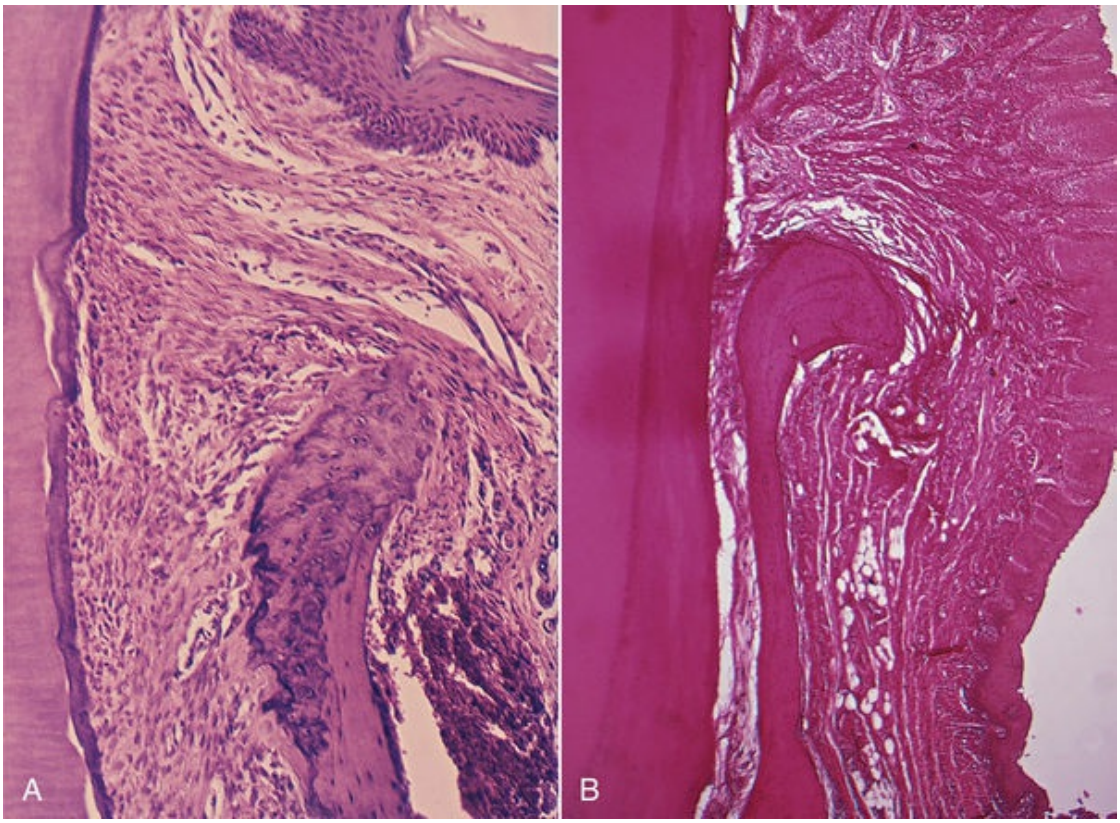

FIG. 25.7 (A) Widening of the periodontal ligament space in the cervical area and a change in the shape of the marginal alveolar bone as a result of chronic prolonged trauma from occlusion in rats. (B) Comparable changes in the shape of the marginal bone found in a human autopsy case.

Stage III: Adaptive Remodeling of the Periodontium

If the repair process cannot keep pace with the destruction caused by the occlusion, the periodontium is remodeled in an effort to create a structural relationship in which the forces are no longer injurious to the tissues.[18] *This results in a widened periodontal ligament, which is funnel shaped at the crest, and angular defects in the bone, with no pocket formation. The involved teeth become loose.*[67] Increased vascularization has also been reported.[9]

The three stages in the evolution of traumatic lesions have been differentiated histometrically by the relative amounts of periodontal bone surface undergoing resorption or formation[5,8] (Fig. 25.8). The injury phase shows an increase in areas of resorption

and a decrease in bone formation, whereas the repair phase demonstrates decreased resorption and increased bone formation. After adaptive remodeling of the periodontium, resorption and formation return to normal.

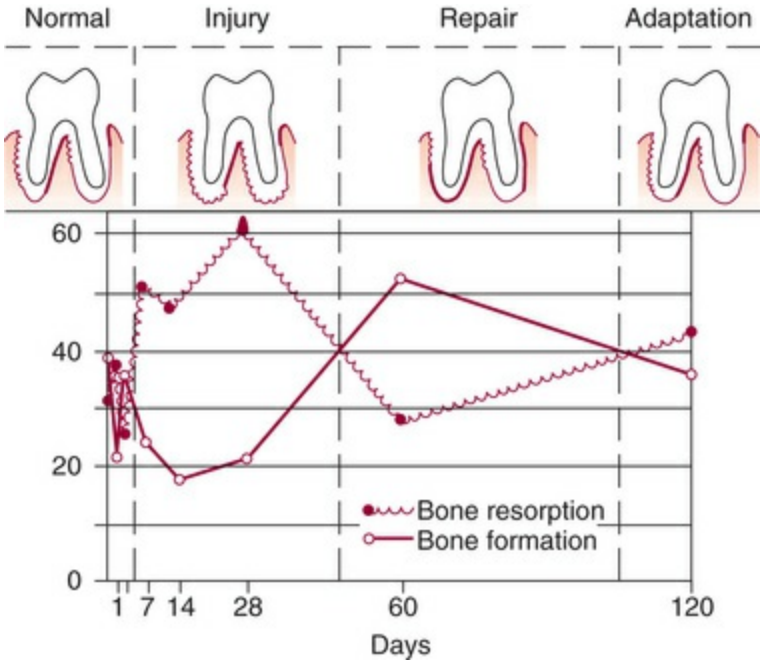

FIG. 25.8 Evolution of traumatic lesions as depicted experimentally in rats by variations in relative amounts of areas of bone formation and bone resorption in periodontal bone surfaces. The horizontal axis shows the number of days after the initiation of traumatic interference. The vertical axis shows the percentage of bone surface undergoing resorption or formation. The stages in the evolution of the lesions are represented in the top drawings, which show the average amount of bone activity for each group.[4]

Effects of Insufficient Occlusal Force

Insufficient occlusal force may also be injurious to the supporting periodontal tissues.[6,36] Insufficient stimulation causes thinning of the periodontal ligament, atrophy of the fibers, osteoporosis of the alveolar bone, and a reduction in bone height. Hypofunction can result from an open-bite relationship, an absence of functional

antagonists, or unilateral chewing habits that neglect one side of the mouth.

Reversibility of Traumatic Lesions

Trauma from occlusion is reversible. When trauma is artificially induced in experimental animals, the teeth move away or intrude into the jaw. When the impact of the artificially created force is relieved, the tissues undergo repair. Although trauma from occlusion is reversible under such conditions, it does not always correct itself, and therefore it is not always temporary or of limited clinical significance. The injurious force must be relieved for repair to occur.[22,49] If conditions in humans do not permit the teeth to escape from or adapt to excessive occlusal force, periodontal damage persists and worsens.

The presence of inflammation in the periodontium as a result of plaque accumulation may impair the reversibility of traumatic lesions.[30,49]

Effects of Excessive Occlusal Forces on Dental Pulp

The effects of excessive occlusal forces on the dental pulp have not been established. Some clinicians report the disappearance of pulpal symptoms after the correction of excessive occlusal forces. Pulpal reactions have been noted in animals subjected to increased occlusal forces,[7,35] but these did not occur when the forces were minimal and occurred over short periods.[35]

Learning Box 25.6

Secondary trauma from occlusion occurs when the adaptive capacity of the tissues to withstand occlusal forces is impaired by bone loss that results from marginal inflammation. This reduces the periodontal attachment area and alters the leverage on the remaining tissues. The periodontium becomes more vulnerable to

injury, and previously well-tolerated occlusal forces become traumatic.

Relationship Between Plaque-Induced Periodontal Diseases and Trauma From Occlusion

The clinical impressions of early investigators and clinicians assigned an important role to trauma from occlusion in the etiology of periodontal lesions. Since then, numerous studies have been performed that have attempted to determine the mechanisms by which trauma from occlusion may affect periodontal disease.

Initial studies involved the placement of high crowns or restorations on the teeth of dogs or monkeys, thereby resulting in a continuous or intermittent force in one direction.[2,20] These investigations provided an orthodontic type of force and gave clear descriptions of changes that were occurring in pressure zones and tension zones. These procedures usually resulted in tooth displacement and consolidation in a new, nontraumatized position.

Trauma from occlusion in humans, however, is the result of forces that act alternatively in opposing directions. These were analyzed in experimental animals with "jiggling forces," which were usually produced by a high crown in combination with an orthodontic appliance that would bring the traumatized tooth back to its original position when the force was dissipated by separating the teeth. With another method, the teeth were separated by wooden or elastic material wedged interproximally to displace a tooth toward the opposite proximal side. After 48 hours, the wedge was removed, and the procedure was repeated on the opposite side.

These studies resulted in a combination of changes produced by pressure and tension on both sides of the tooth, with an increase in the width of the ligament and increased tooth mobility. None of these methods caused gingival inflammation or pocket formation, and the results essentially represented different degrees of functional adaptation to increased forces.[48,67] To mimic the problem in humans more closely, studies were then conducted on the effect produced by jiggling trauma and simultaneous plaque-induced

gingival inflammation.

The accumulation of bacterial plaque that initiates gingivitis and results in periodontal pocket formation affects the marginal gingiva, but trauma from occlusion occurs in the supporting tissues and does not affect the gingiva (Fig. 25.9). The marginal gingiva is unaffected by trauma from occlusion because its blood supply is not affected, even when the vessels of the periodontal ligament are obliterated by excessive occlusal forces.[24] It has been repeatedly proved that trauma from occlusion does not cause pockets or gingivitis[2,20,50,65,66,68] and that it also does not increase gingival fluid flow.[27,33,36,41,42,50] Furthermore, experimental trauma in dogs does not influence the bacterial repopulation of pockets after scaling and root planing.[31] However, mobile teeth in humans harbor significantly higher proportions of *Campylobacter rectus* and *Peptostreptococcus micros* than do nonmobile teeth.[26]

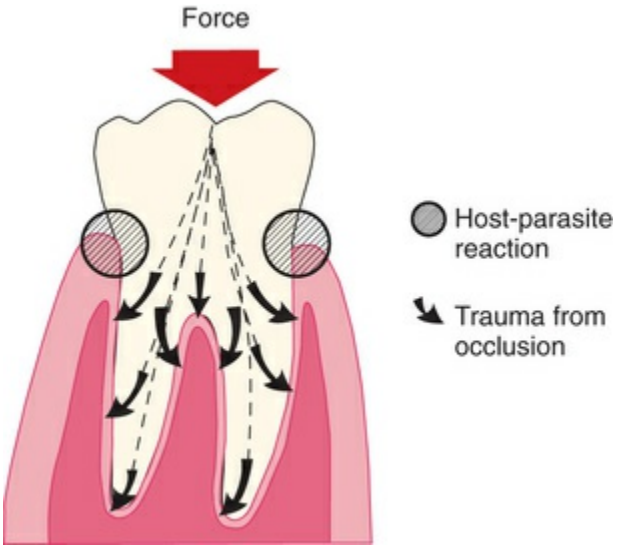

FIG. 25.9 The reaction between dental plaque and the host takes place in the gingival sulcus region. Trauma from occlusion appears in the tissues that are supporting the tooth.

As long as inflammation is confined to the gingiva, the inflammatory process is not affected by occlusal forces.[32] When inflammation extends from the gingiva into the supporting periodontal tissues (i.e., when gingivitis becomes periodontitis), plaque-induced inflammation enters the zone that is influenced by

occlusion, which Glickman has called the *zone of co-destruction.*[14,15,17]

Two groups have studied this topic experimentally, with conflicting results, probably because of the different methods used. The Eastman Dental Center group in Rochester, New York, used squirrel monkeys, produced trauma by repetitive interdental wedging, and added mild to moderate gingival inflammation; experimental times were up to 10 weeks. They reported that the presence of trauma did not increase the loss of attachment induced by periodontitis.[42,45-47] The University of Gothenburg group in Sweden used beagle dogs, produced trauma by placing cap splints and orthodontic appliances, and induced severe gingival inflammation; experimental times were up to 1 year. This group found that occlusal stresses increase the periodontal destruction induced by periodontitis.[11,12,39]

When trauma from occlusion is eliminated, a substantial reversal of bone loss occurs, except in the presence of periodontitis. This indicates that inflammation inhibits the potential for bone regeneration.[30,38,48,49] Thus it is important to eliminate the marginal inflammatory component in cases of trauma from occlusion, because the presence of inflammation affects bone regeneration after the removal of the traumatizing contacts.[30] It has also been shown in experimental animals that trauma from occlusion does not induce progressive destruction of the periodontal tissues in regions that are kept healthy after the elimination of preexisting periodontitis.[11]

Trauma from occlusion also tends to change the shape of the alveolar crest. The change in shape consists of a widening of the marginal periodontal ligament space, a narrowing of the interproximal alveolar bone, and a shelflike thickening of the alveolar margin.[9,39,42] Therefore although trauma from occlusion does not alter the inflammatory process, it changes the architecture of the area around the inflamed site.[17,39] Thus in the absence of inflammation, the response to trauma from occlusion is limited to adaptation to the increased forces. In the presence of inflammation, however, the changes in the shape of the alveolar crest may be conducive to angular bone loss, and existing pockets may become intrabony.

Other theories that have been proposed to explain the interaction

of trauma and inflammation include the following:

- Trauma from occlusion may alter the pathway of the extension of gingival inflammation to the underlying tissues. This may be favored by the reduced collagen density and the increased number of leukocytes, osteoclasts, and blood vessels in the coronal portion of increasingly mobile teeth.[3] Inflammation may then proceed to the periodontal ligament rather than to the bone. Resulting bone loss would be angular, and pockets could become intrabony.[1,17,19,40]
- Trauma-induced areas of root resorption uncovered by apical migration of the inflamed gingival attachment may offer a favorable environment for the formation and attachment of plaque and calculus and therefore may be responsible for the development of deeper lesions.[59]
- Supragingival plaque can become subgingival if the tooth is tilted orthodontically or if it migrates into an edentulous area, which results in the transformation of a suprabony pocket into an intrabony pocket.[10,12,17]
- Increased mobility of traumatically loosened teeth may have a pumping effect on plaque metabolites, thereby increasing their diffusion.[64]

Learning Box 25.7

Despite conflicting scientific data and speculations generated based

on such data on the role of trauma from occlusion in periodontitis, two points are not contested: (1) changes related to trauma from occlusion (bone loss and tooth mobility) are reversible if they occurred in the absence of periodontitis; (2) in situations where both plaque-induced periodontitis and trauma from occlusion are present, elimination of the former will prevent further apical migration of the attachment unit, despite the presence of trauma from occlusion. Therefore in terms of patient care, all facts support the priority that should be given to eliminating the bacterial plaque portion of the disease process.

Clinical and Radiographic Signs of Trauma From Occlusion Alone

The most common clinical sign of trauma to the periodontium is *increased tooth mobility.* During the injury stage of trauma from occlusion, the destruction of periodontal fibers occurs, which increases tooth mobility. During the final stage, the accommodation of the periodontium to increased forces entails a widening of the periodontal ligament, which also leads to increased tooth mobility. Although this tooth mobility is greater than the so-called normal mobility, it cannot be considered pathologic, because it is an adaptation and not a disease process. If it does become progressively worse, it can then be considered pathologic.

Other causes of increased tooth mobility include advanced bone loss, inflammation of the periodontal ligament of periodontal or periapical origin, and some systemic causes (e.g., pregnancy). The destruction of surrounding alveolar bone, such as occurs with osteomyelitis or jaw tumors, may also increase tooth mobility.

Radiographic signs of trauma from occlusion may include the following:

1. Increased width of the periodontal space, often with thickening of the lamina dura along the lateral aspect of the root, in the apical region, and in bifurcation areas. These changes do not *necessarily* indicate destructive changes, because they may result from thickening and strengthening of the periodontal ligament and alveolar bone, thereby

constituting a favorable response to increased occlusal forces.
2. A vertical rather than horizontal destruction of the interdental septum.
3. Radiolucency and condensation of the alveolar bone.
4. Root resorption.

In summary, trauma from occlusion does not initiate gingivitis or periodontal pockets, but it may constitute an additional risk factor for the progression and severity of the disease. An understanding of the effect of trauma from occlusion on the periodontium is useful during the clinical management of periodontal problems.

Pathologic Tooth Migration

Pathologic migration refers to tooth displacement that results when the balance among the factors that maintain physiologic tooth position is disturbed by periodontal disease. Pathologic migration is relatively common. It may be an early sign of disease, or it may occur in association with gingival inflammation and pocket formation as the disease progresses.

Pathologic migration occurs most frequently in the anterior region, but posterior teeth may also be affected. The teeth may move in any direction, and the migration is usually accompanied by mobility and rotation. Pathologic migration in the occlusal or incisal direction is termed *extrusion.* All degrees of pathologic migration are encountered, and one or more teeth may be affected (Fig. 25.10). It is important to detect migration during its early stages and to prevent more serious involvement by eliminating the causative factors. Even during the early stage, some degree of bone loss occurs.

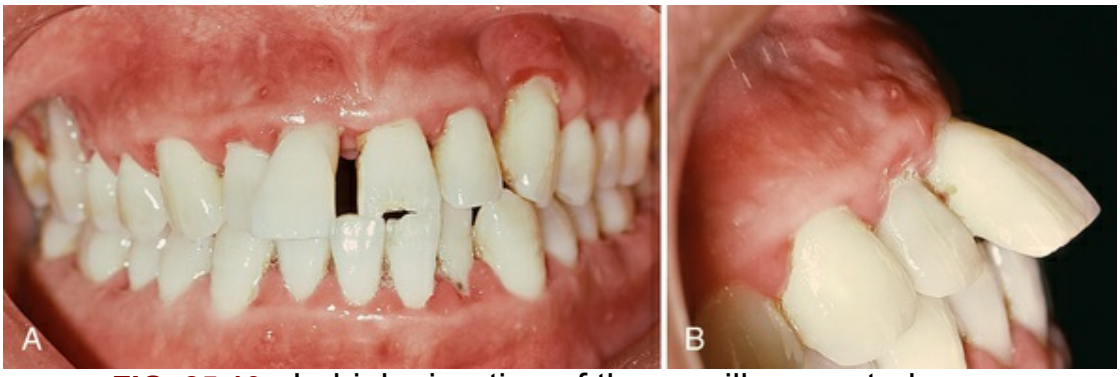

FIG. 25.10 Labial migration of the maxillary central incisors, especially the right incisor. (A) Frontal view. (B) Lateral view.

Pathogenesis

Two major factors play a role in maintaining the normal position of the teeth: the health and normal height of the periodontal attachment apparatus and the forces exerted on the teeth. The latter includes the forces of occlusion and pressure from the lips, cheeks, and tongue. Factors that are important in relation to the forces of occlusion include the following: (1) tooth morphologic features and cuspal inclination; (2) the presence of a full complement of teeth; (3) a physiologic tendency toward mesial migration; (4) the nature and location of contact point relationships; (5) proximal, incisal, and occlusal attrition; and (6) the axial inclination of the teeth. Alterations in any of these factors start an interrelated sequence of changes in the environment of a single tooth or group of teeth that may result in pathologic migration. Thus pathologic migration occurs under conditions that weaken the periodontal support, that increase or modify the forces exerted on the teeth, or both.

Weakened Periodontal Support

The inflammatory destruction of the periodontium in patients with periodontitis creates an imbalance between the forces that maintain the tooth in position and the occlusal and muscular forces the tooth ordinarily needs to bear. The tooth with weakened support is unable to maintain its normal position in the arch and moves away from the opposing force unless it is restrained by proximal contact. The force that moves the weakly supported tooth may be created by

factors such as occlusal contacts or pressure from the tongue.

It is important to understand that the abnormality of pathologic migration rests with the weakened periodontium; the force itself is not necessarily abnormal. Forces that are acceptable to an intact periodontium become injurious when periodontal support is reduced, as in the tooth with abnormal proximal contacts. Abnormally located proximal contacts convert the normal anterior component of force to a wedging force that causes occlusal or incisal movement of the tooth. The wedging force, which can be withstood by the intact periodontium, causes the tooth to extrude when the periodontal support is weakened by disease. *As its position changes, the tooth is subjected to abnormal occlusal forces, which aggravate the periodontal destruction and the tooth migration.*

Pathologic migration may continue after a tooth no longer contacts its antagonist. Pressures from the tongue, the food bolus during mastication, and the proliferating granulation tissue provide the force.

Pathologic migration is also an early sign of localized aggressive periodontitis. Weakened by the loss of periodontal support, the maxillary and mandibular anterior incisors drift labially and extrude, thereby creating diastemata between the teeth.

Changes in the Forces Exerted on the Teeth

Changes in the magnitude, direction, or frequency of the forces exerted on the teeth can induce the pathologic migration of a tooth or group of teeth. These forces do not have to be abnormal to cause migration if the periodontium is sufficiently weakened. Changes in the forces may result from unreplaced missing teeth or other causes.

Unreplaced Missing Teeth

The drifting of teeth into the spaces created by unreplaced missing teeth often occurs. Drifting differs from pathologic migration in that it does not result from the destruction of the periodontal tissues. However, it usually creates conditions that lead to periodontal disease, and thus the initial tooth movement is aggravated by a loss of periodontal support (Fig. 25.11).

FIG. 25.11 Calculus and bone loss on the mesial surface of a canine that has drifted distally.

Drifting generally occurs in a mesial direction in combination with tilting or extrusion beyond the occlusal plane. The premolars frequently drift distally (Fig. 25.12). Although drifting is a common sequela when missing teeth are not replaced, it does not always occur (Fig. 25.13).

FIG. 25.12 Maxillary first molar that has tilted and extruded into the space created by a missing mandibular tooth.

FIG. 25.13 No drifting or extrusion is present here, despite the 4-year absence of the mandibular teeth.

Failure to Replace First Molars

The pattern of changes that may follow the failure to replace missing first molars is characteristic. In extreme cases, it consists of the following:

1. The second and third molars tilt mesially, which results in a decrease in vertical dimension (Fig. 25.14).

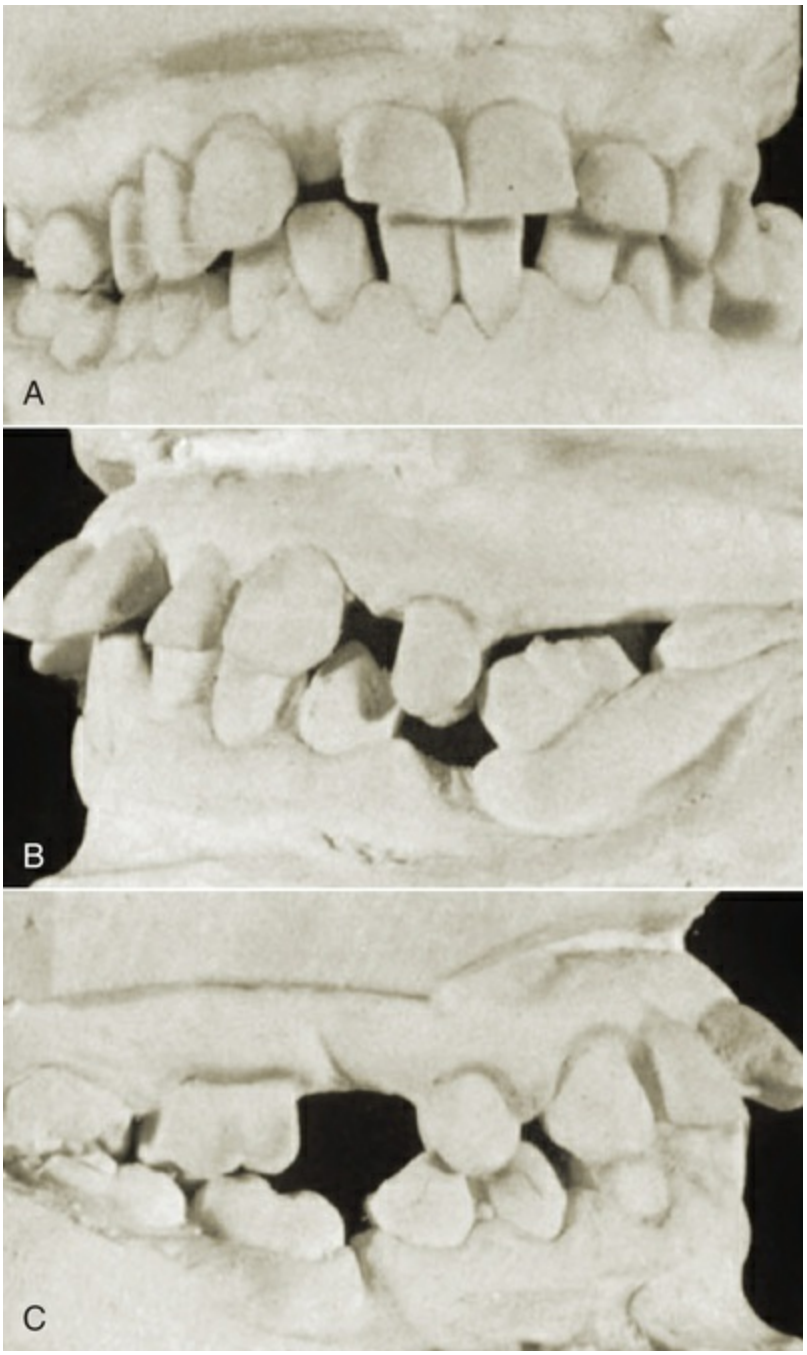

FIG. 25.14 Examples of the mutilation of occlusion associated with unreplaced missing teeth. Note pronounced pathologic migration, disturbed proximal contacts, and functional relationships with closing of the bite.

2. The premolars move distally, and the mandibular incisors tilt or drift lingually. While drifting distally, the mandibular premolars lose their intercuspating relationship with the maxillary teeth, and they may tilt distally.
3. Anterior overbite is increased. The mandibular incisors strike the maxillary incisors near the gingiva or traumatize

the gingiva.

4. The maxillary incisors are pushed labially and laterally (Fig. 25.15).

FIG. 25.15 Maxillary incisors pushed labially in a patient with bilateral unreplaced mandibular molars. Note the extrusion of the maxillary molars.

5. The anterior teeth extrude because the incisal apposition has largely disappeared.
6. Diastemata are created by the separation of the anterior teeth (see Fig. 25.14).

The disturbed proximal contact relationships lead to food impaction, plaque accumulation that results in gingival inflammation, and pocket formation, which are followed by bone loss and tooth mobility. Occlusal disharmonies created by the altered tooth positions traumatize the supporting tissues of the periodontium and aggravate the destruction caused by the inflammation. The reduction in periodontal support leads to the further migration of the teeth and the mutilation of the occlusion.

Other Causes

Trauma from occlusion may cause a shift in tooth position either by itself or in combination with inflammatory periodontal disease. The direction of movement depends on the occlusal force.

Pressure from the tongue may cause drifting of the teeth in the absence of periodontal disease, or it may contribute to the pathologic migration of teeth with reduced periodontal support (Fig. 25.16).

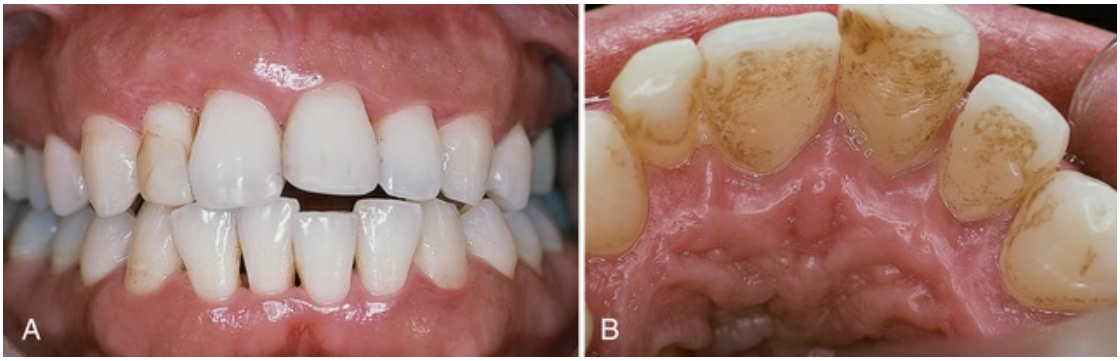

FIG. 25.16 Pathologic migration associated with tongue pressure. (A) Facial view. (B) Palatal view.

When tooth support has been weakened by periodontal destruction, *pressure from the granulation tissue of periodontal pockets* has been mentioned as contributing to pathologic migration.[28,37] The teeth may return to their original positions after the pockets are eliminated, but if more destruction has occurred on one side of a tooth than on the other, the healing tissues tend to pull in the direction of less destruction.

Summary

It is important to understand the etiology of the changes that occur in the periodontal tissues from both the clinical and histologic perspectives. Whatever the etiology, the periodontal tissues have a tremendous adaptive ability to accommodate both the microbial and the traumatic occlusal factors within a certain limit. It is the combination of both and the patient's ability to resist these factors that may complicate the diagnosis and treatment plan of the clinical cases that are presented.

Case Scenario 25.1

Case-Based Question

A patient with severe chronic periodontitis and trauma from occlusion comes to your office. To eliminate further attachment loss, would you give priority to treating the trauma from occlusion or to treating the periodontitis by eliminating/minimizing the biofilm?

Solution and Explanation

To further eliminate attachment loss, removing the biofilm should be a priority.

CHAPTER 26

Masticatory System Disorders That Influence the Periodontium

Michael J. McDevitt

CHAPTER OUTLINE

Temporomandibular Joint
Muscles and Nerves of the Masticatory System
Centric Relation
Biomechanics of the Masticatory System *(e-only)*
Dysfunction and Deterioration
Orofacial Pain
Comprehensive Evaluation
Diagnostic Decision Making

The masticatory system consists of the temporomandibular joints (TMJs), the masticatory muscles, the teeth in occlusion, and the neurologic and vascular supplies that support all of these structures. Research suggests that masticatory system disorders include many varied conditions with multiple possible contributing factors rather than different manifestations of a single disease or syndrome.[2,85,131] The ability to understand the anatomy and function of the masticatory system and to correctly interpret relevant diagnostic information is a prerequisite to fulfilling comprehensive standards of care. Our diagnostic process must have a broad enough base and be inclusive enough to determine the most appropriate cause of masticatory dysfunction.[139]

Temporomandibular Joint

Harmonious function of the TMJs is a product of the coordination of the muscles of mastication by intricate mechanisms of neurologic control. Understanding the dynamics and the relationship of the TMJ to the associated muscles and nerves provides the working knowledge required for effective assessment and diagnosis.

The TMJ is one of the most complex joints in the human body. It is capable of providing both hinging (rotation) and gliding (translation) movements, and it is able to resist incredible forces of mastication. The TMJ is formed by the head of the condyle of the mandible as it fits into the articular fossa of the temporal bone (Fig. 26.1). The body of the mandible effectively connects both condyles so that neither condyle functions independently of the other. Interposed between the head of the condyle and the articular surface of the temporal bone is the articular disc, which consists of dense connective tissue; this results in a compound joint with two joint cavities (Fig. 26.2). The articulating surfaces of the osseous structures are essentially convex in a healthy situation, so the biconcave configuration of the articular disc compensates for the opposing convexities. The articular surfaces of the condyles and the temporal bones consist of fibrous connective tissue, which renders them resistant to breakdown and capable of repair. Deep to the superficial connective tissue layer, articular cartilage provides the cellular and structural basis for the response to the functional

loading and movement of the TMJs.[85,139,191] The discal ligaments and attachments to the capsule, along with the disc itself, become the means of separating the joint into superior and inferior joint spaces (see Figs. 26.1 and 26.2). Synovial lubrication of the articular surfaces is a function of the production of synovial fluid by endothelial cells along the borders of each joint cavity and at the anterior extent of the retrodiscal tissues.[a]

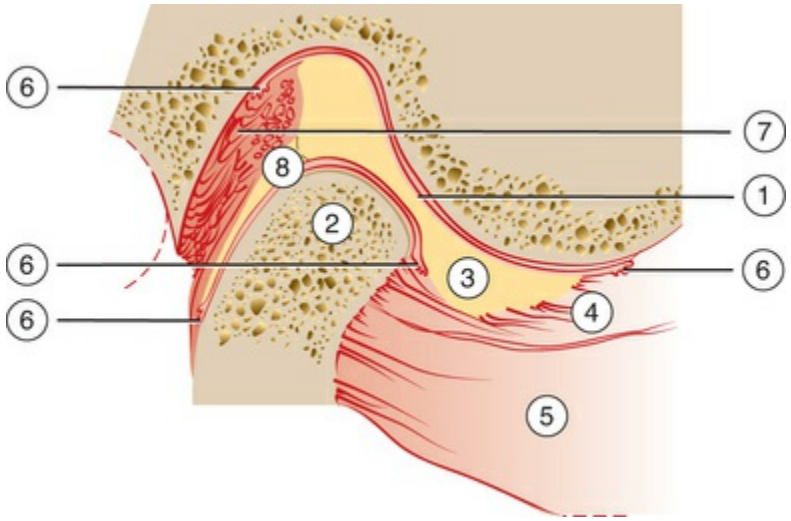

FIG. 26.1 Lateral view of a cross-section through the temporomandibular joint. *1,* Posterior slope of the articular eminence of the temporal bone; *2,* head of the condyle; *3,* articular disc (note the biconcave shape); *4,* superior lateral pterygoid muscle (note the attachment to both the head of the condyle and the articular disc); *5,* inferior lateral pterygoid muscle; *6,* synovial tissue; *7,* retrodiscal tissue; and *8,* discal ligament attachment to the posterior surface of the head of the condyle. (Modified from Dawson PE: *Evaluation, diagnosis, and treatment of occlusal problems,* ed 2, St. Louis, 1989, Mosby.)

Muscles and Nerves of the Masticatory System

The muscles and nerves of the masticatory system are extensively reviewed elsewhere. They are only briefly discussed here for the purpose of understanding the mechanisms involved. Appropriate references are provided for further reading.

The muscles of mastication consist principally of two groups: the *elevator muscles* and the *depressor muscles.* The muscles responsible for elevating the mandible are the masseter, the internal pterygoid, and much of the temporal muscle. The posteriorly oriented fibers of the temporal muscle also retrude the mandible. The superficial muscle bundle of the masseter muscle may also assist with protruding the mandible, whereas the deeper bundle stabilizes the condylar head against the articular eminence. Juxtaposed with the masseter muscle, the medial pterygoid forms a muscular support

for the mandible at its angle. Although its primary function is elevation of the mandible, it is also active during protrusion.[85,139] The lateral pterygoid muscle is now known to function as two distinct muscles, the inferior and superior lateral pterygoid muscles, with independent and almost opposite functions.[6,15] The inferior lateral pterygoid muscle depresses and protrudes the mandible. The superior lateral pterygoid muscle does not contract during depression of the mandible but rather contracts along with the elevator muscles, thereby bracing the condyle anteromedially.[117,127,137,139,161]

Physiologic mandibular posture and movement are products of harmonious muscular contraction among masticatory and supportive muscles. The neurologic input needed to produce the synergy of complementary and antagonistic muscles is extremely complex.

The motor and sensory innervation of the TMJs and the rest of the masticatory system are provided by structures of the trigeminal nerve.

Mechanoreceptors in the skin, the muscle, and the ligamentous structures, especially the periodontal ligament (PDL), discern pressure differences at sensitive degrees of discrimination. Painful stimuli are perceived by nociceptors and result in both pain perception and reflex responses.

The innervation of both the capsular ligaments and the discal ligaments provide essential proprioceptive input with regard to joint position. Efferent or motor neurons cause muscle contraction in response to central cortical stimulation and in response to afferent stimuli during reflex activity.[43,139,191]

Sensory input from the PDL offers the potential to be an important component of the complex neurologic management of the masticatory system. Currently, little evidence of the existence of proprioceptive sensory organs within the neuroanatomy of the PDL is available, although it was once considered likely.

Pain perception causes the nociceptive reflex to open the mouth rapidly via the contraction of depressor muscles and the suppression of elevator muscles; this is consistent with other protective reflexes within the musculoskeletal system.[139] Protective reflexes may be suppressed in individuals who are experiencing

chronic occlusal parafunction (i.e., clenching or grinding of the teeth).[27,53] Pressure perception is a function of the numerous mechanoreceptors within the PDL of teeth that are in contact. Discrimination within the dentition on the basis of the specific teeth in contact, the direction of force, the intensity of force, and their influence on muscle activity have been demonstrated in human study populations and animal studies.[23,39,104,116,164] Both research and clinical observations suggest that elevator muscle contraction is suppressed when anterior teeth promote disclusion or the separation of posterior teeth during excursive mandibular movements.[186]

The loss of attachment that results from periodontitis involves the loss of some mechanoreceptors. Patients with significant bone loss, significant inflammatory disruption of the integrity of the PDL, or chronic occlusal parafunction may experience the compromised regulation of muscle activity.[b]

Centric Relation

The mandible is suspended from the cranial base by ligaments and muscles. The understanding of mandibular movement begins with an initial reference point for each condyle, which is usually referred to as *centric relation;* this clinically determined relationship of the mandible to the maxilla occurs when both condyle–disc assemblies are in their most superior position in the maxillary (or glenoid) fossa and against the slope of the articular eminence of the temporal bone. Verification of centric relation is obtained by loading the TMJs bilaterally with the teeth apart via the bimanual mandibular manipulation technique advocated by Dawson and others.[43-46,176] When both condyles are in this relationship, rotation or hinging action occurs around an axis defined by the medial poles of each condyle (Fig. 26.3).

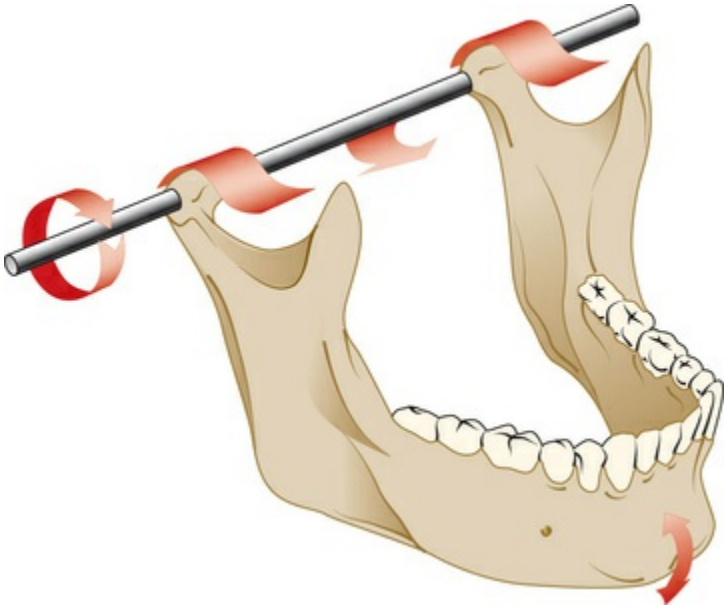

FIG. 26.3 When they are in centric relation, the condyles can rotate on a fixed axis. As long as the rotational axis stays fixed at the most superior position against the eminentiae, the mandible can open or close and still be in centric relation. If the condyle axis moves forward, it is no longer in centric relation. (From Dawson PE: *Evaluation, diagnosis, and treatment of occlusal problems,* ed 2, St. Louis, 1989, Mosby.)

The term *centric relation* is limited to the rotation axis through both condyles while they are seated in their respective glenoid fossae. The only occlusal consideration relative to centric relation occurs when rotation of the mandible initiates the first contact of opposing occlusal surfaces. The term *initial contact* in centric relation can be used to define this relationship (see Chapter 55). If the contraction of elevator muscles occurs at the point of initial occlusal contact and results in the distraction of one or both condyle–disc assemblies from their seated relationship, then centric relation is no longer occurring.[43,44,46]

For TMJs to maintain orthopedic stability, the condyles must remain fully seated in their respective fossae when the teeth occlude in maximal intercuspation. Orthopedic instability occurs when the occlusal relationships are such that the contraction of elevator muscles is required to achieve stable occlusion in the maximal intercuspal position, which results in the unseating of one or both condyles from their respective fossae (Fig. 26.4).

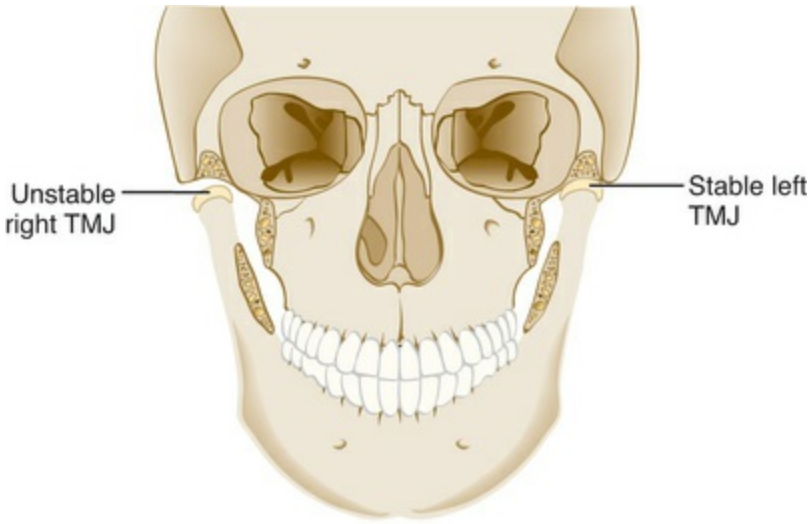

FIG. 26.4 Example of orthopedic instability. Note that, with the teeth in their stable position (i.e., maximum intercuspation), the left temporomandibular joint is in a stable relationship with the fossa. The right temporomandibular joint, however, is not in a stable position with the fossa. When the elevator muscles contract, the right condyle moves superiorly to seek a more stable relationship with the articular disc and fossa (i.e., the musculoskeletally stable position). This type of loading can lead to an intracapsular disorder.
(From Okeson JP: *Management of temporomandibular joint disorders and occlusion,* ed 4, St. Louis, 1998, Mosby.)

The strain on the discal ligaments caused by a loaded joint being displaced from the fossa can lead to internal derangement of that joint, which will be described later in this chapter. Postural and parafunctional stress can also be a source of the orthopedic instability of a TMJ.

An individual's susceptibility to masticatory system disorders determines whether that person adapts with minimal consequence or develops dysfunction or degeneration.[26,43,46,139,176]

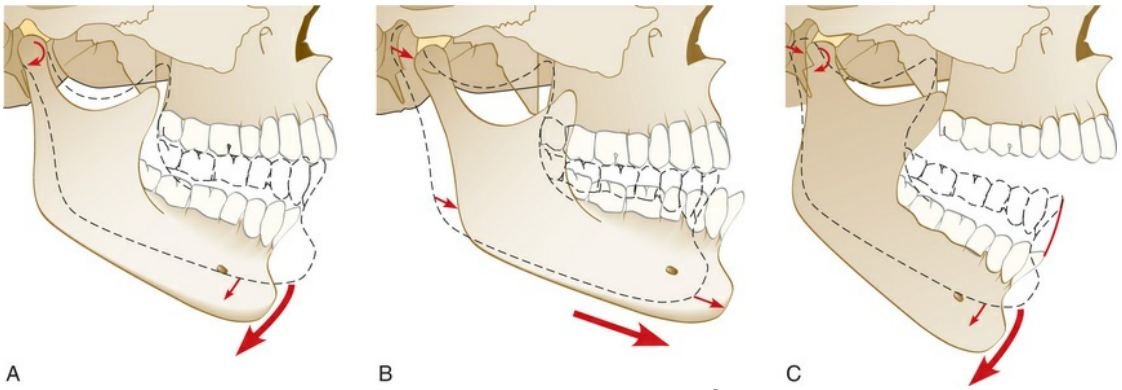
Biomechanics of the Masticatory System

The biomechanics of mandibular movement are a function of

neurologic input from cortical and stomatognathic sources acting to initiate or restrict muscular contraction. Muscular action either stabilizes the condyle against the articular eminence or directs its rotational and translational movements relative to each respective temporal bone. The position and functional movement of one condyle always depend on the status or activity of the other.

Because the maxillary teeth have a fixed relationship with the cranial base (just as mandibular teeth have a fixed relationship with the condyle), the contact of their respective occlusal surfaces may directly influence condylar position or movement.[43,46,139]

The mandible can move within a range of motion that is limited by skeletal, muscular, and ligamentous structures. Pure rotation of up to approximately 25 mm can occur before translation of the condyle is required to continue toward the maximal opening of the jaw. Movement of the condyle is relative to the disc, so rotation effectively occurs within the inferior joint space (eFig. 26.1A). Strict translation protrudes the mandible, whereas the condyle–disc assembly moves anterior and inferior toward the articular eminence of the temporal bone.



EFIG. 26.1 (A) Rotational movement of the mandible with the condyles in centric relation. This pure rotational opening can occur until the anterior teeth are about 20 mm to 25 mm apart. (B) Translational movement of the condyle–disc assembly during protrusion of the mandible. (C) Second stage of rotational movement during opening. Note the dual activity relative to the articular disc. *1,* Rotation of the condylar head, relative to the disc, occurs in the inferior space. *2,* Movement of the disc anteriorly and

inferiorly along the articular surface of the temporal bone. The articular disc moves anteriorly and inferiorly with the head of the condyle, which continues to rotate against the disc. Translation occurs in the superior joint space, and rotation occurs in the inferior joint space.

(From Okeson JP: *Management of temporomandibular joint disorders and occlusion,* ed 4, St. Louis, 1998, Mosby.)

The disc moves relative to the temporal bone, and movement occurs within the upper joint space (see eFig. 26.1B). During combination translation/rotation movement of the condyle, the axis of rotation for each condyle changes as the condyle translates down the articular eminence to a position inferior to its fossa (see eFig. 26.1C). Harmonious muscle function and ligament attachments keep the condyle–disc assembly properly related so that the articular disc remains loaded in its concave avascular central portion between the condyle and the articular surface of the temporal bone. The elasticity and vascularity of the retrodiscal tissues permit anterior movement of the disc during the translation of each respective condyle.

Rotation and translation of the condyle can occur in the absence of any tooth-to-tooth contact, because the condyle–disc assembly can be supported by the muscles of mastication against the articular eminence during rotation, translation, and combination movements. When the teeth are in contact, their ability to influence both the position and the direction of movement of condyle–disc assemblies is defined by the intensity of muscle activity and the steepness of the inclines of those teeth.[43,46,79,92,110,139]

Dysfunction and Deterioration

Ideally, function never exceeds the integrity or adaptive limits of the structural elements of the masticatory system. Clinical experience shows that the tolerance of the components of the masticatory system can be exceeded by both acute trauma and chronic trauma. *Acute trauma* to the head and neck region can range from a distinct event, such as an accident or a blow to the face, to a sustained overuse experience, such as a long dental appointment. Acute trauma can serve as an initiating event that leads to a chronic

condition, so accurate documentation and careful monitoring may prove extremely valuable should symptoms or dysfunction persist.[13,20,47]

Chronic trauma is defined as any experience that repeatedly exceeds the tolerances of the affected masticatory system structure. Postural stresses and parafunctional occlusal habits, with or without occlusal discrepancies, may produce musculoskeletal disharmony and orthopedic instability of the TMJ.

Occlusal relationships that disrupt the condyle during the physiologic movement of rotation or translation require muscular and TMJ compensation. The extent to which the repeated loading of the teeth and the condyles during function and parafunction exceeds the tolerance of an individual will determine whether structural or muscular compromise occurs.[139]

Prospective research has found only a weak association with occlusal disharmonies but significant correlations of both reported bruxism and tooth wear index with symptoms of temporomandibular disorders.[24,119] When TMJ dysfunction could be correlated with specific occlusal relationships, the trend was to recognize that when inclines of posterior teeth dominated occlusal function, masticatory system harmony was disrupted.[c] This observation was additionally supported in a study comparing two groups of patients diagnosed with clenching habits, finding that those with an anterior open bite or a large overjet had much more frequent multiple temporomandibular disorder (TMD) signs and symptoms than those in the group with normal occlusion.[122] A 20-year longitudinal study following 320 individuals from childhood or adolescence found that among those with frequent TMD symptoms, clenching and grinding had the strongest correlation and bruxism had increased in prevalence over those 20 years.[54] Other researchers have found that various occlusal interferences and relationships are common among individuals with and without masticatory system disorders.

The researchers could not distinguish a particular occlusal feature as a specific etiologic or predisposing factor for the development of masticatory system disorders, although some found that several factors occurring together encouraged dysfunction.[38,78,148,149,175] There seems to be less correlation between static references (e.g., the class

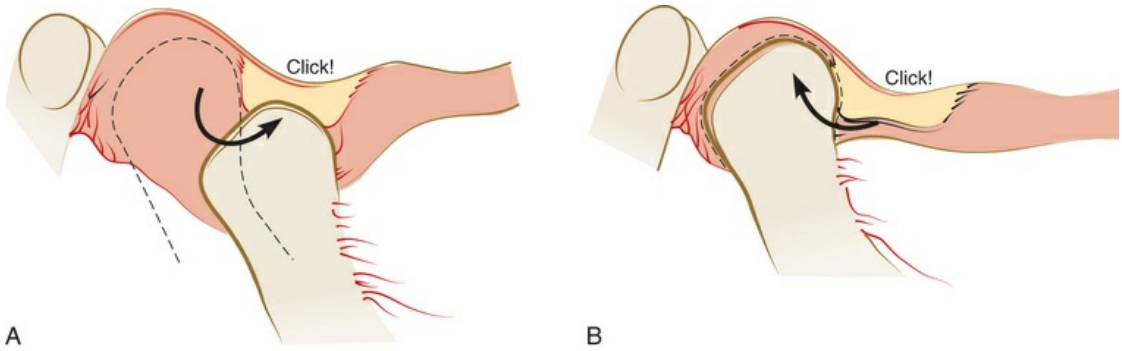
of the malocclusion) and masticatory system disorders than when functional or extrafunctional occlusal forces exceed the tolerance of the TMJ and the masticatory musculature.[139,163]

The general terms for occlusal parafunction used in this text include *bruxism,* which is the grinding of the teeth, and *clenching,* which is when a person holds the teeth firmly together with significant force. Bruxism is usually confirmed by the observation of excessive tooth wear. The clenching type of parafunction can be distinguished from the grinding of the teeth, and it seems to be more often associated with masticatory system disorders than does bruxism.[31,62,64,84,142,147] Sleep bruxism may include both tooth grinding and clenching, and it seems to occur primarily during stage 1 and stage 2 (i.e., non–rapid eye movement) sleep. These episodes often occur in association with short brain and cardiac reactivations called "microarousals." Rhythmic masticatory muscle activity is relatively common among nonbruxers, but the frequency and intensity of the muscle contraction is substantially greater for the sleep bruxer. The central pattern generator of the primate brain stem does not modulate or reduce muscle contraction during sleep as it does during waking hours. In addition, the amplification of oral parafunction has been reported in association with a patient's intake of selective serotonin reuptake inhibitors (e.g., Prozac).[11,43,46,139,150,178]

Discrimination between occlusal function–related and parafunction-related masticatory system disorders and those with other etiologies requires exacting standards of occlusal evaluation. If sufficient evidence exists to suspect that the occlusal relationships in function or parafunction may have exceeded the tolerances of that individual's masticatory system, responsible intervention or monitoring can be initiated.[46,67,142,149]

Disruption of the relationship or alignment of the condyle, the disc, and the articular surface of the temporal bone is typically called an *intracapsular disorder* or an *internal derangement of the TMJ.* The articular disc can be displaced as a result of an acute blow to the jaw, chronic trauma, or the uncoordinated contraction of the lateral pterygoid muscle. When the disc cannot return to its normal relationship to the condyle with full closure of the mouth, it is considered to be displaced or dislocated.

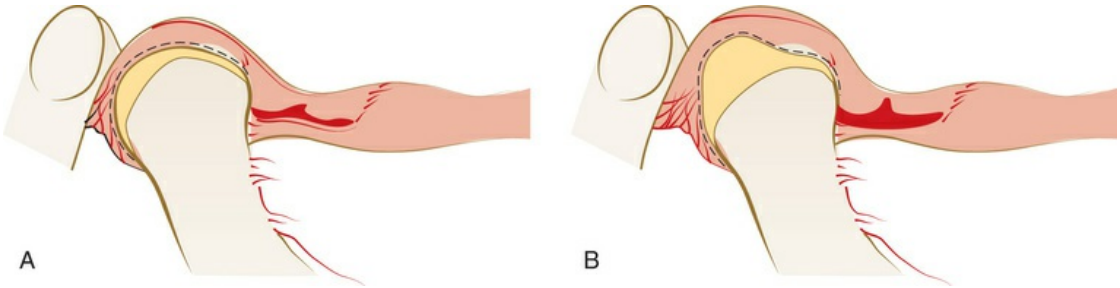
Progressive disc displacement most often begins on its lateral aspect and occurs in an anterior and medial direction as a result of the insertion of muscle fibers into the anteromedial aspect of the disc and the reported variability in resistance of the attachment of the lateral aspect of the disc.[12,165] Stretching of the retrodiscal tissues and collateral ligaments permits the disc to be displaced and function to be limited in response to pain that results from compressive forces on the retrodiscal tissues. At some stage of opening, the remaining elasticity of the retrodiscal tissues and the tension of the capsular ligaments can pull the disc onto the head of the condyle, often with a discernible sound. Closing then results in the disc again becoming dislocated anteriorly, which results in a common joint sound that is often referred to as a *reciprocal click*[37,86,87,105,106,114] (eFig. 26.2).



EFIG. 26.2 Reciprocal click. (A) Reciprocal click occurs when the condyle moves onto the articular disc from a position behind the posterior band of the disc and then (B) clicks off the disc when the condyle moves back. This occurs as the condyle translates forward and back during the opening and closing movements. (From Dawson PE: *Evaluation, diagnosis, and treatment of occlusal problems,* ed 2, St. Louis, 1989, Mosby.)

When the disc remains anterior to the head of the condyle during rotation and the limited range of translation possible, the condition is called *closed lock* or *disc displacement (dislocation) without reduction*[43,139] (eFig. 26.3). The entire disc need not be locked anterior to the head of the condyle for this condition to limit function and cause pain. The lateral aspect of the disc would be more likely than the medial aspect to be displaced anteriorly if a partial anterior disc

displacement without reduction were to occur. A history of joint sounds is usually reported, although this state of the condyle–disc assembly may not result in currently discernible sounds.[43,139]



EFIG. 26.3 Anterior disc displacement without reduction. (A) Condyle positioned in the fossa on the retrodiscal tissues, with the disc remaining anterior to the head of the condyle. (B) During translation, the disc is further misshapen, thereby restricting the full opening of the mandible. (From Dawson PE: *Evaluation, diagnosis, and treatment of occlusal problems,* ed 2, St. Louis, 1989, Mosby.)

The vascular portion of the retrodiscal tissues being loaded between the condyle and the articular surface of the eminentia accounts for most current pain or a history of pain originating within the TMJ. The adaptation of the retrodiscal tissues to completely nonvascular fibrous tissue or perforation of the disc may account for the cessation of the painful symptoms.[143]

The presence of abnormal anatomic features of the condyle and fossa results in deviations in the shape of the affected articular surface to which the disc then must adapt its normal anatomy, thereby resulting in deviations in form and function. If this type of functional limitation or irregularity is observed at a consistently occurring point during jaw opening and closing, it is often within the compensatory mechanisms of the patient and should be distinguished from the disc derangements that were described previously.[139]

When the intensity and duration of the functional and dysfunctional loading of the TMJs result in injury, molecular agents appear to be active in the degeneration of joints. Free radicals, various catabolic enzymes, neuropeptides, estrogen, cytokines, and prostaglandins are implicated in inflammatory reactions that have

an impact on the articular surfaces and the synovial fluid.[d] The loss of the ability of the synovial fluid to lubricate articular surfaces can result in adherence of the disc. The limitation of rotation occurs with adherence between the disc and the condyle, whereas fixation of the disc against the fossa permits rotation but does not allow the disc to move forward during translation.[139]

Hypermobility (subluxation) of the TMJ can permit the condyle to translate beyond the eminentia, with both the disc and the condyle located beyond its prominence. The combination of anatomic features that predisposes individuals to subluxation often allows for the self-reduction of the condyles. When the condyles translate beyond the eminentia but the discs are trapped posteriorly, the combined steepness of the disc and the eminentia prevents the reduction of each condyle, and the mandible is locked open.[139]

Orofacial Pain

Discomfort associated with masticatory system disorders falls under the larger umbrella of orofacial pain. Pain associated with TMJ dysfunction is most frequently muscular in origin,[43] and it may be amplified by both occlusal parafunction and stress.[65] Although pain itself is a complex entity,[172] a working knowledge of even the uncommon sources of pain perceived in the region of the masticatory system is essential to providing comprehensive diagnosis and treatment.

Sources of dental or periodontal pain should be identified by clinical, radiographic, and historic information. Nondental sources of pain include TMJ structures, muscles, cervical structures, neuropathies, vascular inflammation, all types of headache, sleep disorders, systemic disorders, and psychoimmune neurologic sources.[138] A survey of 45,700 American households revealed that 22% of respondents had experienced some type of orofacial pain during the previous 6 months, thereby establishing a meaningful probability that the periodontal patient's list of symptoms includes pain.[10]

Box 26.1 provides the current list of possible sources of orofacial pain. This list was prepared by the American Academy of Orofacial

Pain.[138]

Box 26.1

Differential Diagnosis of Orofacial Pain

Intracranial Pain Disorders[71,77,85,123,138,144]

Neoplasm, aneurysm, abscess, hemorrhage, hematoma, edema

Primary Headache Disorders (Neurovascular Disorders)[93,126]

Migraine, migraine variants, cluster headache, paroxysmal hemicrania, cranial arteritis, carotidynia, tension-type headache[4,95,101,139]

Neurogenic Pain Disorders[123,126]

Paroxysmal neuralgias: Trigeminal, glossopharyngeal, nervus intermedius, and superior laryngeal neuralgias[166]
Continuous pain disorders: Deafferentation pain syndromes (peripheral neuritis, postherpetic neuritis, posttraumatic and postsurgical neuralgia, neuralgia-inducing cavitation osteonecrosis[17,18])
Sympathetically maintained pain[21]

Intraoral Pain Disorders

Dental pulp, periodontium, mucogingival tissues, tongue[14,111,123,189]

Temporomandibular Disorders

Masticatory muscle, temporomandibular joint, associated structures

Associated Structures[36,40,133,138,139]

Ears, eyes, nose, paranasal sinuses, throat, lymph nodes, salivary glands, neck

Axis II Mental Disorders

Somatoform disorders
Pain syndromes of psychogenic origin

Compiled by the American Academy of Orofacial Pain.

Headache pain is perceived primarily within the trigeminal nerve pathways, although other cranial and cervical nerves may offer painful sensory input.[85,138,162] Pain that originates in masticatory system structures, which are also innervated by the trigeminal nerve, requires diagnostic differentiation from headache pain.[163] Headache can present in myriad forms, and it can influence the perception of pain and the diagnosis of the origin of pain.[85,138]

Pain of dental and periodontal origin must be clearly defined and differentiated from heart attack, sinus pain, and myofascial pain.[138,139] Pain that originates in pulpal or periodontal nociceptors can be differentiated with a comprehensive clinical and radiographic evaluation. Orofacial pain that originates in the TMJs or the muscles of mastication can result from neoplasm, macrotrauma, repeated microtrauma, systemic disease, and anatomic predisposition.

Within the joint structures, the inflammation and compression of vascularized components are the direct sources of pain. Synovitis or capsulitis with or without osteoarthritis and the polyarthritides are characterized by local pain, which increases with function while limiting the range of motion of the affected TMJ. In addition to the potential for pain, symptoms of arthritis can include limited mandibular opening, the disruption of other jaw mechanics, and joint sounds that are characteristic of degenerative change to and direct contact between articular surfaces.[e]

Orofacial pain that originates in the muscles of mastication may be perceived in that region, or it may be referred to other structures,

such as individual teeth. Similarly, pain referral to the region of certain muscles requires definition of the origin. Because local provocation at the origin of pain should produce symptoms at the site of pain perception, movement of the jaw would be expected to elicit pain in the painful muscles of mastication. Cranial nerves experience referral on the same side, whereas skeletal nerve referral can occur to the opposite side; both sources generally refer pain centrally or superiorly.[85,139,168]

The muscles of mastication are subject to a variety of disorders and dysfunction, many of which can be painful. The American Academy of Orofacial Pain designates myofascial pain, myositis, muscle spasm (myospasm), local myalgia, and myofibrotic contracture as major categories of these conditions.

Muscle palpation that reveals a taut band of muscle or fascia and that results in pain, which is also frequently referred, is virtually diagnostic for myofascial pain. Myositis of the masticatory muscles arises from direct trauma or infection close to the muscle. Associated pain increases with mandibular movement, thereby limiting the range of motion. Muscle spasm is the sustained involuntary contraction that results in the pain and dramatic shortening of the affected muscle. Myospasm of the masticatory muscles greatly limits mandibular movement, and it can change that occlusion suddenly as a result of its rapid onset. Local myalgia, which is pain that is specific to individual muscles, may result from ischemia or fatigue, and it may present as delayed-onset muscle soreness and protective co-contraction.

Occlusal parafunction, extended dental appointments, metabolic imbalances, and sympathetic nervous system influences have been associated with this painful muscular reaction. An extended period of a limited range of mandibular movement can result in fibrosis of the muscle and related attachments, thereby creating a painless condition called myofibrotic contracture.[138] Chronic myofascial pain TMD patients may actually experience significantly greater background masseter muscle activity as a primary basis for their pain rather than sleep bruxism being the dominant influence.[151] Another study suggests that daytime clenching is more likely the primary reason for myofascial pain rather than rhythmic masticatory muscle activity during sleep even when it is in

conjunction with sleep bruxism.[159]

Otolaryngologic symptoms associated with masticatory system disorders have been reported and include degrees of deafness, tinnitus, and vertigo.[f] Trauma and postural stress in the cervical spine can be responsible for both the perception and the origin of pain within the masticatory system.[13,20,85,139]

Sleep-disordered breathing may also play a role in a patient's orofacial pain through various potential mechanisms.[8] Sleep bruxism has been associated with hypoxia and arousals during sleep disruption.[25,56,181,182] Pain tolerance appears to be diminished with sleep deprivation.[169] Oral appliances that have been prescribed for sleep-disordered breathing have the potential to cause at least transient symptoms of temporomandibular disorders as a result of the mandibular advancement that needs to be experienced for them to be effective.[41,51] Oral appliances prescribed for sleep bruxism may represent an additional airway obstruction for the patient with obstructive sleep apnea.[60] In the light of the increasing emphasis on the effects of sleep-disordered breathing in both medicine and dentistry, Chapter 40 has been developed for this text to serve as a reference for the reader.

The determination of a specific origin or source of pain can become more difficult with pain referral and the modulation of painful experiences by the central nervous system.

The sensitization of peripheral nociceptors by higher neural centers and inflammation at the site of the origin of pain can alter pain perception.[88,120,166] Persistent inflammation may therefore be a contributing factor to chronic pain.[88,120,166] Systemic conditions that may contribute to or predispose an individual to compromised pain regulation include sleep disorders, fibromyalgia, chronic depression, chronic fatigue syndrome, hypothyroidism, insufficient thyroid receptor activity, prolactin feedback disorder, epinephrine sensitivity related to mitral valve prolapse, premenstrual syndrome, androgen excess in women, and posttraumatic stress disorder.

Although some of these situations exhibit gender bias in response to hormonal factors, the influence of stress on pain experiences and the effect of variable coping skills have been reported for both genders.[g]

Comprehensive Evaluation

Patient History and Interview

The written history and personal interview should be designed to invite open-ended responses and reflection by the patient on past experiences and the current condition. Standard dental or medical history forms may require modification to include questions about any history of limited or painful jaw movement, noise in either joint, and masticatory muscle symptoms (Box 26.2). These issues should be documented with regard to timing, duration, frequency, and relationship to any history of trauma.[138]

Box 26.2

Examples of Questions About the Masticatory System to Include in the Patient History

Are you now experiencing or have you ever experienced:

1. Pain in either jaw joint or pain when opening or closing your mouth?[9]
2. Acute or direct trauma to the face, jaw, head, or neck, such as during an accident?
3. Any locking or restricted movement of either jaw joint?[50,170]
4. The inability to bite or close the teeth together completely without discomfort in one or both jaw joints?
5. Earache without infection, especially if it is recurring?
6. Ringing or rushing sounds in either ear?
7. Any type of neuralgia (nerve pain), especially with trigger points?[123,180]
8. Tooth pain without a diagnosed dental problem or after tooth removal?[124,125,173]
9. Fibromyalgia (muscle pain)?[42,146,152,168]
10. Sleep apnea or any sleep disturbance?
11. Any sounds, such as clicks or pops, in either jaw joint, especially when opening or while eating?

12. Chronic or frequently recurring headaches, especially migraines or cluster headaches?[4]
13. Shingles or any painful infection of the face or neck?
14. Having to "adjust" the jaw or manipulate the jaw joint with your hand to be able to open or close your mouth?
15. An occupation or activity that requires a regular stressful posture, such as cradling a telephone between the head and shoulder, working at a computer, playing a musical instrument, or scuba diving?[174,192]
16. An awareness of frequently keeping your teeth together, maintaining a clenched jaw, or holding your jaw in an assumed position, such as holding a pipe?
17. Lyme disease?[71]
18. Neck muscles that are often tired or sore?
19. A sleep position or posture that maintains pressure on your lower jaw?

Clinical Examination

The clinical examination continues the interview process through the co-discovery of the patient's masticatory system status. The dentist leads the patient to understand the meaning of signs and symptoms of dysfunction or deterioration and seeks opportunities to expand the patient's responses to questions.

The physical examination actually begins during the interview, when asymmetries in facial form, head posture, and mandibular movement patterns can be observed. The clinical evaluation of the various structures of the masticatory system, although individual to each practitioner, should afford the patient opportunities for understanding and include the following[11,43,139]:

1. The observation and measurement of the full range of motion of the mandible
2. The auscultation and light palpation of each TMJ in its full range of motion
3. The load testing of each TMJ
4. The palpation of each muscle of mastication and the related head and neck muscles

5. The evaluation of all of the soft tissues of the face, oral cavity, and oropharynx
6. Periodontal and dental examinations
7. Complete occlusal analysis, including accurately mounted diagnostic models

Evaluation of the TMJ begins with range-of-motion analysis. The observation of a departure from a straight path of opening and closing the mandible suggests an intracapsular disorder or masticatory muscle incoordination.[43,46,139] An average maximal opening of 50 mm is common; findings of less than 40 mm of opening suggest limited opening caused by a masticatory system disorder. The range of right and left lateral excursions is usually about 9 mm, and the protrusion of the mandible is typically 7 mm. Limitation in the range of motion may be normal for some patients, but, for most, these observations are of diagnostic value.[11,50,75,139,171] *Auscultation* of the joint by listening with a stethoscope or Doppler instrument, which amplifies joint sound for both the patient and the dentist, can reveal noises that are diagnostic for numerous conditions. The intensity and nature of any sounds, clicks, pops, or crepitus (i.e., grinding, grating, or rubbing sounds) should be recorded accurately. Any sound that is detected as part of the initial evaluation should be tracked consistently to identify any change. Diagnostic interpretation and management on the basis of specific sounds correlated with the status of the TMJ can be found in other reference texts.[7,11,43,46,139,183]

Firm palpation of the TMJ with the mouth closed can be uncomfortable for the patient with inflammation in joint structures or superficial muscles. Palpation while opening may become more uncomfortable if retrodiscal tissues are also inflamed.

Load testing of the TMJ is essentially a means to palpate the head of the condyle, the surface of the glenoid fossa, and the tissue interposed between them, except in the case of bone-to-bone contact. With bimanual mandibular manipulation, the dentist loads the joints equally and may detect resistance or tension on either side. The patient is in a supine position in the dental chair to minimize postural influence on muscle activity. The patient's head is braced by the support of the chair and by being cradled against

the dentist's arm or abdomen. The dentist's middle fingers locate the notch in the mandible just anterior to the angle, and the thumbs are placed near the midline in the mental region of the mandible (eFig. 26.4). Initially, the dentist provides gentle guidance to the hinging action of the mandible, with a slight lifting force applied with the fingers and a slight depressing force applied with the thumbs. If the patient remains comfortable, increasing force can be applied at both points, ultimately with enough pressure to load test the joints. With the avascular fibrous discs interposed, the condyles are in centric relation, and the loading of both joints is comfortable. Discomfort may occur with muscle incoordination or bracing or with an anterior displaced disc and the attempted loading of vascular retrodiscal tissues of either TMJ. When performed properly, the patient can bite firmly as part of guided loading of the TMJs and report the nature or absence of pain or tension.[11,43,69,139]

EFIG. 26.4 Bimanual manipulation load testing in centric relation, with the teeth apart.

Muscle palpation is also a learned technique that requires both experience and expertise so that it may help to derive the most reliable information. Too little pressure is not diagnostic of modest muscle pain or spasm, whereas too much pressure can hurt even when normal musculature is palpated.[63] Externally, the muscles

that are palpated include the anterior, middle, and posterior temporalis; the superficial masseter; the anterior and posterior digastric; the sternocleidomastoid; the trapezius; the posterior cervical muscles; and the insertion of the medial pterygoid muscle. Intraorally, the deep masseter is tested with moderate squeezing pressure, and the medial pterygoid muscle is palpated directly in the general region of the insertion point for local anesthesia with a mandibular block. The lateral pterygoid is difficult to palpate because of the dominance of the medial pterygoid in the same region. Its palpation superior and distal to the palpation point for the medial pterygoid can be attempted distal to the maxillary tuberosity. Offering manual resistance to the patient's efforts to protrude the mandible is also a test of the lateral pterygoid muscle. Neither method of evaluation of the possible soreness of the lateral pterygoid muscle is completely reliable, although both provide some insight into the patient's muscle status.[h]

During muscle palpation, the dentist may be able to detect a particularly taut and uncomfortable band of muscle fibers. This condition represents regional myofascial pain or trigger point myalgia, which can be responsible for the referral of pain to the teeth and to other orofacial regions. The diagnostic injection of local anesthesia can be effective for identifying trigger point pain and pain referral patterns.[139,168]

The *occlusal analysis* is a logical extension of the evaluation of the teeth and the periodontium. Tooth mobility is assessed in both static and dynamic modes. Pressure applied to a tooth with a firm object allows for the detection of movement through both visual and tactile evaluation (see Chapter 55). Asking the patient to perform excursions of the mandible while maintaining firm contact with the opposing teeth also permits visual and tactile assessment.

Sources of tooth mobility include inadequate periodontal support, inflammation of the periodontium, and excessive occlusal loading of the teeth with adequate periodontium, thereby resulting in adaptive mobility.

The physical evaluation of the teeth and any restorations can reflect a history of trauma or wear. Visual observation, registration with marking paper or wax, and the electronic assessment of tooth contacts as the patient moves in all excursions may reveal

disharmonies that are sufficient to cause the orthopedic instability of either TMJ.

If the teeth are found to be relatively firm, the relationship between the maxillary and mandibular teeth may influence the direction of condylar movement as soon as tooth-to-tooth contact is made.

While maintaining the centric relation, the dentist continues the physical examination by positioning the condyles in a fully seated relationship without tooth-to-tooth contact by using bimanual manipulation or a leaf gauge technique. The mandible is manually guided to close until the first tooth-to-tooth contact is made. If that position is also maximum intercuspation, the optimum seating of the condyles is maintained. If the initial contact in centric relation is not maximum intercuspation, the condyles will be directed from a fully seated position to an inferior position relative to their respective fossae, which results in an orthopedic instability.

The direction and extent of the accommodation of the mandible should be carefully measured and recorded during the initial evaluation and consistently evaluated at subsequent appointments to discover any trend.[i]

To increase the reliability of this evaluation, a muscle-deprogramming effort may be employed. The simplest approach is to use cotton rolls that can be placed between the anterior teeth for 5 to 15 minutes to allow for possible muscle relaxation through the avoidance of proprioceptive or pressure neurologic input. A prefabricated or directly fabricated acrylic or composite bite stop for the anterior teeth offers the same advantage.[10,11,139] A more complex means of confirming the seating of the condyles in centric relation is achieved with a maxillary or mandibular muscle relaxation occlusal appliance. These appliances provide full coverage for the respective arch and occlusal contact for at least one cusp or incisal edge of the opposing teeth so that the teeth are protected from spontaneous shifting. The occlusal design provides immediate disclusion of all of the posterior teeth in every protrusive or lateral excursion. This allows for the progressive deprogramming of muscles through the advantage of reduced muscle contractions and limited noxious neurologic input.[44,102,185]

Models of the dentition must be accurately mounted to be

diagnostic. The facebow transfer relates the maxillary cast to the axis of rotation of the articulator as the maxillary teeth relate to the cranial case. With careful bimanual manipulation or the use of an anterior bite stop, a transfer wafer is generated with the condyles fully seated in their glenoid fossa. The maxillary and mandibular teeth of each diagnostic model then relate to one another in centric relation as determined by condylar position. They may reveal an occlusal discrepancy in centric relation, which would require compensation by the patient.[11,43]

Imaging

When the clinical evaluation, panoramic radiographs, and patient history indicate the possibility of structural masticatory system disorders or the possible presence of pathology (especially neoplasm), appropriate imaging of the TMJ is warranted.[109] The state-of-the-art technique for the imaging of soft tissue, especially the articular disc, is magnetic resonance imaging. The current highest standard for the imaging of hard tissue, such as the condyle or the temporal bone, is computed tomography (CT). Cone-beam CT has become much more readily available to dentistry, with software systems able to display the data gathered as both anteroposterior and cross-sectional depictions of the condyle and cranial structures, with image quality that is the same as or better than spiral CT. Less radiation exposure and lower cost to the patient are both reasons to favor cone-beam CT over conventional CT. The interpretation of magnetic resonance and CT images usually requires specialized training for the clinician or access to a radiologist. Arthrography is still being used for certain diagnostic situations, such as the suspected perforation of the articular disc, and nuclear medicine has developed protocols to image the TMJ to determine if active deterioration is occurring.[j]

Although plain-film tomography is occasionally a feature of some of the newer radiographic equipment, the technique that is most readily available to a majority of practitioners is panoramic radiography. The image produced depicts only general relationships and gross anatomy, so the information provided should be used only for screening purposes. When pathology or

marked deformation is suggested by a panoramic radiograph, further diagnostic imaging and procedures may be warranted.[19,85]

Diagnostic Decision Making

The complete evaluation of every patient's periodontal status must include the diagnostic components required to reveal any form of masticatory system disorder. The existence of factors that are responsible for the historical, current, or potential impairment of masticatory system function can be integrated into a comprehensive treatment plan. Patients who require substantial periodontal therapy or who have advanced periodontal disease may be at increased risk for masticatory system disorders, so diagnostic processes must remain consistently thorough and inclusive for all patients.[26,158] For the patient who presents with a symptomatic masticatory system disorder, the diagnostic strategy would logically begin with the inclusion of all potential sources of pain or dysfunction and be followed by the systematic exclusion of possible causative or contributing factors, beginning with the least likely. When no symptoms are reported, the history and clinical examination still need to be thorough, because some patients tend to tolerate modest dysfunction or mild transient discomfort. The diagnostic strategy for the patient who presents with minimal or no signs and symptoms of masticatory system disorders is to attempt to confirm a stable condition while identifying risk factors. The careful documentation of past or current trauma and disharmony provides the basis for the trend analysis and anticipation of possible future problems.[k]

Consistent professional maintenance care has been clearly demonstrated to be a key ingredient in the successful management of a patient's periodontal condition.[74,126] By complementing any treatment sequence, these appointments afford dentists the opportunity at every stage of comprehensive care to provide continuing evaluation of the status of the entire masticatory system and to provide timely and appropriate intervention when needed (see Chapter 72).

Acknowledgments

I would like to acknowledge the encouragement and the recommendation of references provided by Dr. Henry Gremillion during the revision of this chapter.

Case Scenario 26.1

A patient calls the dental office the day after an extensive restorative procedure, which required several hours to complete, to report her condition. Though there is no history of temporomandibular joint (TMJ) disorders, no evidence on recent panoramic radiograph of change in condyle head shape or relationship to the articular fossa, and no history of occlusal disharmony, the patient states she has pain in the region of her right ear and is unable to get the posterior teeth on the right side to touch, despite having a complete dentition in both arches.

Case-Based Questions	Solution and Explanation
1. What is the source of the patient's discomfort and of the inability for the posterior teeth to contact? A. Anterior displacement of the articular disc of the right TMJ B. Dislocation of the left TMJ resulting in teeth on left side contacting first C. Ear infection affecting the comfortable function of her right condyle, resulting in her unconsciously avoiding tooth contact on the right side	**Answer: A** **Explanation:** The patient's articular disc of her right TMJ is displaced anteriorly due to sustained muscle effort during the dental appointment without adequate compensation by the dentist in the form of support or rest. The condyle head is held away from the articular fossa by the swelling of retrodiscal tissue, separating the right posterior teeth, and the rich innervation of the retrodiscal tissue and the state of inflammation account for her pain, especially when she attempts to achieve contact of posterior teeth on the right side.
2. What might a dentist do to help prevent this event from occurring? A. Inform the patient at the beginning of the long appointment that he	**Answer: B** **Explanation:** Extended dental treatment can lead to muscle spasm, TMJ disharmonies, and facial pain, even for patients with no reported history of difficulty. The dentist needs to collaborate with the patient to reduce potential complications of this type with support and rest consistent

or she should expect pain and jaw immobility for several days after that appointment. B. Request that the patient be aware of any discomfort or fatigue of jaw muscles during the appointment, offer a jaw support block or instrument whenever procedure permits, and allow the patient breaks and periods of rest during the appointment. C. Complete the procedures as quickly as possible because slightly imperfect results are preferable to TMJ or masticatory muscle pain and dysfunction.	with the difficulty of the procedures being accomplished. Any history of masticatory system disorders of which the dentist has knowledge and documentation would require even more careful efforts to protect the patient from excessive muscle fatigue or protracted opening.

Key Application

Clinical evaluation of each patient's TMJ condition and function, occlusal relationships, and any discomfort the patient may be experiencing is well within the scope of a dentist's training and abilities.

Key Fact

The muscle mass of elevator muscles is significantly greater than that of juxtaposed depressor muscles, which include the inferior head of the lateral pterygoid muscles, anterior digastric muscles, and those muscles attached to the hyoid bone. This difference, along with the mechanical advantage, between closing and opening accounts for the intensity of bite force and the reaction of periodontal ligament mechanoreceptors.

Key Clinical Application

Evaluation of the interaction of inclines of posterior teeth in contact during excursions is an essential component of accurate diagnosis for patients with masticatory system disorder.

CHAPTER 27

Chronic Periodontitis

Henrik Dommisch, Moritz Kebschull

CHAPTER OUTLINE

Clinical Features
Risk Factors for Disease

Chronic periodontitis is the most prevalent form of periodontitis, and it generally shows the characteristics of a slowly progressing inflammatory disease. Periodontitis belongs to the group of complex inflammatory diseases in humans. In this context, the word *complex* not only describes the fact that there are multiple clinical symptoms that account for the disease, but also explains the multiple factors that lead to and influence periodontal inflammation. Chronic periodontitis occurs most frequently in adults. Nonetheless, it may also be diagnosed in children and adolescents when associated with chronic plaque and calculus accumulation. Therefore chronic periodontitis should be understood as age-associated, but not age-dependent, complex chronic inflammation of the periodontal tissues. As described in this chapter, systemic or environmental factors (e.g., diabetes mellitus, smoking) modify the host immune response to the dental biofilm so that the periodontal destruction becomes more

progressive.

Periodontitis is a highly prevalent progressing disease, and it affects approximately 10.5% to 12% of the world's population.[44] Periodontitis has been found to exert adverse effects on systemic health, and in this context, important pathologic interdependencies with, for example, diabetes mellitus have been identified.[9,32,55,73] Also, it is known that systemic inflammatory markers, such as the C-reactive protein (CRP), are elevated in patients with periodontitis.[69,96] In general, chronic periodontitis is considered as a slowly progressing disease, but in the presence of severe systemic conditions or environmental factors, such as smoking, this inflammatory disease progresses more rapidly.

The classic definition described chronic periodontitis as "an infectious disease resulting in inflammation within the supporting tissues of the teeth, progressive attachment loss, and bone loss."[24] The etiopathologic factors that lead to periodontal inflammation and, subsequently, destruction of periodontal tissues have been widely studied, and the interplay between the microbial environment and the individual host immune response has gained attention in the scientific community (discussed later).

Chronic periodontitis represents major clinical and etiologic characteristics such as (1) microbial biofilm formation (dental plaque), (2) periodontal inflammation (gingival swelling, bleeding on probing), and (3) attachment as well as alveolar bone loss.

Besides the local immune response to the dental biofilm, periodontitis may also be associated with a number of systemic disorders and defined syndromes. In most cases, patients with systemic diseases, which lead to impaired host immunity, may also show periodontal destruction. On the other hand, periodontitis is not only limited to the area of the oral cavity but may be associated with severe systemic diseases such as cardiovascular disease, stroke, and diabetes mellitus.[52,70,73,79]

This chapter discusses clinical features that have been described for chronic periodontitis, based on the consensus of the 1999 World Workshop in Periodontics. In addition, the etiology is summarized in categories explaining the known factors (microbiologic, immunologic, genetic, and environmental) involved in the pathology of chronic periodontitis.

At the time of writing of this chapter, a new World Workshop in Periodontics was jointly planned by the European Federation of Periodontology and the American Academy of Periodontology for November 2017, to further refine the classification of periodontal diseases.

Clinical Features

General Characteristics

Characteristic clinical findings in patients with untreated chronic periodontitis include the following symptoms (see the case presentation in Figs. 27.1 to 27.6):

FIG. 27.1 Clinical features of generalized chronic periodontitis in a 49-year-old, medically healthy male patient who presented to the clinic for the first time. The patient reported smoking 15 cigarettes per day. Note the abundant dental plaque and calculus deposits, gingival redness and swelling, and alteration of the gingival texture (loss of gingival stippling). The patient noticed multiple recessions. In this case, recessions were the result from loss of clinical attachment and alveolar bone. (A) Right lateral view. (B) Frontal view. (C) Left lateral view. (D) Maxillary view. (E) Mandibular view. (Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

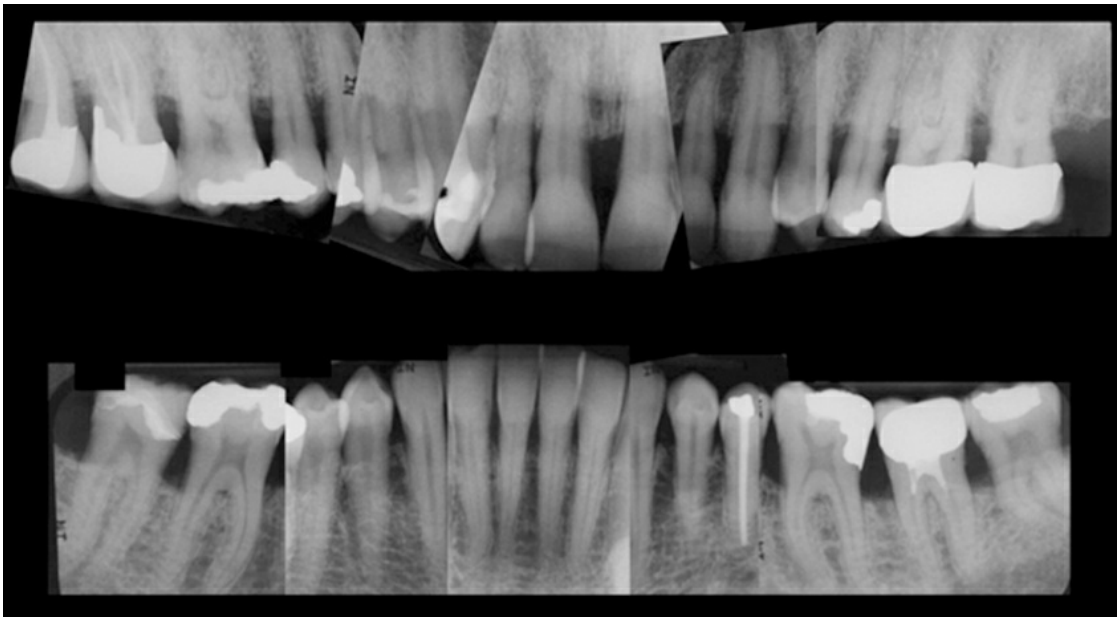

FIG. 27.2 Collage of the radiographic periodontal status (a total of 11 x-rays) at the time of diagnosis (compare Figs. 27.1 and 27.3). Generalized horizontal and localized angular, vertical bone loss on the mesial and distal sites of molars was noted. Radiographs present deep subgingival restorations (teeth #2 and #19), overhanging margins of restorations (teeth #14 and #15), carious lesion (tooth #14), and insufficient root canal treatment (tooth #18). (Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

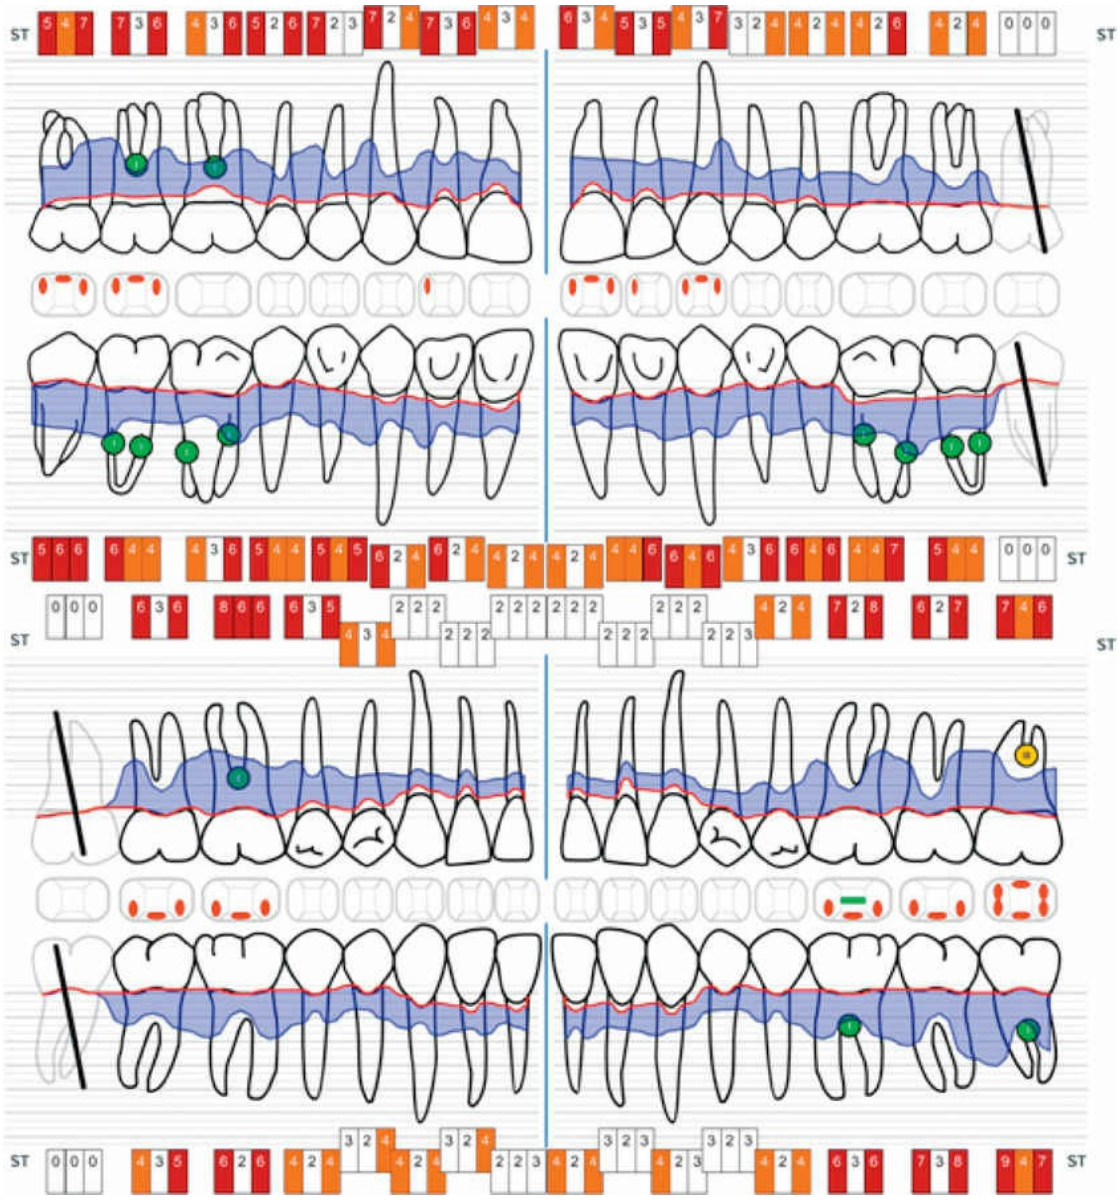

FIG. 27.3 Documentation of the periodontal attachment level in the same patient (see Fig. 27.1) at the time of the first visit. The red line displays the gingival margin reflecting recessions. Clinical attachment loss is illustrated by the filled (blue) area on the root surfaces. The deepest periodontal pocket measured was 9 mm. Class I (green) and class II (yellow) furcation involvement were documented. Bleeding upon periodontal probing (gingival inflammation) is reflected by orange dots. Due to the history of smoking, the bleeding on probing score was relatively low, although the patient presented advanced attachment loss. Tooth mobility is indicated by the green line (tooth #19). (Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

FIG. 27.4 Subsequent to the anti-infective therapy and periodontal reevaluation, resective periodontal surgery was performed in the patient introduced in Figs. 27.1, 27.2, and 27.3. Surgical method: apically repositioned flap. (A) Intrasulcular incision at buccal sites; notice class I furcation involvement on tooth #14. (B) Paramarginal incision at palatal sites, excision of a distal wedge. (C–D) Sutured using 5-0 Prolene, buccal and palatal view, respectively. (E) Occlusal view after suturing. (F) Occlusal view 1 week post surgery. Tooth #14 received endodontic therapy and crown restoration prior to periodontal surgery. (Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

FIG. 27.5 Subsequent to the anti-infective therapy and periodontal reevaluation, resective periodontal surgery was performed in the patient introduced in Figs. 27.1 to 27.4. Surgical method: apically repositioned flap. (A) Intrasulcular incision at buccal sites; notice class I furcation involvement on tooth #19 and horizontal bone loss in teeth #18 to #20. (B) Sutured using 5-0 Prolene, buccal view. (Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

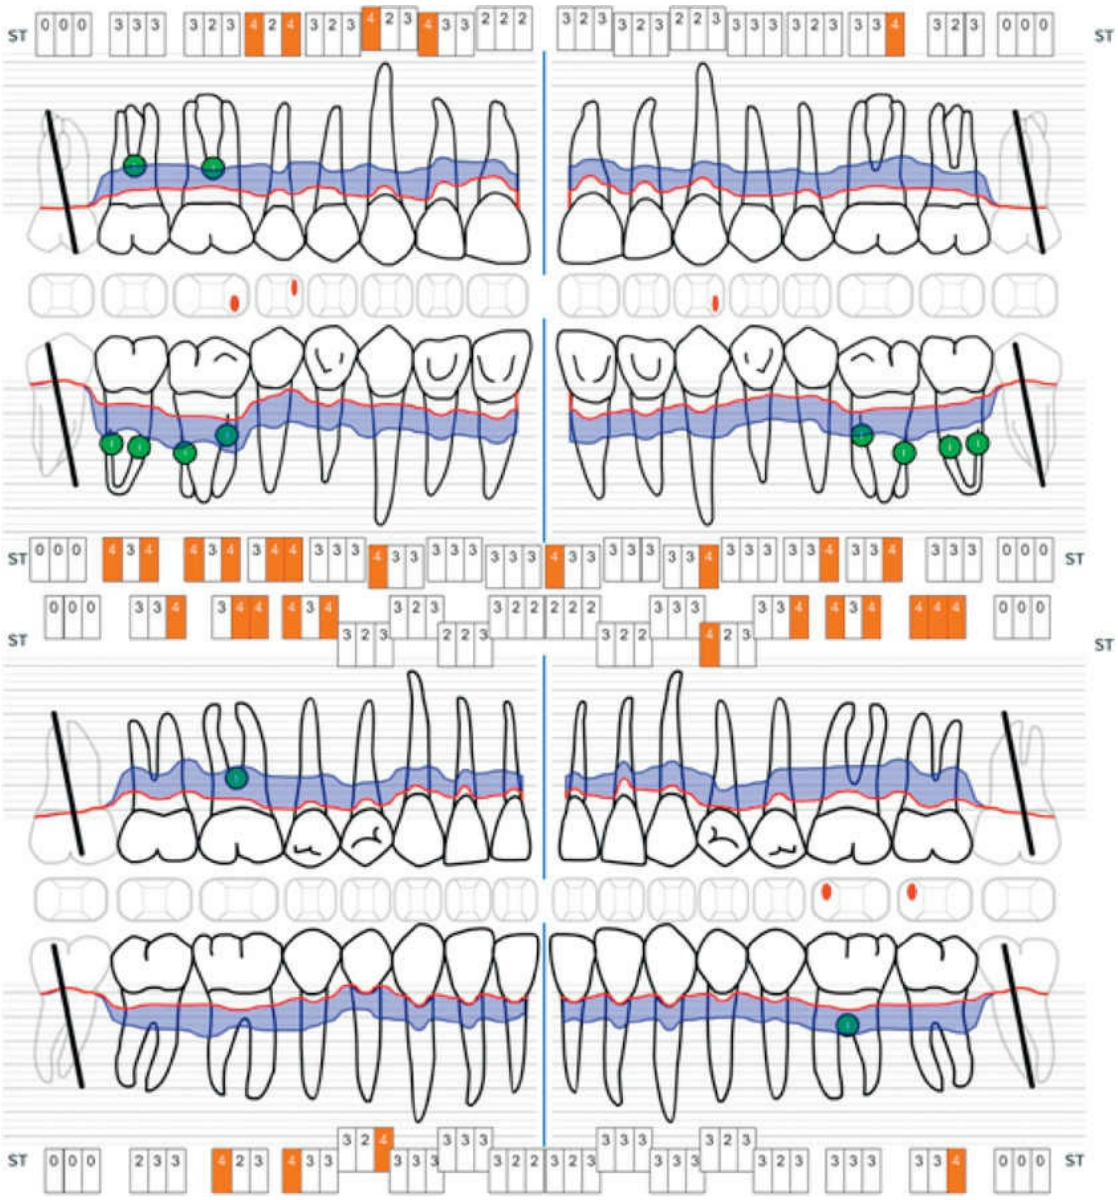

FIG. 27.6 Documentation of the periodontal attachment level in the same patient (see Figs. 27.1 to 27.5) after active periodontal therapy was completed and the supportive periodontal therapy was initiated. The red line displays the gingival margin reflecting recessions after therapy. Clinical attachment loss is illustrated by the filled (blue) area on the root surfaces. The deepest periodontal pocket measured was 4 mm.

(Reprinted from Kebschull M, Dommisch H: Resektive parodontalchirurgie. *Zahnmedizin up-2-date*. 2012; 525–545.)

- Supragingival and subgingival plaque (and calculus)

- Gingival swelling, redness, and loss of gingival stippling
- Altered gingival margins (rolled, flattened, cratered papillae, recessions)
- Pocket formation
- Bleeding on probing
- Attachment loss
- Bone loss (angular/vertical or horizontal)
- Root furcation involvement
- Increased tooth mobility
- Change in tooth position
- Tooth loss

Chronic periodontitis can be clinically revealed by means of periodontal screening and recording (PSR), diagnosed by an assessment of the clinical attachment level, and therewith the detection of inflammatory changes in the marginal gingiva (see Fig. 27.1). Measurements of periodontal probing pocket depth in combination with the location of the marginal gingiva allow conclusions regarding the loss of clinical attachment (see Figs. 27.3 and 27.6). Dental radiographs reveal the extent of bone loss indicated by the distance between the cemento-enamel-junction and the alveolar bone crest (Fig. 27.2).

The distinction between aggressive and chronic periodontitis is sometimes difficult, because the clinical features may be similar at the time of the first examination. At later time points during treatment, aggressive and chronic periodontitis may be differentiated by the rate of disease progression over time, familial nature of aggressive disease, and presence of local as well as systemic factors.

Disease Distribution

Chronic periodontitis exhibits a site-specific clinical picture, where attachment and bone loss are not equally distributed throughout

the dentition as well as around teeth. Local inflammation, pocket formation, attachment loss, and bone loss are the sequelae of the direct exposure to the subgingival plaque (dental biofilm) and local inflammatory responses. Periodontal pocket formation, attachment, and bone loss may develop on one or more sites of a tooth, while other sites remain at a physiologic attachment level. Due to the site-specific nature and based on the number of teeth with clinical attachment loss, chronic periodontitis can be classified into the following categories:

- *Localized chronic periodontitis,* meaning that less than 30% of the teeth show attachment and bone loss
- *Generalized chronic periodontitis,* meaning that 30% or more of the teeth show attachment and bone loss

During chronic periodontitis, the local inflammatory response may lead to different patterns of bone loss, including vertical (angular) and horizontal bone destruction. Although vertical bone loss is associated with intrabony pocket formation, horizontal bone loss is usually associated with suprabony (supraalveolar) pockets.

Key Differences Between Gingivitis and Chronic Periodontitis

Plaque-Induced Gingivitis	Chronic Periodontitis
Inflammation of the gingiva without attachment/bone loss.	Inflammation of periodontal apparatus with attachment/bone loss.
With optimal oral hygiene, this condition can be resolved completely (reversible).	The attachment loss is irreversible, in spite of successfully controlling the inflammation.
Not all sites with gingivitis progress to periodontitis	All patients with chronic periodontitis must have experienced prior gingivitis
The dental implant counterpart of gingivitis is peri-implant mucositis.	The dental implant counterpart of periodontitis is peri-implantitis.

Disease Severity

With chronic periodontitis, severity and extent of periodontal destruction will occur over time in combination with systemic disorders impairing or enhancing host immune responses. Patients with chronic periodontitis experience a progression in attachment and bone loss as they become older. If untreated and oral hygiene behaviors remain unchanged, chronic periodontitis eventually leads to tooth loss and may negatively impact distant organs by the uncontrolled progression of periodontal inflammation and by the systemic spread of infection. Relative to the degree of attachment and bone loss, disease severity can be described as mild, moderate, or severe. These degrees are defined as follows:

- *Mild chronic periodontitis:* clinical attachment loss of 1 to 2 mm
- *Moderate chronic periodontitis:* clinical attachment loss of 3 to 4 mm
- *Severe chronic periodontitis:* clinical attachment loss of 5 mm or more

Symptoms

Chronic periodontitis is commonly a slowly progressing complex disease without a pain experience. Therefore most patients are unaware that they have developed a chronic disease. For the majority of patients, gingival bleeding during oral hygiene procedures or eating may be the first sign of disease occurrence. Areas with advanced periodontal inflammation may present with purulence emanating from the periodontal pocket. As a result of gingival recession, patients may notice black triangles between teeth or tooth sensitivity in response to temperature changes (cold and heat). In addition, food impaction may occur in the space of interdental triangles, leading to increased discomfort and bad breath. In cases with advanced attachment and bone loss, tooth mobility, tooth movement, fanned out or elongated front teeth, and, in rare occasions, tooth loss may be reported. In cases with advanced disease progression, areas of localized dull pain or pain sensations radiating to other areas of the mouth or head may occur.

Key Fact

Site Specificity of Chronic Periodontitis

Not all sites in the mouth are equally prone to chronic periodontitis, and it exhibits site specificity. The progression of the disease occurs in certain sites but not uniformly. Interproximal sites, in general, are more prone to periodontal destruction, compared to buccal/facial sites.

Disease Progression

Chronic periodontitis may develop at any time in life. First clinical signs of inflammation may occur even during adolescence when the oral hygiene is neglected and dental plaque and calculus were allowed to accumulate. In general, the progression rate of chronic periodontitis is slow, so that symptoms of the disease appear around the age of 40 or later in life. Onset and the rate of disease progression, however, may be influenced by a number of modifiable (e.g., smoking, diet) and nonmodifiable (e.g., genetic disorders and risk issues) factors. In this context, patients who develop a metabolic disorder, such as diabetes mellitus, may exhibit a much higher progression rate of chronic periodontitis along with increased alveolar bone loss, periodontal bleeding, and pocketing.[73,95,100] Thus diabetes mellitus and the degree of blood sugar control belong to the most important systemic factors that are directly correlated with periodontal disease.

The progression pattern of chronic periodontitis does not show equal degrees of attachment loss on each affected site over time. Although some sites exhibit more rapid periodontal breakdown over time, the attachment level remains static at other sites in the dentition for longer time periods.[58] Interestingly, disease progression is more rapid at interproximal sites compared to oral or buccal areas of neighboring teeth.[56,59] This phenomenon may be explained by the fact that these interproximal areas become wider along with disease progression, recession development, and the related increased probability of plaque accumulation and food impaction in those areas. Plaque control becomes more difficult,

and interproximal furcation areas, interproximal caries, root caries, overhanging restoration margins, and tooth crowding may further promote interproximal attachment loss.

As chronic periodontitis exhibits individual and heterogeneous progression patterns throughout the dentition, three different models have been proposed to describe the rate of disease progression and determine the degree of attachment loss over time[17] as follows[92]:

- The continuous model:
    - Describes slow and continuous disease progression
    - Suggests that sites exhibit a constant progression rate of attachment loss throughout the duration of the disease
- The random or episodic-burst model:
    - Describes the episodic occurrence of short progressive bursts of periodontal destruction followed by periods of stagnation
    - Sites, teeth, and the chronology of bursts and stagnation are subject to random effects
- The asynchronous, multiple-burst model:
    - Describes the occurrence of periodontal destruction (bursts) during defined periods, which are asynchronously interrupted by periods of stagnation or remission for individual sites and teeth

Prevalence

Chronic periodontitis is considered to be one of the most common

chronic diseases in humans, and the prevalence of the disease increases with age equally in both genders. In general, 40% of patients ≥50 years old and almost 50% of patients ≥65 years old show signs of mild to moderate periodontal destruction. The prevalence of severe forms of periodontitis also increases with age. From 11% to 30% of patients develop severe periodontitis at the age of 40 years or older (Figs. 27.7 and 27.8).[14,22,28,39,94] The worldwide prevalence for severe chronic periodontitis is estimated at 10.5% to 12% of the world's population.[44]

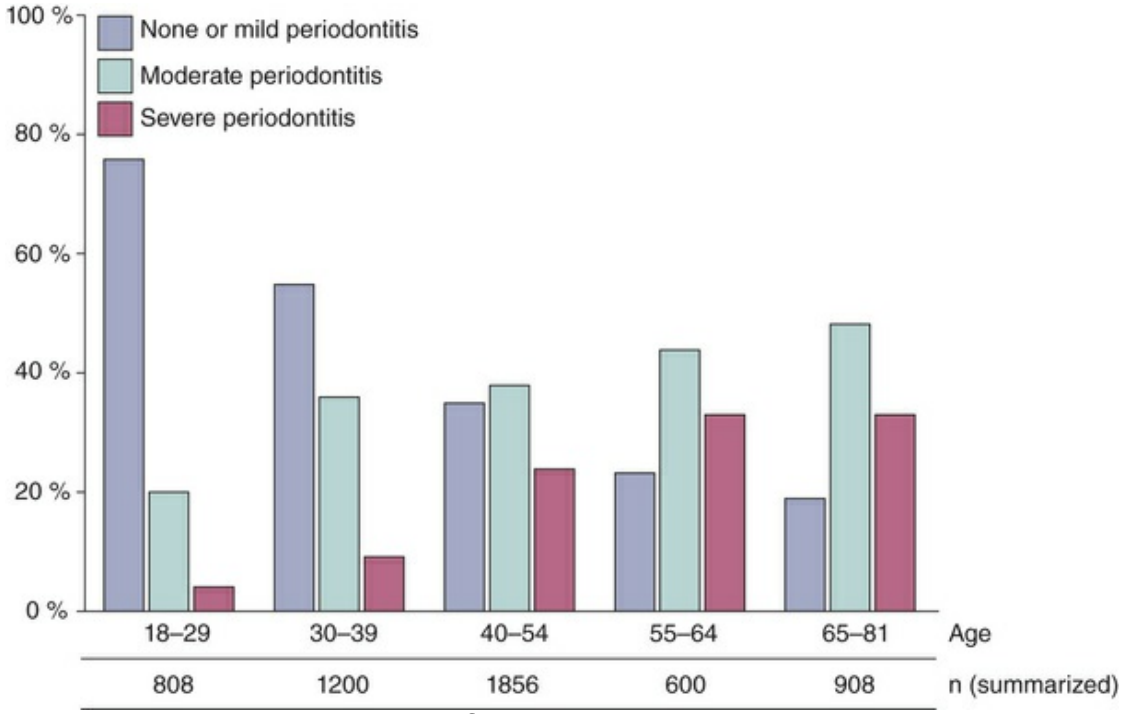

FIG. 27.7 Prevalence for periodontitis in the United States and Germany (2007–2009). (Data from Genco et al., 2007,[28] and Holtfreter et al., 2009,[39] and reviewed in Demmer & Papapanou, 2010.[14])

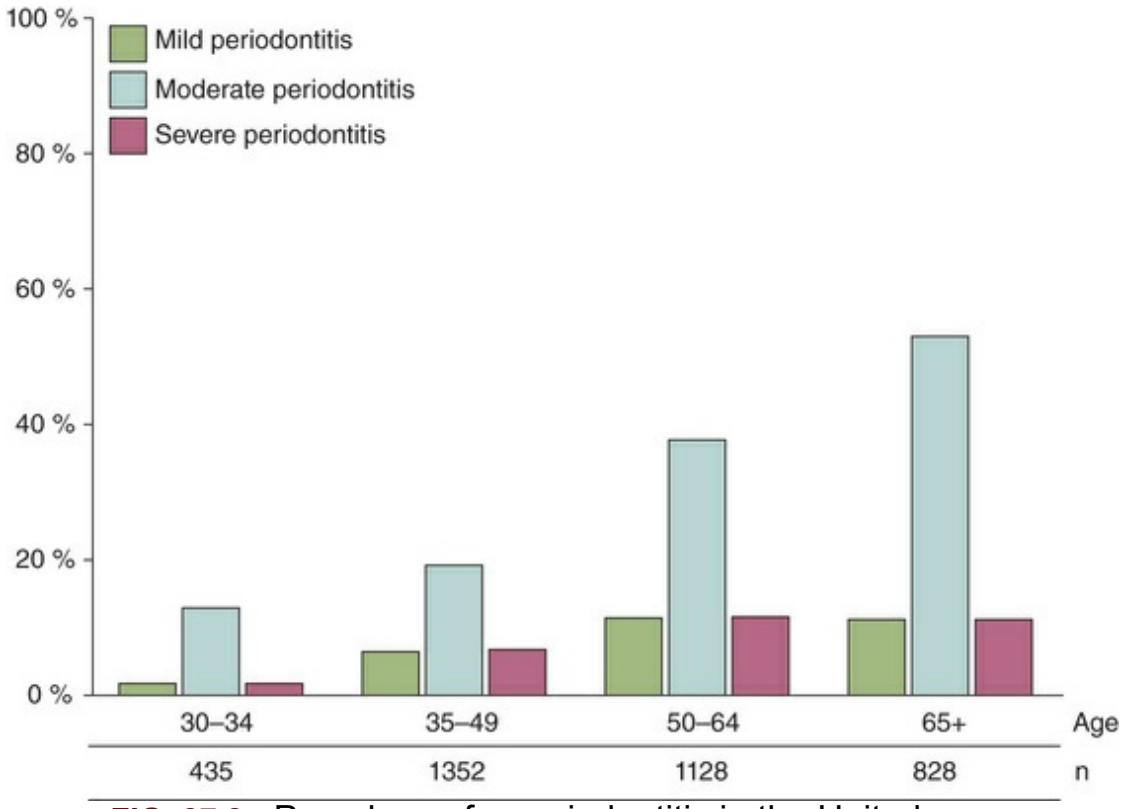

FIG. 27.8 Prevalence for periodontitis in the United States (2009–2010). (Data from Eke PI, Dye BA, Wei L, et al: Prevalence of periodontitis in adults in the United States: 2009 and 2010. *J Dent Res* 91:914–920, 2012.)

Risk Factors for Disease

A number of factors influence the etiopathogenesis of chronic periodontitis. The composition of the oral microflora and the amount of dental biofilm (plaque) are major etiologic factors. In this context, the extent of the periodontal destruction depends on the host immune competence as well as genetic predispositions influencing the individual susceptibility to disease. In addition, both systemic diseases and environmental factors interfere with the development and progression of chronic periodontitis. The risk factors described in the following sections (microbiological, local, systemic, immunologic, genetic, environmental, and behavioral) may occur simultaneously, or a selection of factors is present in patients with chronic periodontitis. The degree of the individual risk factor contribution differs among patients, so it is worthwhile to not only identify the risk factors but also to specify each risk

factor's degree of contribution.

The prior history of gingivitis and periodontitis should be considered as general predictors for the development or progression of chronic periodontitis.[56] It is possible that the disease could not be successfully treated in the first place. The reason for an unsuccessful treatment outcome can be as simple as the patient's unwillingness (noncompliant patients) to understand the disease or perform proper oral hygiene. On the other hand, reasons for disease progression can also be more complex when nonmodifiable factors —such as genetic predispositions/syndromes, severe immunologic disorders, other therapies (e.g., organ transplantations) that affect the patient's immune status, lack of dexterity, or other systemic diseases—are present. This highlights the complexity of not only the development but also the progression/reoccurrence of chronic periodontitis. Several risk factors that contribute to the patient's susceptibility to chronic periodontitis are discussed next.

Microbiologic Aspects

Plaque accumulation on tooth and gingival surfaces (dental biofilm formation) at the dentogingival junction is considered the primary initiating agent in the etiology of gingivitis and chronic periodontitis.[56] As the dental biofilm develops, early signs of an inflammatory reaction occur in the gingival margin (gingivitis) without attachment loss. Generally, optimal plaque control leads to the complete resolution of this early gingival inflammation.[62] With neglected oral hygiene on the other hand, inflammation will progress and eventually result in the loss of attachment around teeth.[56] Although not all patients with gingivitis develop periodontitis, it is known that all patients with periodontitis experienced prior gingivitis. The occurrence of periodontitis depends on the individual immune response that modifies the onset and progression of the disease.[56,68,70]

Attachment and bone loss are associated with an increase in the proportion of gram-negative organisms in the subgingival biofilm, with specific increases in organisms known to be pathogenic and virulent. *Porphyromonas gingivalis*, *Tannerella forsythia*, and *Treponema denticola*, otherwise known as the *red complex bacteria,* are

frequently associated with ongoing attachment and bone loss in chronic periodontitis.[91] Development and progression of chronic periodontitis may not depend on the presence of one specific bacterium or bacterial complex alone. It is assumed that chronic periodontitis is the sequelae of a multispecies infection with a number of different bacteria that influence the proinflammatory immune response of the host.[46,82] Furthermore, the concept of host-microbial interactions has gained scientific attention. It has been found that increased numbers of periodontal pathogens contribute to the development of a dysbiotic microbial environment, which is triggered by the inflammatory milieu in the periodontal pocket.[2,36] This concept describes a shift from a symbiotic microbial environment to the development of dysbiosis within the biofilm involving so-called keystone pathogens, such as *P. gingivalis*, as a polymicrobial synergistic effect.[33–35] Periodontal pathogens like *P. gingivalis* may then invade the periodontal tissue and therewith induce further immune responses with increasing concentrations of proinflammatory mediators that may enhance periodontal breakdown. In addition, a number of periodontal pathogens are capable of producing proteases that directly affect the tissues and host immune responses.[70]

Local Factors

Plaque accumulation and biofilm development are the primary causes of periodontal inflammation and destruction. Therefore factors that facilitate plaque accumulation or prevent plaque removal by oral hygiene procedures can be detrimental to the patient. Plaque-retentive factors are important in the development and progression of chronic periodontitis because they retain microorganisms in proximity to the periodontal tissues, providing an ecologic niche for biofilm maturation. Calculus is considered the most important plaque-retentive factor because of its ability to retain and harbor plaque bacteria on its rough surface as well as inside.[42,89] As a consequence, calculus removal is essential for the maintenance of a healthy periodontium. In addition, the tooth morphology may influence plaque retention. Roots may show grooves or concavities, and in some instances, enamel projections

on the surface or furcation entrances. Those morphologic variations may facilitate plaque retention, subgingival calculus formation, and disease progression.[29,40,78] In addition, subgingival and overhanging margins of restorations, carious lesions that extend subgingivally, and furcations exposed by loss of bone promote plaque retention.[50,101]

Common Retentive Local Factors That Contribute to Chronic Periodontitis

- Dental calculus
- Crown margins
- Restoration overhangs
- Furcation involvement
- Deep probing depths
- Anatomic grooves on the roots
- Subgingival caries or resorptive lesions

Systemic Factors

Chronic periodontitis is a complex disease that may not be limited to infection at local sites, but in several instances periodontitis is also associated with other systemic disorders, such as Haim–Munk syndrome, Papillon–Lefèvre syndrome, Ehlers–Danlos syndrome, Kindler syndrome, and Cohen syndrome. Patients who suffer from diseases that impair host immune responses (e.g., HIV/AIDS) may also show periodontal destruction. Further, it is also known that osteoporosis, severe unbalanced diet, and stress, as well as dermatologic, hematologic, and neoplastic factors, interfere with periodontal inflammatory responses. In addition to defined syndromes, periodontitis is also associated with severe systemic diseases, such as diabetes mellitus, cardiovascular disorders, stroke, and lung disorders.[1,9,45,67,70,98,99,102]

Periodontitis is now considered as the sixth complication of diabetes mellitus.[27,61] For diabetes mellitus and periodontitis, there is a known interaction during which both diseases mutually

correlate to each other.[54] Patients with diabetes mellitus exhibit a higher risk to develop periodontitis, and the periodontal infection/inflammation may negatively interfere with the glycemic control of the diabetic patient.[73] A number of studies showed that prevalence, severity, and prognosis of periodontitis are associated with the incidence of diabetes mellitus. It was found that the average pocket depth as well as the clinical attachment loss was increased in patients with diabetes mellitus (independently from the type of diabetes mellitus).[15,47,73,81] Patients with poor glycemic control tend to experience more severe progression of periodontitis compared to patients with good glycemic control. Regarding the progression of severe periodontitis, no difference was found between patients with good glycemic control and nondiabetic patients.[100] With diabetes mellitus, advanced glycation end products (AGEs) may arise, which lead to the release of free oxygen and proinflammatory mediators (cytokines). AGEs may also promote chemotaxis and adhesion of inflammatory cells to periodontal tissues, and increased apoptosis of fibroblasts and osteoblasts may occur.[31] Furthermore, patients with diabetes mellitus tend to show a higher body mass index, and therefore increased concentrations of adipokines that directly influence inflammatory responses were found.[74] Hyperglycemia per se leads to the release of proinflammatory mediators in the bloodstream, which in turn promote increased glucose concentration.[73] Periodontal therapy may contribute to glycemic control of the diabetic patient. It was shown that the systematic therapy of chronic periodontitis leads to an at least short-term reduction of glycated hemoglobin (HbA1c) of approximately 0.3% up to 0.6%.[7,9,41,57,90] Each therapy regimen that contributes to achieve reduction of glycated hemoglobin may decrease the risk of diabetes-related long-term consequences, such as myocardial infarction, microvascular complications, and many others.[73]

In the context of diabetes mellitus, a number of patients exhibit an increased body weight (obesity), which also correlates with the prevalence and severity of periodontal attachment and bone loss.[66] The negative effect of a high body mass index with regard to the outcome of periodontal therapy was comparable to the negative effect that has been described for smoking.[93]

Immunologic Factors

Chronic periodontitis is a disease induced by bacteria organized in the dental biofilm. Onset, progression, and severity of the disease depend, however, on the individual host immune response.[26,68] Patients may show alterations of peripheral monocytes, which relate to reduced reactivity of lymphocytes or enhanced B-cell response.[68,70] Not only B cells and macrophages, but also periodontal ligament cells, gingival fibroblasts, and epithelial cells synthesize proinflammatory mediators—such as interleukin-1 beta (IL-1 beta), IL-6, IL-8, prostaglandin-E2 (PGE2), tumor-necrosis factor alpha (TNF-alpha), and many others—that modify innate and adaptive immune responses at periodontal sites.[11,18–21,48,75] Proinflammatory mediators regulate synthesis and secretion of matrix-metalloproteinases (MMPs) and receptor-activator-of-NF-kappaB-ligand (RANKL). In periodontal lesions, MMPs contribute to soft and hard tissue degradation during active inflammatory processes.[26] RANKL binds to its receptor RANK on the cell surface of premature osteoclasts, and therewith it initiates osteoclast differentiation leading to degradation of alveolar bone.[26,48,75] Physiologically, osteoprotegerin (OPG) is an inhibitor of RANKL, and during periodontitis, an imbalance between OPG and RANKL promotes further bone degradation.[26]

In addition, reduced counts in neutrophils (polymorphonuclear neutrophils [PMNs]) influence the degree of periodontal inflammation. Congenital neutropenia (Kostmann syndrome) leads not only to an increased susceptibility to infection in general, but also to severe chronic periodontitis. Patients with Kostmann syndrome show reduced levels of antimicrobial peptides, such as the cathelicidin (LL-37) and neutrophil peptides (alpha defensins), which impair their innate immune response.[8,76] LL-37 is an effective antimicrobial peptide that is synthesized from inactive precursors, and mutations in the cathepsin C gene hinder cleavage, and therewith activation, of LL-37. Those genetic alterations contribute to the severity and progression of chronic periodontitis (Papillon–Lefèvre syndrome, Haim–Munk syndrome).[13,38]

Genetic Factors

Periodontitis is considered to be a complex inflammatory disease influenced by local, systemic, and immunologic factors (discussed earlier). Each factor is in turn directly related to individual genetic conditions. Several genetic disorders are known to show periodontal destruction as one of their major symptoms. For example, Papillon–Lefèvre syndrome is a well-known genetic disorder (a defect on chromosome 11) that exhibits not only palmoplantar hyperkeratosis but also severe periodontitis.[23,37,51] Besides Papillon–Lefèvre syndrome, Haim–Munk syndrome, Ehlers–Danlos syndrome, Down syndrome, Kindler syndrome, Cohen syndrome, and congenital neutropenia (Kostmann syndrome) are other genetic disorders that have been related to periodontal disease. These genetic conditions are discussed extensively in Chapter 11.

Periodontal disease has been found in different family members (twins, siblings) and generations of one family. Early twin studies suggested the involvement of genetic susceptibility factors in the etiopathogenesis of periodontitis.[63] In a number of studies, the prevalence of aggressive and chronic periodontitis has been investigated in families with a history of one or more family members with periodontitis. The data from those studies showed variable results with a likelihood for heritability of up to 50%. Variations are mainly due to different study designs as well as the number of evaluated individuals.[3,60,64,83]

Treatment of Chronic Periodontitis

Chronic periodontitis can be treated effectively by a systematic periodontal therapy that includes optimal long-term plaque control, debridement of soft and hard deposits, or surgical pocket reduction (case-dependently either resective osseous surgery or regenerative surgery; Figs. 27.4 and 27.5). Depending on the individual periodontal risk, each patient should be remotivated, reinstructed, and retreated (if necessary) during a systematic supportive periodontal therapy regimen (revisits every 3, 6, or 12 months; Fig. 27.6).

In addition, other genetic variations (single nucleotide polymorphisms [SNPs], genetic copy number variations) that have so far not been identified as responsible for certain syndromes may also directly influence innate and adaptive immune responses as well as the structure of periodontal tissues. The identification of genes that are relevant to the development of periodontitis has led to new scientific concepts and findings. There are at least two different strategies (candidate genes and genome-wide associations) to identify genetic variances in relation to disease. In candidate gene studies, certain already known variances (SNPs) are correlated to a specific phenotype such as periodontitis. Therefore a hypothesis is required in order to choose specific SNPs in relevant genes. The data from those studies showed variable results, making it challenging to draw clear conclusions. In this context, studies on SNPs in the IL-1 gene led to the early conclusion that alterations in sequences of immunologically relevant genes may explain the heritability of periodontitis.[49] Conflicting data in the literature, however, indicate inconclusive knowledge regarding SNPs in the IL-1 gene and their potential role in the heritability and etiopathogenesis of periodontitis.[53] Also, it seems implausible that a single polymorphism in a specific gene sequence can cause a complex inflammatory disease, such as periodontitis, without causing any other symptoms relevant to one's systemic health. Thus genome-wide association studies (GWASs) have become more relevant. Here, a high number of DNA-sequence variances are evaluated at the same time. In contrast to candidate gene studies, no hypotheses are required for GWASs, so that there is no potential bias during analysis. In several GWASs, a number of new genes have been identified to be associated with periodontitis. One of the best replicated genes is called *ANRIL* (antisense RNA in the Inc locus). *ANRIL* is associated not only with periodontitis but also with cardiovascular disease, which underlines potential systemic interactions.[12,85–87] The role of *ANRIL* during the development of periodontitis is subject to ongoing investigations. It is known that it represents a noncoding regulatory RNA, which is involved during the regulation of cell division and in affecting other genes that play a role in the glucose and lipid metabolism *(ADIPOR1, VAMP3, C11ORF10).*[6,16,103] In addition to *ANRIL*, genetic variances (SNPs) in

the sequences of the glucosyltransferase-6 domain containing 1 gene *(GLT6D1),* the plasminogen gene (*PLA*), and the neuropeptide Y gene *(NPY)* have been associated with periodontal disease.[25,84,88] Due to the current technical and scientific progress, it may be expected that more genes will be identified to be associated with periodontitis in the future.

Environmental and Behavioral Factors

In addition to microbial, immunologic, and genetic factors, the development and progression of chronic periodontitis is further influenced by environmental and behavioral factors such as smoking and psychological stress[68,70] Smoking is a major risk factor for the development and progression of generalized chronic periodontitis.[4] Periodontitis is influenced by smoking in a dose-dependent manner. The intake of more than 10 cigarettes per day tremendously increases the risk of disease progression when compared to nonsmokers and former smokers, respectively.[97]

Compared to nonsmokers, the following features are found in smokers[5,43,72,80]:

- Increased periodontal pocket depth with more than 3 mm
- Increased attachment loss
- More recessions
- Increased loss of alveolar bone
- Increased tooth loss
- Fewer signs of gingivitis (less bleeding upon probing)
- A greater incidence of furcation involvement

Due to the consumption of tobacco, reactive oxygen (radicals) is released that chemically irritates periodontal tissues by DNA damage, lipid peroxidation of cell membranes, damage of endothelial cells, and the induction of smooth muscle cell growth.[65]

Psychological factors, such as stress and depression, also

negatively influence the progression of chronic periodontitis.[30] Patients with periodontitis often report the experience of family- or work-related stress.[71] Positive correlations between cortisol levels and periodontal indices (plaque index, gingival index), bone loss, and missing teeth were recorded.[17,30,77] In addition, stress as an etiologic factor was even strongly associated with periodontitis when patients were smokers compared to nonsmokers.[10]

Stress and Periodontal Disease: Potential Mechanisms

1. Immunosuppression via cortisol secretion
2. Poor oral hygiene compliance in patients with chronic stress
3. Patients with stress are less likely to seek professional care
4. Patients with stress may smoke more frequently

Case Scenario 27.1

Patient:
46-year-old female

Chief Complaint:
"My lower incisors are becoming loose."

Background Information
This patient is a smoker (20 cigarettes per day, 30 pack-years) with controlled hypertension. She did not report any other systemic conditions. The patient is currently taking lisinopril for hypertension management and receives annual medical examinations. She reports brushing once a day but not using interdental cleaning aids. For 2 years, she recognized tooth loosening in the lower incisor region.

Current Findings:
Probing depths were in the range of 5 to 8 mm, bleeding on probing was 65%, poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Which type of nonsurgical periodontal therapy is most effective in reducing periodontal probing depths and gaining clinical attachment level in patients with chronic periodontitis? A. Quadrant-wise scaling and root planing B. Full-mouth scaling C. Full-mouth disinfection D. All of the above	**Answer: D** **Explanation:** According to a current systematic review of the Cochrane Collaboration, no one periodontal nonsurgical treatment modality is superior to others with regard to its efficacy in reducing probing pocket depth, clinical attachment gain, and reduction of bleeding on probing.[44]
2. Does the adjunctive administration of systemic antibiotics provide added benefit for reducing periodontal probing depth in smokers with generalized chronic periodontitis, in addition to nonsurgical periodontal therapy? A. Yes B. No	**Answer: B** **Explanation:** A current systematic review and meta-analysis showed no benefit for smokers after systemic adjunctive antibiotic therapy. Instead, a majority of studies noted that smokers benefited from locally administered antibiotics.[73]
3. Smoking is a well-known risk factor for chronic periodontitis. Does the risk for chronic periodontitis change in patients who quit smoking compared to patients who continue to smoke?	**Answer: B** **Explanation:** The risk for periodontal disease after smoking cessation lowers continuously. In the first few years after smoking cessation, the risk ranges between the risk for smokers and that for never-smokers.[9] Three years following smoking cessation, the risk for periodontal disease is three times higher in former smokers when compared to the risk of never-smokers. After eleven years, the risk for periodontal

A. The risk for future periodontal disease immediately following smoking cessation is comparable to never-smokers. B. The risk lowers continuously, and 11 years after smoking cessation the risk is comparable to a never-smoker. C. The risk for periodontal disease does not change after smoking cessation.	disease is similar between former smokers and never-smokers.[32]

Case Scenario 27.2

Patient:

48-year-old male

Chief Complaint:

"My gum is bleeding so much."

Background Information

This patient is a nonsmoker suffering from type 2 diabetes mellitus. His hemoglobin A1c parameter has ranged from 8.5% to 9.3% within the past 10 years. He takes 500 mg metformin three times a day. Furthermore, he reports a high normal blood pressure and is not taking antihypertensive medications. The patient reports brushing his teeth twice a day and not using interdental cleaning aids.

Current Findings:

Probing depths were in the range of 4 to 7 mm, bleeding on probing was 72%, poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What percentage change of glycated hemoglobin (HbA1c as a percentage) can be expected 3 months after nonsurgical periodontal therapy in patients with diabetes mellitus and chronic periodontitis? A. Approximately 0.5% B. Approximately 1% C. More than 1%	**Answer: A** **Explanation:** A current systematic review and meta-analysis detected an improvement of 0.48% (95% confidence interval: 0.18%–0.78%) regarding the glycated hemoglobin (HbA1c) 3 months after nonsurgical periodontal therapy in patients with diabetes mellitus. Systemic adjunctive antibiotics did not result in additional improvements in hemoglobin A1c reduction.[44]
2. Does locally administered antibiotics in combination with nonsurgical periodontal	**Answer: B** **Explanation:** Current data indicate an improvement of clinical periodontal parameters (pocket probing depths

therapy lead to improvements of periodontal pocket depths in patients with chronic periodontitis and diabetes? A. Yes, independent of the glycemic control, there will be an improvement in periodontal probing depths. B. Yes, especially well-controlled diabetic patients benefit from locally administered antibiotics. C. No, periodontal parameters will not improve after usage of locally administered antibiotics in diabetic patients.	and clinical attachment level), especially in patients with well-controlled diabetes.[73]
3. Do diabetic patients with chronic periodontitis benefit from adjunctive systemic antibiotics? A. Yes B. No	**Answer: A** **Explanation:** Adjunctive use of systemic antibiotics in diabetic patients provides a small but measurable additional benefit in terms of reductions in mean periodontal pocket depths and mean percentage of bleeding on probing.[9]

CHAPTER 28

Aggressive Periodontitis

Moritz Kebschull, Henrik Dommisch

CHAPTER OUTLINE

Overview
Historical Background
Classification and Clinical Characteristics
Epidemiology
Pathobiology and Risk Factors
Therapeutic Considerations in Aggressive Periodontitis Patients

Overview

Periodontitis is the pathologic manifestation of the host response against bacterial challenge that stems from a polymicrobial biofilm at the biofilm–gingival interface.[55] There are several subforms of the disease primarily defined by their clinical phenotype (i.e., the rate of disease progression and other features) rather than their (still

partially unknown) etiology. This chapter addresses aggressive periodontitis, a clinically challenging subform of periodontitis featuring rapid loss of periodontal attachment and tooth supporting bone in otherwise healthy patients.

Historical Background

In 1923 Gottlieb reported on a patient with a fatal case of epidemic influenza and a disease that Gottlieb called "diffuse atrophy of the alveolar bone."[25] This disease was characterized by a loss of collagen fibers in the periodontal ligament and their replacement by loose connective tissue and extensive bone resorption, resulting in a widened periodontal space. The gingiva apparently was not involved. In 1928 Gottlieb attributed this condition to the inhibition of continuous cementum formation, which he considered essential for maintenance of the periodontal fibers.[26] He then termed the disease *deep cementopathia* and hypothesized that this was a "disease of eruption" and that cementum initiated a foreign body response. As a result, it was postulated that the host attempted to exfoliate the tooth, resulting in the observed bone resorption and pocket formation.

In 1938 Wannenmacher described incisor–first molar involvement and called the disease *parodontitis marginalis progressiva*.[85] Several explanations evolved for the etiology and pathogenesis of this type of disease. Many authors considered this to be a degenerative, noninflammatory disease process and therefore gave it the name *periodontosis*.[24,57,81] Other investigators denied the existence of a degenerative type of periodontal disease and attributed the changes observed to trauma from occlusion.[11,51] Finally, in 1966, the World Workshop in Periodontics concluded that the concept of "periodontosis" as a degenerative entity was unsubstantiated and that the term should be eliminated from periodontal nomenclature.[62] The committee did recognize that a clinical entity different from *adult periodontitis* might occur among adolescents and young adults.

The term *juvenile periodontitis* was introduced by Chaput and colleagues in 1967 and by Butler in 1969.[10] In 1971, Baer defined it as "a disease of the periodontium occurring in an otherwise healthy

adolescent which is characterized by a rapid loss of alveolar bone about more than one tooth of the permanent dentition. The amount of destruction manifested is not commensurate with the amount of local irritants."[6] In 1989 the World Workshop in Clinical Periodontics categorized this disease as *localized juvenile periodontitis (LJP),* a subset of the broad classification of *early-onset periodontitis (EOP).*[12] Under this classification system, age of onset and distribution of lesions were of primary importance when making a diagnosis of LJP.

In 1999 the World Workshop in Periodontics introduced a novel classification that was meant to eliminate the shortcomings of earlier endeavors in classifying periodontal disease. Importantly, the new 1999 classification sought "to discard classification terminologies that were age-dependent or required knowledge of rates of progression."[3] In the new classification scheme, several rapidly progressing periodontitis forms were united under the term *aggressive periodontitis.*

A new World Workshop in Periodontics was jointly planned by the European Federation of Periodontology and the American Academy of Periodontology for November 2017 in order to further refine the classification of periodontal diseases. Please check Expert Consult site for update.

Classification and Clinical Characteristics

Features

The 1999 international classification workshop defined the entity of aggressive periodontitis to be characterized by three primary features (Table 28.1)[43]:

TABLE 28.1

Diagnostic Criteria to Distinguish Chronic and Aggressive Periodontitis

Criterion	Aggressive Periodontitis	Chronic Periodontitis
Rate of progression	Rapid	Slow; rapid episodes possible
Familiar aggregation	Typical	Can be present when families

		share imperfect oral hygiene habits
Presence of etiologic factors (plaque, calculus, overhanging restorations, etc.)	Often minimal	Often commensurate with observed periodontal destruction
Age	Often in young patients (<35 years) but can be found in all age groups	Often in older patients (>55 years) but can be found in all age groups
Clinical inflammation signs	Sometimes lacking (especially in localized aggressive periodontitis)	Commensurate with etiologic factors

1. *Rapid loss of attachment and tooth-supporting bone.* In aggressive periodontitis, as compared to the more common variant chronic periodontitis, the loss of attachment progresses significantly faster. To evaluate this rapid course of destruction, the evaluation of clinical or radiographic data from earlier points in time (allowing for making an estimate of the start of disease) is necessary.[56] Note that the age of the patient is per se no primary criterion for the diagnosis of aggressive periodontitis. Because earlier clinical records are often not available, many clinicians argue that severe loss of attachment in young patients conceivably must be due to a rapid course of disease progression. This is, however, not generally true—neglect of all oral hygiene in a periodontitis-susceptible individual over a decade will lead to severe attachment loss, even with a slow rate of progression. On the other hand, severe attachment loss in an older individual is not necessarily the result of long-lasting, slowly progressing disease. It is therefore inappropriate to use the age of an individual as a primary diagnostic criterion for the distinction of aggressive and chronic periodontitis. Note that in chronic periodontitis, there are reportedly periods of rapid disease progression that can by themselves be misinterpreted as aggressive periodontitis.
2. *Subject is otherwise healthy (i.e., not suffering from any systemic disease or condition that could be responsible for the present periodontitis).* There are systemic diseases that lead to severely altered host defenses against periodontal pathogens, often resulting in rapid loss of attachment and tooth loss at an early age. This disease is designated

"periodontitis as a manifestation of systemic disease" (see Chapter 14). Note that the specific properties or abnormalities of some types of immune cells listed here and reported to be often associated with the diagnosis of aggressive periodontitis do not themselves qualify for the aforementioned diagnosis.

3. *Familiar aggregation.* Familiar aggregation of aggressive periodontitis cases is a feature that can be evaluated by medical/dental history questionnaires and interviewing the patient. It is, however, advisable to verify similar cases in the family, if possible, as many individuals may not be fully aware of their diagnoses and not a few cases of "bad teeth that run in the family" turn out to be caries related or likely due to chronic periodontitis. In addition, the workshop defined several secondary features that are generally found in aggressive periodontitis cases but that are not universally necessary to diagnose the disease entity:
    a. Inconsistency of the low amounts of present etiologic factors and the observed pronounced tissue destruction
    b. Strong colonization by *Aggregatibacter actinomycetemcomitans* and (in some populations) *Porphyromonas gingivalis*
    c. Immunologic differences that do not entail the diagnosis "periodontitis as a manifestation of systemic disease":
        - Hyperresponsive macrophages
        - Abnormalities of neutrophil function
    d. Self-limiting disease

Subgroups

Aggressive periodontitis can be subclassified into a localized and generalized form. The diagnosis of the subcategory is based on clinical, radiographic, and historical data. These include the age of onset, the involvement of teeth other than first molars and incisors (the first permanent teeth to erupt), and the presence of a systemic antibody response against periodontal pathogens (see Table 28.2).

TABLE 28.2

Diagnostic Criteria for Localized and Generalized Aggressive Periodontitis

Criterion	Localized Aggressive Periodontitis	Generalized Aggressive Periodontitis
Age of onset	Circumpubertal	Most often <30 years of age, but can occur in older individuals too
Serum antibody response against infecting agents	Robust	Poor
Destruction pattern	Localized attachment loss at incisors and first molars—interproximal attachment loss at ≥ 2 permanent teeth, one of which is a first molar, and involvement of ≤ 2 teeth, other than first molars and incisors	Generalized interproximal attachment loss at ≥3 permanent teeth other than first molars and incisors
Additional		Episodic nature of attachment loss

Generalized Aggressive Periodontitis

Generalized aggressive periodontitis (GAP) is the subgroup of periodontal disease characterized by the highest severity and extent of disease, but also by its large heterogeneity. The diagnosis of GAP encompasses the diseases previously classified as *generalized juvenile periodontitis (GJP)* and *rapidly progressive periodontitis (RPP).*

Two gingival tissue responses can be found in cases of GAP (Figs. 28.1 and 28.2). One is a severe, acutely inflamed tissue, often proliferating, ulcerated, and fiery red. Bleeding may occur spontaneously or with slight stimulation. Suppuration may be an important feature. This tissue response is believed to occur in the destructive stage, in which attachment and bone are actively lost.

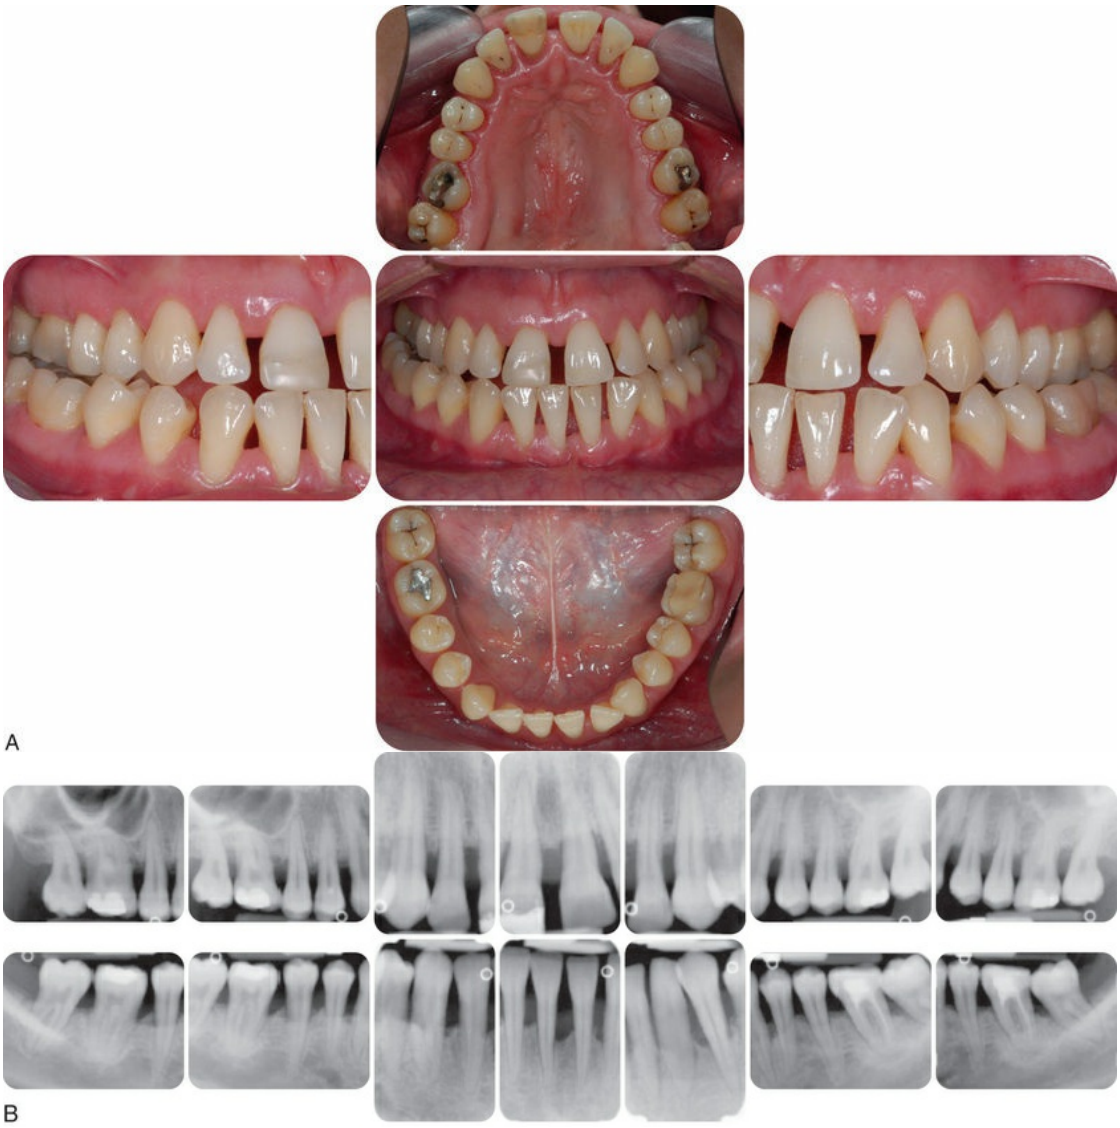

FIG. 28.1 **Case Presentation: Generalized Aggressive Periodontitis**
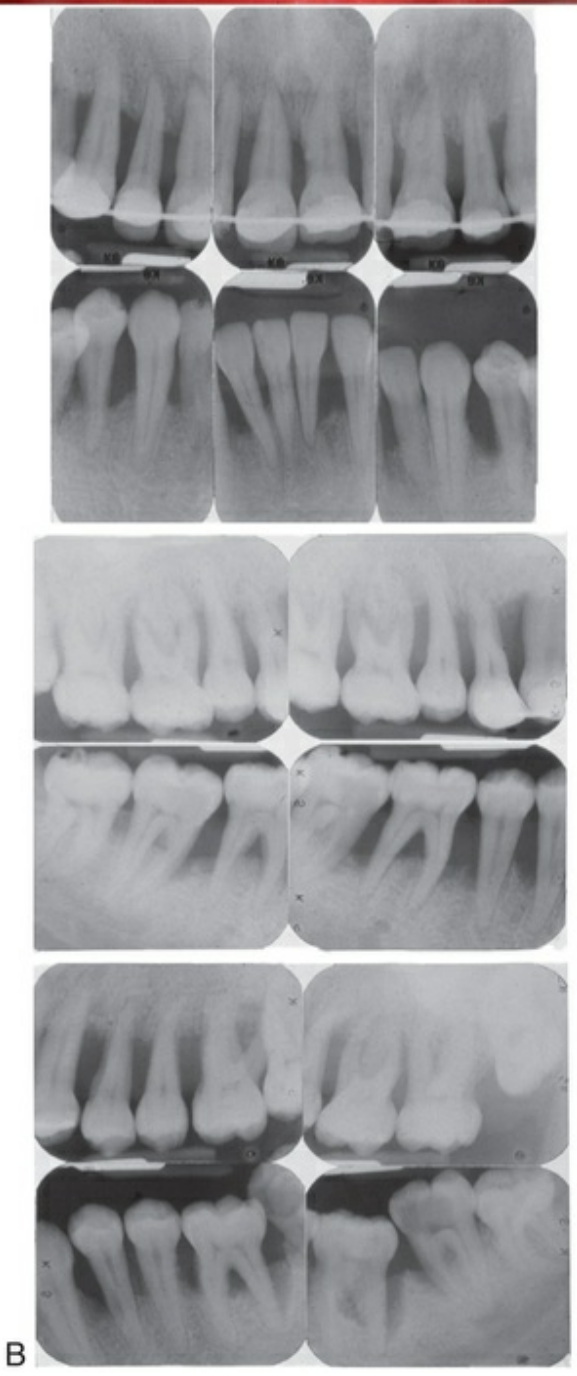
Generalized aggressive periodontitis in a 28-year-old white female, nonsmoking patient. (A) Clinical views with minimal amounts of calculus and plaque. (B) Radiographically, bone loss ≥50% was present at all teeth.



1924

FIG. 28.2 Case Presentation: Generalized Aggressive Periodontitis Severe generalized aggressive periodontitis in a 22-year-old black male patient with a family history of early tooth loss through periodontal disease. (A) Clinical view showing minimal plaque and inflammation. A provisional wire-and-resin splint had been placed by the general-practice dentist to stabilize the teeth. (B) Radiographs showing the severe, generalized nature of the disease with all erupted teeth affected.

In other cases the gingival tissues may appear pink, free of inflammation, and occasionally with some degree of stippling, although stippling may be absent. However, despite the apparently mild clinical appearance, deep pockets can be demonstrated by probing. Page and Schroeder believed that this tissue response coincides with periods of quiescence in which the bone level remains stationary.[58]

Localized Aggressive Periodontitis

Localized aggressive periodontitis (LAP) is usually found in younger individuals than those affect by GAP (Figs. 28.3 and 28.4). It is characterized by more pronounced systemic antibody titers against periodontal pathogens than found in GAP patients. This could indicate that in individuals susceptible to disease, but with the ability to enact a robust response against pathogens, the disease might be limited in extent (i.e., LAP), whereas in individuals with a lesser humoral response, the disease would not be limited to the first permanent teeth (i.e., the patient would develop GAP). This would mean that LAP and GAP would merely be phenotypic variations of the same underlying disease. This assumption is backed by several reports that show a sequence of LAP and GAP in the same individuals over time.[9,31,74] On the other hand, several lines of evidence exist that support a claim that LAP constitutes a disease on its own, with dissimilar underlying molecular and cellular mechanisms.

FIG. 28.3 **Case Presentation: Localized Aggressive Periodontitis** Localized aggressive periodontitis in a 15-year-old black female patient who had a twin with a similar disease. (A) Clinical view showing minimal plaque and inflammation except for localized inflammation on the distal side of the maxillary left central incisor and the mandibular right central incisor. (B) Radiographs showing localized, vertical, angular bone loss associated with the maxillary and mandibular first molars and the mandibular central incisors. The maxillary incisors show no apparent involvement. (C) Surgical appearance of the localized, vertical, angular bony defects affecting the mandibular incisors. Note the wide circumferential nature of the defects and the lack of calculus on the root surfaces.

FIG. 28.4 **Case Presentation: Localized Aggressive Periodontitis**
Localized aggressive periodontitis in an 18-year old white female, nonsmoking patient. Familiar aggregation was reported. (A) Clinical view showing recessions at incisors and first molars. (B) Intraoperative view showing massive localized, angular bony defect associated with a first molar. (C) Radiographs showing pronounced

localized, angular bone loss. (Courtesy Dr. Hendrik Schulze, Bonn, Germany.)

Epidemiology

The question of the prevalence of aggressive periodontitis in different populations is complicated by the fact that the currently used classification[3] is relatively young and not easy to apply in epidemiologic studies. Therefore many available studies either (1) report on older, previously used entities of periodontitis that showed early onset or rapid progression but are not interchangeable with aggressive periodontitis or (2) report only on periodontitis severity, not on diagnosis (for detailed reviews, see Albandar[2] and Susin and Albandar[78]). The problem of a lacking universal case definition for epidemiologic research is critical, because different case definitions for periodontitis in adolescents described differences in prevalence of up to 10-fold.[47]

Case Definition

The diagnosis of aggressive periodontitis in epidemiologic studies is difficult, because all primary criteria for the disease—rapid progression, systemic health, and familiar aggregation—are difficult to reliably assess in the setting of such a study. The criteria of systemic health and familiar aggregation would require extensive interviews and thorough verification. The rapid progression of disease can consistently be documented only by following a subject longitudinally and performing at least two subsequent examinations within a reasonable time frame or (as noted previously) be extrapolated from older clinical or radiographic records. These, however, are frequently not available and would add extensive bias to the study, as prior providers of oral care were not calibrated. Radiographic examinations at the time of examination are, in the setting of an epidemiologic study, most often unfeasible.[2]

As a result, to date, methodologically sound epidemiologic studies investigating aggressive periodontitis as defined by the 1999 workshop are sparse (e.g., the study performed in a population of

young Israeli army recruits).[44]

Therefore to be able to assess the prevalence of aggressive periodontitis in other populations, Demmer and Papapanou[16] proposed to utilize the generally accepted case definition (see Chapter 6) for periodontitis proposed by a working group of the US Centers for Disease Control and Prevention (CDC) and the American Academy of Periodontology[17,59] in combination with the age of the study subject. Specifically, they assessed available studies for the proportion of subjects of ≤25 years of age who suffered from moderate or severe periodontitis according to the CDC definition, and the proportion of subjects 26 to 35 years of age who suffered from severe periodontitis (CDC definition). Similarly, Susin and Albandar[78] used a combination of diagnostic criteria to identify possible aggressive periodontitis cases in studies not designed following the 1999 classification.

Localized Aggressive Periodontitis

The prevalence of LAP in an Israeli army population ages 18 to 30 years was 4.3%. In this cohort, the presence of LAP was highly correlated with North African origin and current smoking.[44] A study of 830 Moroccan school students ages 12 to 25 years using the modified aggressive periodontitis definition of Albandar and coworkers[2] reported a prevalence of 4.9% for aggressive periodontitis, with approximately 70% exhibiting strong attachment loss at the molar sites.[37]

In addition to these data, several studies have examined the prevalence of LJP, the predecessor of LAP (however, not exactly interchangeable), from diverse populations. The prevalence of this disease in geographically diverse adolescent populations was estimated at less than 1%. Most reports suggested a low prevalence of about 0.2%.[45] Two independent radiographic studies of 16-year-old adolescents, one in Finland[66] and the other in Switzerland,[39] followed the strict diagnostic criteria delineated by Baer[6] and reported a prevalence rate of 0.1%. A clinical and radiographic study of 7266 English adolescents 15 to 19 years old also showed a prevalence rate of 0.1%.[65] In the United States, a national survey of adolescents ages 14 to 17 reported that 0.53% had LJP.[45] Blacks were

at much higher risk for LJP, and black male teenagers were 2.9 times more likely to have the disease than black female adolescents. In contrast, white female teenagers were more likely to have LJP than white male adolescents. Several other studies have found the highest prevalence of LJP among black males,[9,49,65] followed in descending order by black females, white females, and white males.[49]

JCP was reported to affect both males and females and is seen most frequently in the period between puberty and 20 years of age. Some studies have suggested a predilection for female patients, particularly in the youngest age groups,[31] whereas others reported no male–female differences in incidence when studies are designed to correct for ascertainment bias.[28]

Generalized Aggressive Periodontitis

Among young Israeli army recruits, 1.8% suffered from GAP.[44] When using extrapolation, as proposed by Demmer and Papapanou, a prevalence of about 1% to a maximum of 15% within the age range was found, depending on the study. Specifically, data from the German Study of Health in Pomerania indicate an extrapolated prevalence within the age group of 13% (≤29 years) and 7% (30–39 years), whereas the highest extrapolated prevalence was found in the Eerie County study, with up to 15% of the age group.

Note that, as indicated previously, using prior epidemiologic data for the heterogeneous predecessors of GAP, GJP, and RPP to assess GAP prevalence is not possible because these entities are not interchangeable with GAP. In contrast, LJP, although still different from LAP by definition, can be used as a surrogate for LAP.

Current Understanding

Taken together, these data primarily show that the discrimination of aggressive periodontitis and other forms of periodontitis is not always easy, especially when the patient is seen for only a single examination, as is the case in most epidemiologic studies. The prevalence of aggressive periodontitis of approximately 1% to 15% in subjects of ≤35 years of age, in combination with the severity and

tendency for rapid progression of this disease, strongly suggests that all patients in this age group should be screened regularly for the presence of periodontal disease.

Pathobiology and Risk Factors

All forms of periodontitis share certain common pathobiologic principles as polymicrobial, biofilm-mediated chronic inflammatory diseases at the biofilm-gingival interface. These principles are addressed in detail in Chapters 7 to 9. Herein we focus on the biologic reasons for the rapid course of destruction in aggressive periodontitis, including work investigating the specific properties of aggressive periodontitis in periodontal microbiology, immunology, and genetics.

Microbiology

Periodontitis is caused by specific microorganisms in a susceptible host.[61] In the subgingival biofilm, up to 700 bacterial species have been identified,[40] some of which were identified to be causative.[14] Details on the current knowledge on different periodontal microorganisms are summarized in Chapters 8 and 9.

The observed higher rate of disease progression in aggressive versus chronic periodontitis could possibly be explained by the presence of specific microorganisms that cause and perpetuate tissue destruction. In addition, the reported familiar aggregation of aggressive periodontitis cases could also be, to a certain point, explained by an infection and within-family transmission of specific microorganisms.

Therefore several studies have sought to identify the specific microbial properties of aggressive periodontitis cases. However, when evaluating generalized and localized aggressive periodontitis as a single entity and solely focusing on a small number of "classic" pathogens, it has been concluded that microbiologic infection patterns could not reliably distinguish between this entity and chronic periodontitis cases.[52]

However, data from a limited number of studies using both classic microbiologic tools and more recent molecular techniques

suggest that differences exist in the microbiologic composition between (1) localized aggressive periodontitis and both generalized aggressive and chronic periodontitis and (2) generalized aggressive and chronic periodontitis[20,23,41,63] (for a review, see Armitage[4]).

Specific Bacteria in Localized Aggressive Periodontitis

In localized aggressive periodontitis, the situation seems to be different. Here, several lines of evidence point to a strong role of specific microorganisms, most notably *A. actinomycetemcomitans.* For decades, this bacterial species has been associated with LAP[7,13,75] and could predict the development of LAP in two longitudinal studies.[21,30] Longitudinal studies are of critical importance for demonstrating a causal relationship, whereas cross-sectional studies can by definition only show correlations that cannot be used to infer causality.

In the first longitudinal study, age-, gender- and race-matched juvenile carriers and noncarriers of *A. actinomycetemcomitans* (serotypes a, b, c equally distributed, no JP2) were followed longitudinally. After 1 year of follow-up, 80% of the carriers, but only 10% of the noncarriers, had developed periodontitis.[21]

In the second, larger longitudinal study, the highly leukotoxic *A. actinomycetemcomitans* (serotype b) strain JP2, which has a 530-bp deletion in its leukotoxin gene operon that leads to a 10- to 20-fold higher production of leukotoxin,[29] was found to be directly related to the occurrence of LAP in children in northern Africa. Specifically, the OR for future attachment loss in carriers of the JP2 strain was 18.0, as compared to 3.0 for carriers of other, non-JP2 strains of *A. actinomycetemcomitans*.[30] Similar findings can be found in West African countries (e.g., Ghana[1]) in contrast to eastern parts of Africa where no studies have reported on JP2 clone strain in periodontitis patients.[18]

A recent study on the occurrence of JP2 clone strains in aggressive periodontitis patients shows a high incidence in both LAP and GAP, suggesting that both subclasses could be more related than initially thought.[19]

In addition, it needs to be noted that, as with all entities of periodontitis, LAP is clearly not a monoinfection with *A. actinomycetemcomitans* but features a polymicrobial biofilm.

Supporting this notion are reports of confirmed cases of LAP that did not carry *A. actinomycetemcomitans*.[41,53]

Host Response to Bacterial Challenge

The inflammatory host response toward pathogens is generally attributed to be responsible for a larger proportion of the tissue destruction in periodontitis than the invading periodontal pathogens themselves. The rapid progression of aggressive periodontitis implies that, in addition to the aforementioned composition of the subgingival microbiologic flora, specific properties of this inflammatory response renders the individuals suffering from aggressive periodontitis both more susceptible to disease and more prone to lose more attachment in a shorter time.

Host Responses Specific to Aggressive Periodontitis

In generalized aggressive periodontitis, one review concluded that "there appears to be no difference between aggressive and chronic periodontitis in terms of their histopathology and immunopathology."[76] Still, it has to be acknowledged that this could mean that no differences exist or rather that "the differences between both disease entities only reflect variations in the degree of severity of susceptibility rather than actual different immune-pathologies."[22]

However, stronger activation of natural killer cells and natural killer T cells in aggressive periodontitis has been suggested to be causative for the observed more pronounced tissue destruction in aggressive periodontitis.[38,54] A distinction of chronic and aggressive periodontitis based on molecular markers (gingival tissue transcriptional signatures) using machine learning algorithms was possible with excellent sensitivity and specificity. At the same time, this work identified substantial diagnostic imprecision in the current classification.[33]

Abnormalities in Localized Aggressive Periodontitis

Earlier work has suggested that individuals suffering from LAP were characterized by an inherited defect of neutrophil function, leading to a dampened immune response against the microflora

inhabiting the periodontal pocket.[84] Specifically, when challenged with periodontal pathogens, the LAP neutrophils were reported to show impaired chemotaxis, phagocytosis, and killing of bacteria. Alternatively, it was also hypothesized that these impaired defense properties were in fact acquired defects caused by prolonged exposure to an inflammatory microenvironment.

Today, the understanding of neutrophil biology is that neutrophils arriving at a site with uncontrolled periodontal inflammation are primed to attack the invading pathogens by releasing lytic enzymes. These enzymes may on the other hand accelerate tissue destruction. It is hypothesized that the observed dampened neutrophil function in deep aggressive periodontitis lesions is due to the heavy commitment of primed neutrophils to debridement, so that less potency remains for chemotaxis and defense.[64]

Genetics: Family Studies

A familiar aggregation of aggressive periodontitis cases is a secondary feature of the disease entity (i.e., it is often, but not always, found in aggressive periodontitis). To assess the familiar component of the disease, twin studies were performed[8,48] showing a strong genetic component with likely autosomal dominant inheritance mode and a 70% (African Americans) to 73% (Caucasians) penetrance.[48]

Genetics: Polymorphisms

Accordingly, there has been extensive work on the inherent genetic traits underlying this familiar aggregation.[42,77] First, it was suspected that an inherent susceptibility for periodontitis would likely be due to mutations of the DNA encoding for proteins of inflammatory mediators (candidate gene approach). DNA regions selected based on a priori knowledge of the disease pathobiology were assessed for sequence variations, most often single nucleotide polymorphisms (SNPs). Based on small sample sizes and often suboptimal study design, conceivably leading to false-positive results,[42,72] SNPs within genes encoding for cytokines such as interleukins (e.g., IL-1α, IL-1β, IL-6) were reported to be associated with aggressive periodontitis. However, with current knowledge, it

has to be realized that these findings were possibly spurious or the result of confounding—all of the "classical" candidate gene associations could not be replicated in today's larger and better controlled cohorts.[68] Note that in the case of genetic association studies, meta-analyses are not generally suitable tools to overcome the problems of small, heterogeneous cohorts.

Use of the genome-wide association study (GWAS) has been made possible by technologic advances in the field of high-throughput analysis. Using a GWAS of a large number of aggressive periodontitis cases and controls, a number of common susceptibility loci for myocardial infarction and aggressive periodontitis could be identified and replicated in independent cohorts.[67,69–71]

Taken together, these data indicate that there is evidence for a strong genetic component in aggressive periodontitis. It is very likely that the low number of identified and replicated susceptibility loci for aggressive periodontitis are due to too few samples and issues in study design rather than to a lacking biologic association (for reviews, see Laine et al.[42] and Vaithilingam et al.[83]).

Environmental Factors Affecting Susceptibility

The amount and duration of smoking are important variables that can influence the extent of destruction seen in young adults.[82] Patients with GAP who smoke have more affected teeth and more loss of clinical attachment than nonsmoking patients with GAP.[27] However, smoking may not have the same impact on attachment levels in younger patients with LAP.[73]

Current Developments

Based on the aforementioned still incomplete current understanding of the specific microbiologic, immunologic, and genetic properties of the clinical symptom-based periodontitis entities aggressive and chronic periodontitis, research now focuses on the assessment of whether these entities are in fact sufficiently distinct with respect to their underlying pathobiology to form etiology-based clinical classes. For these analyses, novel unbiased high-throughput methodology such as microarrays and next-generation sequencing are employed.[32,34–36]

Therapeutic Considerations in Aggressive Periodontitis Patients

Clinician's Corner

Aggressive periodontitis is defined by rapid attachment loss in clinically healthy individuals. There is considerable familiar aggregation. Aggressive periodontitis is most often found in younger individuals but can occur at any age. The entity is subdivided into two categories, localized and generalized aggressive periodontitis

Localized aggressive periodontitis (LAP) primarily affects first molars and incisor teeth in adolescents with deep pockets and advanced bone loss. It occurs in less than 1% of adolescents. There is a strong, hitherto only partially understood genetic component. In addition, the anaerobic gram-negative bacterium *Aggregatibacter actinomycetemcomitans* in the subgingival plaque biofilm was causally linked to LAP development in adolescents.

Generalized aggressive periodontitis (GAP) usually occurs first in young adults and may be present in some populations in up to 15% of the age group. Smoking may play a role because smokers with GAP have more teeth involved and more advanced pockets than nonsmokers.

Considerations for Anti-infective Therapy of Aggressive Periodontitis

Anti-infective therapy in patients with aggressive periodontitis seems to benefit strongly from the adjunctive use of systemic antibiotics[15] (see Chapter 52).

Considerations for Surgical Therapy of Aggressive Periodontitis

In general, individuals with aggressive periodontitis, especially LAP, have to undergo surgical therapy more often than the average

periodontitis patient.[15] This is due to (1) the often much more pronounced loss of attachment with deep periodontal pockets that are challenging to instrument[5,46] and (2) the high prevalence of vertical defects, notably in LAP, that need to be resolved.[60]

Considerations for Supportive Periodontal Therapy of Aggressive Periodontitis Patients

Aggressive periodontitis patients are understood to suffer from an especially virulent microbiologic burden in combination with alterations in their host defense that render them more prone to rapid attachment loss, even in the absence of seemingly adequate numbers of etiologic factors. This suggests that during the maintenance phase, utmost care needs to be taken to optimize the self-performed oral hygiene in order to minimize the amount of plaque that could eventually lead to a new, rapid loss of attachment. Therefore many clinicians recommend performing supportive periodontal therapy, including regular assessments of periodontal parameters, at least every 3 months—even in subjects who show particularly high levels of oral hygiene proficiency and independent of the periodontal risk assessment (PRA) tool that seems to be of limited use in aggressive periodontitis.[50]

Considerations for Oral Rehabilitation and Implant Therapy in Aggressive Periodontitis Patients

Dental implants today allow for the routine, predictable, functional, and esthetic replacement of lost teeth. Still, there are concerns about the incidence of periimplantitis, an inflammatory condition of dental implants with parallels to periodontal disease for which no defined, predictable treatment protocols exist to date. Periimplantitis risk is linked to a history of periodontal disease in the individual treated with dental implants. Limited data exist that show an even stronger risk for developing the disease in patients suffering from aggressive periodontitis, as compared to chronic periodontitis patients or periodontally healthy controls.[79,80]

Case Scenario 28.1

Patient:
26-year-old male of Northern African origin

Chief Complaint:
"I have bad breath, and occasionally my gums bleed."

Background Information
This patient is an immigrant from Northern Africa. He is generally healthy but smokes (20 cigarettes per day for the past 10 years).

He has not been seen by a dentist for up to 10 years and only visited the periodontology department after losing a tooth (FDI 22/no. 10) in a bar fight; it was subsequently replaced with a dental implant.

Current Findings:
PSR code 4 in all sextants; subsequent periodontal examination revealed substantial attachment loss with probing depths of 4 to 8 mm on all teeth.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION

1. What is the periodontal diagnosis for this patient? A. Chronic periodontitis B. Gingivitis C. Aggressive periodontitis D. Possible AgP; further examinations needed E. Generalized juvenile periodontitis	**Answer: D** **Explanation:** The primary criteria to diagnose AgP are (1) rapid attachment loss in (2) systemically healthy subjects with (3) familiar aggregation. Criterion 2 is fulfilled here, and criterion 1 is likely, based on the age of the patient. We need further information (old radiographs, family history) to confirm the diagnosis of AgP.
2. Northern African patients are known to often harbor a specific pathogen strain implicated in aggressive periodontitis. Which statement describes this condition? (Check all that apply.) A. Yes, it is called *Tunesia forsythia* JP2. B. The strain produces substantially more leukotoxin. C. Adolescent carriers of the strain carry an 18-fold risk for future attachment loss over noncarriers. D. This strain is also often detected in Denmark. E. The JP2 strain is endemic in all African countries.	**Answers: B and C** **Explanation:** In a large longitudinal study, the highly leukotoxic *A. actinomycetemcomitans* (serotype b) strain JP2, which has a 530-bp deletion in its leukotoxin gene operon that leads to a 10- to 20-fold higher production of leukotoxin,[29] was found to be directly related to the occurrence of LAP in children in northern Africa. Specifically, the OR for future attachment loss in carriers of the JP2 strain was 18.0, as compared to 3.0 for carriers of other, non-JP2 strains of *A. actinomycetemcomitans*.[30] Similar findings can be found in West-African countries (e.g., Ghana[1]) in contrast to eastern parts of Africa where no studies have reported on the JP2 clone strain in periodontitis patients.[18]
3. This patient received a dental implant to replace the missing lateral incisor. Which statement describes this	**Answers: A, B, and D** **Explanation:** Patients with a history of periodontitis carry an increased risk for periimplant biologic complications. Subjects with a history of aggressive periodontitis seem to exhibit an even stronger risk, as compared to chronic periodontitis patients or subjects without a history of periodontal diseases. The

condition? (Check all that apply.) A. Periodontitis patients can be treated with dental implants after successful periodontal treatment. B. Subjects with a history of periodontitis carry an increased risk for biologic implant complications. C. Implants are safe in periodontitis patients because they are not affected by caries. D. Aggressive periodontitis patients possibly carry an increased risk over chronic periodontitis patients. E. The increased risk for biologic complications is mediated by a single-nucleotide polymorphism (SNP) in the IL-1 locus that links aggressive periodontitis and periimplantitis.	mechanisms underlying this risk profile are incompletely understood. SNPs within genes encoding for cytokines such as IL-1α, IL-1β, IL-6 and so on were reported to be associated with aggressive periodontitis. However, with current knowledge, it has to be realized that these findings were possibly spurious or the result of confounding—all of the "classical" candidate gene associations could not be replicated in today's larger and better controlled cohorts.

Case Scenario 28.2

Patient:
28-year-old white female

Chief Complaint:
"I needed to come in for a checkup."

Background Information
This patient presented in the office for a regular checkup. She reported that she had seen general dentists every 2 years to have bitewings done. The patient is a smoker and generally healthy. She did not notice any gingival bleeding, loosening of teeth, or bad breath.

Current Findings:
PSR code 4 in all sextants; subsequent periodontal examination revealed substantial attachment loss with probing depths of 4 to 10 mm of most teeth.

Case-Based Questions	Solution and Explanation
1. What is the periodontal diagnosis for this patient? A. Chronic periodontitis, because subgingival calculus can be identified in the radiographs. B. Localized aggressive periodontitis, because of the pronounced	**Answer: D** **Explanation:** The prominent loss of attachment in this young patient suggests rapid attachment loss that needs to be confirmed using the older radiographs performed at the office of the general dentist the patient visited for earlier checkups. Furthermore, the family history needs to be assessed for aggregation of the disease. The presence of subgingival calculus does not rule out aggressive periodontitis—the "inconsistency of low amounts of etiologic factors and observed destruction" is a secondary feature that is not universally found in aggressive periodontitis cases.

breakdown at the first molars. C. Generalized aggressive periodontitis, because more than 30% of sites are affected. D. Possible generalized aggressive periodontitis, but further examinations are needed. E. There is no evidence of bone loss.	
2. This disease can be differentiated from chronic periodontitis by measuring the numbers of subgingival *Aggregatibacter actinomycetemcomitans.* A. True. B. False. C. True, but only in IL-1 polymorphism positive patients. D. True, but only in smokers. E. True, all patients with the JP2 strain suffer from aggressive periodontitis.	**Answer: B** **Explanation:** Chronic and aggressive periodontitis cannot be distinguished based on the presence of single periodontal pathogens. It is correct that localized, but not generalized, aggressive periodontitis features a strong role of specific microorganisms, most notably *A. actinomycetemcomitans*. However, localized aggressive periodontitis (LAP), as with all entities of periodontitis, is clearly not a monoinfection with *A. actinomycetemcomitans* but features a polymicrobial biofilm. Supporting this notion, there are also reports of confirmed cases of LAP that did not carry *A. actinomycetemcomitans.*
3. Which statement describes the epidemiology of this condition? (Check all that apply.) A. Periodontitis is generally more common in males than in females. B. Periodontitis is generally more common in females than in males. C. There is no	**Answers: A and E** **Explanation:** Male subjects show a higher prevalence for periodontitis than female subjects. It is difficult to study the prevalence of aggressive periodontitis at a single time point in an epidemiologic study, but all available information points to a significantly higher prevalence of the disease in Africans or African Americans as compared to Caucasians.

difference in disease prevalence between genders. D. Caucasians have a higher prevalence for aggressive periodontitis than African Americans. E. Epidemiologic studies reporting on aggressive periodontitis are sparse because the 1999 World Workshop case definition is difficult to test in a study setting.

CHAPTER 29

Necrotizing Ulcerative Periodontitis

Perry R. Klokkevold, Fermin A. Carranza

CHAPTER OUTLINE

Clinical Features
Microscopic Findings
Patients With HIV/AIDS
Etiology of Necrotizing Ulcerative Periodontitis
Malnutrition
Conclusion

Necrotizing ulcerative periodontitis (NUP) may be an extension of *necrotizing ulcerative gingivitis (NUG)* into the periodontal structures that leads to periodontal attachment loss and bone loss. Alternatively, NUP and NUG may be different diseases. To date, there is little evidence to support the progression of NUG to NUP

or to establish a relationship between the two conditions as a single disease entity. However, numerous clinical descriptions and case reports of NUP clearly demonstrate many clinical similarities between the two conditions. Until a distinction between NUG and NUP can be proved or disproved, it has been suggested that NUG and NUP be classified together under the broader category of *necrotizing periodontal diseases,* although with differing levels of severity.[1,15,20]

NUG has been recognized and described in the literature for centuries.[23] The features of NUG are presented in Chapter 20. The lesions of NUG are confined to the gingiva without a loss of periodontal attachment or alveolar bone support; this is the feature that distinguishes NUG from NUP.

The term *necrotizing ulcerative periodontitis* was first adopted at the 1989 World Workshop in Clinical Periodontics.[3] It was changed from the 1986 term *necrotizing ulcerative gingivoperiodontitis,* which represented the condition of recurrent NUG that progresses to a chronic form of periodontitis that includes attachment and bone loss. The adoption of NUP as a disease entity occurred in 1989 when there was a heightened awareness and an increase in the number of necrotizing periodontitis cases being diagnosed and described in the literature. Specifically, more cases of NUP were being described among immunocompromised patients, especially those who were human immunodeficiency virus (HIV) positive or who had acquired immunodeficiency syndrome (AIDS). In 1999, the subclassifications of NUG and NUP were included as separate diagnoses under the broader classification of "necrotizing ulcerative periodontal diseases."[1]

Clinical Features

Clinical cases of NUP are defined by necrosis and ulceration of the coronal portion of the interdental papillae and gingival margin, with a painful, bright-red marginal gingiva that bleeds easily. This is similar to the clinical features of NUG. The distinguishing feature of NUP is the *destructive progression* of the disease, which includes periodontal attachment and bone loss. Deep interdental osseous craters typify periodontal lesions of NUP (Fig. 29.1). However,

"conventional" periodontal pockets with deep probing depth are not found, because the ulcerative and necrotizing nature of the gingival lesion destroys the marginal epithelium and connective tissue, resulting in gingival recession. Periodontal pockets are formed because the junctional epithelial cells remain viable and can therefore migrate apically to cover areas of lost connective-tissue attachment. The necrosis of the junctional epithelium in patients with NUG and NUP creates an ulcer that prevents this epithelial migration, and a pocket cannot form. Advanced lesions of NUP lead to severe bone loss and tooth mobility, and may ultimately lead to tooth loss. In addition to these manifestations, as previously mentioned, patients with NUP may present with oral malodor, fever, malaise, or lymphadenopathy.

FIG. 29.1 Necrotizing ulcerative periodontitis in a 45-year-old, HIV-negative, white, male patient. (A) Buccal view of the maxillary cuspid–bicuspid area. (B) Palatal view of the same area shown in part A. (C) Buccal view of the mandibular anteriors. Note the deep craters associated with bone loss.

Key Fact

Necrotizing ulcerative periodontitis (NUP) cases are defined by necrosis and ulceration of the coronal portion of the interdental papillae. Gingival margins are bright red and bleed easily. Lesions are painful. The feature that distinguishes NUP from NUG is the destructive progression of NUP, which includes periodontal attachment and bone loss.

Microscopic Findings

In a study involving the use of transmission electron microscopy and scanning electron microscopy of the microbial plaque overlying the necrotic gingival papillae, Cobb and colleagues[4] demonstrated striking histologic similarities between NUP in HIV-positive patients and previous descriptions of NUG in HIV-negative patients. Microscopic examination revealed a surface biofilm composed of a mixed microbial flora with different morphotypes and a subsurface flora with dense aggregations of spirochetes (i.e., the bacterial zone). Below the bacterial layers were dense aggregations of polymorphonuclear leukocytes (PMNs) (i.e., the neutrophil-rich zone) and necrotic cells (the necrotic zone). The biopsy technique used in this study did not allow for the observation of the deepest layer and thus was not able to identify the spirochetal infiltration zone, which is classically described in NUG lesions. In addition to the NUG-like microscopic features of NUP described in this study, high levels of yeasts and herpes-like viruses were observed. This latter finding is most likely indicative of the conditions afforded to opportunistic microbes in the immunocompromised host (i.e., HIV-positive patients).

Patients With HIV/AIDS

Gingival and periodontal lesions with distinctive features are frequently found in patients with HIV infection and AIDS. Many of these lesions are atypical manifestations of inflammatory periodontal diseases that arise during the course of HIV infection

and as a result of the patient's concomitant immunocompromised state. Linear gingival erythema, NUG, and NUP are the most common HIV-associated periodontal conditions reported in the literature.[21] Chapter 30 provides detailed descriptions of these and other atypical periodontal diseases that occur in the patient with HIV.

NUP lesions found in patients with HIV or AIDS can present with features similar to those seen in HIV-negative patients. Alternatively, NUP lesions in patients with HIV or AIDS can be much more destructive and frequently result in complications that are extremely rare among patients without HIV or AIDS. For example, periodontal attachment and bone loss associated with NUP in an HIV-positive patient may be extremely rapid. Winkler and colleagues[31] described cases of NUP in HIV-positive patients with teeth that lost more than 90% of periodontal attachment and 10 mm of bone over a 3- to 6-month period. Ultimately, many of these lesions resulted in tooth loss. Other complications reported in this population included the progression of the lesions to involve large areas of soft-tissue necrosis, with the exposure of bone and the sequestration of bone fragments. This type of severe, progressive lesion with extension into the vestibular area and the palate is referred to as *necrotizing ulcerative stomatitis*.

The reported prevalence of NUP among patients with HIV infection varies.[6,13,21,23] Riley and colleagues[24] described only two cases of NUP in 200 HIV-positive patients (1%), whereas Glick and colleagues[13] found a prevalence of 6.3% for NUP cases in a prospective study of 700 HIV-positive patients. Variations in reported findings may be related to differences in the populations studied (e.g., intravenous drug users versus homosexuals versus patients with hemophilia) and differences in the immune statuses of the study subjects.

Necrotizing forms of periodontitis appear to be more prevalent among patients with more severe immunosuppression.[21,22] Case reports have depicted NUP as a progressive extension of HIV periodontitis (i.e., chronic to necrotic progression).[25] Glick and colleagues[13,14] found a high correlation between the diagnosis of NUP and immunosuppression in HIV-positive patients. The patients who presented with NUP were 20.8 times more likely to

have CD4+ counts of less than 200 cells/mm^3 as compared with HIV-positive patients without NUP. The authors consider a diagnosis of NUP to be a marker of immune deterioration and a predictor of the diagnosis of AIDS.[13] Others have suggested that NUP may be used as an indicator of HIV infection in undiagnosed patients. Shangase and colleagues[28] reported that a diagnosis of NUG or NUP in systemically healthy, asymptomatic South African patients was strongly correlated with HIV infection. Of patients presenting with NUG or NUP, 39 of 56 (69.6%) were subsequently found to be infected with HIV (see Chapter 30).

Clinical Correlation

Periodontal attachment and bone loss associated with NUP in an immunocompromised host (i.e., HIV-positive or AIDS) may be extremely rapid. NUP lesions in these patients are likely to be much more destructive and may also be associated with complications that are extremely rare among patients without HIV or AIDS.

Etiology of Necrotizing Ulcerative Periodontitis

The etiology of NUP has not been determined, although a mixed fusiform–spirochete bacterial flora appears to play a key role. Because bacterial pathogens are not solely responsible for causing the disease, some predisposing "host" factors may be necessary. Numerous predisposing factors have been attributed to NUG, including poor oral hygiene, preexisting periodontal disease, smoking, viral infections, immunocompromised status, psychosocial stress, and malnutrition. One case report attributed heavy tobacco use as the most significant contributing factor associated with NUP in a 21-year-old who had been smoking (>20 cigarettes/day) and chewing tobacco since the age of 7 years.[32]

NUG and NUP are more prevalent and more severe among patients with HIV. These patients require urgent treatment, because untreated lesions can progress rapidly; within a few days, severe

bone loss around affected teeth can be seen.

Smoking, malnutrition, and high plaque levels all increase the risk of NUG and need to be changed so that treatment success is obtained.

Clinicians should check all patients who present with NUP to ascertain their HIV status. NUP can progress rapidly and lead to tooth exfoliation, so treatment should include local debridement, local antiplaque agents, and systemic antibiotics. The early diagnosis and treatment of NUP are crucial, because the osseous defects that occur during the late stages of the disease are extremely difficult to resolve.

Microbial Flora

Assessment of the microbial flora of NUP lesions is almost exclusively limited to studies involving patients with HIV or AIDS, with some conflicting evidence. Murray and colleagues[20] reported that cases of NUP in HIV-positive patients demonstrated significantly greater numbers of the opportunistic fungus *Candida albicans* and a higher prevalence of *Aggregatibacter actinomycetemcomitans, Prevotella intermedia, Porphyromonas gingivalis, Fusobacterium nucleatum,* and *Campylobacter* species as compared with HIV-negative controls. In addition, they reported a low or variable level of spirochetes, which is inconsistent with the flora associated with NUG. Citing differences in microbial flora, they refuted the notion that the destructive lesions seen in HIV-positive patients were related to NUG lesions; they suggested that the flora of NUP lesions in HIV-positive patients is comparable to that of chronic periodontitis lesions, thus supporting their concept that necrotizing periodontitis in the HIV-positive patient is an aggressive manifestation of chronic periodontitis in the immunocompromised host.

In contrast with these findings, Cobb and colleagues[4] reported that the microbial composition of NUP lesions in HIV-positive patients was very similar to that of NUG lesions, as discussed previously. Researchers used electron microscopy to describe a mixed microbial flora with various morphotypes in 81.3% of specimens. The subsurface microbial flora featured dense

aggregations of spirochetes in 87.5% of specimens. The authors also reported opportunistic yeasts and herpes-like viruses in 65.6% and 56.5% of NUP lesions, respectively. The differences between these reports may be explained by the limitations of obtaining viable cultures of spirochetes[20] as compared with the more complete sample assessment with electron microscopic observation of spirochetes.[4]

In a review article, Feller and Lemmer suggested that spirochetes, herpesviruses, candida, and HIV all have potentially pathogenic roles in NUP lesions in the HIV-seropositive individual.[12] Spirochetes have the ability to modulate the host's innate and adaptive immune responses and to stimulate host inflammatory reactions,[8] which may reduce the local immune competence and facilitate the development of necrotizing disease.[12] Activated herpesviruses have the capacity to deregulate the host's immune system, which may lead to an increase in the colonization and activity of other pathogenic microorganisms. *Candida albicans* has been reported to produce eicosanoids, leading to the release of proinflammatory mediators, which may facilitate spirochete colonization and invasion and promote the development of necrotizing periodontal diseases.[11,12]

Key Fact

Patients with NUP are more likely to be immunocompromised. Although a mixed fusiform–spirochete bacterial infection appears to play a key role in the etiology of NUP, bacterial pathogens are not solely responsible. Predisposing "host" factors appear to be necessary. Factors that have been attributed to NUG include poor oral hygiene, preexisting periodontal disease, smoking, viral infections, immunocompromised status, psychosocial stress, and malnutrition.

Immunocompromised Status

Clearly, both NUG and NUP lesions are more prevalent among patients with compromised or suppressed immune systems. Numerous studies—particularly those evaluating patients with HIV

or AIDS—support the concept that a diminished host response is present in those individuals who have been diagnosed with necrotizing ulcerative periodontal diseases.[31] Whereas a compromised immune system (i.e., "immune compromise") in the HIV-infected patient is driven by impaired T-cell function and altered T-cell ratios, evidence indicates that other forms of compromised immunity predispose individuals to NUG and NUP as well.

Cutler and colleagues[6] described the impaired bactericidal activity of PMNs in two children with NUP. In a comparative assay of PMNs and periodontal pathogens, two brothers who were 9 and 14 years old showed significant depression of PMN phagocytosis and killing function as compared with gender- and age-matched controls. Furthermore, Batista and colleagues[2] reported periodontal findings and NUP in an adolescent patient with a rare genetic disease (multifactorial congenital immunodeficiency) that causes the impaired secretion of immunoglobulin; the oral lesions resolved with the administration of intravenous immunoglobulin.

Psychologic Stress

Most studies evaluating the role of stress on necrotizing periodontal disease have involved subjects with NUG[7,16,29,30] and thus have not specifically addressed the role of stress on NUP. Patients with NUG have been found to have had significantly more anxiety, higher depression scores, a greater magnitude of recent stressful events, more overall distress and adjustments related to these events, and more negative life events.[5,14] Although the role of stress in the development of NUP has not been reported specifically, the many similarities between NUG and NUP would suggest that similar relationships to stress may exist.

The mechanisms that predispose an individual with stress to necrotizing ulcerative periodontal diseases have not been established. However, it is well known that stress increases the systemic cortisol levels, and sustained increases in cortisone have a suppressive effect on the immune response. In an investigation of 474 military personnel, Shannon and colleagues[29] found that urinary levels of 17-hydroxycorticosteroid were higher among

subjects with NUG than in all other subjects who had been diagnosed with periodontal health, gingivitis, or periodontitis. Experimentally, noma-like lesions have been produced in rats by administering cortisone[27] and causing mechanical injury to the gingiva[26] and in hamsters via total body irradiation.[19] Thus stress-induced immunosuppression may be one mechanism that impairs the host response and leads to necrotizing periodontal disease. The scientific evidence supporting an etiologic role of stress in chronic periodontitis is not as clear (see Chapter 14).

Malnutrition

Direct evidence of the relationship between malnutrition and necrotizing periodontal disease is limited to descriptions of necrotizing infections in severely malnourished children. Lesions that resemble NUG but that progress to become *gangrenous stomatitis* or noma have been described in children with severe malnutrition in underdeveloped countries. Jimenez and Baer[18] reported cases of NUG among malnourished children and adolescents between the ages of 2 and 14 years in Colombia. In the advanced stages, NUG lesions extended from the gingiva to other areas of the oral cavity, becoming gangrenous stomatitis (noma) and causing exposure, necrosis, and sequestration of the alveolar bone. Later, Jimenez and colleagues reported that 44 of the 45 cases of necrotizing disease (NUG = 29, NUP = 7, and noma = 9) documented from 1965 to 2000 were from a low socioeconomic group and that malnutrition was associated with nearly all of the necrotizing conditions (29/29 NUG cases, 6/7 NUP cases, and 9/9 noma cases).[17] In a study of socioeconomically deprived Nigerian children with NUG (153 cases), Enwonwu and colleagues confirmed malnutrition by measuring circulating micronutrients.[10] As compared with neighborhood counterparts, the children with NUG and micronutrient deficiencies demonstrated dysregulated cytokine production with a complex interplay of elevated proinflammatory and antiinflammatory mediators.

Key Fact

A fusiform–spirochete infection along with weakened host immune system seem to play a major role in the pathogenesis of necrotizing ulcerative periodontitis.

A possible explanation is that malnutrition, particularly when extreme, contributes to a diminished host resistance to infection and necrotizing disease. It is well documented that many of the host defenses—including phagocytosis; cell-mediated immunity; and complement, antibody, and cytokine production and function—are impaired in malnourished individuals.[9] The depletion of nutrients to cells and tissues results in immunosuppression and increases disease susceptibility. Thus it is reasonable to conclude that malnutrition can predispose an individual to opportunistic infections or intensify the severity of existing oral infections.

Conclusion

NUP and NUG share many clinical and microbiologic features, but NUP is distinguished by a more severe condition with periodontal attachment and bone loss. Some individuals with NUP have severe and rapidly progressive disease. It appears that an impaired immune response and a lowered host resistance to infection are significant factors in the onset and progression of NUP. The best example of an immunocompromised host with a predisposition for NUP is the patient with HIV or AIDS. As with the other infection-related complications of HIV and AIDS, the immunocompromised status of affected patients renders them vulnerable to opportunistic periodontal infections, including NUP. Several predisposing factors have been identified in cases of NUG that may also play a role in NUP, including smoking, viral infections, psychosocial stress, and malnutrition. Although none of these factors alone is sufficient to cause necrotizing disease, when they occur together with an immunocompromised status, there is a potential to adversely influence the host response or resistance to infection.

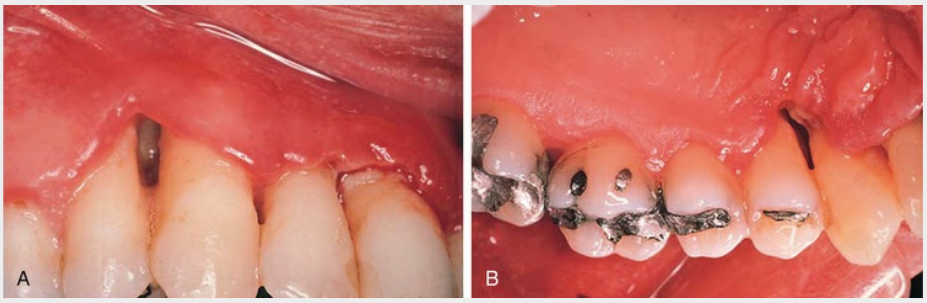
Case Scenario 29.1

Patient:
38-year-old Caucasian male

Chief Complaint:
“There's a gap between my teeth. It hurts, and my teeth are loose.”

Background Information
This is an HIV type C3 patient. His CD4 count is 150 cells/μL, and his viral load is undetectable. He has no known drug allergies. The patient has had multiple episodes of recurrent pneumonia over the past 12 months. He has a history of smoking (one pack per day for 28 years).

Current Findings:
Generalized probing depth ranges from 2 to 4 mm. There is severe, localized recession with necrosis and ulceration of the interproximal tissues between the maxillary right premolar and canine. There is localized moderate-severe biofilm with moderate-severe gingival erythema.



Case-Based Questions	Solution and Explanation
1. What does it mean when a patient has been categorized by the Centers for Disease Control and Prevention (CDC) as C3? A. Symptomatic with CD4 count ≥500 cells/μL B. Symptomatic with CD4 count <200 cells/μL	**Answer: D** **Explanation** According to the CDC, HIV patients can be categorized into group A (asymptomatic), B (symptomatic), or C (AIDS indicator condition) based on clinical findings. The number is determined by the CD4 count categories: 1. ≥500 cells/μL 2. 200 to 499 cells/μL 3. <200 cells/μL

C. AIDS indicator condition with CD4 count ≥500 cells/μL D. AIDS indicator condition with CD4 count <200 cells/ μL	
2. What is the periodontal diagnosis? A. Acute herpetic gingivostomatitis B. Necrotizing ulcerative gingivitis C. Necrotizing ulcerative periodontitis D. None of the above	**Answer: C** **Explanation** The classic clinical signs of pain, necrosis, and ulceration of the interdental papilla define necrotizing ulcerative condition. In this case, the destruction of periodontal attachment and bone are consistent with a diagnosis of necrotizing ulcerative gingivitis. The immunocompromised status predisposes an individual to necrotizing disease.
3. What is the likely etiology? A. Spirochetes only B. Mixed fusiform-spirochete bacterial flora C. Immunocompromised status D. All of the above E. B and C	**Answer: E** **Explanation** The etiology of necrotizing ulcerative periodontitis has not been determined, but similar to necrotizing ulcerative gingivitis, a mixed fusiform-spirochete bacterial flora likely plays a key role. The immunocompromised status is believed to be a predisposing factor. The role of spirochetes (alone) is inconsistent.

CHAPTER 30

Pathology and Management of Periodontal Problems in Patients With Human Immunodeficiency Virus Infection

Terry D. Rees

CHAPTER OUTLINE

Pathogenesis *(e-only)*
Epidemiology and Demographics *(e-only)*
Classification and Staging *(e-only)*

Oral and Periodontal Manifestations of Human Immunodeficiency Virus Infection
Dental Treatment Complications
Gingival and Periodontal Diseases
Periodontal Treatment Protocol

Acquired immunodeficiency syndrome (AIDS) is characterized by profound impairment of the immune system. The condition was first reported in 1981, and a viral pathogen, the *human immunodeficiency virus (HIV),* was identified in 1984.[221] The condition was originally thought to be restricted to male homosexuals. Subsequently, it was also identified in male and female heterosexuals and bisexuals who participated in unprotected sexual activities or who abused injected drugs.[187] Currently, sexual activity and drug abuse remain the primary means of transmission.

HIV has a strong affinity for cells of the immune system, most specifically those that carry the CD4 cell surface receptor molecule. Thus helper T lymphocytes (T4 cells) are most profoundly affected, but monocytes, macrophages, Langerhans cells, and some neuronal and glial brain cells may also be involved.[125] Viral replication occurs continuously in the lymphoreticular tissues of the lymph nodes, the spleen, the gut-associated lymphoid cells, and the macrophages.[282,283]

In 1986 a second type of HIV was isolated in Western Africa, and subsequently the two were named HIV-1 and HIV-2. Infection with HIV-2 was first reported in the United States in 1987 in an individual who had migrated from Western Africa. The two viruses apparently originated in different simian species. HIV-2 is very similar to HIV-1, but it appears to be less virulent and causes AIDS much more slowly. Infection with HIV-2 is rarely identified outside of Africa and countries that have been intimately associated with that area. During subsequent years, various subgroups of the viruses have been identified. HIV-1 consists of three named subgroups: M (main or major), N (new or non-M), and O (outlier).

HIV-1 subgroup M is primarily responsible for the worldwide HIV epidemic. There are at least 10 subtypes of HIV-1 M, with subtype B being the most common. It has also been learned that coinfection with varying groups or subgroups can result in circulating recombinant forms of viral strains. There are also eight known HIV-2 subgroups. There is evidence that this growing plethora of viral mutations may play a role in the increasing resistance to antiretroviral therapy. It is known, for example, that HIV-2 possesses a natural resistance to non-nucleoside reverse transcriptase inhibitor antiretroviral drugs, and circulating recombinant forms may also develop resistance to drugs that are being used for treatment.[126,162,217]

Combined therapeutic regimens that consist of antiretroviral agents and protease-inhibiting drugs have resulted in marked improvement in the health status of HIV-infected individuals and occasionally a reduction in viral plasma bioloads to below detectable levels (i.e., <50 copies/mL), although the infection may still be transmissible.[79,108,114,290] Evidence indicates that the virus is never completely eradicated; rather, it is sequestered at low levels in resting CD4 cells, even in individuals with no detectable plasma viral ribonucleic acid (RNA).[49,78] These findings suggest that effective combination drug therapy may be necessary for the lifetime of infected individuals. Long-term control of the infection may be difficult, because the antiviral agents that are currently used have many adverse side effects and drug-resistant variant viral strains readily develop.[282] In addition, growing evidence suggests that oral pathogenic microorganisms (including putative periodontal pathogens) may help to induce HIV recrudescence by reactivating latently infected dendritic cells, macrophages, or T cells.[97,123,124]

Pathogenesis

In patients with untreated or inadequately treated HIV infection, the overall effect is the gradual impairment of the immune system via interference with T4 (CD4) lymphocytes and other immune cell functions.[283] Evidence indicates that innate immune response may play a role in controlling HIV replication. Chemokine receptor type

5 (CCR5) is found on the surface of CD4 cells, and it often serves as a point of entry for HIV into the cell. A genetic variation associated with the expression of CCR5 and its ligand has been found to decrease an individual's susceptibility to HIV infection and delay clinical progression independent of their effects on viral replication. This may partially explain the lack of progression of HIV infection in some individuals, and it may ultimately lead to a cure.[125,253]

B lymphocytes are not infected, but the altered function of infected T4 lymphocytes secondarily results in B-cell dysregulation and altered neutrophil function.[147] This may place HIV-positive individuals at increased risk for malignancy and disseminated infections with microorganisms such as viruses, mycobacterioses, and mycoses.[107,202,210] HIV-positive individuals are also at increased risk for adverse drug reactions as a result of altered antigenic regulation.[196]

Epithelial cells of the mucosa may become infected, and they may allow the virus to access the bloodstream. Some evidence suggests that oral epithelial cells may harbor HIV virions and infect CD4+ cells by direct cell-to-cell transfer or by transporting and releasing low levels of infectious virions.[271] Most evidence, however, indicates that oral transmucosal viral transmission occurs after mild or severe traumatic injury or puncture of the mucous membranes. This allows for the infection of circulating host defense cells such as lymphocytes, macrophages, and dendritic cells.[43,245]

HIV has been detected in most body fluids, although it is found in high quantities only in blood, semen, and cerebrospinal fluid. Transmission occurs almost exclusively by sexual contact, illicit use of injection drugs, or exposure to blood or blood products. Transmission after human bites has been reported, although the risk is extremely low.[207,277]

The high-risk population includes homosexual and bisexual men, users of illegal injection drugs, persons with hemophilia or other coagulation disorders, recipients of blood transfusions before April 1985, infants of HIV-infected mothers (in whom transmission occurs by fetal transmission, at delivery, or by breastfeeding), promiscuous heterosexuals, and individuals who engage in unprotected sex with HIV-positive cohorts.[113] Heterosexual transmission is a common cause of AIDS in the world population,

and it is increasing significantly in the United States.[42,197] Transmission is more likely to occur through contact with HIV-infected individuals harboring a high plasma bioload of the virus.[197,223] HIV transmission has also been reported to occur through organ transplantation and artificial insemination.[46]

Some short-term studies have suggested that HIV-positive individuals who have been successfully treated with antiretroviral therapy (i.e., who have no detectable viral load) cease to be infectious to others.[32,208] However, Wilson and colleagues[284] have developed a mathematical model that indicates that the potential for HIV transmission to an uninfected individual by a heterosexual partner with an undetectable viral load is low but not without some risk. This risk appears to increase with more frequent exposure and the presence of other sexually transmitted diseases. Incomplete adherence to antiretroviral therapy could further increase the risk of transmission. Unprotected sex in this scenario creates a risk of HIV transmission that is four times greater than that associated with condom use.

The concept of serosorting has been advocated with increasing frequency in an effort to allow unprotected sex among male homosexuals who are both HIV positive or both HIV negative. This is the practice of preferentially having sex only with partners of concordant HIV status while selectively using condoms with HIV-discordant partners. There does appear to be some reduction in risk to others by HIV-positive individuals who only have sex with other seropositive individuals. However, the degree of risk for other sexually transmitted diseases remains high. Among HIV-negative individuals, serosorting presents an increased risk of the transmission of HIV and other sexually transmitted diseases, because some HIV-infected individuals are not aware of their disease status or do not reveal their status. Consequently, consistent use of condoms is strongly recommended for both HIV-concordant and HIV-discordant sexual activity.[95,122,140]

Epidemiology and Demographics

In November 2012 the Foundation for AIDS Research provided worldwide estimates indicating that more than 34 million people

were living with HIV/AIDS, 3.3 million of whom were younger than 15 years old. In 2011 an estimated 2.5 million individuals were newly infected, and 1.7 million people died from AIDS that year. Since the beginning of the epidemic, more than 60 million have contracted HIV, and approximately 30 million have died. Sub-Saharan Africa continues to be the global epicenter of the AIDS pandemic, and 23.5 million individuals in that area (69% of the worldwide total) are living with HIV/AIDS. Ninety-one percent of the world's HIV-positive children live in the area, and 74% of AIDS deaths worldwide occurred there in 2013.[82] The increase in the numbers of patients living with AIDS in the United States and other developed countries has resulted in part from prolonged survival since the advent of multidrug highly active antiretroviral therapy (HAART).[23,79,198,273,276] Thus AIDS represents the most serious medical crisis in world history.[36,269]

AIDS affects individuals of all ages, but more than 98% of cases occur among adults and adolescents who are older than 12 years of age. The Centers for Disease Control and Prevention (CDC) estimates indicate that, in 2010, approximately 29,800 newly infected adult victims in the United States were men who had sex with men (MSM), accounting for 63% of all new infections. Disturbingly, the greatest increase in HIV-infected MSM was seen in the youngest age group (13 to 24 years old), and it was especially prevalent among young black MSM. An additional 4% of the MSM group also used illicit injection drugs. HIV transmission through injection drug use alone infected 12%, whereas 25% of all new HIV infections in the United States were contracted through heterosexual contact, usually with a high-risk individual.[40,42] More than 25% of newly infected people were women, the majority of whom had sex with intravenous drug users or bisexual men.[36]

Other women with AIDS were born in countries such as Haiti or one of several high-incidence African nations in which heterosexual contact is the major mode of transmission. Only one individual contracted AIDS from blood products or blood transfusions in the United States in 2007 as a result of stringent blood bank controls; these data are no longer maintained as a single entity. This mode of transmission continues to be a threat, however, in undeveloped countries. A disproportionately high number of black/African

American and Hispanic male homosexuals, male and female heterosexuals, and children of affected women have HIV infection. The major risk factor for this disparity appears to be a more frequent history of the use of injection drugs and needle sharing as well as unprotected sexual activity in these groups.[40,42,154] It is of interest to note that the mother-to-child transmission of HIV in the United States has progressively decreased since its peak in 1992 because of the use of antiretroviral therapy.[264]

Transmission from health care workers to patients has been documented on three occasions, with one dentist infecting six patients either accidentally or deliberately.[146,161] Conversely, seroconversion has been documented in 103 health care workers after occupational injury, usually related to the management of patients with high plasma viral loads. The majority of these incidents involved nurses, and no documented seroconversion has been reported among dental health care workers.[80,128,161,289]

Classification and Staging

The World Health Organization (WHO) and the CDC have published guidelines regarding the definition of HIV infection and HIV disease staging. In both sets of guidelines, HIV infection is confirmed, if possible, with the use of laboratory criteria. However, in many parts of the world, laboratory testing is not available. Consequently, in the WHO concept, clinical findings may be used to establish the diagnosis and determine a patient's eligibility for antiretroviral therapy.

The WHO staging and case definition system was developed in 1990 and revised in 2007. Staging is primarily based on the clinical appearance of the disease, and it includes the following:

Clinical stage 1: Asymptomatic infection or persistent generalized lymphadenopathy

Clinical stage 2: Mild symptoms such as mild unexplained weight loss, angular cheilitis, herpes zoster, recurrent oral ulcerations, papular pruritic eruptions, seborrheic dermatitis, fungal infections, and recurrent respiratory infections

Clinical stage 3: Advanced symptoms such as severe weight

loss, chronic diarrhea, persistent intermittent or constant fever, pulmonary tuberculosis, severe bacterial infections, unexplained anemia, neutropenia, chronic thrombocytopenia persistent oral candidiasis, oral hairy leukoplakia, acute necrotizing stomatitis, gingivitis, and periodontitis

Clinical stage 4: Severe symptoms such as HIV wasting syndrome, *Pneumocystis* pneumonia, chronic herpes simplex infection of more than 1 month's duration, esophageal candidiasis, extrapulmonary tuberculosis, Kaposi sarcoma, cytomegalovirus (CMV) infection, lymphoma, candidiasis (of the trachea, bronchi, or lungs), invasive cervical carcinoma, among others[281]

AIDS may be present with either clinical stage 3 or stage 4 disease. A CD4 count of less than 350/mm^3 is considered diagnostic for AIDS in adults and in children who are 5 years old or older. Advanced HIV infection in infants is based on a CD4+ cell value of less than 30% if the patient is younger than 12 months old, less than 25% among patients between 12 and 35 months old, and less than 20% among those between 36 and 59 months old. (These are the WHO case definitions of HIV for surveillance and the revised clinical staging and immunologic classifications of HIV-related disease in adults and children.[3,39])

In 1982 the CDC developed a surveillance case definition for AIDS based on the presence of opportunistic illnesses or malignancies secondary to defective cell-mediated immunity in HIV-positive individuals.[38,39] The 1993 revision added invasive cervical cancer in women, bacillary tuberculosis, and recurrent pneumonia to the AIDS designation. Currently, any of 25 specific clinical conditions found in HIV-positive individuals can establish a diagnosis of AIDS (eBox 30.1). The most significant change in the most recent CDC case definition was the inclusion of severe immunodeficiency (CD4+ T lymphocyte count of <200/mm^3 or CD+ T lymphocyte percentage of <14% of total lymphocytes) as being definitive for AIDS. This change was based on the recognition that severe immunodeficiency results in an increased risk for opportunistic, life-threatening conditions. Many HIV-positive individuals have been designated as patients with AIDS solely

because of a low CD4 cell count or percentage, even in the absence of life-threatening conditions. More recently, HIV plasma bioload has been identified as a significant factor related to the transmissibility and severity of the disease.

eBox 30.1

Centers for Disease Control and Prevention Acquired Immunodeficiency Syndrome Surveillance Case Definition Conditions

Candidiasis, bronchial, tracheal, or pulmonary
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, human immunodeficiency virus related
Herpes simplex: chronic ulcer(s) (>1 month's duration) or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii,* disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jiroveci pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy

Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome caused by human immunodeficiency virus

From the Centers for Disease Control and Prevention: 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR* 41:RR-17, 1993.

HIV infection among children younger than 13 years old is based on immunologic categories. Category N–infected children show no evidence of suppression; category A designates evidence of mild suppression; category B designates moderate suppression; and category C represents severe symptomatic suppression. Perinatally exposed infants are usually not categorized until their HIV status is determined at the age of 18 months, because standard anti-HIV immunoglobulin G antibody tests are not reliable for patients younger than this age. Infants born to HIV-positive mothers usually possess maternal anti-HIV immunoglobulin G antibodies, which cross the placental barrier and offer some perinatal protection. Despite this fact, 15% to 30% of these infants ultimately become infected with HIV.[36]

Testing for Human Immunodeficiency Virus Infection

The enzyme-linked immunosorbent assay (ELISA) and Western blot (WB) tests were the original methods for determining the presence of HIV-1 and HIV-2 antibodies in serum or plasma, and they are still considered the gold standard of confirmatory testing. The ELISA test is performed first, and it is repeated if the first test is positive. If it is positive a second time, WB is performed, and a positive finding is considered diagnostic for the infection. WB is based on the reactivity of antibodies to specific viral proteins. It tests for the proteins p24 (capsid protein), gp41, and gp120 through gp160. In many laboratories, a positive band to two of these three proteins is considered positive, whereas anything less is considered indeterminate or negative if no antigenic proteins are detected. Both ELISA and WB require the presence of circulating HIV antibodies, which may take several weeks or even months to become detectible.

Thus false-negative tests are possible and repeat testing may be required, although modern testing methods are highly accurate. Today, several other test methods are based on the presence of an HIV antigen. Although these tests are expensive, they may be of benefit, especially for early diagnosis after exposure.[65,75]

The window of time between exposure and the development of antibodies can lead to an increased risk for disease transmission, and some evidence suggests that early treatment during that window can significantly minimize the intensity of the infection and positively influence treatment outcomes. Consequently, several test methods have been developed that detect the presence of HIV genes, RNA, or deoxyribonucleic acid (DNA). These tests may offer the advantage of earlier confirmation of recent exposure and infection. Several rapid HIV tests are currently available that can provide results in minutes as opposed to days. In some instances, collection kits are available for personal use, including one that collects oral fluids. At this time, the US Food and Drug Administration has approved approximately seven of these rapid tests as well as three that test for HIV and coinfection with the hepatitis C virus; one of these also tests for hepatitis B virus. Rapid tests may require the collection of oral fluids, plasma, serum, or whole blood, and the CDC encourages their use in most health care settings. It must be recognized that rapid tests may have a relatively high number of false-negative results as well as some false-positive results, so repeat testing and follow-up testing with ELISA and WB are often indicated.[75] Rapid tests may be of special benefit in undeveloped countries, where medical laboratory testing may not be readily available.[59,65]

The number of individuals living with AIDS in the United States has greatly increased as a result of the development of HAART, which combines various types of antiretroviral drugs, protease inhibitors, and fusion inhibitors.[110,132] Infected individuals treated with HAART may experience a marked rise in CD4 cell levels and a decreased plasma viral load. CD4 counts may reach normal levels, and viral bioload may decrease to a point below the level of detection.[19,201] Despite this improvement, these individuals are still considered to have AIDS, because the virus is apparently sequestered somewhere in the body. Patients remain potentially

infectious to others, and viral activity may resume if medications are discontinued or if severe coinfections with sexually transmitted diseases or other diseases occur.[78,83,127,221,272,273] Some evidence suggests that severe oral infections, including periodontal diseases, may sometimes represent a significant coinfection.

A few weeks to a few months after initial exposure, some HIV-infected individuals may experience acute symptoms, such as the sudden onset of an acute mononucleosis-like illness that is characterized by malaise, fatigue, fever, myalgia, erythematous cutaneous eruption, oral candidiasis, oral ulcerations, and thrombocytopenia.[83,160,272] This acute phase may last for up to 2 weeks, with seroconversion occurring 3 to 8 weeks later.[273] However, antigenic viremia may sometimes be present for an extended time before seroconversion occurs.[127,145] Some individuals experience asymptomatic HIV infection, whereas others may become asymptomatic after the initial acute infection. In either case, infected individuals eventually become seropositive for HIV antibody, but the mean time from infection until the development of AIDS is now estimated to be up to 15 years or more.[127,145]

Centers for Disease Control and Prevention Surveillance Case Classification

Patients with AIDS have been grouped as follows, according to the 1993 CDC Surveillance Case Classification[39]:

Category A includes patients with acute symptoms or asymptomatic diseases as well as individuals with persistent generalized lymphadenopathy with or without malaise, fatigue, or low-grade fever (eFig. 30.1).

Category B patients have symptomatic conditions such as oropharyngeal or vulvovaginal candidiasis, herpes zoster, oral hairy leukoplakia, or idiopathic thrombocytopenia, or constitutional symptoms of fever, diarrhea, or weight loss.

Category C patients are those with outright AIDS as manifested by life-threatening conditions or as identified by CD4+ T-lymphocyte levels of less than 200 cells/mm^3.

EFIG. 30.1 Cervical lymphadenopathy in an asymptomatic individual with human immunodeficiency virus.

The CDC staging categories reflect progressive immunologic dysfunction, but patients do not necessarily progress serially through the three stages, and the predictive value of these categories is not known. However, because HAART drugs may cause severe adverse side effects, many AIDS treatment centers continue to follow these guidelines to determine when to initiate or discontinue multidrug therapy.[15,27,30,111]

Antiretroviral Therapy

To date, 36 drugs or drug combinations from six separate drug classes have been approved by the US Food and Drug Administration for the treatment of HIV and AIDS infection (eBox 30.2). However, two of these drugs, Hivid and Fortovase, are no longer marketed.[1] The goals of therapy are to reduce morbidity and mortality and to improve and prolong life. To achieve this, it is necessary to suppress plasma viremia and to improve or preserve immunologic function. However, total eradication of HIV does not

appear to be possible currently, because reservoirs of latently infected CD4 cells are established early during the infection and persist even with treatment.[185] Anatomic reservoirs of infection have been located in the gastrointestinal and reproductive tracts and in breast, lung, and brain tissue. The oral cavity has been proposed as an anatomic reservoir, because a small percentage of HIV-infected individuals were found to be salivary hyperexcretors of HIV.[245]

eBox 30.2

Antiretroviral Drugs Approved for Use by the US Food and Drug Administration

Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

Abacavir (Ziagen, ABC)
Abacavir plus lamivudine (Epzicom)
Abacavir plus lamivudine plus zidovudine (Trizivir)
Didanosine (Videx, DDI)
Emtricitabine (Emtriva, FTC, Coviracil)
Emtricitabine plus tenofovir DF (Truvada)
Lamivudine (Epivir, 3TC)
Lamivudine plus zidovudine (Combivir)
Stavudine (Zerit, d4T)
Tenofovir (Viread, TDF)
Zalcitabine (Hivid, ddC)
Zidovudine (Retrovir, AZT, ZDM)

Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Delavirdine (Rescriptor, DLV)
Etravirine (Intelence)
Efavirenz (Sustiva, EFV)
Nevirapine (Viramune, NVP)

Protease Inhibitors (PIs)

Amprenavir (Agenerase, APV)
Atazanavir (Reyataz, ATV)
Darunavir (Prezista)
Fosamprenavir (Lexiva, FPV)
Indinavir (Crixivan, IDV)
Lopinavir/ritonavir (Kaletra, LPV/r)
Nelfinavir (Viracept, NFV)
Ritonavir (Norvir, RTV)
Saquinavir (SQV, Invirase)
Tipranavir (Aptivus)

Fusion Inhibitor (FI)

Enfuvirtide (Fuzeon, T20)

Entry Inhibitor/Chemokine Receptor Type 5 Co-Receptor Antagonist

Maraviroc (Selzentry)

Human Immunodeficiency Virus Integrase Strand Transfer Inhibitor

Raltegravir (Isentress)

Multiclass Combination Product

Efavirenz plus emtricitabine plus tenofovir (Atripla)

From the US Food and Drug Administration: http://www.fda.gov.

Nucleoside reverse transcriptase inhibitors (NRTIs) were the first class of antiretrovirals to be developed. They act by competing for incorporation into the proviral chain, thereby eliminating chain elongation. They are effective against both HIV-1 and HIV-2. NRTIs

are the principal drugs in use today in drug combinations.

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) bind to the active site in the developing HIV-1 viral chain and arrest its development. These drugs are quite effective, but the virus rapidly develops resistance to them via a single-step mutation.

Protease inhibitors are active against both HIV-1 and HIV-2. They bind to the HIV protease enzyme and result in the formation of noninfectious HIV virions. Fusion inhibitors bind to the gp41 glycoprotein membrane on HIV and prevent virus fusion into susceptible CD4 cells. The drugs are administered by subcutaneous injection.[83,188,268] Some entry inhibitors block the access of HIV to CCR5 receptors on macrophages and to T cells that are helping to preserve immune function and reduce viral load.[2] Integrase inhibitors block the incorporation of viral DNA into CD4 cell DNA after viral RNA has been converted into DNA by the reverse transcription enzyme.[252] Combination antiviral agents are composed of multiple drugs with various sites of viral disruption of incorporation into CD4 cells. These combinations represent the transformation of antiretroviral therapy into HAART.[188]

Drugs in each category potentially have adverse effects. NRTIs may induce a nonspecific gastrointestinal syndrome that begins with nausea, vomiting, and abdominal pain and may rapidly progress to hepatic or respiratory failure and pancreatitis. Other NRTIs may induce bone marrow suppression, peripheral neuropathy, pancreatitis, hepatotoxicity, or visceral adiposity (lipodystrophy).

NNRTIs are potent, but they may lead to the rapid development of resistance and cross-resistance to all drugs in the category. NNRTIs have the potential for adverse interactions with other HIV drugs, especially protease inhibitors, and adverse drug interactions are common with all drugs that are metabolized by the hepatic p450 system, principally the CYP3A4 enzyme. Stevens–Johnson syndrome may develop, and hepatic and central nervous system manifestations are common.[196]

Protease inhibitors are potent antiretrovirals that are also metabolized by the CYP3A4 isoenzyme of the hepatic p450 system, which means that adverse drug interactions with other antiretroviral agents and non-HIV agents are common.

Gastrointestinal intolerance, hyperlipidemia, insulin resistance, and lipodystrophy are common.[188,268]

The only fusion inhibitor that has currently been approved is enfuvirtide. Because it is administered subcutaneously, injection site reactions are common. Enfuvirtide is rarely used alone for the management of HIV infection.[283]

Combined antiretroviral drug therapy has been extremely successful in changing HIV infection from a rapidly progressive fatal disease to a chronic condition that often can be managed successfully. This type of therapy has improved survival rates to nearly normal while suppressing or eliminating susceptibility to some opportunistic diseases and disorders.

Highly Active Antiretroviral Therapy

With HAART therapy, combinations of three or more antiretroviral drugs are administered simultaneously for long periods of time in an effort to block HIV replication and plasma viral load and to restore immune function while minimizing antiretroviral drug resistance and adverse drug effects. The goals are to improve the patient's quality of life and reduce HIV-related morbidity and mortality. Three commonly used combinations are one NNRTI plus two NRTIs, one or two protease inhibitors plus two NRTIs, or three NRTIs. One NRTI three-drug combination is available in a single tablet, but this antiretroviral therapy does not necessarily qualify as HAART.[81,196]

It has now been many years since the advent of HAART, and some authorities propose that drug combinations be personalized for each HIV-positive individual on the basis of the specific characteristics of the drugs (e.g., toxicity, potency, central nervous system/sanctuary site penetration), the virus (e.g., resistance pattern, history of antiretroviral use, CCR5 tropism), and the host (e.g., lifestyle, compliance, drug interactions, non-AIDS comorbidities, organ dysfunction, pregnancy).[196]

Considerable controversy has existed for several years with regard to determining the best time to initiate HAART. Some authorities felt that the drugs should not be administered until significant immune suppression occurred. It was thought that this

approach would minimize the side effects as well as the risk of developing drug resistance. Others advocated the initiation of therapy as soon as the diagnosis was established. Evidence has indicated that early treatment is far more successful than delayed treatment.[20,196]

HAART has proved to be very successful at achieving a significant increase in the survival and quality of life of HIV-infected individuals, and life expectancy is markedly increased for many individuals using this therapy.[4] However, not everyone benefits equally from HAART. Survival time is shorter despite HAART among individuals who are injected drug abusers, those with AIDS before the initiation of therapy, those with a very high viral load before the initiation of therapy (i.e., >100,000 copies/mL), those who are inconsistent in their adherence to the drug regimen, and those who discontinue the drugs. Other factors that affect life expectancy in the era of HAART include smoking; excessive alcohol consumption; older age at initiation of therapy; comorbidities such as hepatitis C or other viral, bacterial, or fungal infections; chronic liver, kidney, or cardiovascular conditions; and diabetes mellitus. Low socioeconomic status is also a negative factor that is perhaps related to access to care, and HIV-related deaths continue to occur earlier among Hispanics and non-Hispanic blacks.[69,97]

Before the advent of antiretroviral therapy, opportunistic infections were the principal cause of morbidity and mortality among HIV-infected persons. Opportunistic infections continue to occur among those who are unaware of their HIV infection, those who do not take recommended medications, and those who are resistant or react adversely to recommended medications. In some instances, HAART has not altered the rate of occurrence or severity of certain opportunistic infections, whereas it is associated with the increased occurrence of others. Commonly described systemic conditions that may be found more often after HAART are lipodystrophy, increased insulin resistance, gynecomastia, blood dyscrasias, and dermatologic disorders. In the oral cavity, candidal infections are markedly reduced among individuals who are responsive to antiretroviral therapy[261]; hairy leukoplakia, Kaposi sarcoma, deep mycoses, necrotizing ulcerative gingivitis (NUG), and necrotizing ulcerative periodontitis (NUP) are reduced in these

patients as well. Conversely, the incidence and severity of oral condylomata and herpes simplex virus (HSV) infection appear unchanged, whereas neutropenia-associated oral aphthous-like ulcers; lichenoid reactions; and oral melanotic macules of the lip, gingiva, palate, or buccal mucosa may increase.[238] On the basis of these observations, the presence or absence of oral opportunistic infections associated with HIV infection or its treatment may serve as markers for the success or failure of antiretroviral therapy.[a]

Immune Reconstitution Inflammatory Syndrome

Complications from rapid immune recovery have been described, usually among individuals with bone marrow transplants and cancer chemotherapy. However, this phenomenon has been identified as a common complication associated with the recovery of immunity that occurs with HAART, and it has been termed *immune reconstitution inflammatory syndrome (IRIS).* In patients with this syndrome, preexisting subclinical or minimally symptomatic infections worsen. Recurrent lesions of Kaposi sarcoma may be particularly ominous. More often, infectious diseases (e.g., tuberculosis, disseminated *Mycobacterium avium* complex disease, hepatitis B, hepatitis C, herpes zoster virus) are reactivated, which causes an overwhelming inflammatory response that makes the symptoms of infection more severe. The triggering antigen may be a viable infectious agent (i.e., unmasking form) or even a dead or dying infectious organism, a tumor antigen, or a host autoimmune antigen (i.e., paradoxical form).[266] In most instances, a single antigen is responsible for the condition. However, it occasionally presents with multiple manifestations.[2] IRIS seems to occur among individuals with low baseline CD4 counts who are responsive to HAART, and it causes a rapid increase in CD4 cell numbers and a hyperinflammatory response that may cause fever and worsening of an existing bacterial, viral, or fungal infection.[248] In the oral cavity, IRIS lesions could include CMV infection, varicella-zoster virus infection, histoplasmosis, cryptococcal infections, Kaposi sarcoma, and other conditions. Although sometimes described years after the initiation of antiretroviral therapy (ART), IRIS most

often occurs within the first 2 to 12 weeks after starting ART in individuals with rapidly decreasing HIV viremia and rapidly increasing CD4+ T lymphocyte counts, in individuals who are starting ART for the first time, in those who are changing their treatment regime, or in those who were not compliant and discontinued their ART treatment for a period of time and then restarted therapy. The condition is difficult to diagnosis and manage, and it may take months to subside, but it does not appear to affect patient survival in most instances.[1] However, as mentioned previously, recurrent Kaposi sarcoma may indicate a grim prognosis. At this time, the implications of IRIS as they apply to oral opportunistic infections are largely unknown, but parotid enlargement has been reported as a common oral manifestation for reasons that have not yet been elucidated.[119,184,185,216]

Oral and Periodontal Manifestations of Human Immunodeficiency Virus Infection

Oral lesions are common in HIV-infected patients, although geographic and environmental variables may exist. Previous reports have indicated that most patients with AIDS have head and neck lesions,[223] whereas oral lesions are common among HIV-positive individuals who do not yet have AIDS.[16,93] Several reports have identified a strong correlation between HIV infection and oral candidiasis, oral hairy leukoplakia, atypical periodontal diseases, oral Kaposi sarcoma, and oral non-Hodgkin lymphoma.[68,71,153]

Oral lesions less strongly associated with HIV infection include melanotic hyperpigmentation, mycobacterial infections, necrotizing ulcerative stomatitis (NUS), miscellaneous oral ulcerations, and viral infections (e.g., herpes simplex virus [HSV], herpes zoster, and condyloma acuminatum). Lesions that are seen in HIV-infected individuals with undetermined frequency include less common viral infections (e.g., CMV, molluscum contagiosum), recurrent aphthous stomatitis, and bacillary angiomatosis (epithelioid angiomatosis).[68]

The advent of HAART has resulted in a greatly diminished

frequency of oral lesions associated with HIV infection and AIDS.[34,179,261]

However, some medical protocols delay the use of HAART drugs until immune suppression is relatively severe. These protocols also discontinue HAART if immune stability has been achieved or if the targeted virus becomes drug resistant.[74,167,233,262] In theory, these protocols suggest that patients with HIV and AIDS may experience a greater number of oral manifestations than patients who start HAART therapy earlier. The dental practitioner must continue to be prepared to diagnose and manage these conditions in coordination with the patient's physician. However, HIV resistance to antiretroviral drug therapy is an ongoing problem, and this resistance may even be transmitted to newly infected sexual partners or newborns of infected mothers.[87]

Oral Candidiasis

Candida, a fungus that is found in the normal oral flora, proliferates on the surface of the oral mucosa under certain conditions. A major factor associated with the overgrowth of *Candida* is diminished host resistance, which is seen in debilitated patients or in patients who have received immunosuppressive therapy. The incidence of candidal infection has been demonstrated to increase progressively in relationship to diminishing immune competency.[158,159,249] Most oral candidal infections (i.e., 85% to 95%) are associated with *Candida albicans,* but other species of *Candida* may also be involved. Currently, at least 11 strains of *Candida* have been identified, and non–*Candida albicans* infections are more common among immunocompromised individuals who are already receiving antifungal therapy for *C. albicans*.[155,236]

Candidiasis is the most common oral lesion associated with HIV disease, and it has been found in approximately 90% of patients with AIDS.[194,246] It usually has one of four clinical presentations: pseudomembranous, erythematous, or hyperplastic candidiasis or angular cheilitis.[115,178]

Pseudomembranous candidiasis ("thrush") presents as painless or slightly sensitive, yellow-white, curdlike lesions that can be readily scraped and separated from the surface of the oral mucosa. This

type is most common on the hard and soft palate and the buccal or labial mucosa, but it can occur anywhere in the oral cavity (Fig. 30.1).

FIG. 30.1 Palatal pseudomembranous candidiasis.

Erythematous candidiasis may be present as a component of the pseudomembranous type, appearing as red patches on the buccal or palatal mucosa, or it may be associated with depapillation of the tongue. If the gingiva is affected, it may be misdiagnosed as desquamative gingivitis (Figs. 30.2, 30.3, and 30.4). Some evidence suggests that erythematous candidiasis is more common among HIV-positive individuals with CD4+ counts between 200 and 500 cells/μl, whereas the pseudomembranous form occurs in patient with less than 200 CD4+ cells/μl. Viral load is most often elevated to more than 100,000 copies/mL. However, it should be emphasized that any form of candidiasis can be found in individuals who are only minimally immunocompromised.[181]

FIG. 30.2 Palatal erythematous candidiasis.

FIG. 30.3 Gingival erythematous candidiasis that is suggestive of desquamative gingivitis.

FIG. 30.4 Mixed erythematous and pseudomembranous candidiasis of the palate.

Hyperplastic candidiasis is the least common form, and it may be seen in the buccal mucosa and the tongue. It is more resistant to removal than the other types (Figs. 30.5 and 30.6).

FIG. 30.5 Mixed erythematous and hyperplastic candidiasis of the corner of the mouth.

FIG. 30.6 Hyperplastic candidiasis in the corner of the mouth. The lesion persisted despite the use of systemic antifungal drugs.

In *Candida*-related *angular cheilitis,* the commissures of the lips appear erythematous, with surface crusting and fissuring.

The diagnosis of candidiasis is made by clinical evaluation, culture analysis, or microscopic examination of a tissue sample or smear of material scraped from the lesion (oral cytology), which shows hyphae and yeast forms of the organisms (Fig. 30.7). When oral candidiasis appears in patients with no apparent predisposing cause, the clinician should be alerted to the possibility of HIV infection.[68] Many patients who are at risk for HIV infection who present with oral candidiasis also have esophageal candidiasis, which is a diagnostic sign of AIDS.[263]

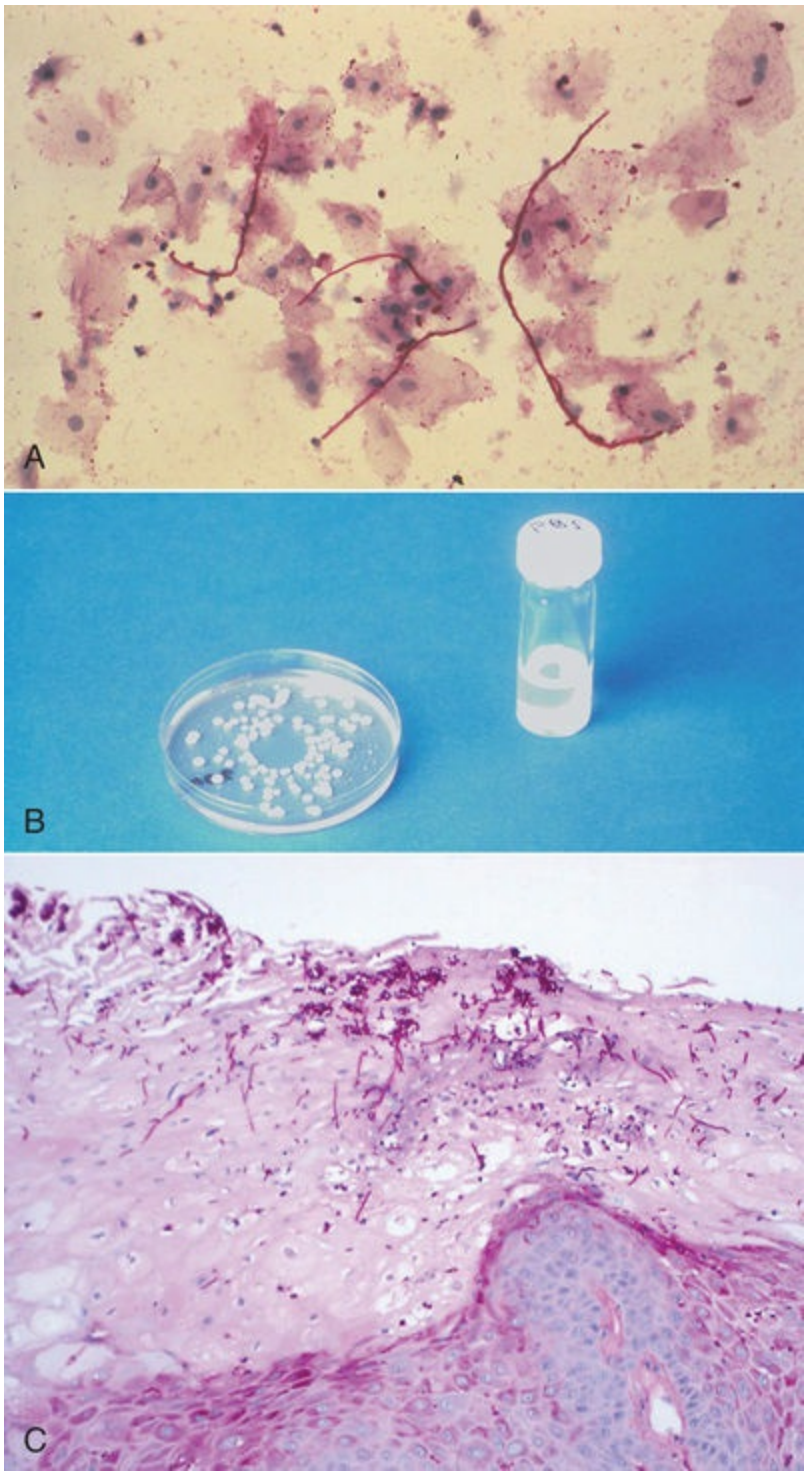

FIG. 30.7 Techniques for the diagnosis of candidiasis. (A) Candidal hyphae in a tissue smear after periodic acid–Schiff staining. (B) Culture media specific for *Candida* species. (C) Candidal hyphae in the epithelium of biopsied tissue.

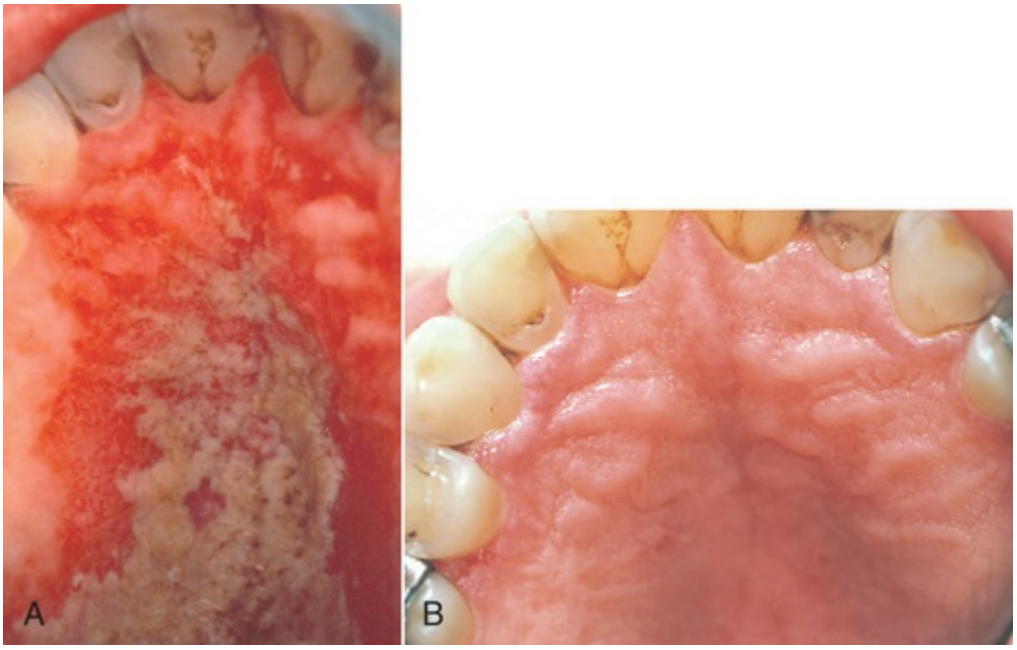
Although oropharyngeal candidiasis occurs with some frequency among immunocompetent individuals, it and esophageal

candidiasis are especially common among HIV-infected people. Some evidence suggests that the Th17 subset of T helper cells may be very important in the resistance of infections caused by common oral commensal microorganisms. Its selective loss in HIV infection may allow candidal species to express their pathogenic potential by creating an environment that allows for the overexpression of fungal virulence factors that can degrade host defense components, such as histatin-5 and E-cadherin. Some evidence suggests that the fungus may actually bind to the HIV proteins.[31] Because non–*C. albicans* candidal species appear to be especially prone to the development of azole resistance, species identification may become more important for the control of candidiasis.[136] A study from India reported that oral candidiasis infections are more common among males than females, although 92% of infected men and 95% of infected women reported acquiring the infection through heterosexual contact.[215] Others have shown that previous ART reduced the risk for oral candidiasis, whereas smoking and the presence of removable full or partial dentures increased the risk.[285] Although the incidence of oral candidiasis has been reported to decrease significantly after HAART treatment, colonization and oral infection remain common among HIV-positive individuals of all ages, either as evidence of unsuccessful therapy or as a result of IRIS.[180,192,205,260]

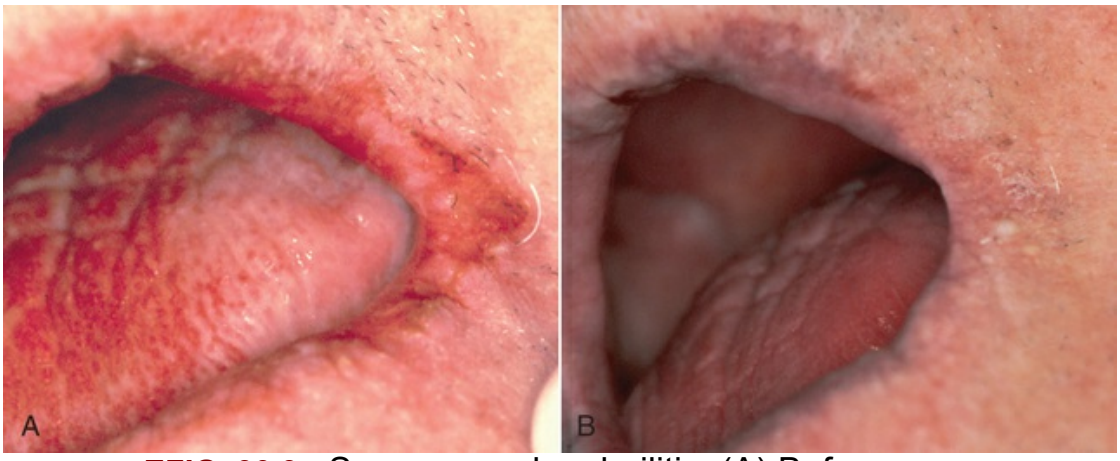
Although candidiasis in HIV-infected patients may respond to antifungal therapy, it is often refractory or recurrent. In the past, 30% of patients with AIDS-related candidiasis relapsed within 4 weeks of treatment, and 60% to 80% relapsed within 3 months. This relapse may have resulted from decreasing immunocompetency or the development of antifungal-resistant candidal strains.[117] As many as 10% of candidal organisms become resistant to long-term fluconazole therapy, and cross-resistance to other azoles (i.e., ketoconazole, itraconazole, miconazole, or clotrimazole) and amphotericin B may develop.[b] Resistant candidiasis is more common among late-presenting individuals with AIDS who have low CD4 counts and high viral loads at baseline.[117] Non–*C. albicans* candidal species in HIV-positive individuals most often include *Candida glabrata, Candida tropicalis, Candida krusei, Candida parapsilosis, Candida lusitaniae, Candida guilliermondii*, and other as

yet unidentified strains. Individuals with recurrent episodes of oropharyngeal candidiasis and previous exposure to antifungal drugs were more likely to colonize non–*C. albicans* species and develop azole resistance.[170]

Reports indicate that the administration of HAART to patients with HIV infection has resulted in a significant decrease in the incidence of oropharyngeal candidiasis and oral candidal carriage, and it has also reduced the rate of fluconazole resistance.[33,55,67,155,176,179,219] When esophageal candidiasis is present during HAART, there is an increased incidence of non–*C. albicans* species and fluconazole-resistant organisms.[263] Early oral lesions of HIV-related candidiasis are usually responsive to topical antifungal therapy (eFig. 30.2). More advanced lesions, including hyperplastic candidiasis, may require systemic antifungal drugs; systemic therapy is mandatory for esophageal candidiasis[235,242] (eFig. 30.3).



EFIG. 30.2 Palatal pseudomembranous candidiasis. (A) Before treatment with nystatin oral suspension. (B) Remission after 2 weeks of treatment.



EFIG. 30.3 Severe angular cheilitis. (A) Before treatment. (B) After treatment with systemic fluconazole.

With any therapy, lesions tend to recur after the drug is discontinued, and resistant strains of candidal organisms have been described, especially with the use of systemic agents.[62,235,274] eBox 30.3 identifies the therapeutic agents that are often prescribed for the treatment of candidal infections. Most oral topical antifungal agents contain large quantities of sucrose, which may be cariogenic after long-term use. For this reason, some authorities recommend oral use of vaginal tablets because they do not contain sucrose. However, such tablets are relatively low in active units (100,000) as compared with usual oral dosages of 200,000 to 600,000 units. Sucrose-free nystatin is also available in a powder form, which may be mixed extemporaneously with water at each use (i.e., 1 teaspoon of powder in a glass of water). In addition, many compounding pharmacies can provide sucrose-free nystatin on request. Sucrose-free oral suspensions of itraconazole and amphotericin B oral rinse have become available. To date, few comparative studies have been performed to address the effectiveness of these products. Amphotericin B oral suspension is more effective against *C. albicans* than it is against other species. Patients should be instructed to rinse with the oral suspension for several minutes and then swallow it.[206] Fluconazole oral suspension has been reported to be more effective as an antifungal than liquid nystatin. Chlorhexidine and cetylpyridinium chloride oral rinses may also be of some prophylactic value against oral candidal infection.[88] The long-term prophylactic effectiveness of once-weekly systemic fluconazole also

has been described.[235]

Systemic antifungal agents such as ketoconazole, fluconazole, itraconazole, and amphotericin B are effective for the treatment of oral candidiasis[186] (see eBox 30.3). Fluconazole may be the agent of choice when systemic therapy is required.[7,61,241,246] As previously mentioned, however, resistant strains of candidal organisms may develop with prolonged use of any systemic agent, potentially rendering the drugs ineffective against life-threatening candidal infections during the later stages of immunosuppression.[29,212] In addition, significant adverse side effects may occur with long-term use of any systemic antifungal agent. For example, long-term use of ketoconazole may induce liver damage in individuals with preexisting liver disease. The increased risk of chronic hepatitis B or hepatitis C infection in immunosuppressed individuals may put some patients at risk for ketoconazole-induced liver damage. If ketoconazole is prescribed, patients should receive liver function tests at baseline and at least monthly during therapy. The drug is contraindicated if the patient's aspartate transaminase level is more than 2.5 times higher than normal.[270] Ketoconazole absorption may also be impaired by the gastropathy experienced by many HIV-infected individuals.[141]

eBox 30.3

Common Antifungal Therapeutic Agents for Oral Candidiasis

Topical Drugs

1. Clotrimazole (Mycelex), 10-mg tablets: Dissolve 3 to 5 tablets in mouth daily for 7 to 14 days.
2. Nystatin (Mycostatin, Nilstat).
    a. Oral suspension.
        - 100,000 U/mL: Administer 240 mL.
        - Rinse with 1 tsp (5 mL) qid.
    b. Oral suspension (extemporaneous).
        - Administer 2 to 4 billion U.

- Mix 1 tsp (500,000 U) in 4 oz of water in a cup.
- Rinse qid.
- Note: Extemporaneous nystatin is sucrose free.

c. Tablets (500,000 U): Dissolve one tablet in mouth four or five times daily.

d. Pastilles (200,000 U): Dissolve one or two pastilles in mouth four or five times daily.

e. Vaginal tablets (100,000 U): Dissolve one tablet in mouth tid.

- Note: Vaginal tablets are sucrose free.

f. Ointment (for angular cheilitis), 15-g tube: Apply to the affected area tid or qid.

3. Clotrimazole ointment, 15-g tube: Apply to the affected area qid.
4. Miconazole 2% ointment, 15-g tube: Apply to the affected area qid.
5. Itraconazole oral suspension (Sporanox): Take 100 mg to 200 mg once daily for 7 to 14 days.
6. Fluconazole oral suspension (Diflucan): Take 3 mg/kg to 6 mg/kg (max, 400 mg/dose) once daily for 7 to 14 days.
7. Amphotericin B oral suspension (Fungizone): Take 100 mg qid for 2 weeks.

Systemic Drugs

1. Ketoconazole (Nizoral), 200-mg tablets: Take 2 tablets immediately and then 1 or 2 tablets daily with food for 5 to 14 days.
2. Fluconazole (Diflucan), 100-mg tablets: Take 2 tablets immediately and then 1 tablet daily for 7 to 14 days.
3. Itraconazole (Sporanox), 100-mg capsules: Take 200 mg once daily with meals for 7 to 14 days. Patients with acquired immunodeficiency syndrome or neutropenia should take this medication as described for 4 weeks.

max, Maximum; *mg,* milligrams; *mL,* milliliters; *qid,* four times daily; *tid,* three times daily; *tsp,* teaspoon; *U,* units.

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) primarily occurs in persons with HIV infection.[101,104] It is found on the lateral borders of the tongue, it frequently has a bilateral distribution, and it may extend to the ventrum. OHL is caused by the Epstein–Barr virus (EBV), and it is the only EBV lesion with which viral shedding in saliva is common.[181] The lesion is characterized by an asymptomatic, poorly demarcated, keratotic area that ranges in size from a few millimeters to several centimeters (Fig. 30.8A). Often, characteristic vertical striations are present, and these impart a corrugated appearance; the surface may also be shaggy and appear hairy when dried. The lesion does not rub off, and it may resemble other keratotic oral lesions.

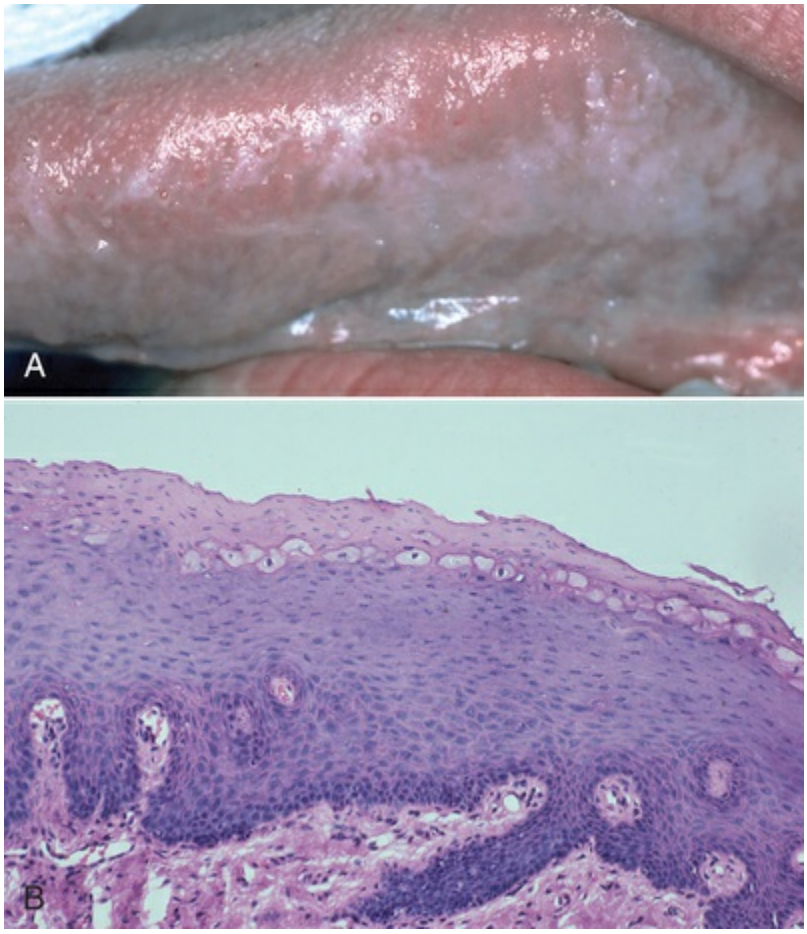


FIG. 30.8 Oral hairy leukoplakia on the left lateral border of the tongue. (A) Clinical view. (B) Biopsy confirmation of oral hairy leukoplakia. Note the ballooned epithelial cells near the surface of the

epithelium.

Microscopically, the OHL lesion shows a hyperparakeratotic surface with projections that often resemble hairs. Beneath the parakeratotic surface, acanthosis and some characteristic "balloon cells" that resemble koilocytes are seen (Fig. 30.8B). It has been demonstrated that these cells contain viral particles of the human herpesvirus group; these particles have been interpreted as EBV.[101,105]

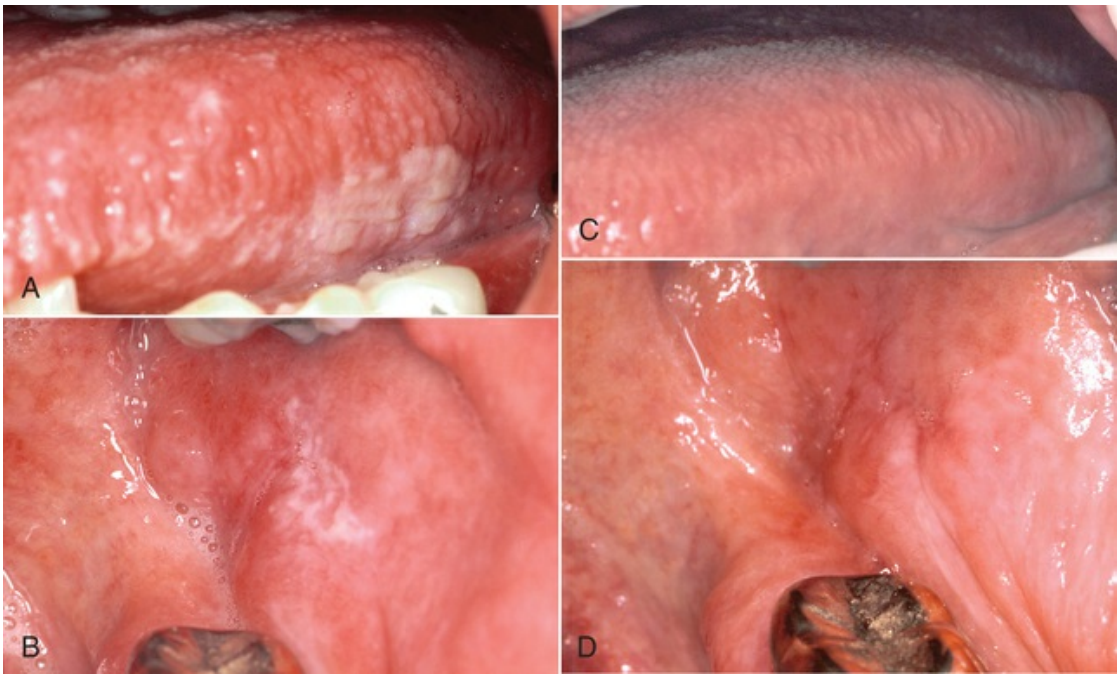
Epithelial dysplasia is not a feature, and, in most OHL lesions, little or no inflammatory infiltrate in the underlying connective tissue is present.[232]

OHL is found almost exclusively on the lateral borders of the tongue, although it has been reported on the dorsum of the tongue, the buccal mucosa, the floor of the mouth, the retromolar area, and the soft palate.[73,101,135] In addition, most of these lesions reveal surface colonization by *Candida* organisms, which are secondary invaders and not the cause of the lesion.

OHL was originally thought to be caused by the human papillomavirus, but subsequent evidence has indicated an association with EBV.[73,101,103,279] During the late 1980s, so-called pseudo-hairy leukoplakia was described in HIV-negative and EBV-negative individuals with lesions that are clinically identical to OHL. In addition, several case reports have described OHL in EBV-infected but HIV-negative individuals who have a variety of immunosuppressed conditions (e.g., acute myelogenous leukemia) or who develop immunosuppression as a result of organ transplantation or extensive systemic corticosteroid therapy.[103,257] Regardless of the cause, biopsy identification of a lesion that is suggestive of OHL should dictate that HIV testing be performed. It should be emphasized that the severity of the lesion is not correlated with the likelihood of developing AIDS; thus small lesions are as diagnostically significant as extensive lesions.[190]

The differential diagnosis of OHL includes several white lesions of the mucosa, such as dysplasia, carcinoma, frictional and idiopathic keratosis, lichen planus, tobacco-related leukoplakia, secondary syphilis, psoriasiform lesions (e.g., geographic tongue), and hyperplastic candidiasis.[5,191] The microscopic confirmation of

OHL of the tongue in a high-risk patient is considered to be a specific early sign of HIV infection and an indication that the patient will develop AIDS.[104,225] Before the advent of effective therapy for HIV, survival analysis indicated that 83% of HIV-infected patients with hairy leukoplakia would develop AIDS within 31 months, and the number of patients with hairy leukoplakia who eventually developed AIDS approached 100%.[104] The use of HAART, however, has resulted in a greatly diminished incidence of OHL[18,34,74,262,280] (eFig. 30.4).



EFIG. 30.4 (A) Oral hairy leukoplakia of the tongue before the initiation of highly active antiretroviral therapy (HAART). (B) Oral hairy leukoplakia of the buccal mucosa before the initiation of HAART. (C) Tongue lesion in remission after the initiation of HAART. (D) Remission of a lesion on the buccal mucosa after HAART.

If OHL occurs despite HAART, it may represent an increasing immunodeficiency resulting from therapeutic failure, a failure to take medications as prescribed, or a reduced dosages of medications that are used to prevent adverse side effects.[71] Vigorous treatment of OHL is usually not indicated. However, the lesions are often responsive to HIV drug therapy or to the use of

antiviral agents such as acyclovir, desciclovir, ganciclovir, foscarnet, or valacyclovir.[280,282] Lesions can be successfully removed with laser or conventional surgery. Some have advocated the topical application of podophyllin, retinoids, oral acyclovir, or interferon, but these agents can induce unwanted local or systemic side effects. Regardless of the choice of treatment, OHL lesions tend to recur when therapy is discontinued.[7,279,280]

Kaposi Sarcoma and Other Malignancies

Oral malignancies occur more frequently in severely immunocompromised individuals than in the general population. An HIV-positive individual with non-Hodgkin lymphoma (NHL) or Kaposi sarcoma (KS) is categorized as having AIDS (Fig. 30.9). Oral lesions are reported in approximately 4% of individuals with NHL, and the gingiva and palate are common sites. The incidence of oral squamous cell carcinoma may also increase among HIV-infected individuals.[22] KS was a rare disease until the early 1980s. In its classic form, it is found in older men and occasionally in patients after organ transplants, and it is endemic in parts of Africa. An epidemic form has subsequently been described in HIV-positive individuals, and it is an AIDS-defining condition.[193]

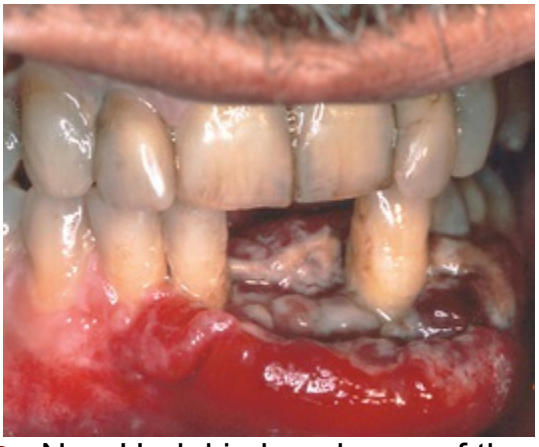


FIG. 30.9 Non-Hodgkin lymphoma of the anterior mandibular gingiva.

KS is the most common oral malignancy associated with AIDS. This angioproliferative tumor is a rare, multifocal, vascular

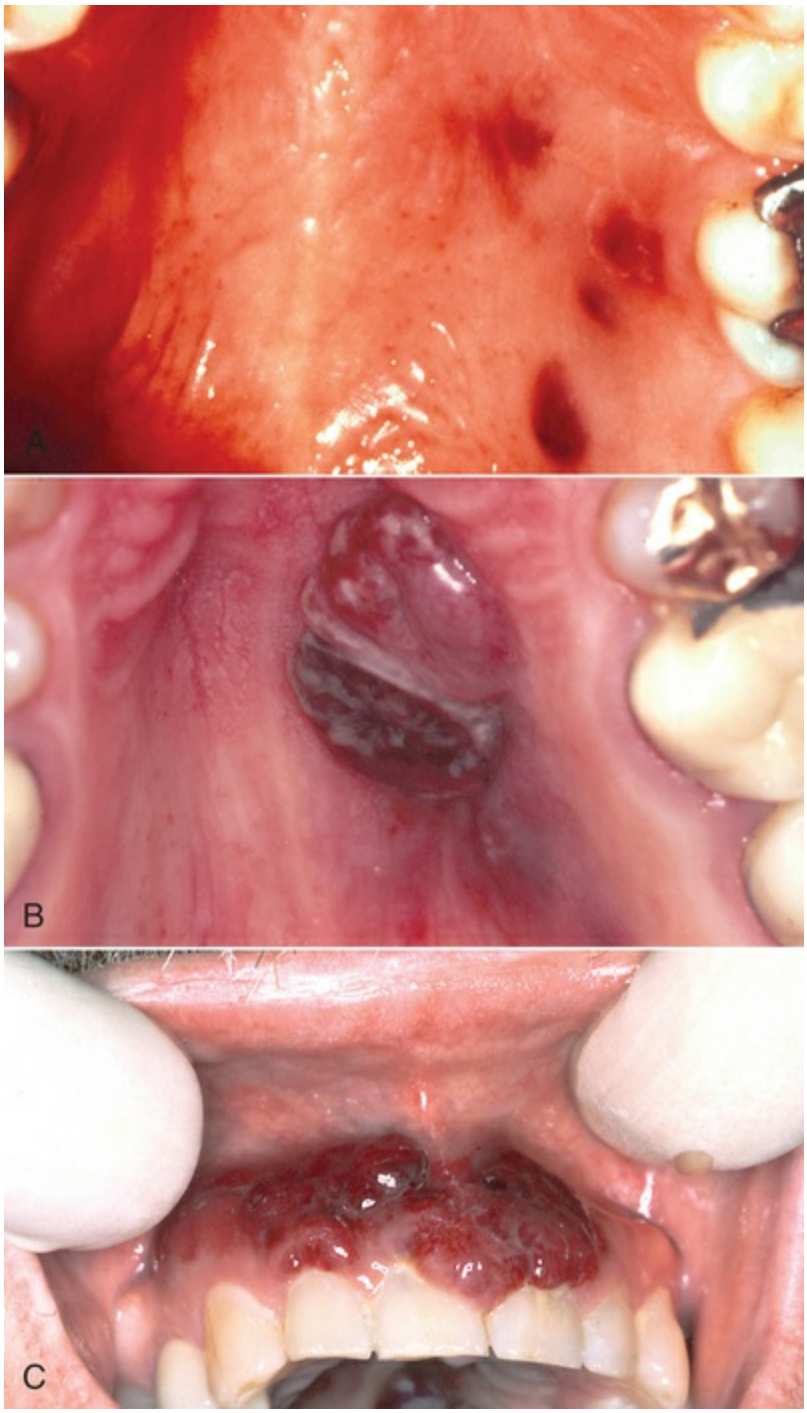
neoplasm; it was originally described in 1872 as occurring in the skin of the lower extremities of older men of Mediterranean origin. Today, it is closely associated with homosexual and heterosexual transmission, but it occurs 5 to 10 times more often among male homosexuals than in other groups at high risk for HIV. The causative agent has been identified as human herpesvirus-8 (HHV-8).

As far as is known, HHV-8 seroconversion precedes the development of epidemic KS by 5 to 10 years. It has been associated with both AIDS-related and non–AIDS-related KS.[84,223] However, untreated HIV-infected individuals are 7000-fold more likely to develop KS.[4] HHV-8 seroconversion is common, and the virus has been isolated from 29% of American adults and 8% of children in the general population without AIDS. It has also been isolated from lesions of NHL, multicentric Castleman disease, primary effusion lymphoma, and other lymphoproliferative disorders, as well as from lesions of a variety of additional abnormalities, although these findings may coincide with those of the healthy general population.[96,130,247] By contrast, one study identified HHV-8 in more than 90% of HIV-related and non–HIV-related KS lesions.[138] Thus it appears that decreasing immunocompetence results in the activation of latent HHV-8. As mentioned previously, the virus may be sexually transmitted, but it may also be transmitted from infected mothers to their children.[237,258]

AIDS-related KS can develop at any age, even in newborns, and oral lesions are more common in children than adults in sub-Saharan Africa.[189] Although KS is a malignant tumor, in its classic and endemic forms, it is a localized and usually slow-growing lesion. The KS that occurs in HIV-infected patients presents different clinical features (eFigs. 30.5 and 30.6). In these individuals, KS is a much more aggressive lesion, and the majority of patients (71%) develop lesions of the oral mucosa, particularly the palate, the gingiva, and the tongue[133,189] (eFig. 30.7). Oral lesions may be unifocal or multifocal. The oral cavity may often be the first or only site of the lesion.[13]

EFIG. 30.5 Cutaneous Kaposi sarcoma on the right chin.

EFIG. 30.6 Ocular Kaposi sarcoma causing loss of vision.



EFIG. 30.7 Intraoral Kaposi sarcoma. (A) Multiple painless, nonelevated palatal lesions. (B) A palatal Kaposi lesion that interfered with function and required treatment. (C) A gingival lesion that created an aesthetic concern for the patient.

Lymphedema of the neck and face has been reported in association with oral lesions. The cause of lymphedema has not been determined, but it may result from the compression of

lymphatics by expanding lesions. The presence of facial lymphedema is considered to be an ominous sign that is associated with a fatal outcome.[189]

During the early stages, the oral lesions are painless, reddish-purple macules of the mucosa. As they progress, the lesions frequently become nodular, and they can easily be confused with other oral vascular entities, such as hemangiomas, hematomas, varicosities, or pyogenic granulomas (when occurring in the gingiva).[237]

Lesions may manifest as nodules, papules, or nonelevated macules that are usually brown, blue, or purple, although occasionally they may display normal pigmentation. The lesions may become painful if they become ulcerated or traumatized by opposing teeth as they enlarge. Diagnosis is based on histologic findings.[218]

Gingival KS lesions may be exacerbated by existing periodontal lesions, or necrotizing periodontal diseases may be superimposed on existing gingival KS. On occasion, the expansion of gingival lesions may result in bone resorption, and increased tooth mobility and loss has been reported.[189]

Microscopically, Kaposi sarcoma consists of four components: (1) endothelial cell proliferation with the formation of atypical vascular channels, (2) extravascular hemorrhage with hemosiderin deposition, (3) spindle cell proliferation in association with atypical vessels, and (4) a mononuclear inflammatory infiltrate that consists mainly of plasma cells[99] (Fig. 30.10).

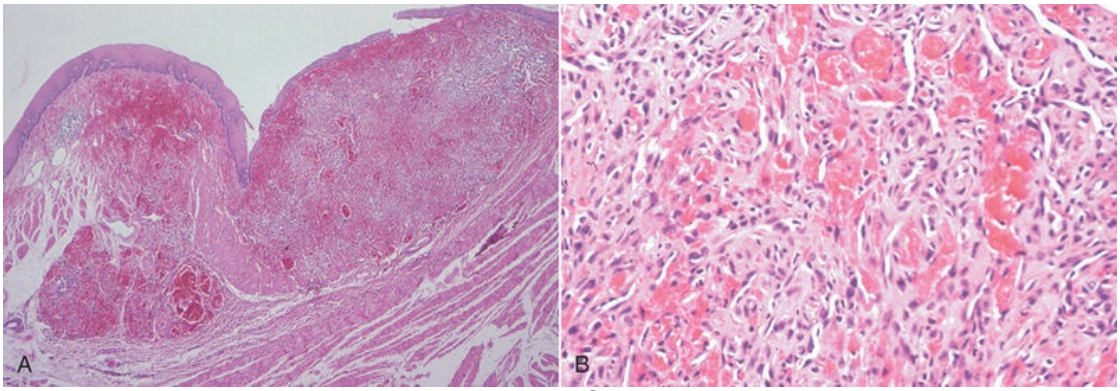


FIG. 30.10 (A) Histologic view of Kaposi sarcoma. This lesion is exophytic and only minimally inflamed (low

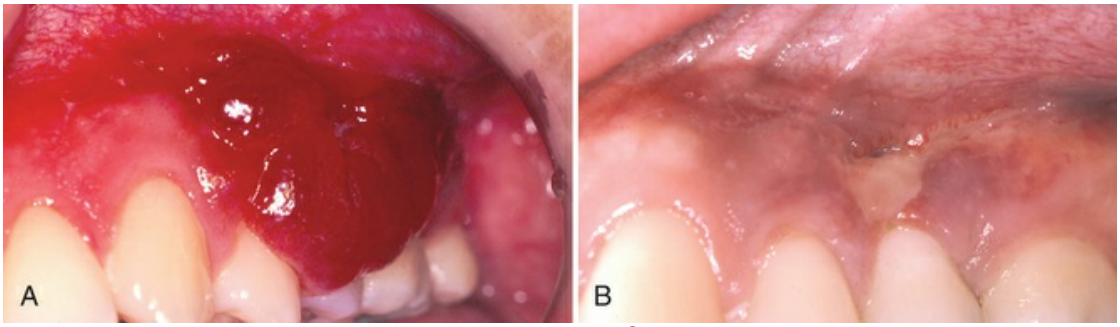
magnification). (B) Note the sheets of endothelial cells and numerous small blood vessels (high magnification).

Regional and gender differences are apparent; oral KS is more common in the United States than in Europe, and the male-to-female ratio is 20 : 1.[265] KS has also been reported in patients with lupus erythematosus who are receiving immunosuppressant therapy as well as in renal transplant patients and other individuals receiving corticosteroid or cyclosporine therapy. Case reports describe gingival KS in HIV-negative patients experiencing cyclosporine-induced gingival enlargement.[209,272] In an HIV-positive individual, the presence of KS signifies the transition to outright AIDS. Before the advent of combined drug therapy for AIDS, the median survival time after the onset of KS ranged from 7 to 31 months.[52]

The differential diagnosis of oral KS includes pyogenic granuloma, hemangioma, atypical hyperpigmentation, sarcoidosis, bacillary angiomatosis, angiosarcoma, pigmented nevi, and cat-scratch disease of the skin.[223]

The advent of HAART has resulted in a marked reduction in the incidence of KS. However, the lesions may still be found in severely immunocompromised individuals who are unaware of their HIV-positive status or who are untreated or unresponsive to therapy.[84] HHV-8 may be found more frequently in the saliva of HIV-positive individuals with higher CD4 cell counts, which suggests that viral shedding may occur relatively early during the disease process.[52,118] Treatment of oral KS includes antiretroviral agents, laser excision, cryotherapy, radiation therapy, and intralesional injection with vinblastine, interferon-γ, sclerosing agents, or other chemotherapeutic drugs.[7,71,242,265] Nichols and colleagues[177] described the successful use of intralesional vinblastine injections at a dose of 0.1 mg/cm^2 with the use of a 0.2 mg/mL solution of vinblastine sulfate in saline (eFig. 30.8). In responsive patients, treatment was repeated at 2-week intervals until resolution or stabilization of the lesions occurred. Side effects included some posttreatment pain and occasional ulceration of the lesions, but in general the therapy was well tolerated. Total resolution was achieved in 70% of 82 intraoral KS lesions with one to six treatments. Lesions tended to recur,

however, thereby indicating that treatment probably should be reserved for oral KS lesions that are easily traumatized or that interfere with chewing or swallowing. Occasionally, treatment may be indicated when KS lesions create an unsightly appearance on the lips or in the anterior oral cavity. In a double-blind randomized clinical trial involving a small group of patients with oral KS lesions, the authors concluded that vinblastine injections remain the most effective treatment for the management of localized lesions.[212] However, comparable results may be obtained with injections of 3% sodium tetradecyl sulfate, a sclerosing agent that was previously used for the treatment of varicose veins. The sclerosing agent offers the advantage of being relatively inexpensive and easy to use. Destructive periodontitis has also been reported in conjunction with gingival KS. In such patients, scaling and root planing as well as other periodontal therapy may be indicated in addition to intralesional or systemic chemotherapy.[242,265]



EFIG. 30.8 (A) Management of gingival Kaposi sarcoma interfering with function. (B) Nearly complete resolution of the lesion after intralesional injection with vinblastine.

Today, some authorities recommend treating oral KS with a combination of HAART and systemic cytotoxic therapy.

The incidence of KS among HIV-positive individuals has decreased precipitously since its peak in 1989 as a result of the emphasis on safer sexual practices as well as the introduction of HAART. Today, AIDS-related KS is uncommon except in those who are unaware of their HIV-positive status, those who are not taking HAART, or those who have discontinued HAART for one reason or another.[26,158] However, approximately 7% of individuals

with KS who begin treatment with HAART for the first time may experience a flare of existing KS lesions or have new lesions develop.[76] In sub-Saharan Africa, which is resource poor when it comes to treating HIV infection, HSV-8 is endemic; the incidence of KS is very high among HIV-positive individuals, and its presence may represent the first recognized indication that HIV infection has occurred. Although oral KS may regress with ART, it may flare as part of the immune reconstitution inflammatory syndrome and increase mortality among individuals who were in the late stages of AIDS when diagnosed.[48]

Non-Hodgkin Lymphoma

Lymphoma represents a heterogeneous malignancy that is characterized by the proliferation of lymphoid cells. It is broadly classified as Hodgkin disease (14%) or non-Hodgkin lymphoma (NHL). NHL in individuals with HIV infection is an AIDS-defining condition, and elevated cumulative viremia may be a strong predictor of AIDS-related lymphoma.[292]

The risk of NHL is associated with a number of infections; EBV-associated lesions may include Burkitt lymphoma and HIV-associated lymphoma. However, the role of EBV in tumor formation has not been clarified, and a viral etiology has not been confirmed. NHL is characterized by malignancy of B or T lymphocytes, and tumors are typed by the WHO classification system as indolent, aggressive, or highly aggressive. NHL is treated by chemotherapy, and HAART does not appear to significantly reduce the incidence or prognosis of the malignancies, although HIV-associated NHL may be less common.[157]

Oral lesions usually appear as erythematous, painless enlargements that may become ulcerated as a result of traumatic injury (Fig. 30.11). In some cases, bone involvement occurs, although this is rare in the United States. Lesions commonly affect the gingival, palatal, and alveolar mucosa, and they may mimic dental infections. Diagnosis is based on physical examination, complete blood count with differential, imaging studies, and lymph node and tissue biopsy.[172]

FIG. 30.11 Bacillary angiomatosis mimicking Kaposi sarcoma.

Patients with HIV and benign lymphoepithelial involvement of the salivary glands may have a markedly increased risk of developing benign or malignant lymphoma.[71] NHL of the diffuse B-cell type with plasmoblastic differentiation (i.e., plasmoblastic lymphoma) is a particularly aggressive form of lymphoma that occurs most often in the oral cavity and jaws. Prognosis is guarded, especially in patients with AIDS, but HAART has somewhat reduced the incidence of this malignancy. Some evidence suggests that HHV-8 may have a role in its development. The tumor must be differentiated from plasma cell myeloma via its plasmoblastic features.[112,121]

Patients with AIDS and NHL may require management of HIV-related opportunistic infections, chemotherapy-induced mucositis and thrombocytopenia, and possibly graft-versus-host disease, if hematopoietic cell transplantation is performed.[71,157]

Bacillary (Epithelioid) Angiomatosis

Bacillary (epithelioid) angiomatosis (BA) is an infectious vascular proliferative disease with clinical and histologic features similar to those of KS. BA is caused by facultative intracellular gram-negative mobile bacilli of the genus *Bartonella* and the order Rickettsia (e.g., *Bartonella henselae, Bartonella quintana*).[68,211,230] Cats are the primary host of *B. henselae,* and the infection is usually transmitted to humans by bites, scratches, or fleas (i.e., cat-scratch fever). Humans are the primary reservoir for *B. quintana,* and it is usually transmitted by human lice. BA can occur in immunocompetent

persons, but it is most commonly associated with AIDS. Skin lesions are similar to those associated with KS or cat-scratch disease.[57,254] Gingival BA manifests as red, purple, or blue edematous soft-tissue lesions that may cause the destruction of periodontal ligament and bone[91] (see Fig. 30.11).

The condition is more prevalent in HIV-positive individuals with low CD4 levels.[165]

The diagnosis of BA is based on biopsy, which reveals an "epithelioid" proliferation of angiogenic cells accompanied by an acute inflammatory cell infiltrate. The causative organism in the biopsy specimen may be identified with the use of Warthin–Starry silver staining or electron microscopy.[86]

The differential diagnosis of BA includes KS, angiosarcoma, hemangioma, pyogenic granuloma, and nonspecific vascular proliferation.[45] BA is usually treated with broad-spectrum antibiotics such as erythromycin or doxycycline. Gingival lesions may be managed by using the antibiotic in conjunction with conservative periodontal therapy and possibly excision of the lesion.[45,91,92,219] To date, no reports have been found regarding the effect of HAART on BA incidence among HIV-positive individuals. However, one case report described a fatal outcome of *B. quintana*–derived BA during HAART-induced immunity restoration.[171]

Oral Hyperpigmentation

An increased incidence of *oral hyperpigmentation* has been described in HIV-infected individuals.[50,139,143,291] Oral pigmented areas often appear as spots or striations on the buccal mucosa, the palate, the gingiva, or the tongue (Fig. 30.12). At present, most reports describing the oral features of HIV/AIDS or post-HAART HIV/AIDS come from areas of the world where racial pigmentation may be common. In these areas, oral evaluation may often be accomplished by non-dental health care workers. Consequently, it is not possible to accurately assess the degree of HIV-related oral hyperpigmentation before or after ART.

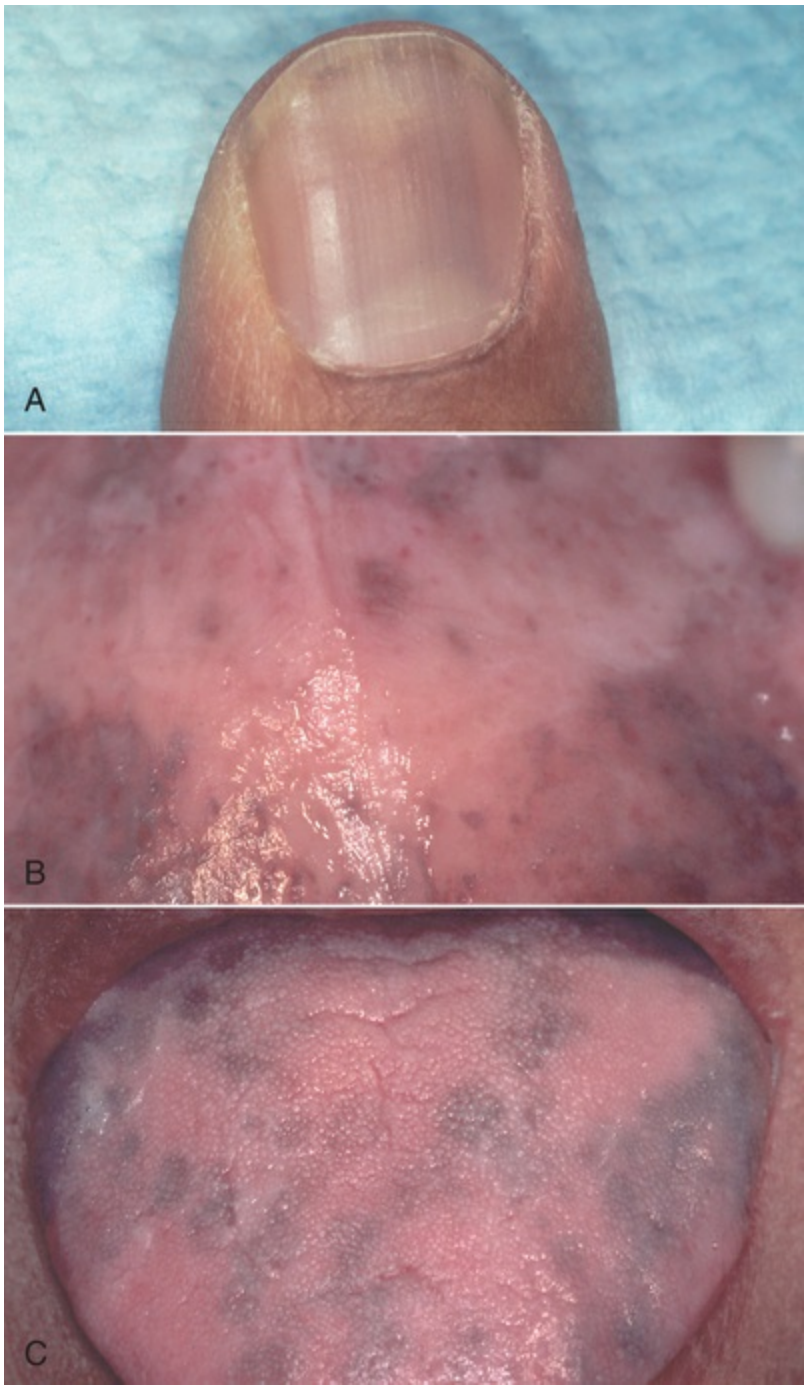


FIG. 30.12 Drug-induced hyperpigmentation as a result of zidovudine use. (A) Fingernail bed discoloration. (B) Palatal hyperpigmentation in the same patient. (C) Tongue hyperpigmentation in the same patient. Note the similarity between the oral lesions and those caused by adrenal cortex hypofunction (i.e., Addison disease).

In some cases, the pigmentation may relate to the prolonged use of drugs such as zidovudine, ketoconazole, or clofazimine.[291]

Zidovudine is also associated with excessive pigmentation of the skin and nails, although similar hyperpigmentation has been reported in some individuals who have never taken zidovudine. On occasion, oral pigmentation may be the result of adrenocorticoid insufficiency that has been induced in an HIV-positive individual via the prolonged use of ketoconazole or by *Pneumocystis jiroveci*, CMV, or other viral infections[143] (see Fig. 30.12).

Atypical Ulcers

Atypical ulcers (nonspecific oral ulcerations) in HIV-infected individuals may have multiple etiologies that include neoplasms such as lymphoma, KS, and squamous cell carcinoma. HIV-associated neutropenia may also feature oral ulcerations.

Neutropenia has been successfully treated with the use of recombinant human granulocyte colony-stimulating factor, with the resultant resolution of oral ulcers.[148] Severe and prolonged oral ulcers have been successfully managed with the use of prednisone or thalidomide, a drug that inhibits tissue necrosis factor-α. Recurrence is likely, however, if either drug is discontinued.[96,132]

HIV-infected patients have a higher incidence of recurrent herpetic lesions and aphthous stomatitis (Figs. 30.13 and 30.14). Approximately 10% of HIV-infected patients have herpes infection,[199] and multiple episodes are common. The CDC HIV classification system indicates that mucocutaneous herpes that lasts more than 1 month is diagnostic of AIDS in HIV-infected individuals.[39] Aphthae and aphthae-like lesions are common when patients are followed throughout the course of their immunosuppression.[93]

FIG. 30.13 Abnormal herpetic lesions in individuals with human immunodeficiency virus. (A) The lip crusting of primary herpetic gingivostomatitis. (B) Ulcerations of the gingiva, the alveolar mucosa, and the vestibule in the same patient. (C) Severe herpes labialis in the commissures of the lip. (D) A close-up view of herpes labialis. Note the fluid-filled vesicles.

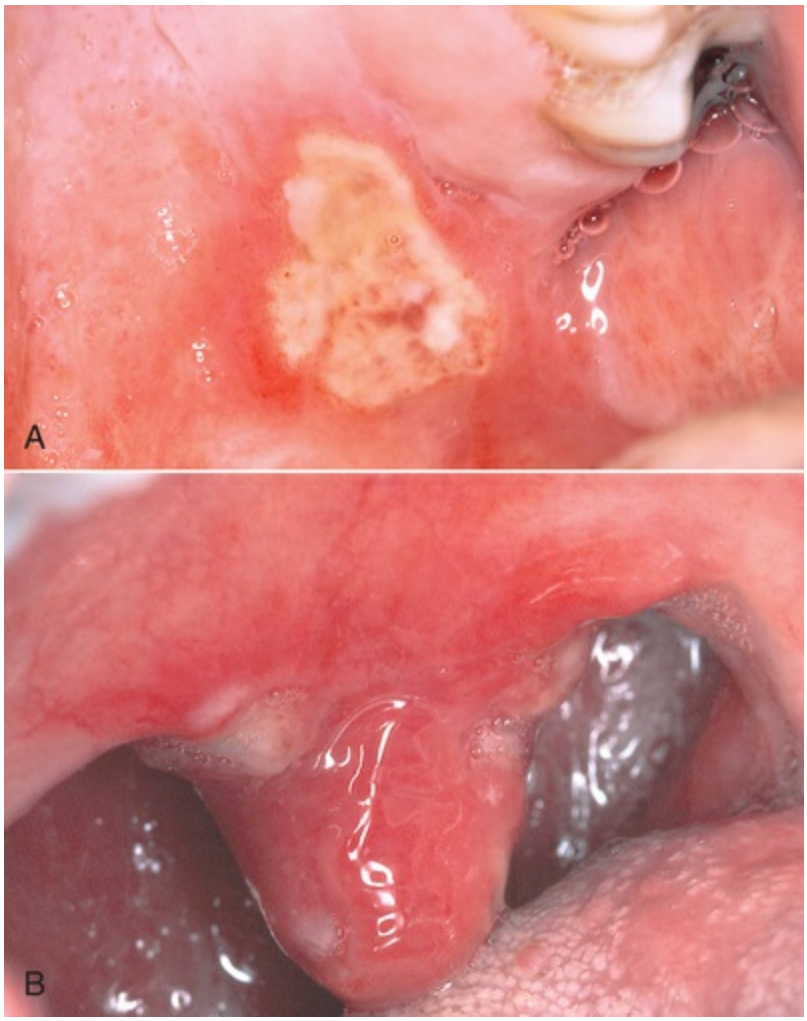

FIG. 30.14 Intraoral aphthous stomatitis in a patient with acquired immunodeficiency syndrome. (A) Major aphthous lesion in the left soft palate. (B) Ulcerations of the uvula in the same patient.

In healthy patients, herpetic and aphthous lesions are self-limiting and relatively easy to diagnose as a result of their characteristic clinical features (i.e., herpes on the keratinizing mucosa and aphthae on the nonkeratinizing surfaces). In HIV-infected patients, the clinical presentation and course of these lesions may be altered. Herpes may involve all mucosal surfaces and extend to the skin, and it may persist for months[72] (see Fig. 30.13). Atypical large, persistent, nonspecific, and painful ulcers are common in immunocompromised individuals. If healing is delayed, these lesions are secondarily infected, and they may become indistinguishable from persistent herpetic or aphthous lesions.[219]

A wide variety of bacterial and viral infections may produce

severe oral ulcerations in HIV-infected individuals.[258] Essentially, immunocompromised individuals are at risk for infectious agents that are endemic to their geographic location.[21,286] Atypical or nonhealing ulcers may require biopsy, microbial cultures, or both to determine the etiology. Oral ulcerations have been described in association with enterobacterial organisms such as *Klebsiella pneumoniae, Enterobacter cloacae,* and *Escherichia coli.*[219] Such infections are rare, and they are usually associated with systemic involvement. Specific antibiotic therapy is indicated, and the close coordination of oral therapy with the patient's physician is usually necessary.[219]

HSV, varicella-zoster virus, EBV, and CMV are frequently retrieved from nonspecific oral ulcers, thereby indicating a possible etiologic role.[258] Some atypical ulcers were found to be coinfected with both HSV and CMV or with both EBV and CMV.[222,267] These ulcers may be more common in individuals who are neutropenic in conjunction with their HIV infection. Neutropenia may also be induced by drugs such as zidovudine, trimethoprim-sulfamethoxazole, and gancyclovir.[148] Atypical ulcers may be more severe and persistent in individuals with low CD4 cell counts, and the presence of oral CMV-induced ulcers may be indicative of systemic CMV infection.[93]

Herpes labialis in HIV-infected individuals may be responsive to topical antiviral therapy (e.g., acyclovir, penciclovir, docosanol), thus reducing the healing time of lesions. In other patients, however, oral or labial herpetic lesions may require the use of systemic antiviral agents (e.g., acyclovir, valacyclovir, famciclovir).[8,70,72]

Recurrent aphthous stomatitis has been described in HIV-infected individuals, but the overall incidence may be no greater than that found in the general population.[68] Recurrent aphthous stomatitis may occur, however, as a component of the initial acute illness of HIV seroconversion. The incidence of major aphthae may be increased, and the oropharynx, esophagus, or other areas of the gastrointestinal tract may be involved[8] (see Fig. 30.14).

Available evidence indicates that the incidence of herpesvirus infections is not reduced by HAART, whereas the incidence of neutropenic ulcerations may actually increase.

Proven methods for the treatment of recurrent aphthous stomatitis include topical or intralesional corticosteroids, chlorhexidine or other antimicrobial mouth rinses, oral tetracycline rinses, and topical amlexanox. Systemic corticosteroid therapy may be necessary in some cases. Consequently, in patients with HIV infection and recurrent aphthae, closely coordinated medical and dental therapy may be necessary.[70,72]

Evidence indicates that many nonspecific oral ulcerations may be of viral origin, with HSV, EBV, and CMV being the most common[93] (eFig. 30.9). For this reason, the practitioner should consider the viral culturing of such lesions and the use of antiviral agents in treatment where appropriate.

EFIG. 30.9 A solitary ulcer in the soft palate. Culture confirmed the presence of cytomegalovirus.

Oral viral infections in immunocompromised individuals are often treated with acyclovir (200 mg to 800 mg administered 5 times daily for at least 10 days). Subsequent daily maintenance therapy (200 mg 2 to 5 times daily) may be required to prevent recurrence. Resistant viral strains are treated with foscarnet, ganciclovir, or valacyclovir.[7,263]

Topical corticosteroid therapy (fluocinonide gel applied three to six times daily) is safe and efficacious for the treatment of recurrent aphthous ulcers or other mucosal lesions in immunocompromised individuals.[70] However, topical corticosteroids may predispose immunocompromised individuals to candidiasis. Consequently, prophylactic antifungal medications should be prescribed.

Occasionally, large aphthae in HIV-positive individuals may prove to be resistant to conventional topical therapy. In these patients, medical consultation is recommended, and the administration of systemic corticosteroids (e.g., prednisone, 40 mg to 60 mg daily) or alternative therapy (e.g., thalidomide, levamisole, pentoxifylline) should be considered.[44,129] These agents may have significant side effects, however, and the clinician should remain alert for any evidence that is suggestive of an adverse drug reaction or interaction with currently prescribed medications.[68] Because virtually all antiviral agents used for the treatment of HIV infection have the potential for adverse side effects or drug interactions, the dental clinician should consider topical therapy when appropriate.

Salivary Gland Disorders and Xerostomia

Saliva is an important component of the oral mucosal immune system, and it contains many HIV inhibitors, such as HIV-1–specific antibodies, lysozyme, peroxidases, cystatins, lactoferrin, histatins, and others.[11,243] Saliva may also contain a specific salivary anti-HIV factor known as *secretory leukocyte protease inhibitor.* Its immune properties plus its flushing action may help to explain why HIV concentrations are low in saliva and why the oral cavity is rarely a site of HIV transmission. Conversely, dryness of the mouth (xerostomia) is common in HIV-positive individuals, and it worsens as the viral load increases to more than 100,000 copies/mm^3. In addition, the enlargement of the major salivary glands, particularly the parotids, is more common in HIV-positive individuals.[147]

Salivary gland hypofunction and xerostomia may be most common among HIV-infected men during both the early and advanced stages of HIV infection and immunosuppression. Salivary function does not appear to be affected by HAART, despite the fact that some individual antiretroviral medications are reported to induce xerostomia. However, it is clear that xerostomia is a relatively common condition among HIV-infected individuals and that up to 10% of these patients may be affected. Xerostomia appears to become more severe as immunosuppression worsens, and increased candidal carriage is associated with reduced salivary flow rate.[131]

One longitudinal study indicated that submandibular and sublingual hypofunction occurs earlier than parotid hypofunction, but the parotid glands become progressively less functional over time.

Reports of a possible interrelationship between salivary gland function and HIV infection have been difficult to assess, because there is little standardization of protocols to study salivary hypofunction and many medications used for the treatment of HIV infection and associated conditions may induce xerostomia. Despite these limitations, a carefully conducted study of xerostomia in HIV-positive and HIV-negative women indicated that HIV-positive individuals were nearly three times as likely to have zero unstimulated salivary flow rate as HIV-negative individuals. Zero unstimulated salivary flow rate was significantly associated with a CD4 count of less than 200, but no differences were found relative to viral load.[173]

Although some antiretroviral medications are reported to contribute to xerostomia, the overall effect of antiretroviral therapy may indicate that the drugs serve to prevent salivary gland hypofunction by controlling HIV replication.[173] Parotid enlargement associated with HIV infection may occur as the result of a condition described as diffuse infiltrative lymphocytosis syndrome, which is characterized by persistent circulating CD8+ lymphocytosis as well as visceral lymphocytic infiltration and parotid infiltration.[77] Other causes include cystic lymphoepithelial lesions, hyperplastic lymphadenopathy, bacterial and viral infections, Sjögren syndrome, and lymphoma.[77] In addition, HAART is associated with lipodystrophy syndrome, which may result in fat hypertrophy in the parotid glands in association with facial thinning and visceral fatty deposits. This syndrome is associated with dyslipidemia and increased insulin resistance.[124]

Dental Treatment Complications

Concerns have been expressed regarding the potential for postoperative complications (e.g., hemorrhage, infection, delayed wound healing) in individuals with HIV or AIDS. Medically compromised patients must be carefully managed in the dental

office to avoid undue treatment complications.[60] However, *systematic reviews of the literature indicate that special precautions are usually not necessary based simply on the HIV status of patients when performing periodontal treatment procedures such as dental prophylaxis, scaling and root planing, periodontal surgery, extractions, and the placement of implants.* On occasion, the poor overall health status of an individual with AIDS may limit periodontal therapy to conservative, minimally invasive procedures, and antibiotic therapy may be required.[10,63,64,90,195] When possible, antibiotics should be avoided in significantly immunocompromised individuals to minimize the risk of opportunistic infections (e.g., candidiasis), superinfection, and microorganism drug resistance.[169]

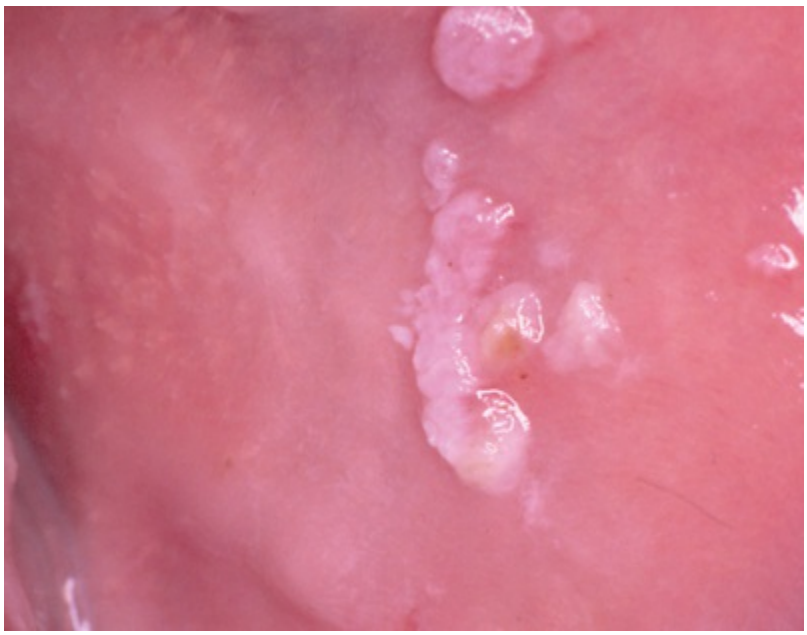
Adverse Drug Effects

A number of adverse drug-induced effects have been reported in HIV-positive patients, and the dentist may be the first to recognize an oral drug reaction. Foscarnet, interferon, and 2-3-dideoxycytidine occasionally induce oral ulcerations, and erythema multiforme has been reported with the use of didanosine.[54] Zidovudine and ganciclovir may induce leukopenia, which results in oral ulcers.[161] Xerostomia and altered taste sensation have been described in conjunction with diethyldithiocarbamate (Ditiocarb). HIV-positive patients are thought to be generally more susceptible to drug-induced mucositis and lichenoid drug reactions than the general population.[14,54,164] In some patients, mouth ulcers and mucositis resolve if drug therapy is continued beyond 2 to 3 weeks, but when drug effects are severe or persistent, an alternative therapy with different drugs should be used.

HAART drugs may induce adverse side effects, which range from relatively mild conditions such as nausea to the development of kidney stones. Individuals with hepatitis and HIV coinfection are susceptible to liver cirrhosis.[220] A newly identified adverse effect is lipodystrophy, a condition that features the redistribution of body fat. Affected individuals may develop gaunt facial features yet display excessive abdominal fat or even a fat pad on the rear of the shoulders (i.e., "buffalo hump"). This may be accompanied by severe systemic hyperlipidemia.[c] Other adverse effects of HAART

include increased insulin resistance,[111] gynecomastia,[152] toxic epidermal necrolysis, blood dyscrasias,[236] and possibly an increased incidence of oral warts.[27,100,222,278] Other reported oral or perioral adverse effects include oral lichenoid reactions, xerostomia, altered taste sensation, perioral paresthesia, and exfoliative cheilitis[24,25,30,166] (eFigs. 30.10 and 30.11).

EFIG. 30.10 Exfoliative cheilitis associated with highly active antiretroviral therapy.



EFIG. 30.11 Condyloma acuminatum in the left buccal mucosa of a patient with human immunodeficiency

virus who is receiving highly active antiretroviral therapy. Available evidence suggests that such human papillomavirus–induced lesions occur with increased frequency after the initiation of multidrug therapy for acquired immunodeficiency syndrome.

Gingival and Periodontal Diseases

Considerable research has focused on the nature and incidence of periodontal diseases in HIV-infected individuals. Some studies suggest that chronic periodontitis is more common in this patient population, but others do not. Periodontal diseases are more common among HIV-infected users of injection drugs, but this may relate to poor oral hygiene and a lack of dental care rather than decreased CD4 cell counts. However, some unusual types of periodontal diseases do seem to occur with greater frequency among HIV-positive individuals.[12,106,142,199,213,259]

Linear Gingival Erythema

A persistent, linear, easily bleeding, erythematous gingivitis has been described in some HIV-positive patients. The intensity of the erythema is disproportionate to the amount of plaque present. There is no ulceration, pocketing, or attachment loss,[268] and the condition does not respond predictably to conventional periodontal therapy. Lesions that are clinically identical to linear gingival erythema were observed before the advent of HIV in association with severely immunocompromised individuals or in those with NUG.

Linear gingival erythema (LGE) may or may not serve as a precursor to rapidly progressive NUP[92,94] (Figs. 30.15 and 30.16). The microflora of LGE may closely mimic that of periodontitis rather than gingivitis. However, *Candida* infection has been implicated as a major etiologic factor, and human herpesviruses have been proposed as possible triggers or cofactors.[7,53,226,250,268] Linear gingivitis lesions may be localized or generalized in nature. The erythematous gingivitis may be limited to marginal tissue, extend into attached gingiva in a punctate or diffuse erythema, or

extend into the alveolar mucosa.

FIG. 30.15 Linear gingival erythema and necrotizing ulcerative gingivitis in a patient with acquired immunodeficiency syndrome.

FIG. 30.16 Mild linear gingival erythema. The patient had a T4 count of 9 and a viral load that was too numerous to count.

The diagnosis of LGE may be difficult, because it can be mistaken for conventional marginal gingivitis. This may be especially true in studies from undeveloped countries or countries with newly identified and largely untreated patients with HIV and AIDS. This makes it difficult to identify the true prevalence of LGE in HIV-infected and noninfected individuals. This prompted the report from the Fifth World Workshop on Oral Health and Disease in AIDS to limit the diagnosis of LGE only to individuals who do not respond to conventional periodontal debridement procedures.[268]

Although LGE may sometimes be unresponsive to corrective therapy, such lesions may undergo spontaneous remission. Concomitant oral candidiasis and LGE lesions have been identified,

which suggests a possible etiologic role for candidal species in LGE.[142] In one study, direct microscopic cultures from LGE lesions implicated *Candida dubliniensis* in four patients, all of whom experienced complete or partial remission after systemic antifungal therapy.[274] It is not yet known whether candidal infection is an etiologic factor in all LGE cases. A systematic review indicates that LGE is more common among HIV-infected populations but that most individuals who are HIV positive do not experience LGE.[194]

Others have reported that LGE is most often found in HIV-positive individuals whose CD4+ counts are depressed (200 to 500 cells/mm^3 or <200 cells/mm^3) or whose viral loads are elevated, suggesting that it may represent an early marker of progressive immunodeficiency or even the transition to outright AIDS.[194,251]

LGE-like lesions can sometimes be adequately managed by following the therapeutic principles associated with marginal gingivitis. However, as mentioned previously, it has been suggested that gingivitis lesions that respond to conventional therapy do not represent LGE.[264] The affected sites should be scaled and polished. Subgingival irrigation with chlorhexidine or 10% povidone–iodine may be beneficial. The patient should be carefully instructed regarding the performance of meticulous oral hygiene procedures. The condition should be reevaluated 2 to 3 weeks after initial therapy. If the patient is compliant with home care procedures and the lesions persist, the possibility of a candidal infection should be considered. It is doubtful that topical antifungal rinses will reach the base of the gingival crevices. Consequently, the treatment of choice may be the empiric administration of a systemic antifungal agent, such as fluconazole, for 7 to 10 days.[116]

It is important to remember that LGE is often refractory to treatment. If so, the patient should be carefully monitored for developing signs of more severe periodontal conditions (e.g., NUG, NUP, NUS). The patient should be placed on a 2- to 3-month recall maintenance interval and re-treated as necessary. As mentioned previously, despite the occasional resistance of LGE to conventional periodontal therapy, spontaneous remission may occur for reasons that are not yet known.

Necrotizing Ulcerative Gingivitis

Some reports have described an increased incidence of NUG among HIV-infected individuals, although this has not been substantiated by other studies.[66,93,94,120,228,256]

There is no consensus regarding whether the incidence of NUG increases in HIV-positive patients.[191,195,220,239] However, one study evaluated the HIV status of individuals who presented with necrotizing periodontal diseases, and 69% were found to be HIV seropositive.[239] The treatment of NUG in these patients does not differ from that in HIV-negative individuals (see Chapter 43).

The affected gingiva may be exquisitely painful, and caution must be taken to avoid undue patient discomfort. Basic treatment may consist of the cleaning and debriding affected areas with a cotton pellet soaked in peroxide after applying a topical anesthetic. Escharotic oral rinses such as hydrogen peroxide should be used only rarely for any patient, and they are especially contraindicated in immunocompromised individuals. The patient should be seen daily or every other day for the first week, and debridement of affected areas is repeated at each visit. Plaque-control methods are gradually introduced. A meticulous plaque-control program should be taught and started as soon as the sensitivity of the area allows it. After initial healing has occurred, the patient should be able to tolerate scaling and root planing, if needed.

The patient should avoid tobacco, alcohol, and condiments. An antimicrobial oral rinse such as chlorhexidine gluconate 0.12% should be prescribed.

Systemic antibiotics such as metronidazole or amoxicillin may be prescribed for patients with moderate to severe tissue destruction, localized lymphadenopathy, or systemic symptoms. Metronidazole may be the antibiotic of choice, because it has been demonstrated to be effective for the treatment of NUG, and its narrow bactericidal spectrum may minimize the risk of secondary opportunistic infections such as candidiasis.[288] The use of prophylactic antifungal medication should be considered if antibiotics are prescribed.

The periodontium should be reevaluated 1 month after the resolution of acute symptoms to assess the results of treatment and to determine whether further therapy will be necessary.

Necrotizing Ulcerative Periodontitis

A necrotizing, ulcerative, rapidly progressive form of periodontitis occurs more frequently among HIV-positive individuals, although such lesions were described long before the onset of the AIDS epidemic. NUP appears to represent an extension of NUG in which bone loss and periodontal attachment loss occur.[182,239]

NUP is characterized by soft-tissue necrosis, rapid periodontal destruction, and interproximal bone loss[94,204] (Figs. 30.17, 30.18, and 30.19). Lesions may occur anywhere in the dental arches; they are usually localized to a few teeth, although generalized NUP is sometimes present after marked CD4+ cell depletion. Bone is often exposed, which results in necrosis and subsequent sequestration. NUP is severely painful at onset, and immediate treatment is necessary. Occasionally, however, patients undergo spontaneous resolution of the necrotizing lesions, which leave painless, deep, interproximal craters that are difficult to clean and that may lead to conventional periodontitis.[92]

FIG. 30.17 Necrotizing ulcerative periodontitis. Note the adjacent linear gingival erythema.

FIG. 30.18 Necrotizing ulcerative periodontitis in an otherwise healthy 19-year-old man without human immunodeficiency virus. (A) Anterior maxilla. (B) Palatal view.

FIG. 30.19 Early necrotizing ulcerative periodontitis in a patient with acquired immunodeficiency syndrome. (A) Facial view. (B) Lingual view. (C) Facial view of the complete resolution of necrotizing ulcerative periodontitis after treatment. (D) Lingual view.

Some evidence suggests slight differences between the microbial flora found in NUP lesions and that found in chronic periodontitis,[169,190] but most data implicate a similar microbial component in both diseases. An increasing number of studies, however, have identified the presence of candidal organisms and human herpesviruses of various types in individuals with necrotizing ulcerative periodontal diseases. The exact role of these organisms is not yet fully understood.[51,250] As discussed previously,

the reported periodontal health of HIV-infected individuals is subject to wide variations.[224,287] Riley and colleagues[224] examined 200 HIV-positive patients and found that 85 were periodontally healthy; none had NUG; 59 had gingivitis; 54 experienced mild, moderate, or advanced periodontitis; and only 2 had NUP. Glick and colleagues[94] reported the prevalence of NUP as 6.3% in an HIV-positive population, and they described a positive correlation between the presence of NUP and outright AIDS.[94]

Therapy for NUP includes local debridement; scaling and root planing; in-office irrigation with an effective antimicrobial agent such as chlorhexidine gluconate or povidone–iodine (Betadine); and the establishment of meticulous oral hygiene, including the home use of antimicrobial rinses or irrigation.[195,203,229] This therapeutic approach is based on reports that involved only a small number of patients.

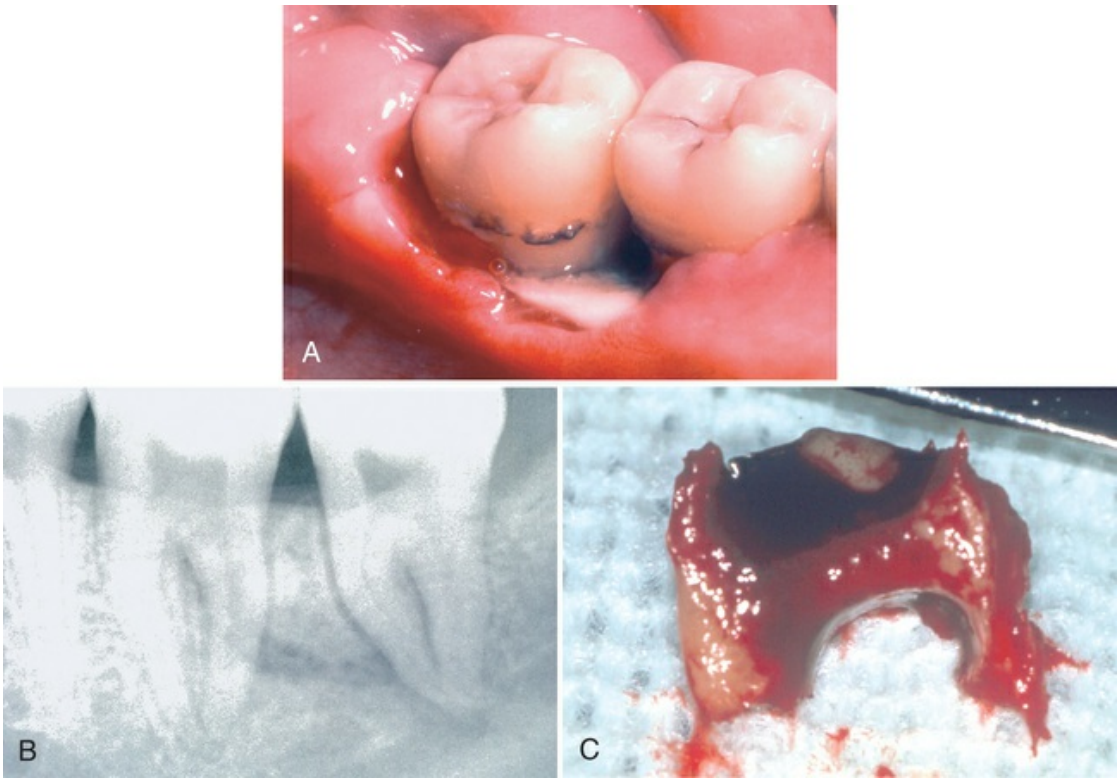
In patients with severe NUP, antibiotic therapy may be necessary, but it should be used with caution in HIV-infected patients to avoid an opportunistic and potentially serious localized candidiasis or even candidal septicemia.[166] If an antibiotic is necessary, metronidazole (250 mg, with two tablets taken immediately and then two tablets taken four times daily for 5 to 7 days) is the drug of choice. The prophylactic prescription of a topical or systemic antifungal agent is prudent if an antibiotic is used.

Necrotizing Ulcerative Stomatitis

NUS has occasionally been reported in HIV-positive patients. NUS may be severely destructive and acutely painful, and it may affect significant areas of oral soft tissue and underlying bone. It may occur separately or as an extension of NUP,[120,203] and it is often associated with the severe suppression of CD4 immune cells and an elevated viral load. The condition appears to be identical to cancrum oris (noma), a rare necrotizing destructive process that has been variously described as stomatitis gangrenosa, cancrum oris, or noma but that was originally reported in nutritionally deprived individuals, especially in Africa. However, today noma is very common in sub-Saharan African children with HIV.[47] NUS may be associated with severe immunodeficiency, regardless of the cause of

onset.[9,17,225]

Treatment for NUS may include an antibiotic such as metronidazole and the use of an antimicrobial mouth rinse such as chlorhexidine gluconate. If osseous necrosis is present, it is often necessary to remove the affected bone to promote wound healing[9] (eFig. 30.12).



EFIG. 30.12 (A) Necrotizing ulcerative stomatitis in the left mandibular molar area. (B) Radiographic view. Note the large osseous sequestrum. (C) The osseous sequestrum has been removed.

Chronic Periodontitis

A number of longitudinal studies and prevalence studies have suggested that HIV-positive individuals are more likely to experience chronic periodontitis than the general population.[12,163,174,214] Most studies, however, do not take into account the level of oral hygiene, the presence of preexisting gingivitis, poor diet, the age of the patient, smoking, other periodontal disease risk factors, the degree of immunodeficiency in

the population studied, or whether the individuals in the study are injection drug users (IDUs); these confounding factors cloud the issue.

Despite these limitations, most studies of chronic periodontitis (CP) in HIV-positive individuals report that the incidence is similar to that found in the general population. In addition, the periodontal pathogenic organisms that are routinely found in conventional CP are also found in HIV-associated CP. However, numerous studies have also reported a high prevalence of microorganisms in HIV-associated CP that are not found in the general population, including *Acinetobacter baumannii, Candida* spp., *Clostridium difficile, Clostridium clostridioforme, Entamoeba gingivalis, Enterobacter* spp., *Enterococcus faecalis, Enterococcus avium, Klebsiella pneumoniae, Mycoplasma salivarium,* and *Pseudomonas aeruginosa*.[58,268] Viral organisms such as EBV-1, HHV-7, and CMV have previously been found in gingivitis and mild to moderate periodontitis in systemically healthy individuals as well as in HIV-positive individuals. However, EBV and HHV-6 were reported at a higher frequency among HIV-positive patients. Even HHV-8, which is the KS virus, has been found in HIV-associated CP in the absence of KS. Whether or not these rare organisms influence periodontal pathogenesis has not been determined. However, it is certainly possible that these microorganisms may alter the subgingival biofilm environment and cause an HIV-infected individual to experience more rapid CP progression.[58,268] Many of these organisms are also associated with systemic diseases, thereby suggesting the possibility that CP in HIV-positive individuals may increase the risk for nosocomial infections as well as the development of antimicrobial resistance in affected individuals.

In previous studies, Shugars and colleagues reported that HIV-1 RNA was detectable in the saliva of some seropositive individuals and that both salivary and plasma levels were higher in those with HIV-associated periodontal diseases, leading some to suggest that periodontal infections may contribute to HIV viremia, as discussed previously.[244]

EBV-1 has been reported to be present more frequently in HIV-positive patients than in HIV-negative patients.[98] Lamster and colleagues[142] compared the frequency of oral lesions and

periodontal diseases between HIV-positive and HIV-negative individuals, some of whom were IDUs. Those researchers concluded that the lifestyles of IDUs may play a larger role in oral disease than the individual's HIV status. They also found that tongue lesions consistent with hairy leukoplakia were most common among seropositive homosexual males, whereas oral candidiasis and LGE were most common among IDUs.

Others have reported that the incidence and severity of chronic periodontitis are similar in HIV-positive and HIV-negative groups.[227,229] Klein and colleagues[137] evaluated heterosexuals with AIDS and found a larger percentage of women (91%) than men (73%) with gingivitis or periodontitis. Overall, most heterosexuals with AIDS had only gingivitis (70%), whereas others had moderate (27%) to severe (27%) periodontitis. This study suggests that periodontal diseases are no more frequent among heterosexuals with AIDS than they are among the general population. The finding of more frequent disease in women may reflect more women with AIDS being IDUs.

Drinkard and colleagues[66] evaluated the periodontal status of asymptomatic HIV-positive individuals and those with signs and symptoms of declining immune status. They reported that both groups were generally in good periodontal health, with no significant differences seen between groups. Others have described similar findings.[222,226,227,229,231]

A well-controlled study indicated that gingival recession and early attachment loss are more common in HIV groups than matched groups from the general population.[226] This appears to affirm that immunocompromised individuals are slightly more susceptible to chronic periodontitis than those with robust immune systems. In support of this theory, Ceballos-Salobrena and colleagues[34] reported a 30% decrease in the prevalence of chronic periodontitis among patients with AIDS who were receiving HAART. The majority of HIV-positive individuals experience gingivitis and chronic periodontitis in a manner similar to the general population. However, several studies have suggested that proinflammatory cytokines are increased in HIV-positive individuals, which suggests that chronic periodontitis may tend to be more severe in this population should it be present.[288]

There has been considerable interest in comparing the periodontal health of HIV-positive individuals before and after HAART.[156] At present, HAART appears to have significantly modified the course of HIV disease by changing it into a manageable chronic disease with improved quality of life for infected individuals and a life expectancy approaching that of individuals without HIV. HAART appears to have significantly reduced the incidence and severity of periodontal diseases in adults but not in children.[65] However, studies that have followed the post-HAART era for an extended period of time report that the potential for oral opportunistic infections such as candidiasis may still be present, whereas others note that comorbid conditions such as chronic obstructive pulmonary disease, cardiovascular disease, and diabetes may affect life expectancy among HAART-maintained individuals. Liberali and colleagues have suggested that early methods of identifying periodontal diseases in HIV-positive individuals may have underestimated their prevalence, because these methods did not measure the clinical attachment loss that may be markedly increased in the presence of necrotizing gingival and periodontal diseases but without a significant increase in probing depths.[144] By using current diagnostic criteria, those researchers determined that moderate to severe periodontal disease and gingivitis continue to be elevated in HIV-positive patients as compared with age-matched controls.[144] This information—in combination with the realization that ongoing periodontal diseases may adversely affect some systemic conditions and that CP may influence HIV recrudescence—indicates that achieving periodontal health in populations with HIV and AIDS is extremely important.

With proper home care and appropriate periodontal treatment and maintenance, HIV-positive individuals can anticipate reasonably good periodontal health throughout the course of their disease.[134] The median period between initial HIV infection and outright AIDS is approximately 15 years, and the life expectancy of persons living with AIDS has been significantly prolonged with current anti-HIV drug therapy.[23,42]

This indicates that HIV-infected patients are potential candidates for conventional periodontal treatment procedures, including surgery and implant placement. Treatment decisions should be

based on the overall health status of the patient, the degree of periodontal involvement, and the motivation and ability of the patient to perform effective oral hygiene (Fig. 30.20).

FIG. 30.20 Periodontal health in an individual with advanced acquired immunodeficiency syndrome.

Clearly, some less common periodontal diseases do occur more frequently in HIV-positive individuals, but these same conditions are also reported among HIV-negative persons. Consequently, definitions for these conditions and discussions of their management should not be construed as limiting them to individuals with HIV or AIDS.

Periodontal Treatment Protocol

It is imperative that medically compromised patients, including those with HIV or AIDS, be safely and effectively managed in dental practice.[240] Several universal treatment considerations are important to ensure that this goal is achieved.

Health Status

The patient's health status should be determined from the health history, the physical evaluation, and consultation with the patient's physician. Treatment decisions will vary, depending on the patient's state of health. For example, delayed wound healing and an increased risk of postoperative infection are possible complicating factors in patients with AIDS, but neither concern

should significantly alter treatment planning for an otherwise healthy, asymptomatic, HIV-infected patient with a normal or near-normal CD4 count and a low viral bioload.[85,109,153,207]

It is important to obtain information about the patient's immune status with questions such as the following:

- What is the CD4+ T4 lymphocyte level?
- What is the current viral load?
- How do current CD4+ T4 cell and viral load counts differ from previous evaluations? How often are such tests performed?
- How long ago was the HIV infection identified? Is it possible to identify the approximate date of original exposure?
- Is there a history of drug abuse, sexually transmitted diseases, multiple infections, or other factors that may alter immune response? For example, does the patient have a history of chronic hepatitis B, hepatitis C, neutropenia, thrombocytopenia, nutritional deficiency, or adrenocorticoid insufficiency?
- What medications is the patient taking?
- Does the patient describe or present with possible adverse side effects from medications?

Infection Control Measures

The clinical management of HIV-infected periodontal patients requires strict adherence to established methods of infection control, which should be based on guidance from the American Dental Association and the CDC. Compliance, especially with universal precautions, will eliminate or minimize risks to both patients and the dental staff.[85,150,275] Immunocompromised patients are potentially at risk for acquiring as well as transmitting

infections in the dental office and other health care facilities.[146,168,183]

Goals of Therapy

A thorough oral examination will determine the patient's dental treatment needs. The primary goal of dental therapy should be the restoration and maintenance of oral health, comfort, and function. At the very least, periodontal treatment goals should be directed toward the control of HIV-associated mucosal diseases, such as chronic candidiasis and recurrent oral ulcerations. Acute periodontal and dental infections should be managed, and the patient should receive detailed instructions regarding the performance of effective oral hygiene procedures.[90,116]

Conservative nonsurgical periodontal therapy should be a treatment option for virtually all HIV-positive patients, and the performance of elective surgical periodontal procedures, including implant placement, have been reported.[89,229] NUP or NUS can be severely destructive to periodontal structures, but a history of these conditions does not automatically dictate the extraction of involved teeth, unless the patient is unable to maintain effective oral hygiene in the affected areas. Decisions regarding elective periodontal procedures should be made with the informed consent of the patient and after medical consultation, when possible.

Maintenance Therapy

It is imperative for the patient to maintain meticulous personal oral hygiene. In addition, periodontal maintenance recall visits should be conducted at short intervals (i.e., every 2 to 3 months), and any progressive periodontal disease should be treated vigorously.[288]

As mentioned previously, systemic antibiotic therapy should be administered with caution. Blood and other medical laboratory tests may be required to monitor the patient's overall health status, and close consultation and coordination with the patient's physician are necessary.

Psychological Factors

HIV infection of neuronal cells may affect brain function and lead

to dementia. This may profoundly influence the responsiveness of affected patients to dental treatment. However, psychological factors are numerous in virtually all HIV-infected patients, even in the absence of neuronal lesions.

Patients may be greatly concerned with the maintenance of medical confidentiality, and such confidentiality must be upheld. Coping with a life-threatening disease may elicit depression, anxiety, and anger in such patients, and this anger may be directed toward the dentist and the staff. It is important to display concern and understanding for the patient's situation. Treatment should be provided in a calm, relaxed atmosphere, and stress to the patient must be minimized.[6]

The dentist should be prepared to advise and counsel patients regarding their oral health status. Dentists often encounter HIV-infected patients who are unaware of their disease status. The early diagnosis and treatment of HIV infection can have a profound effect on the patient's life expectancy and quality of life, and the dentist should be prepared to assist the patient with obtaining testing.[234,241] Any patient with oral lesions that are suggestive of HIV infection should be informed of the findings and, if appropriate, questioned about any previous exposure to HIV. If HIV testing is requested, it must be accompanied by patient counseling; therefore it may be best to obtain such tests through medical referral. However, if the dentist elects to request testing for the HIV antibody, the patient must be informed. In most circumstances, written informed consent is desirable before testing.

Levels of Clinical Significance

Philippe P. Hujoel

CHAPTER OUTLINE

Tangible Versus Intangible Benefits
Size of the Treatment Effect
Defining Four Levels of Clinical Significance
Summary

In one study of periodontal tissue regeneration, investigators reported that treatment that resulted in a gain of 1.2 mm in clinical attachment level and a reduction of 1 mm in probing pocket depth "may not have a great clinical impact."[5] In another study of a local antimicrobial, the investigators reported that a treatment that resulted in a gain of 0.0 mm in clinical attachment level and a reduction of 0.2 mm in probing depth had such clinical significance that it should "be used universally."[32] The American Dental Association defined a substantial effect as a mean change in attachment level greater than 0.6 mm.[28] These examples illustrate

that different individuals will reach different decisions regarding what is meant by the term *clinical significance.* As a result, the term *clinically significant* has become more useful to marketers than to clinicians.

The term *clinically significant* could be made more relevant by recognizing (1) the nature of the benefits (tangible/intangible) and (2) the size of the treatment effect (large/small). The presence or absence of these two criteria can be used to classify clinical significance into four levels. Before doing so, each classification term is described.

Tangible Versus Intangible Benefits

Controversies remain as to whether outcomes tested in clinical trials designed for drug approval are tangible to the patient.[8,33] Some will argue that the clinical significance of a treatment should depend exclusively on whether the benefits identified are tangible or intangible to the patient who undergoes the procedure.

Tangible benefits are treatment outcomes that reflect how a patient feels, functions, or survives. The word *tangible* is defined as "capable of being precisely identified or realized by the mind." Examples of tangible benefits could include improved oral health–related quality of life,[15,16] a decrease in self-reported symptoms (e.g., bleeding) after brushing, prevention of tooth loss, or elimination of a painful periodontal abscess. These examples of treatment benefits can precisely be identified or realized by the *patient's mind*—that is, they are tangible. Tangible benefits can also be referred to as "clinically relevant" or "clinically meaningful" benefits.

Key Fact

The issues with surrogate endpoints were recognized when the first randomized controlled trial in periodontics was published.[4] Almost half a century later, these issues remain largely unaddressed.

Intangible benefits cannot be realized or perceived by the patient's

mind. Changes in probing attachment level as a result of scaling, changes in enamel mineralization level as a result of fluoride application, and changes in the size of a periapical radiolucency as a result of root canal treatment are examples of changes that the patient's mind cannot identify or realize; thus they are described as intangible treatment benefits. Intangible treatment benefits can often be measured objectively by the clinician or by laboratory methods.

The first and most important step in assessing the clinical significance of a treatment is to determine whether the documented treatment benefits are tangible or intangible. This distinction is important because intangible benefits often do not translate into tangible benefits. A medication that lowers elevated blood lipid levels (an intangible benefit) may shorten lifespan (a tangible patient harm). A treatment that increases bone density (an intangible benefit) can increase fracture risk (a tangible patient harm).[11] A treatment that provides extensive periodontal bone regeneration (an intangible benefit) may lead to tooth loss (a tangible harm).[14] A treatment that has been shown to provide tangible benefits has a higher level of clinical significance than a treatment for which only evidence of intangible benefits exists. The finding that implant-supported dentures improve quality of life[1] has a higher level of clinical significance than the finding that scaling increases probing attachment levels. The finding that an endodontic treatment reliably eliminates tooth pain has a higher level of clinical significance than the finding that chlorhexidine reduces *Streptococcus mutans* levels.

Clinical Correlation

We do not have high-level evidence on all periodontal treatments. Obtaining such information will be helpful in documenting their treatment efficacy as we move into the 21st century, as future economic policies may channel limited health care resources to treatments with a proven tangible benefit.

Size of the Treatment Effect

A second important criterion for assessing clinical significance is the size of the treatment effect. The size of the treatment effect is a comparison of the success rates of the experimental treatment and the control treatment. This comparison can be a subtraction of the success rates, a division of the success rates, or some other mathematical operation. The size of the treatment effect, regardless of how it is calculated, has long been recognized as an important part of assessing clinical significance. The larger the likelihood of obtaining an expected benefit of a treatment (relative to a control treatment), the more clinically significant the treatment is. We suggest that the number needed to treat (NNT) may be a good measure to separate large and small treatment effects.

The likelihood of obtaining a treatment benefit (relative to the control) largely determines the methodological and analytic rigor required to establish treatment effectiveness. At one extreme, in all-or-none situations, reliable evidence may result from observations of a small number of patients. For example, no concurrent controlled trials were conducted to assess the effectiveness of general anesthesia. Determining the effectiveness of treatments that achieve a dramatic and immediate effect is straightforward, and only essential scientific principles (e.g., consistency of observations across different operators) are considered sufficient evidence of treatment effectiveness. Reportedly, the words "Gentleman, this is no humbug" were sufficient to convince an audience that general anesthesia was effective.

Key Fact

As in medicine, randomized controlled trials conducted in periodontics have primarily focused on surrogate endpoints. Having true endpoints in future randomized controlled trials will enhance the clinical applicability and relevance of their results.

At another extreme, if the likelihood of obtaining an expected treatment benefit is small, substantial rigor in both design and analysis of controlled clinical trials is required. The benefits of mammography screening for early detection of breast cancer, of one "clot-buster" drug over another after a myocardial event, and of

local antibiotics in the treatment of periodontitis are all so small that large randomized controlled trials are required to provide reliable evidence as to whether small benefits indeed are associated with treatment.

The likelihood of obtaining a treatment benefit is a determinant of clinical significance; the larger the likelihood, the more confident a patient can feel that a treatment will be successful. Although it is possible to have a clear, unequivocal definition of what constitutes a tangible benefit associated with treatment, it is not possible to have a similar rigorous definition of what can be considered a large likelihood. We define a "large treatment effect" as an NNT of 5, which under fortuitous and very unusual circumstances can be reliably identified with nonexperimental study designs.[7,29]

Clinical Correlation

Many periodontal treatments result in small changes in clinical attachment levels or probing depths and consequently lead to questions regarding the clinical significance of periodontal therapy. For instance, one systematic review reported by the American Dental Association (ADA) indicated that the addition of metronidazole to scaling and root planing provided an additional gain of 0.18 mm in attachment level. The ADA refers to such an effect as a "zero effect."[28] Small to zero treatment effects are common in clinical trials in medicine.

Defining Four Levels of Clinical Significance

Based on the nature of the benefit (tangible/intangible) and the size of the treatment effect (large/small), four levels of clinical significance can be defined (Table 31.1). In order of decreasing levels of significance, these are numbered from 1 to 4.

TABLE 31.1

Definition of Levels of Significance Based on Size and Nature of the Benefit

SIZE OF THE BENEFIT			
Clinical Significance		**Large**[c]	**Small**[d]
Nature of the Benefit	Tangible[a]	Level 1	Level 2
	Intangible[b]	Level 3	Level 4

[a]Tangible benefits are outcomes that directly measure how a patient feels, functions, or survives.

[b]Intangible benefits are outcomes that are not perceivable by the patient's mind.

[c]A large benefit is defined as one that can reliably be identified using epidemiologic methodology.

[d]A small benefit is defined as one that requires randomized controlled trials for reliable identification.

Clinical Significance Level 1

Treatments of clinical significance level 1 are the "magic bullets" or "miracle cures," in which the treatment provides a tangible benefit and a large treatment effect. Examples include the use of vitamin C to treat scurvy, bone marrow transplantation to treat leukemia, and a very-low-carbohydrate diet to prevent all forms of dental decay. In all three examples, the benefits of the treatment are tangible and the size of the treatment effect is large.

Understanding the biologic mechanisms of a treatment is not required to establish that the treatment has clinical significance level 1. Lemon juice was identified as an effective method to prevent scurvy in 1601, but it was not until the beginning of the 20th century that vitamin C was isolated.[25] The dangers of carbohydrates in dental decay were recognized millennia before potential mechanisms of action were understood. Digitalis was discovered as a treatment for "dropsy" long before physicians became aware of the drug's cardiac effects.[31] Lithium is an effective drug for bipolar disorder, but its mechanism of action remains largely unknown.[27] In contrast, hormone replacement therapy (HRT), for which the biologic mechanisms explaining how the drug provided benefits were supposedly so well understood, resulted in more harm than good.[12]

Key Fact

The size of the anticipated treatment effect has a profound impact on the planning of randomized clinical trials. The smaller the treatment effect, the larger the number of patients who will need to be recruited.

Treatments of clinical significance level 1 are not always immediately accepted or widely used. It took the British Navy 264 years from the time of the observations of Captain James until a universal preventive policy was established to prevent scurvy.[3] The lack of appreciation for this treatment of clinical significance level 1 was unfortunate:

It is estimated that 5000 lives a year were needlessly lost from scurvy during this period: that is a total of nearly 800,000. In the 200 years from 1600 to 1800 nearly 1,000,000 men died of an easily preventable disease. There are in the whole of human history few more notable examples of official indifference and stupidity producing such disastrous consequence to human life.[24]

Although it is easy to determine clinical significance level 1 in retrospect, it may be difficult to recognize at the time of discovery.

Clinical Significance Level 2

Treatments of clinical significance level 2 are those that have demonstrated a tangible benefit but for which the likelihood of obtaining the benefit from treatment is small. As the size of the benefit of one therapy over another decreases, randomized controlled trials (RCTs), large in size and rigorous in execution and analysis, are required to provide unequivocal evidence that the treatment provides tangible patient benefits. Examples of such treatments include the advantage of tissue plasminogen activator (t-PA) over streptokinase[30] and the benefits of penciclovir in the treatment of herpetic lesions.[12]

Determining the clinical relevance of treatments of clinical significance level 2 is an individual choice in which issues such as cost and side effects often play a more important role. For example, administering antibiotics to 25 individuals could prevent 1 person

from experiencing early implant loss.[6] Is a 4% increased survival probability of dental implants worth the potential side effects of antibiotics? Different individuals, different governments, and different health insurance companies may decide differently on this important question.

The use of penciclovir in the treatment of herpetic lesions provides another example of a drug of clinical significance level 2. When applying a 1% penciclovir cream, 70% of patients reported lesion healing by day 6. When applying placebo cream, 59% of patients reported lesion healing by day 6.[21] Is an 11% increased probability of lesion healing (NNT of 9) by day 6 of sufficient magnitude to refer to the treatment as "clinically relevant"? Once again, the answer to this question is highly subjective; the cream might be worth its weight in gold to a teenager when prom night is approaching, but it may be clinically irrelevant to an adult. By using the terminology "clinical significance level 2," the concept of small, tangible patient benefit can quickly be communicated without becoming trapped in meaningless discussions regarding the clinical relevance of small benefits.

Key Fact

An all-or-none situation is defined as one of the following two scenarios in evidence-based medicine: either when all patients experienced an adverse tangible outcome before the treatment became available but some do not experience this adverse outcome, or when some patients experienced the tangible adverse outcome before the treatment became available but none now experience it. All-or-none situations reflect the highest level of evidence.[19]

Clinical Significance Level 3

Treatments of clinical significance level 3 are the magic bullets or miracle cures in the surrogate world, in which the beneficial but intangible effects are so convincing that the need for RCTs may appear unethical. Examples of such treatments include highly active antiretroviral therapy (HAART) in patients with acquired

immunodeficiency syndrome (AIDS),[18] imatinib (Gleevec) in the treatment of chronic myeloid leukemia,[31] and chlorhexidine varnish in the prevention of caries.[26] In periodontics, examples of treatments of clinical significance level 3 could be complete restoration of periodontal attachment and bone around teeth that had extensive destruction of the periodontal apparatus, and reconstruction of voluminous amounts of bone on an atrophic mandible for the purpose of placing dental implants.

With a treatment that has the label "clinical significance level 3," there is always uncertainty as to whether the intangible benefits translate into real, tangible patient benefits. For instance, bone marrow transplantation to the periodontal defect indeed resulted in regenerating prodigious amounts of bone, but about 50% of the teeth were lost due to root resorption.[14] Nonetheless, the larger the effect size observed on the surrogate, the more likely the surrogate benefit translates into a real, tangible patient benefit.[9]

Clinical Correlation

It is easy to overlook all-or-none situations in dentistry. For instance, root caries in periodontal patients can be prevented with a very-low-carbohydrate diet.[13] Such a conclusion can be made because carbohydrates and dental caries reflect an all-or-none situation.

For certain treatments, such as HAART for AIDS or Gleevec for chronic leukemia, the opportunity may exist to avoid RCTs, and treatments of clinical significance level 3 can become those of level 1 by means of epidemiologic studies in which large secular changes are observed in the incidence of true endpoints since the introduction of the novel treatment. For example, drastic changes in the viral load of human immunodeficiency virus (HIV) have been shown to lead to large reductions in the risk of AIDS and death. Using historical controls, it was shown that HAART treatment reduced AIDS risk by 38% and mortality risk by 34%.[17] A large surrogate benefit (clinical significance level 3) translated into a large survival benefit (clinical significance level 1).

However, assuming that large, intangible treatment benefits

invariably translate into tangible benefits remains dangerous, no matter how large the effect on the surrogate endpoint. A 40% chlorhexidine varnish used for the prevention of caries was reported to result in a 99.9% reduction in mutans streptococci counts in all 20 subjects treated, and the counts stayed below detectable levels for at least 4 weeks in 9 subjects. In contrast, the placebo varnish sealant led to only a 32% mutans streptococci reduction, and none of the 20 subjects had mutans streptococci below detectable levels for 4 weeks.[19] Based on these data, it was reported that "Chlorzoin will wipe out dental decay much like smallpox." A subsequent RCT in 1240 children at high risk for caries did not translate into a reduction of large cavities in the teeth: the Chlorzoin group had 6.8 D3 lesions (standard deviation, 6.2), and the placebo group had 6.4 D3 lesions (standard deviation, 6.4) —in other words, fewer lesions.[29] It has become clear since then that most forms of chlorhexidine are contraindicated in the treatment of caries.[10] A large treatment effect on a surrogate in this instance did not translate into a tangible benefit.

Clinical Significance Level 4

Treatments of clinical significance level 4 are those that have reliable evidence on small, intangible treatment benefits. Because the treatment effects are small, epidemiologic studies are incapable of identifying treatments of clinical significance level 4. In other words, rigorously conducted RCTs are necessary to reliably identify a small surrogate benefit. Examples of treatments of clinical significance level 4 include those that cause a small decrease in lipid level, a small drop in blood pressure, or a small decrease in pocket depth. A large leap of faith is often required to jump from the observation that small changes in surrogate endpoints translate into real, tangible benefits.

Clofibrate, used to lower lipid levels, is an example of a drug of clinical significance level 4. Clofibrate reduced mean cholesterol levels from 324 mg to 224 mg and mean triglyceride levels from 271 to 125 (which can be argued are "not so small" mean changes).[2] Clofibrate was the most widely prescribed lipid-lowering agent in the United States, but uncertainty remained as to whether it

actually provided a tangible patient benefit. Advertisements that were widely used in medical journals accurately reflected the clinical uncertainty surrounding use of this drug. A textbox within the advertisements stated, "It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the mortality and the morbidity due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question." A subsequent World Health Organization (WHO) cooperative trial on clofibrate revealed the wisdom of this disclaimer. The trial outcome showed that clofibrate resulted in excess mortality of 47%, providing yet another example of a misleading surrogate.[22]

Treatment of clinical significance level 4 may cause more harm than good.[20] This observation has significant consequences in periodontics, because approved periodontal therapies are commonly of clinical significance level 4 and information on their long-term safety and lack of harm is minimal.

Summary

Two important determinants of clinical significance are the nature of benefit (tangible versus intangible) and the likelihood of obtaining the benefit (when compared to the control treatment). These two characteristics can be used to define four hierarchic levels of clinical significance. Treatments that provide a tangible patient benefit (levels 1 and 2) are of greater value and should correspond to a higher level of clinical significance than treatments with evidence of only intangible benefits (levels 3 and 4). Similarly, treatments with a large likelihood of clinical improvement (levels 1 and 3) are clinically more significant than treatments with a small likelihood of clinical improvement (levels 2 and 4). Providing four hierarchical levels of clinical significance may help clinicians and patients communicate more effectively regarding the clinical significance of a treatment. In particular, dental clinicians should inform their periodontal patients that no unequivocal evidence is available showing that periodontal treatments provide tangible patient benefit. We hope that we provide tangible benefits to our

patients, but the RCTs are lacking to ensure that we really do.

Dental History
Photographic Documentation
Clinical Examination
Tactile Periodontal Examination
Periodontal Charting *(e-only)*
Examination of the Teeth and Implants
Radiographic Examination
Laboratory Aids to Clinical Diagnosis
Periodontal Diagnosis
Assessment of Biofilm Control and Patient Education
Conclusion

Proper diagnosis is essential to intelligent treatment. Periodontal diagnosis should first determine whether disease is present. It should then identify the disease, and its severity and extent. Finally, it should provide an understanding of the underlying pathologic processes and their causes. Part 2 of this book provide detailed descriptions of the different diseases that can affect the periodontium.

The periodontal diagnosis is determined after careful analysis of the case history and evaluation of the clinical signs and symptoms as well as the results of various diagnostic procedures (e.g., probing, mobility assessment, radiographs, blood tests, and biopsies).

The interest should be in the patient who has the disease and not simply the disease itself. Diagnosis must therefore include a general evaluation of the patient and a consideration of the oral cavity.

Diagnostic procedures must be systematic and organized for specific purposes. It is not enough to assemble facts. Findings must be pieced together so that they provide a meaningful explanation of the patient's periodontal problem. The following is a recommended sequence of procedures for the diagnosis of periodontal diseases.

Overall Appraisal of the Patient

From the first meeting, the clinician should attempt an overall appraisal of the patient. This includes consideration of the patient's mental and emotional status, temperament, attitude, and physiologic age.

Health History

Most of the health history is obtained at the first visit, and it can be supplemented by pertinent questioning at subsequent visits. The health history can be obtained verbally by questioning the patient and recording his or her responses in the patient chart or by means of a questionnaire that the patient completes prior to the

appointment. Fig. 32.1 shows the health history form recommended by the American Dental Association.

Health History Form

Has a physician or previous dentist recommended that you take antibiotics prior to your dental treatment? ☐ ☐ ☐

Name of physician or dentist making recommendation: _____ Phone: _____

Do you have any disease, condition, or problem not listed above that you think I should know about? ☐ ☐ ☐
Please explain:

NOTE: Both doctor and patient are encouraged to discuss any and all relevant patient health issues prior to treatment.
I certify that I have read and understand the above and that the information given on this form is accurate. I understand the importance of a truthful health history and that my dentist and his/her staff will rely on this information for treating me. I acknowledge that my questions, if any, about inquiries set forth above have been answered to my satisfaction. I will not hold my dentist, or any other member of his/her staff, responsible for any action they take or do not take because of errors or omissions that I may have made in the completion of this form.

Signature of Patient/Legal Guardian: _____ Date: _____

FOR COMPLETION BY DENTIST

Comments: _____

FIG. 32.1 Medical history form from the American Dental Association. (From © American Dental Association. Reprinted with permission.)

The importance of the health history should be clearly explained, because patients often omit information that they cannot relate to their dental problems. The patient should be made aware of the following: (1) the possible impact of certain systemic diseases,

conditions, behavioral factors, and medications on periodontal disease, its treatment, and treatment outcomes; (2) the presence of conditions that may require special precautions or modifications of the treatment procedure (see Chapter 39); and (3) the possibility that oral infections may have a powerful influence on the occurrence and severity of a variety of systemic diseases and conditions (see Chapter 15).

The health history should include reference to the following:

1. The date of the last physical exam and the frequency of physical exams and physician visits. If the patient is under the care of a physician, the nature and duration of the problem and its therapy should be discussed. The name, address, and telephone number of the physician should be recorded, because direct communication with him or her may be necessary.
2. Details regarding hospitalizations and operations, including the diagnosis, the type of operation, and any untoward events (e.g., anesthetic, hemorrhagic, or infectious complications) should be obtained.
3. All medical problems (e.g., cardiovascular, hematologic, endocrine), including infectious diseases, sexually transmitted diseases, high-risk behavior for human immunodeficiency virus infection, and possible occupational disease, should be inquired.
4. Abnormal bleeding tendencies, such as nosebleeds, prolonged bleeding from minor cuts, spontaneous ecchymosis, a tendency toward excessive bruising, and excessive menstrual bleeding, should be cited. These symptoms should be correlated with the medications that the patient is taking.
5. Information is needed for females regarding the onset of puberty, menopause, menstrual disorders, hysterectomy, pregnancies, and miscarriages.
6. A list of all medications being taken and whether they were prescribed or obtained over the counter should be included. All of the possible effects of these medications should be carefully analyzed to determine their effect, if any, on the

oral tissues and also to avoid administering medications that would interact adversely with them. Special inquiry should be made regarding the dosage and duration of therapy with anticoagulants and corticosteroids. Patients who are taking any of the family of drugs called bisphosphonates (e.g., Actonel, Fosamax, Boniva, Aredia, Zometa), which are often prescribed for osteoporosis, should be cautioned about possible problems related to osteonecrosis of the jaw after undergoing any form of oral surgery involving bone.

7. The patient's allergy history should be taken, including that related to hay fever, asthma, sensitivity to foods, sensitivity to drugs (e.g., aspirin, codeine, barbiturates, sulfonamides, antibiotics, procaine, laxatives), and sensitivity to dental materials (e.g., latex, eugenol, acrylic resins).
8. A family history should be taken, including that of bleeding disorders, cardiovascular disease, diabetes, or periodontal diseases.
9. Detailed information on current and history of alcohol, recreational drugs, and tobacco use, and desire to quit should be elicited.

As part of the overall patient appraisal, baseline vitals—at minimum, blood pressure—should be obtained. For patients who are on medications such as bisphosphonates, anticoagulants, or antiplatelets or patients who do not know the control of their systemic disease, such as diabetes, hypertension, or immunodeficiency, a medical consultation is required before any treatment can be rendered.

Dental History

Chief Complaint and Current Illness

Some patients may be unaware of any problems. However, many may report bleeding gums, loose teeth, spreading of the teeth with the appearance of spaces where none existed before, foul taste in the mouth, or an itchy feeling in the gums that is relieved by

digging with a toothpick. There may also be pain of varied types and duration, including constant, dull, gnawing pain; dull pain after eating; deep radiating pain in the jaws; acute throbbing pain; sensitivity when chewing; sensitivity to hot and cold; burning sensation in the gums; or extreme sensitivity to inhaled air.

The dental history should include reference to the following:

1. Visits to the dentist should be listed, including their frequency, the date of the most recent visit, the nature of the treatment, and dental prophylaxis, periodontal maintenance, or scaling and root planing by a dentist or hygienist, including the frequency of cleaning and date of the most recent cleaning.
2. The patient's oral hygiene regimen should be described, including toothbrushing frequency, time of day, method, type of toothbrush and dentifrice, and interval when brushes are replaced. Other methods for mouth care, such as mouthwashes, interdental brushes, other devices, water irrigation, and dental floss, should also be listed.
3. Any orthodontic treatment, including its duration and the approximate date of termination, should be noted.
4. If the patient is experiencing pain in the teeth or in the gingiva, the manner in which the pain is provoked, its nature and duration, and the manner in which it is relieved should be described.
5. Note the presence of any gingival bleeding, including when it first occurred; whether it occurs spontaneously, on brushing or eating, at night, or with regular periodicity; whether it is associated with the menstrual period or other specific factors; and its duration of the bleeding and the manner by which it is stopped.
6. A bad taste in the mouth and areas of food impaction should be mentioned.
7. Assess whether the patient's teeth feel “loose” or insecure, if he or she has any difficulty chewing, and whether there is any tooth mobility.
8. Note the patient's general dental habits, such as grinding or clenching of the teeth during the day or at night. Do the

teeth or jaw muscles feel “sore” in the morning? Are there other habits to address, such as tobacco smoking or chewing, nail biting, or biting on foreign objects?

9. Discuss the patient's history of previous periodontal problems, including the nature of the condition and, if it was previously treated, the type of treatment received (surgical or nonsurgical) and the approximate period of termination. If, in the opinion of the patient, the present problem is a recurrence of previous disease, what does he or she think caused it?
10. Note whether the patient wears a removable prosthesis. Does the prosthesis enhance or is it a detriment to the existing dentition or the surrounding soft tissues?
11. Does the patient have implants to replace any missing teeth?

Learning Box 32.1

Periodontal examination and diagnosis must include obtaining a thorough health and dental history.

Photographic Documentation

An important part of periodontal examination and diagnosis is the documentation of clinical findings. Digital photographic documentation is important and useful for record-keeping, education of both the clinician and the patient, communication with referrals and colleagues, and planning and treatment of high aesthetic demand cases. Photographs can provide details that a clinician may not otherwise remember and allow the clinician to evaluate the mouth after the patient leaves and to monitor changes in the tissue over time. If possible, at the beginning of the clinical examination, a set of intraoral photos (Fig. 32.2) should be taken before the tissue is probed and manipulated to obtain an undisturbed baseline of the patient's mouth with gingiva and biofilm intact. These initial photos, when presented to the patient on a large-screen monitor, can be extremely powerful in educating and helping the patient to understand the conditions of his or her

mouth; the presence and location of biofilm, inflammation, and any tissue abnormality; and the need for improvement in oral hygiene or treatment (Fig. 32.3).

FIG. 32.2 At minimum, an initial set of photographs for a periodontal patient contains nine images. (A) The retracted frontal image is a direct shot, whereas the remaining eight images are mirror shots. (B) The two buccal shots are flipped horizontally and compiled with the remaining seven images to create a composite of the whole dentition. (Copyright Jonathan H. Do, DDS. All rights reserved.)

FIG. 32.3 An image capturing the palatal surfaces of the anterior maxilla is presented on a 27-inch computer screen to help a patient understand her periodontal disease. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Learning Box 32.2

Initial photographs should be taken before the tissue is probed and manipulated to obtain an undisturbed baseline of the patient's mouth with gingiva and biofilm intact.

Clinical Examination

Examination of Extraoral Structures

Clinical examination should begin with an evaluation of the extraoral structures for abnormalities. The temporomandibular joints should be assessed for pain, crepitus, clicking, and range of motion. The muscles of mastication should be palpated for pain and tenderness.

Because periodontal, periapical, and other oral diseases may result in lymph node changes, the clinician should routinely examine and evaluate the lymph nodes of the head and neck. Lymph nodes can become enlarged or indurated as a result of an infectious episode, malignant metastases, or residual fibrotic

changes.

Inflammatory nodes become enlarged, palpable, tender, and fairly immobile. The overlying skin may be red and warm. Patients are often aware of the presence of "swollen glands." Primary herpetic gingivostomatitis, necrotizing ulcerative gingivitis, and acute periodontal abscesses may produce lymph node enlargement. After successful therapy, lymph nodes return to normal in a matter of days to weeks.

Examination of the Oral Cavity

The entire oral cavity should be carefully examined, beginning with oral hygiene. The cleanliness of the oral cavity is appraised in terms of the extent of accumulated food debris, biofilm, calculus, and tooth surface stains, as well as biofilm coating of the dorsum of the tongue (Fig. 32.4). Oral malodor, which is also termed *fetor ex ore, fetor oris,* or *halitosis,* is a foul or offensive odor that emanates from the oral cavity. When present, mouth odors may be of diagnostic significance, and their origin may be either oral or extraoral (remote).[63] Chapter 49 discusses in detail the problems related to oral malodor.

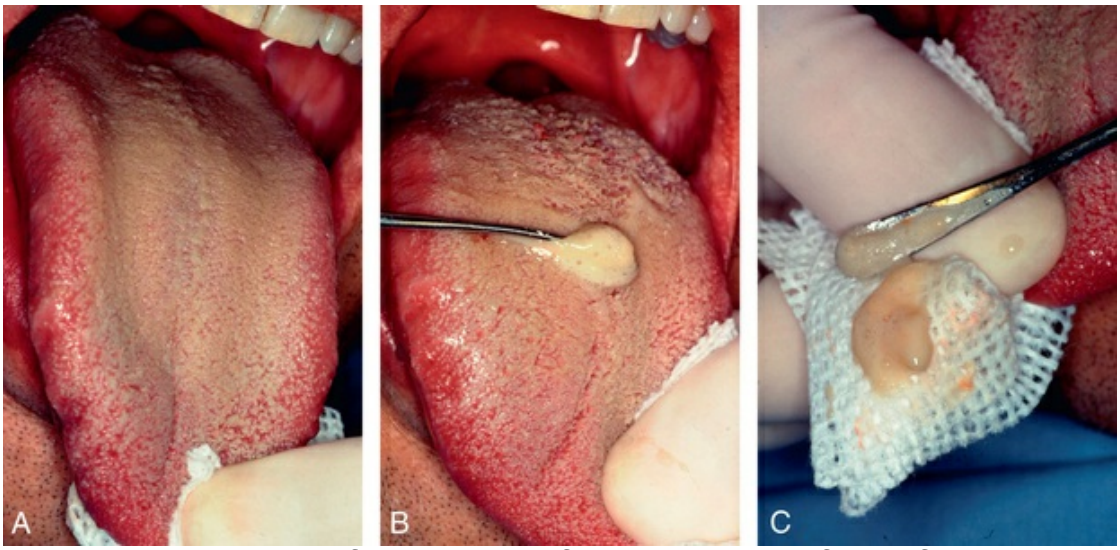

FIG. 32.4 A biofilm coating of the dorsum surface of the tongue (A) can be a source of oral malodor. When the tongue is heavily coated, the biofilm may need to be scraped off with a spatula (B and C).

The lips, the floor of the mouth, the tongue, the palate, the vestibule, and the oropharyngeal region should be evaluated for abnormalities and pathologies. The oral mucosa in the lateral and apical areas of the tooth may be palpated for tenderness to detect periapical and periodontal abscesses.

Although not all findings are related to periodontal problems, the dentist should detect all pathologic changes that are present in the mouth and, if necessary, make the appropriate dental or medical referral.

Examination of the Periodontium

The periodontal examination should be systematic and should not immediately begin with insertion of the periodontal probe into the gingival crevice, which can be uncomfortable and traumatic for a patient and may induce bleeding that may make visualization of inflammatory changes in the soft tissue challenging. Periodontal disease occurs as a result of biofilm accumulating on the tooth surface and the adjacent tissue responding to it. Therefore the periodontal examination should begin with a thorough and careful visual evaluation of the gingival margin to assess biofilm and calculus accumulation as well as inflammatory changes in the soft tissue (Fig. 32.5). Once a thorough visual periodontal assessment has been completed, the gingiva, the gingival crevice, and the subgingival tooth surface are carefully probed. Thorough probing of the gingival crevice and the surrounding tissue provides a wealth of valuable information beyond probing depth and bleeding on probing that is essential to the diagnosis and treatment of periodontal disease.

FIG. 32.5 The inflammatory response in the marginal gingiva is a result of biofilm accumulation on the tooth surface along the gingival margin. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Learning Box 32.3

Examination of the periodontium consists of two parts: visual examination and tactile examination.

Visual Periodontal Examination

Visual examination begins with drying the tissue and taking a survey of biofilm and calculus accumulation to assess oral hygiene as well as clinical signs of inflammation (erythema, edema, etc.) and recession to assess the presence and severity of disease.

Visual Examination of Biofilm and Calculus

There are many methods available for assessing biofilm and calculus accumulation.[19] The presence of biofilm and supragingival calculus can be observed directly. Biofilm frequently accumulates in concavities along the gingival margins and in embrasure spaces, especially in difficult-to-reach places, such as the distal surface of the distal-most tooth in the quadrant and the lingual surfaces of the mandibular molars (Fig. 32.6). Supragingival calculus commonly accumulates on the lingual surfaces of the mandibular anterior teeth and the buccal surfaces of the maxillary molars due to the

presence of the respective Wharton and Stensen salivary ducts and ineffective biofilm removal. The amount and location of biofilm and supragingival calculus may provide insights into the effectiveness of the patient's biofilm control as well as possible inflammatory changes in the tissue. Biofilm on the buccal and facial surfaces of teeth closest to the midline are most accessible for removal. The presence of biofilm in these areas may suggest inadequate oral hygiene (see Fig. 32.5). The absence of biofilm may not necessarily indicate that the patient practices good oral hygiene at home or that the disease is absent, as many patients, out of courtesy, brush their teeth thoroughly before seeing a dentist. The presence or absence of biofilm should be correlated to the presence and severity or absence of gingival inflammation.

FIG. 32.6 Biofilm frequently accumulates on tooth surfaces in concavities along the gingival margin and interproximal spaces. (Copyright Jonathan H. Do, DDS. All rights reserved.)

The presence of subgingival calculus may not be easily detected. Sometimes shallow subgingival calculus may be visible along the gingival margin or through the soft tissue if the soft tissue is thin (Fig. 32.7). Most of the time, subgingival calculus will need to be detected by careful probing of the root surface. The presence of inflammatory changes in the soft tissue may provide clues to the location of the subgingival calculus.

FIG. 32.7 (A) Subgingival calculus can be visible on the tooth surface *(arrows)* along the gingival margin. Its presence is associated with inflammatory changes in the tissue. Where biofilm and calculus are absent, the gingiva is pink, firm, and stippled (circle). (B) Subgingival calculus may be visible through the marginal gingiva. (C) Retraction of the gingiva confirms its presence. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Although radiographs may sometimes reveal heavy calculus deposits interproximally and even on the facial and lingual

surfaces, they cannot be relied on for thorough detection of calculus.

Visual Examination of the Gingiva

The gingiva is the keratinized collar of masticatory mucosa around the teeth. It extends from the gingival margin to the mucogingival junction. On the palate, where the mucogingival junction is absent, the gingiva extends apically from the mucogingival junction and merges seamlessly with the mucosa of the hard palate.

The width of the gingiva is the distance from the mucogingival junction to the gingival margin. The mucogingival junction can be determined by stretching the lip and cheek or by placing a probe horizontally in the vestibule and rolling to the mucosa coronally. The mucogingival junction is where the mucosa stops rolling or moving. It is common for teeth to be surrounded by gingiva. However, there may be sites where keratinized tissue is absent and the gingival margin is lined by nonkeratinized mucosa.

Evaluation of the gingiva requires the tissue to be dried before accurate observations can be made. The presence of saliva can obscure details (Fig. 32.8). Once the gingiva is thoroughly dried with gauze, it is evaluated and assessed for inflammatory changes. Subtle inflammatory changes in the marginal gingiva may be best detected by comparing the marginal gingiva to the gingival tissue 2 or 3 mm away from the gingival margin, where the tissue is likely to be healthy (Fig. 32.9). Inflammatory changes at each site are correlated with the presence and severity of biofilm and calculus. If biofilm and supragingival calculus are insignificant, inflammatory changes may suggest the presence of subgingival calculus or other contributing factors.

FIG. 32.8 Saliva obscures details. (A) The gingiva appears smooth when covered in saliva. (B) Once dried, stippling is visible, and erythema and edema become more obvious. (Copyright Jonathan H. Do, DDS. All rights reserved.)

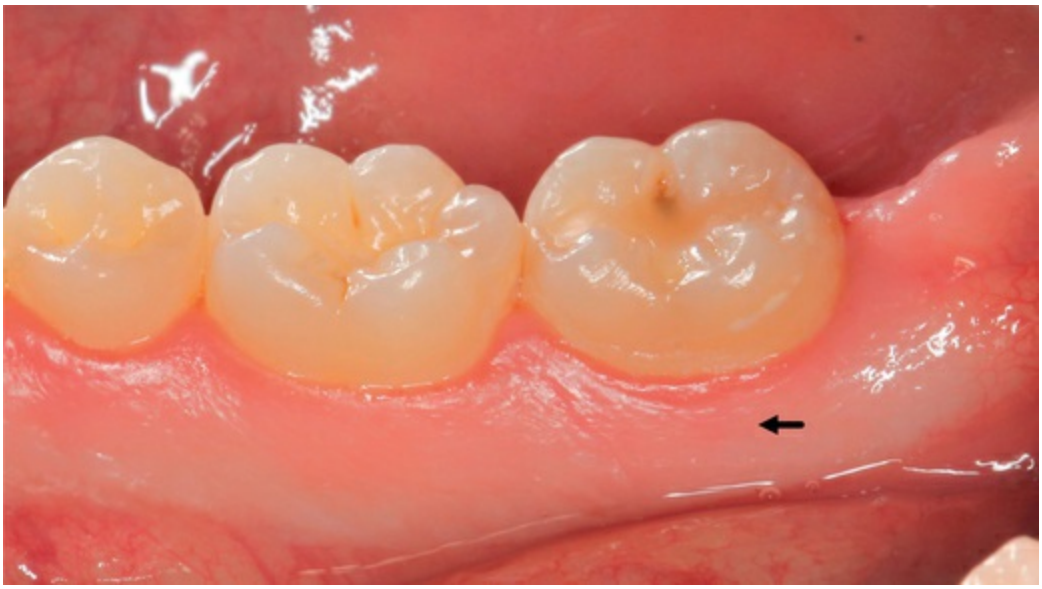

FIG. 32.9 When the marginal gingiva is compared to the gingiva 2 to 3 mm away from the gingival margin *(arrow)*, it is obvious that the marginal gingiva is erythematous and edematous. (Copyright Jonathan H. Do, DDS. All rights reserved.)

The appearance of the soft tissue adjacent to a tooth may vary from patient to patient, and from tooth to tooth within the same patient, depending on the location and the anatomy of the area. Generally, healthy gingiva is coral pink or salmon pink in color. The gingival contour consists of sharp, thin, knife-edge margins with scalloped gingival architecture and sharp papillae. The surface texture of healthy gingiva is matte and stippled. The presence of stippling can vary between individuals and sites within the same individual. The absence of stippling does not necessarily imply inflammatory changes in the tissue.

In the presence of inflammatory periodontal disease, the color of the gingiva may be erythematous or cyanotic. Instead of having knife-edge margins and sharp papillae gingival contours, inflamed gingiva may have rolled margins and bulbous papillae. The surface texture in the presence of inflammation may be smooth and shiny, and the gingiva may appear swollen and edematous. Table 32.1 summarizes clinical findings of healthy and inflamed gingiva. Chapter 18 further discusses the clinical features of gingival inflammation.

TABLE 32.1

Gingiva: Healthy	Gingiva: Inflammation
• Color: coral pink or salmon pink • Consistency: firm/tight, well adapted • Contour: scalloped, sharp papillae, knife-edge margin • Surface texture: matte, stippled • Marginal bleeding: absent or slight • Probing depth: 2–3 mm • Tissue resistance: present to probe penetration • Bleeding on probing: absent or slight • Pain on probing: absent or slight	• Color: erythematous cyanotic • Consistency: edematous, sp loosely adapt • Contour: bull swollen papil rolled margin • Surface textu smooth, shiny • Marginal blee moderate or s • Probing dept mm • Tissue resista minimal to pr penetration • Bleeding on probing: mod to severe • Pain: modera severe

In individuals with physiologic pigmentation, the gingiva may be pigmented and dark in color. Even so, if healthy, it should exhibit the other features associated with gingival health. Likewise, in the presence of inflammation and disease, it should exhibit many of the characteristics of gingival inflammation (Fig. 32.10).

FIG. 32.10 Papillary *(arrows)* and marginal erythema and edema in a patient with physiologic pigmentation.

(Copyright Jonathan H. Do, DDS. All rights reserved.)

Gingival Recession

The location of the gingival margin around teeth should be evaluated and recorded, especially when recession is present. In the absence of attachment loss, the gingival margin is located coronal to the cementoenamel junction. The exact location of the gingiva with respect to the cementoenamel junction is difficult to ascertain, as the detection of a subgingival cementoenamel can be challenging. When the cementoenamel junction is supragingival, recession is the distance from the cementoenamel junction to the gingival margin. The presence of recession indicates that attachment loss has occurred, but not necessarily that inflammation is present. At sites with recession, the amount of recession should be recorded, and the presence of biofilm and calculus, the inflammatory changes in the gingiva, and the width of the keratinized tissue should be carefully

evaluated (Fig. 32.11).

FIG. 32.11 The canine and first premolar exhibit gingival recession and minimal keratinized tissue. Both teeth are at risk of further recession due to the presence of gingival inflammation and a frenum pull *(arrow).* (Copyright Jonathan H. Do, DDS. All rights reserved.)

Learning Box 32.4

Periodontal examination begins with the visual evaluation of the gingival margin for the presence of tooth surface accretion and inflammatory changes in the gingiva.

Tactile Periodontal Examination

Tactile periodontal examination begins with the evaluation of the consistency of the gingiva and its adaptation to the tooth as well as the presence of marginal bleeding and suppuration. The gingival crevice is then probed to evaluate the subgingival environment. The tooth surface is carefully probed for aberrations, concavities, furcation, and subgingival calculus. The response of the gingival tissue to probing is appraised in terms of resistance to probe penetration, depth of probe penetration, bleeding on probing, and pain on probing.

Tactile Examination of the Marginal Gingiva

The marginal gingiva is palpated with a periodontal probe to assess its consistency and adaptation to the tooth. Healthy gingiva is firm, resilient, and well adapted to the tooth due to the presence of dense collagen fiber bundles in the lamina propria of the gingiva. When inflamed, the gingiva is edematous, spongy, and loosely adapted to the tooth surface due to the degradation of collagen and the influx of cells and fluid into the lamina propria (Fig. 32.12). In cases of chronic inflammation and in smokers, the gingival tissue may be fibrotic.

FIG. 32.12 The severely inflamed gingiva is loosely adapted to the tooth. The marginal gingiva is easily retracted to reveal heavy subgingival biofilm and calculus. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Marginal Bleeding

Marginal bleeding is associated with inflammatory changes in the marginal gingiva. Marginal bleeding can be evaluated by running an instrument such as a probe or rubber tip along the gingival margin. Under pressure, healthy gingival tissue will blanch and not bleed, whereas in the presence of gingival inflammation, marginal bleeding may be observed. The ease and severity of marginal bleeding are correlated with the severity of gingival inflammation.

Suppuration

Palpation of the marginal gingiva with a probe, or digitally by placing the ball of the index finger on the gingiva apical to the margin, and pushing coronally toward the gingival margin (Fig. 32.13) may squeeze a white-yellowish exudate from the gingival crevice. The presence of an abundance of neutrophils in the gingival fluid transforms it into a purulent exudate.[5] Suppuration does not occur in all periodontal pockets, but pressure often reveals it in pockets where its presence is not suspected. Several studies[10,11,15,31] have evaluated the association between suppuration and the progression of periodontitis and have reported that this sign is present in a very low percentage of diseased sites (i.e., 3% to 5%).[5] Therefore, absence of suppuration does not indicate absence of disease.

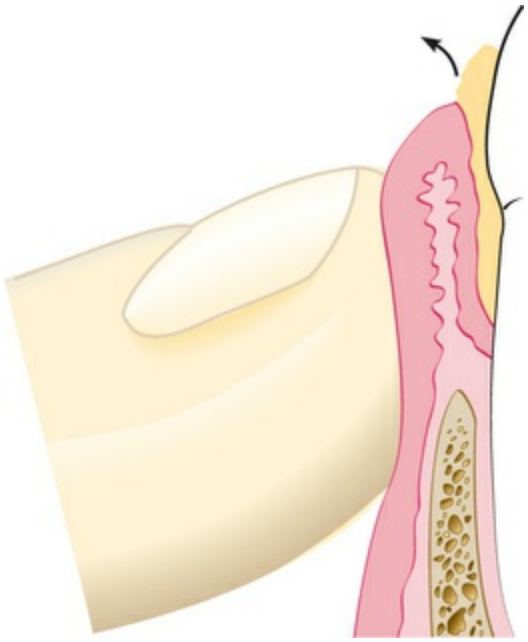

FIG. 32.13 Purulent exudate expressed from a

periodontal pocket by digital pressure.

Tactile Examination of the Gingival Crevice

The probe is inserted into the gingival crevice vertically with the tip of the probe touching and sliding down along the tooth surface to the bottom of the crevice. The probe is "walked" circumferentially around each surface of each tooth to detect the areas of deepest penetration. As the probe tip slides down along the tooth surface, attention is paid to the tactile feel of the gingival tissue and the tooth surface. Healthy gingival tissue will feel tight and resist probe penetration. The tightness of the tissue will increase and the probe will come to a stop. In fact, it is the adhesion of the junctional epithelium to the tooth surface that stops probe penetration in healthy tissue. If the gingival tissue is severely inflamed, the probe may not have any resistance at all as it "falls" to the depth of the gingival crevice.

As the probe tip slides along the tooth surface, if there is no irregularity or subgingival calculus, the tooth surface will feel smooth. If the tooth surface feels rough or if the probe tip stops on a hard surface, its path may be impeded by the presence of subgingival calculus. The probe may need to be moved axially away from the tooth to navigate around the calculus in order for it to penetrate to depth. The presence of subgingival calculus is usually associated with inflammatory changes in the gingival tissue (see Fig. 32.7), the absence of gingival tightness, and the presence of bleeding on probing.

Learning Box 32.5

When probing, the probe tip should be in contact with the tooth surface as it slides down along the tooth surface to get to the bottom of the gingival crevice. This allows for detection of tooth surface irregularities, furcation invasion, and subgingival calculus.

Additionally, attention should be directed to detecting the presence of periodontal defects, interdental craters, root surface

concavities, and furcation invasion. Periodontal defects tend to be associated with deep probing depths and gingival inflammation. To detect an *interdental crater*, the probe should be placed obliquely from both the facial and lingual surfaces to explore the deepest point of the pocket located beneath the contact point. The root surface should be carefully explored and probed to detect concavities and *furcation invasion*. The use of specially designed probes (e.g., Nabers probes) allows for an easier and more accurate exploration of the horizontal component of furcation lesions.

Tactile detection of inflammatory changes in the soft tissue is just as valuable as, if not more valuable than, measuring probing depth and evaluating bleeding on probing. The detection of inflammatory changes in the tissue, subgingival concavities, furcation invasion, and subgingival calculus via probing is instrumental in accurate diagnosis, prognosis, and treatment.

Learning Box 32.6

Thorough probing of the gingival crevice and the surrounding tissue provides a wealth of valuable information beyond probing depth and bleeding on probing that is essential to the diagnosis and treatment of periodontal disease.

Probing Around Implants

Because implants are susceptible to biofilm-induced inflammatory diseases, probing around them becomes part of the examination and diagnosis. A traditional periodontal probe may be used under light force (e.g., 0.25 N) without damaging the peri-implant mucosal seal.[18] Peri-implant evaluation and probing of implants are further discussed in Chapter 86.

When Not to Probe

Thorough probing of the periodontal pocket and accurate probing depth measurement before, during, and after treatment are essential for diagnosing and monitoring periodontal disease. In the presence of severe gingival inflammation (see Figs. 32.5 and 32.12), accurate probing depth measurement is difficult to obtain without

anesthesia due to the pain and discomfort inflicted on the patient with insertion of the periodontal probe into the inflamed periodontal pocket. Therefore, when periodontal disease is overt and obvious clinically and radiographically, thorough probing of the periodontal pocket and accurate probing depth measurement should only occur once the tissue is anesthetized. In cases that require scaling and root planing with anesthesia, accurate probing depth measurement should be delayed until the scaling and root planing appointment. After anesthesia has been administered and before root instrumentation occurs, the periodontal pocket should be thoroughly probed for subgingival calculus, root surface concavities, furcation invasions, and probing pocket depths. Furthermore, in moderate and advanced cases, probing depths will change dramatically with improvement in biofilm control and scaling and root planing (Fig. 32.14). As such, obtaining accurate probing depths at the reevaluation following nonsurgical therapy is much more important than obtaining accurate probing depth at the pretreatment periodontal examination.

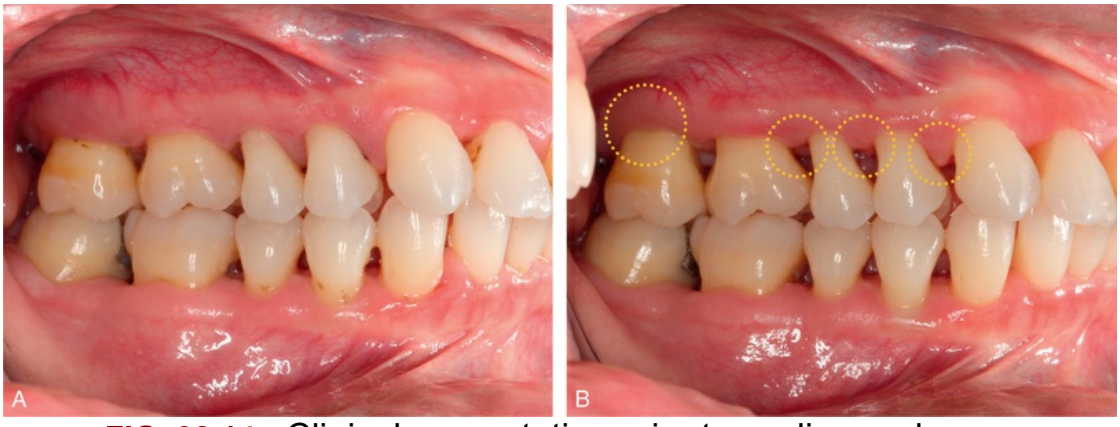

FIG. 32.14 Clinical presentation prior to scaling and root planing (A). Note the presence of supra- and subgingival calculus along the gingival margin. Following scaling and root planing, at the 6-week reevaluation (B), resolution of gingival inflammation resulted in dramatic gingival shrinkage *(circles)*. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Learning Box 32.7

In the presence of overt and obvious periodontal disease, it may be best to delay accurate probing depth measurement until the scaling and root planing appointment, when the tissue is anesthetized.

Probing Depth

There are two different pocket depths: (1) the biologic or histologic depth and (2) the clinical or probing depth[29] (Fig. 32.15).

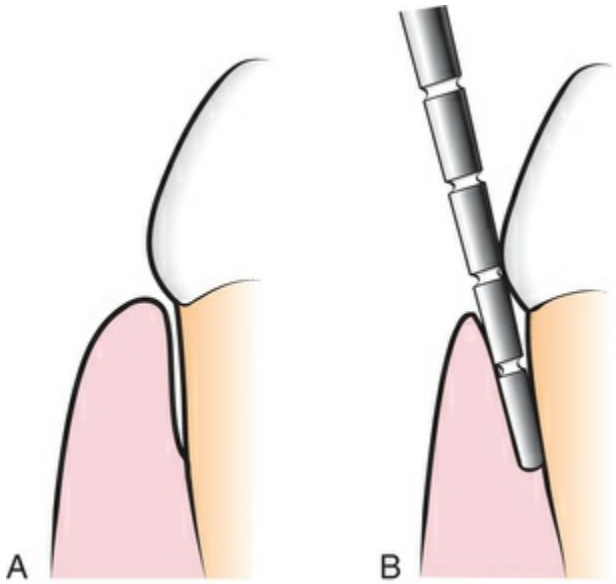

FIG. 32.15 (A) The biologic or histologic pocket depth is the actual distance between the gingival margin and the attached tissues (i.e., the bottom of the pocket). (B) The probing or clinical pocket depth is the depth of probe penetration.

Biologic depth is the distance between the gingival margin and the base of the gingival crevice (i.e., the coronal end of the junctional epithelium). This can be measured only in carefully prepared and adequately oriented histologic sections.

Probing depth is the distance from the gingival margin to the bottom of the probeable crevice (i.e., where the probe tip stops). Probes that are presently used are described in Chapter 50.

Probe penetration can vary depending on the force of introduction, the shape and size of the probe tip, the direction of penetration, the resistance of the tissues, the convexity of the crown,

and the degree of tissue inflammation.[5] Probing depth is generally ≤3 mm in gingival health and >3 mm in the presence of gingival inflammation. Several studies have been done to determine the depth of penetration of a probe in a sulcus or pocket. Armitage and colleagues[8] used beagle dogs to evaluate the penetration of a probe with the use of a standardized force of 25 g. They reported that in healthy gingiva, the probe penetrated the junctional epithelium to about two-thirds of its length; in gingivitis cases, it stopped 0.1 mm short of its apical end; and in cases of periodontitis, the probe tip consistently went past the most apical cells of the junctional epithelium (Fig. 32.16).

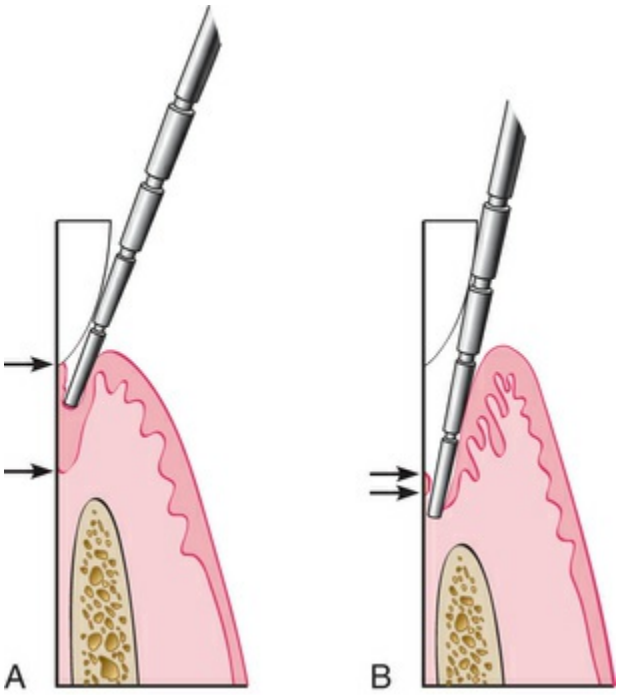

FIG. 32.16 (A) In a normal sulcus, the probe penetrates about one-third to half the length of the junctional epithelium *(between arrows).* (B) In an inflamed periodontal pocket, the probe penetrates beyond the apical end of the junctional epithelium *(between arrows).*

In human periodontal pockets, the probe tip penetrates to the most coronal intact fibers of the connective tissue attachment.[38,72] The depth of penetration of the probe in the connective tissue apical to the junctional epithelium in a periodontal pocket is about 0.3

mm.[38,66,72] This is important when evaluating differences in probing depth before and after treatment, because the reduction in probe penetration may be a result of reduced inflammatory response rather than a gain in attachment.[37,40]

Probing depth may change from time to time, even in patients with untreated periodontal disease, as a result of changes in the position of the gingival margin. Therefore it may be unrelated to the existing attachment of the tooth.

Learning Box 32.8

The biologic/histologic pocket depth is always shallower than the clinical/probing pocket depth.

Automatic and Electronic Periodontal Probing

The use of the periodontal probe is the classic method to detect probing depth and attachment loss. However, it presents some problems in terms of reproducibility of the measurements. Accuracy and reproducibility depend not only on root morphology and tissue changes but also, importantly, on the probing technique, the probing force, the size of the probe, the angle of insertion of the probe, and the precision of the probe's calibration.

Probing Force

One of the main problems of reproducibility has been variation of probing force, which several investigators have explored.[20,75,76] A force of 0.75 N has been found to be well tolerated and accurate.[73] With forces of up to 30 g, the tip of the probe remains within the junctional epithelium,[7] whereas forces of up to 50 g are necessary to reach the bone level.[32] Interexaminer error (i.e., depth discrepancies between examiners) has been reported to be as much as 2.1 mm (with an average of 1.5 mm) in the same areas.[29] The development of pressure-sensitive probes has helped to provide consistent probing force.

Probe Angulation

Standardization of the probe tip (i.e., <1 mm) and the addition of

registration stents to maintain reproducible probe angulation have been used to overcome this error.[12] New commercially available computer-assisted technology has been used to improve probing accuracy and reproducibility. In addition to more accurate measurement, the data derived from automatic probing can become part of the electronic record. Once incorporated, clinical changes and patterns of disease activity can be easily determined. These records also provide feedback to patients. The Florida Probe System[2] consists of a probe handpiece, a digital readout, a foot switch, a computer interface, and a computer. The end of the probe is 0.4 mm, and it reciprocates through a sleeve that provides a reference by which measurements are made.

These measurements are made electronically and transferred automatically when the foot switch is pressed or when a voice command is given. Constant probing force is provided by coil springs inside the probe handpiece and a digital readout. This method combines the advantages of a constant probing force with precise electronic measurement and computer storage of data, thereby eliminating the potential errors associated with visual reading and the need for an assistant to record the measurements.

Several studies have been made comparing the Florida Probe with conventional probing. The automatic probe appears to underestimate deep probing depths[57] but show less variability than conventional probing.[16,62,80] The automatic probe also has the problem of providing little tactile sensitivity, thereby making it more difficult to "walk" the probe.

Electronic systems such as the Interprobe and the Periprobe provide constant probing force and computer storage of data, but their reproducibility is only slightly better than that of conventional methods.[62,80]

The lack of standardization among probings by different individuals and at different times by the same individual depends not only on root morphology and tissue changes but also on the probing technique, the probing force, the size of the probe, the angle of insertion of the probe, and the precision of the probe's calibration. For measurements of clinical attachment loss, it is necessary to identify the location of the cementoenamel junction, and this offers another hurdle for the standardization of

measurements.

Bleeding on Probing

The insertion of a probe to the bottom of the pocket elicits bleeding if the gingiva is inflamed and if the pocket epithelium is atrophic or ulcerated. Noninflamed sites rarely bleed. In most cases, bleeding on probing is an earlier sign of inflammation than gingival color changes[45] (see Chapter 18). However, color changes may be present without bleeding on probing.[26] Depending on the severity of inflammation, bleeding can vary from a tenuous red line along the gingival sulcus to profuse bleeding.[1] If periodontal treatment is successful, bleeding on probing will cease.[3]

To test for bleeding after probing, the probe is carefully introduced to the bottom of the pocket and gently moved laterally along the pocket wall. Sometimes bleeding appears immediately after the removal of the probe; other times it may be delayed for a few seconds. Therefore the clinician should recheck for bleeding 30 to 60 seconds after probing.

As a single test, bleeding on probing is not a good predictor of progressive attachment loss; however, its absence is an excellent predictor of periodontal stability.[5] When bleeding is present in multiple sites of advanced disease, bleeding on probing is a good indicator of progressive attachment loss.[5,22] Armitage analyzed the literature on this subject up to 1996; he performed a meta-analysis of the various papers and concluded that the presence of bleeding on probing in a "treated and maintained patient population" is an important risk predictor for increased loss of attachment.[5]

Learning Box 32.9

The absence of bleeding on probing is an excellent predictor of periodontal stability.

Pain on Probing

Pain is a cardinal sign of inflammation. Gingival inflammation and periodontal disease in general are painless. However, periodontal probing of the gingival crevice can elicit pain in the gingival tissue.

The presence of pain suggests that the gingival tissue is inflamed, and the level of pain is usually related to the severity of gingival inflammation. Unless gingival inflammation is generalized and severe, patients will not feel the same level of pain at every site. Probing of healthy sites will not produce pain, and probing of sites with inflammation will produce pain. Sites that do not exhibit bleeding or obvious clinical signs of inflammation can exhibit pain on probing. Although the clinician cannot directly measure pain on probing, it is useful to make the patient aware that pain indicates inflammation and to ask the patient to pay attention to its presence.

Attachment Loss

Attachment loss is the apical migration of the dentogingival junction —the periodontal attachment apparatus—as a result of the inflammatory response. The dentogingival junction consists of the epithelial attachment and the connective tissue attachment. The dimension of the dentogingival junction is called the biologic width and averages 2.04 mm.[21] In healthy conditions, without attachment loss, the connective tissue attachment of the dentogingival junction begins coronally at the cementoenamel junction, and the epithelial attachment exists coronal to the connective tissue attachment. With attachment loss, the cementoenamel junction becomes exposed. *Clinical attachment loss* measures the *amount* of attachment loss that has occurred, with the cementoenamel junction as the reference point. Clinical attachment loss is measured as the distance from the cementoenamel junction to the bottom of the probeable crevice.

When the *gingival margin is located on the anatomic crown,* clinical attachment loss is determined by subtracting the distance from the gingival margin to the cementoenamel junction from the probing depth. If both are the same, clinical attachment loss is zero.

When the gingival margin coincides with the cementoenamel junction, clinical attachment loss is equal to probing depth.

When the gingival margin is located apical to the cementoenamel junction, clinical attachment loss is greater than probing depth. Therefore clinical attachment loss, or the distance between the cementoenamel junction and the bottom of the probeable crevice, is the sum of gingival recession and probing depth. Drawing the gingival margin on the chart where probing depths are entered

helps to clarify this important point.[70]

Clinical attachment loss is automatically calculated in many dental practice management software programs as the sum of probing depth and recession. This calculation is accurate only when both probing depth and recession are entered into the software correctly. However, when recession is not entered, many software programs assume the cementoenamel junction is at the level of the gingival margin and equate clinical attachment loss to probing depth. This is not necessarily correct, as many clinicians do not enter a value for recession when the cementoenamel junction is subgingival and not visible. As such, automatically calculated clinical attachment loss values must be scrutinized before they are used to help make a diagnosis.

Attachment Level

Attachment level describes the location *where* the dentogingival junction begins coronally on a tooth. For example, the attachment level of a tooth can be on the coronal third of the root or the apical third of the root. *Clinical attachment level* measures the distance between the attachment level and a reference point on a tooth, such as the cementoenamel junction. For example, the attachment level is 3 mm apical to the cementoenamel junction. Changes in the attachment level can be the result of a gain or a loss of attachment, and they can provide a better indication of the degree of periodontal destruction or gain. *Shallow pockets attached at the level of the apical third of the root connote more severe destruction than deep pockets attached at the coronal third of the root* (see Chapter 23).

Learning Box 32.10

Clinical attachment loss measures *how much* attachment loss has occurred using the cementoenamel junction as the reference point. Clinical attachment level measures the distance between *where* the periodontal attachment apparatus begins coronally on a tooth and a fixed reference point.

Attached Gingiva

It is important to establish the relationship between the bottom of the pocket and the mucogingival junction, especially at sites with gingival recession and narrow gingival width (see Fig. 32.11). The width of the attached gingiva is the distance between the mucogingival junction and the projection on the external surface of the bottom of the gingival sulcus or the periodontal pocket. It should not be confused with the width of the gingiva, because the latter also includes the marginal gingiva (see Fig. 32.17).

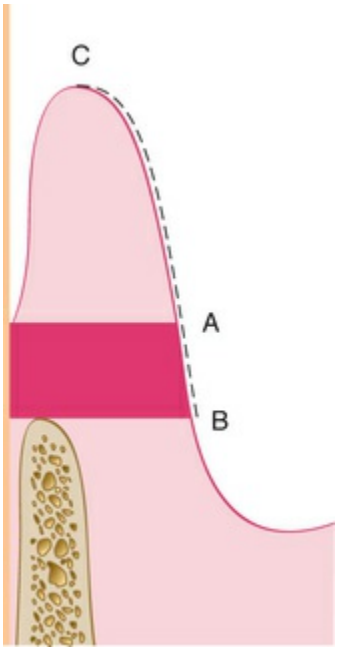

FIG. 32.17 The shaded area shows the attached gingiva, which extends between the projection on the external surface of the bottom of the pocket (A) and the mucogingival junction (B). The keratinized gingiva may extend from the mucogingival junction (B) to the gingival margin (C).

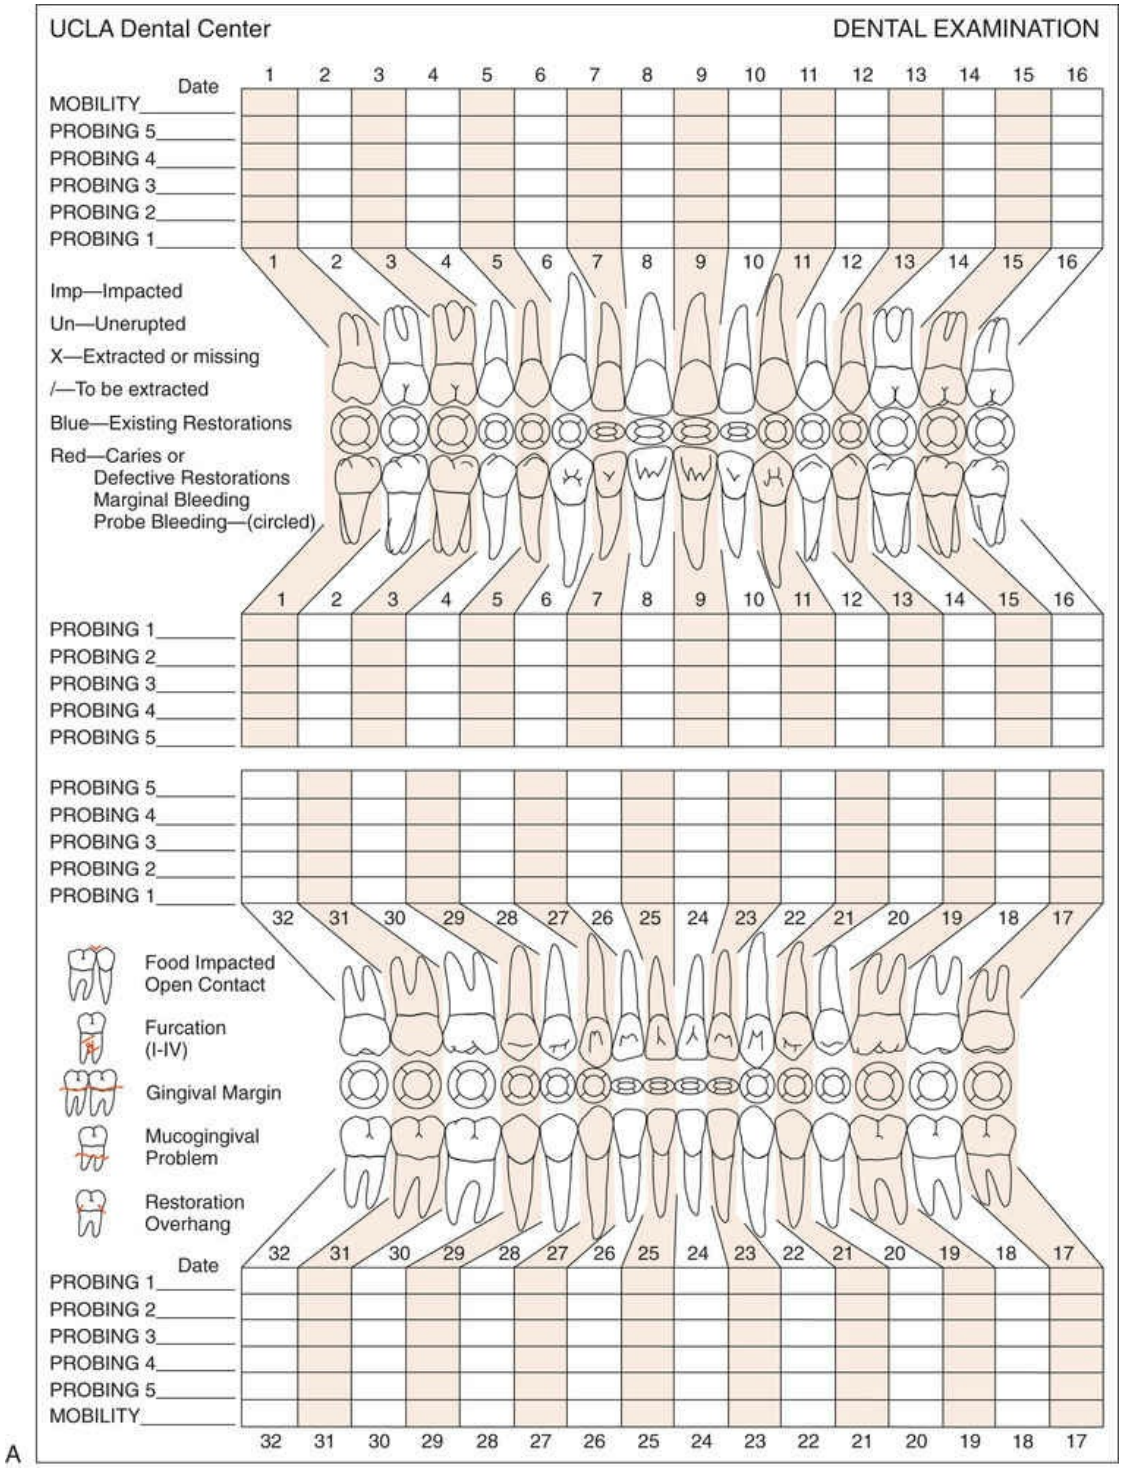
The width of the attached gingiva is determined by subtracting the sulcus or pocket depth from the total width of the gingiva (i.e., the gingival margin to the mucogingival line). The amount of attached gingiva is generally considered to be insufficient when the stretching of the lip or cheek induces the movement of the free gingival margin.

Other methods that are used to determine the amount of attached gingiva include pushing the adjacent mucosa coronally with a dull

instrument and painting the mucosa with Schiller's potassium iodide solution, which stains keratin.

Periodontal Charting

Charts to record the periodontal and associated findings provide a guide for a thorough examination and record of the patient's condition (eFig. 32.1). They are also used to evaluate the response to treatment and for comparison at recall visits. However, excessively complicated mouth charting may lead to a frustrating maze of minutiae rather than clarification of the patient's problem.



EFIG. 32.1 University of California, Los Angeles, periodontal chart.

Electronic clinical records provide rapid and easy access to information and allow for the incorporation of digital clinical and radiographic images.[64] Computerized dental examination systems that make use of high-resolution graphics and voice-activated

technology allow easy retrieval and comparison of data.[13]

Use of Clinical Indices in Dental Practice

There has been a tendency to extend the use of indices that were originally designed for epidemiologic studies into dental practice (see Chapter 6). Of all of the indices proposed, the gingival index and the sulcus bleeding index appear to be the most useful and most easily transferred to clinical practice.

The *gingival index*[39] provides an assessment of the gingival inflammatory status that can be used in practice to compare gingival health before and after phase 1 therapy or before and after surgical therapy. It can also be used to compare the gingival status at recall visits. Attaining good intraexaminer and interexaminer calibration is imperative in the dental office.

The *sulcus bleeding index*[51] provides an objective and easily reproducible assessment of the gingival status. It is extremely useful for detecting early inflammatory changes and the presence of inflammatory lesions located at the base of the periodontal pocket, which is an area inaccessible to visual examination. Patients can easily understand this index; therefore it can be used to enhance the patient's motivation for plaque control.

Periodontal Pockets

Examination for periodontal pockets must include their presence and distribution on each tooth surface, the probing depth, the level of attachment on the root, and the type of pocket (i.e., suprabony or infrabony).

Signs and Symptoms

Although probing is the only reliable method of detecting pockets, clinical signs such as color changes (i.e., a bluish red marginal gingiva or a bluish red vertical zone that extends from the gingival margin to the attached gingiva); a "rolled" edge separating the gingival margin from the tooth surface; or an enlarged, edematous gingiva may suggest their presence. The presence of bleeding, suppuration, and loose, extruded teeth may also denote the

presence of a pocket.

Periodontal pockets are generally painless, but they may give rise to symptoms such as localized or sometimes radiating pain or the sensation of pressure after eating that gradually diminishes. A foul taste in localized areas, sensitivity to hot and cold, and toothache in the absence of caries are also sometimes present.

Detection of Periodontal Pockets

The only accurate method of detecting and measuring periodontal pockets is careful exploration with a periodontal probe. Pockets are not detected by radiographic examination. The periodontal pocket is a soft-tissue change. Radiographs indicate areas of bone loss in which pockets may be suspected, but they do not show pocket presence or depth, and consequently they show no difference before and after pocket elimination unless bone has been modified.

Gutta-percha points or calibrated silver points[30] can be used with the radiograph to assist with determining the level of attachment of the periodontal pockets. They may be used effectively for individual pockets or in clinical research, but their routine use throughout the mouth would be difficult to manage. Clinical examination and probing are more direct and efficient. See Chapter 33 for detailed information about radiographic examination.

Determination of Disease Activity

Currently, there are no accurate methods to determine the activity or inactivity of a lesion. Inactive lesions may show little or no bleeding with probing and minimal amounts of gingival fluid. Active lesions bleed more readily with probing and have large amounts of fluid and exudate, although active and nonactive sites may show no differences with regard to bleeding with probing, even in patients with aggressive periodontitis.[32] The bacterial flora in a healthy gingival sulcus, as revealed by dark-field microscopy, consists mostly of coccoid cells. The bacterial flora of a periodontal pocket shows a greater number of spirochetes and motile bacteria.[27]

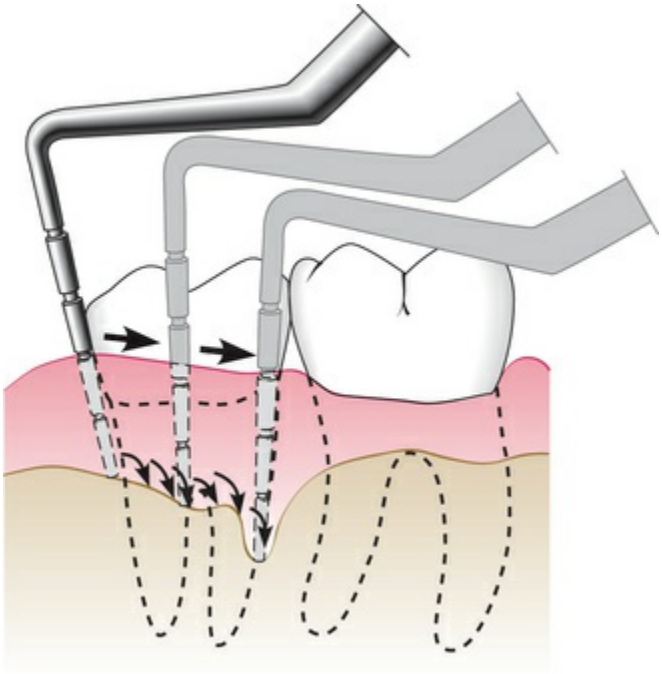
To determine probing depth or attachment levels to provide information about whether the lesion is in an active or inactive state, measurements taken at different times have to be compared.

The precise assessment and comparison of the clinical attachment level at different intervals of time can determine whether the attachment is being lost, which indicates that the lesion is active. The exact measurement of this important clinical parameter is done from the cementoenamel junction (CEJ) to the bottom of the pocket and therefore requires that the location of this landmark be determined exactly and reproducibly.

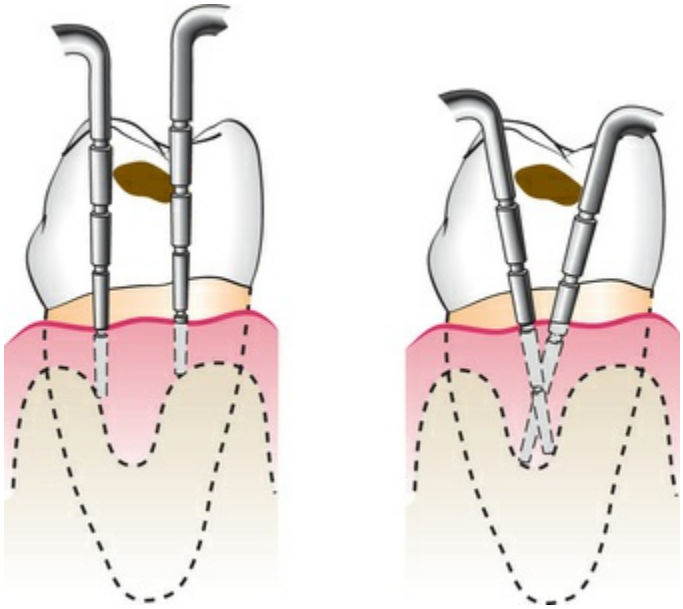
The Florida Probe provides a means of recording relative clinical attachment level changes over time. A later model of the probe has a modified sleeve with a prominent 0.125-mm edge to facilitate a "catch" of the cementoenamel. The width of this edge is considered small enough not to interfere with probing-depth measurements, thus providing concurrent measurements of clinical attachment level and pocket depth.[33,67] Of course, this measurement does not predict the future but only shows what happened during the period of time between the two measurements. See Chapters 8, 9 and 11 for descriptions of other methods used to determine disease activity that is still in a developmental stage. The precise determination of disease activity will have a direct effect on diagnosis, prognosis, and therapy. The goals of therapy may change, depending on the state of the periodontal lesion.

Alveolar Bone Loss

Alveolar bone levels are evaluated via both clinical and radiographic examination. Probing is helpful for determining the following: (1) the height and contour of the facial and lingual bones, which are obscured on the radiograph by the roots, and (2) the architecture of the interdental bone. Transgingival probing (eFigs. 32.2 and 32.3), which is performed after the area is anesthetized, is a more accurate method of evaluation, and it provides additional information about bone architecture.[25,34,73]



EFIG. 32.2 Bone sounding: under local anesthesia, the probe is inserted down to bone and then “walked” along the tooth to explore the bone architecture.



EFIG. 32.3 Vertical insertion of the probe *(left)* may not detect interdental craters; oblique positioning of the probe *(right)* reaches the depth of the crater.

Furcation Invasion

Attachment loss can result in *furcation invasion*, the pathologic resorption of interradicular bone within a furcation of a multirooted tooth due to periodontal disease. Furcation invasion is detected by carefully probing the root surface for horizontal concavities where the roots diverge. Specialized probes, such the Nabers probe, may facilitate detection of mesial and distal furcation invasion on maxillary molars where access is limited. Several classifications of furcation invasion exist. The Glickman Classification[23] of furcation invasion is the most commonly used, and it is as follows:

- Grade I: pocket formation into the flute but intact interradicular bone
- Grade II: loss of interradicular bone and pocket formation of varying depths into the furcation but not completely through to the opposite side of the tooth
- Grade III: through-and-through lesion
- Grade IV: same as grade III with gingival recession, rendering the furcation clinically visible

Chapter 64 further discusses furcation invasion and its treatment.

Periodontal Abscess

A periodontal abscess is a localized accumulation of exudate within the gingival wall of a periodontal pocket (see Chapters 23 and 45). Periodontal abscesses may be acute or chronic.

The *acute periodontal abscess* appears as an ovoid elevation of the gingiva along the lateral aspect of the root. The gingiva is edematous and red, with a smooth, shiny surface. The shape and consistency of the elevated area vary; the area may be domelike and relatively firm, or it may be pointed and soft. In most cases, exudate may be expressed from the gingival margin with gentle digital pressure.

The acute periodontal abscess is accompanied by symptoms such as throbbing, radiating pain, and tenderness of the gingiva to palpation. Other symptoms may include sensitivity of the tooth to palpation; tooth mobility and lymphadenitis; and, less frequently, systemic effects such as fever, leukocytosis, and malaise. Occasionally the patient may have symptoms of an acute periodontal abscess without any notable clinical lesion or radiographic changes.

The *chronic periodontal abscess* usually presents a sinus that opens onto the gingival mucosa along the length of the root. There may be a history of intermittent exudation. The orifice of the sinus may appear as a difficult-to-detect pinpoint opening, which, when probed, reveals a sinus tract that leads deep into the periodontium. The sinus may be covered by a small, pink, beadlike mass of granulation tissue. A chronic periodontal abscess is usually asymptomatic. However, the patient may report episodes of dull, gnawing pain; a slight elevation of the tooth; and a desire to bite down and grind the tooth. A chronic periodontal abscess often undergoes acute exacerbation, with all of the associated symptoms.

Diagnosis of the periodontal abscess requires the correlation of the history with the clinical and radiographic findings. The suspected area should be probed carefully along the gingival margin in relation to each tooth surface to detect a channel from the marginal area to the deeper periodontal tissues. Continuity of the lesion with the gingival margin is clinical evidence that the abscess is periodontal.

An abscess is not necessarily located on the same surface of the root as the pocket from which it is formed. A pocket at the facial surface may give rise to a periodontal abscess interproximally. It is common for a periodontal abscess to be located at a root surface other than that along which the pocket originated, because drainage is more likely to be impaired when a pocket follows a tortuous course.

In children, a sinus orifice along the lateral aspect of a root is usually the result of periapical infection of a deciduous tooth. In the permanent dentition, such an orifice may be caused by a periodontal abscess or by apical involvement. The orifice may be patent and draining, or it may be closed and appear as a red,

nodular mass. The exploration of such masses with a probe usually reveals a pinpoint orifice that communicates with an underlying sinus.

Periodontal Abscess and Gingival Abscess

The principal differences between the periodontal abscess and the gingival abscess are location and history (see Chapters 23 and 45). The gingival abscess is confined to the marginal gingiva, and it often occurs in previously disease-free areas. It is usually an acute inflammatory response to the forcing of foreign material into the gingiva. The periodontal abscess involves the supporting periodontal structures, and it generally occurs during the course of chronic destructive periodontitis.

Periodontal Abscess and Periapical Abscess

Several characteristics can be used as guidelines when differentiating a periodontal abscess from a periapical abscess. If the tooth is nonvital, the lesion is most likely periapical. However, a previously nonvital tooth can have a deep periodontal pocket that can abscess. Moreover, a deep periodontal pocket can extend to the apex and cause pulpal involvement and necrosis.

An apical abscess may spread along the lateral aspect of the root to the gingival margin. However, when the apex and lateral surface of a root are involved with a single lesion that can be probed directly from the gingival margin, the lesion is more likely to have originated as a periodontal abscess.

Radiographic findings are helpful in differentiating between a periodontal lesion and a periapical lesion (see Chapter 33). Early acute periodontal and periapical abscesses present no radiographic changes. Ordinarily, a radiolucent area along the lateral surface of the root suggests the presence of a periodontal abscess, whereas apical rarefaction suggests a periapical abscess. However, acute periodontal abscesses that show no radiographic changes often cause symptoms in teeth with long-standing, radiographically detectable periapical lesions that are not contributing to the patient's complaint. Clinical findings such as the presence of extensive caries, pocket formation, lack of tooth vitality, and the

existence of continuity between the gingival margin and the abscess area often prove to be of greater diagnostic value than the radiographic appearance.

A draining sinus on the lateral aspect of the root suggests periodontal rather than apical involvement; a sinus from a periapical lesion is more likely to be located further apically. However, sinus location is not conclusive. In many instances, particularly in children, the sinus from a periapical lesion drains on the side of the root rather than at the apex (see Chapter 46).

Examination of the Teeth and Implants

The teeth are examined for caries, poor restorations, developmental defects, anomalies of tooth form, wasting, hypersensitivity, and proximal contact relationships. The stability, position, and number of implants and their relationship to the adjacent natural dentition are also examined.

Wasting Disease of the Teeth

Wasting is defined as any gradual loss of tooth substance, which is characterized by the formation of smooth, polished surfaces without regard to the possible mechanism of this loss. The forms of wasting are erosion, abrasion, attrition, and abfraction.[47,65]

Erosion, which is also called *corrosion*, is a sharply defined wedge-shaped depression in the cervical area of the facial tooth surface.[55] The long axis of the eroded area is perpendicular to the vertical axis of the tooth. The surfaces are smooth, hard, and polished. Erosion generally affects a group of teeth. During the early stages, it may be confined to the enamel, but it generally extends to involve the underlying dentin as well as the cementum.

The etiology of erosion is not known. Decalcification by acidic beverages[44] or citrus fruits in combination with the effect of acid salivary secretion is a suggested cause. Sognnaes[71] refers to these lesions as *dentoalveolar ablations* and attributes them to forceful frictional action between the oral soft tissues and the adjacent hard

tissues. In patients with erosion, the salivary pH, the buffering capacity, and the calcium and phosphorus content have been reported as normal, and the mucin level is elevated.[43]

Abrasion refers to the loss of tooth substance that is induced by mechanical wear other than that of mastication. Abrasion results in saucer-shaped or wedge-shaped indentations with a smooth, shiny surface (Fig. 32.18). Abrasion starts on exposed cementum surfaces rather than on the enamel, and it extends to involve the dentin of the root. A sharp "ditching" around the cementoenamel junction appears to be the result of the softer cemental surface as compared with the much harder enamel surface.

FIG. 32.18 Noncarious cervical lesions are attributed to a combination of abrasion, abfraction, and erosion.

(Copyright Jonathan H. Do, DDS. All rights reserved.)

Continued exposure to the abrasive agent in combination with decalcification of the enamel by locally formed acids may result in a loss of enamel followed by a loss of the dentin of the crown.

Toothbrushing[26] with an abrasive dentifrice and the action of clasps are frequently mentioned, but aggressive toothbrushing with an abrasive dentifrice is the most common cause.[34] Tooth position (facial) is also a major factor in the abrasive loss of the root surface. The degree of tooth wear from toothbrushing depends on the abrasive effect of the dentifrice and the angle of brushing.[41,42] Horizontal brushing at right angles to the vertical axis of the teeth results in the severest loss of tooth substance. Occasionally, abrasion of the incisal edges occurs as a result of habits such as

holding objects (e.g., bobby pins, tacks) between the teeth.

Attrition is occlusal wear that results from functional contact with opposing teeth. Such physical wear patterns may occur on incisal, occlusal, or approximal tooth surfaces. A certain amount of tooth wear is physiologic, but accelerated wear may occur when abnormal anatomic or unusual functional factors are present.

Occlusal or incisal surfaces worn by attrition are called *facets*. When active tooth grinding occurs, the enamel rods are fractured and become highly reflective to light.[79] Thus shiny, smooth, and curviplanar facets are usually the best indicators of ongoing frictional activity (Fig. 32.19). If dentin is exposed, a yellowish brown discoloration is frequently present. Facets vary with regard to size and location, depending on whether they are produced by physiologic or abnormal wear.[14,77] At least one significant wear facet has been reported in 92% of adults,[68] and facet prevalence approaches universality.[11,78] Facets are usually not sensitive to thermal or tactile stimulation.

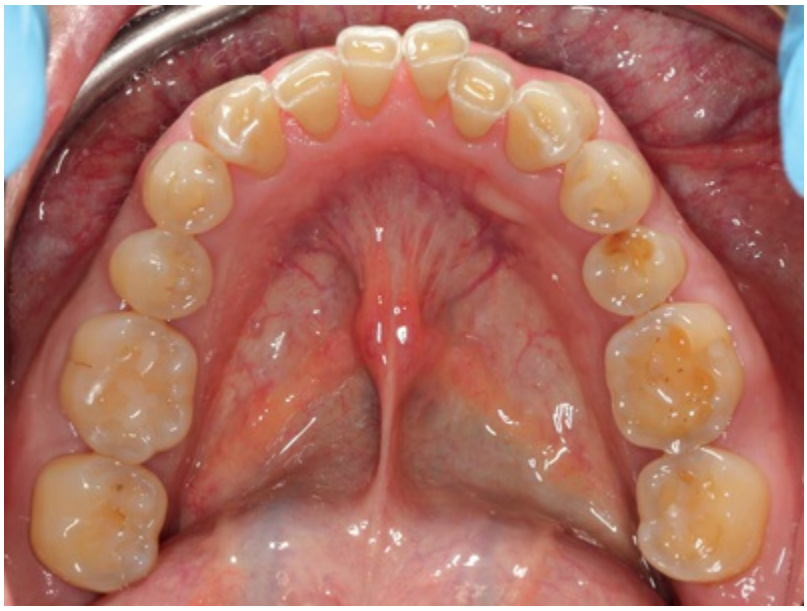


FIG. 32.19 Flat, shiny, discolored surfaces produced by occlusal wear.

Facets generally represent functional or parafunctional wear as well as iatrogenic dental treatment through coronoplasty (occlusal adjustment). However, coronoplasty does not appear to contribute to higher ratings of wear.[69] Excessive wear may result in the

obliteration of the cusps and the formation of either a flat or cuneiform (cupped-out) occlusal surface. Contrary to earlier thought, attrition in young adults from modern societies is not age related.[17,69] This suggests that a significant amount of attrition, when present in young adults, is unlikely to occur as a result of functional wear,[36] and it is probably the result of bruxing activity.[69] Attrition has been correlated with age when older adults are considered.[9,67]

The angle of the facet on the tooth surface is potentially significant to the periodontium. Horizontal facets tend to direct forces on the vertical axis of the tooth to which the periodontium can adapt most effectively. Angular facets direct occlusal forces laterally and increase the risk of periodontal damage. However, gradual attrition may be compensated for by continuous tooth eruption without alveolar bone growth, and it is characterized by a lack of inflammatory changes on the alveolar bone surfaces.[74]

Another mechanism of tooth wear that has been studied is called *abfraction,* and it results from occlusal loading surfaces causing tooth flexure and mechanical microfractures the cervical area.[28] Mechanical microfractures from abfraction weakens the cervical tooth structure and makes it much more susceptible to loss of tooth structure via abrasion (see Fig. 32.18).

These four mechanisms of tooth wear (corrosion, abrasion, attrition, and abfraction) can combine to increase the degree of tooth wear.

Dental Stains

Dental stains are pigmented deposits on the teeth. They should be carefully examined to determine their origin (see Chapter 13).

Hypersensitivity

Root surfaces exposed by gingival recession may be hypersensitive to thermal changes or tactile stimulation. Patients often direct the clinician to the sensitive areas. These may be located by gentle exploration with a probe or cold air.

Proximal Contact Relations

Open contacts allow for food impaction. The tightness of contacts should be checked by means of clinical observation and with dental floss. Abnormal contact relationships may also initiate occlusal changes, such as a shift in the median line between the central incisors with labial flaring of the maxillary canine, buccal or lingual displacement of the posterior teeth, and an uneven relationship of the marginal ridges. Teeth opposite an edentulous site may supererupt, thereby opening the proximal contacts.

Tooth Mobility

All teeth have a slight degree of physiologic mobility, which varies for different teeth and at different times of the day.[52,56] It is greatest when arising in the morning, and it progressively decreases. The increased mobility in the morning is attributed to slight extrusion of the tooth as a result of limited occlusal contact during sleep. During the waking hours, mobility is reduced by chewing and swallowing forces, which intrude the teeth in the sockets. These 24-hour variations are less marked in persons with a healthy periodontium than in those with occlusal habits such as bruxism and clenching.

Single-rooted teeth have more mobility than multirooted teeth, with incisors having the most mobility. Mobility occurs primarily in a horizontal direction, although some axial mobility occurs to a lesser degree.[54]

Tooth mobility occurs in the following two stages:

1. The initial or intrasocket stage occurs when the tooth moves within the confines of the periodontal ligament. This is associated with viscoelastic distortion of the ligament and the redistribution of the periodontal fluids, interbundle content, and fibers.[35] This initial movement occurs with forces of about 100 lb, and it is on the order of 0.05 mm to 0.10 mm (50 μm to 100 μm).[48]
2. The secondary stage occurs gradually and entails elastic deformation of the alveolar bone in response to increased horizontal forces.[50] When a force of 500 g is applied to the crown, the resulting displacement is about 100 μm to 200 μm for incisors, 50 μm to 90 μm for canines, 8 μm to 10 μm

for premolars, and 40 μm to 80 μm for molars.[48]

When a force such as that applied to teeth in occlusion is discontinued, the teeth return to their original position in two stages: the first is an immediate, springlike elastic recoil; the second is a slow, asymptomatic recovery movement. The recovery movement is pulsating, and it is apparently associated with the normal pulsation of the periodontal vessels, which occurs in synchrony with the cardiac cycle.[49]

Many attempts have been made to develop mechanical or electronic devices for the precise measurement of tooth mobility.[49,53,55,68] Although standardization of grading mobility would be helpful for the diagnosis of periodontal disease and for evaluating treatment outcomes, these devices are not widely used. As a general rule, mobility is graded clinically by holding the tooth firmly between the handles of two metallic instruments or with one metallic instrument and one finger (Fig. 32.20). An effort is then made to move it in all directions. Abnormal mobility most often occurs faciolingually. Mobility is scored according to the ease and extent of tooth movement according to the Miller Index[46] as follows:

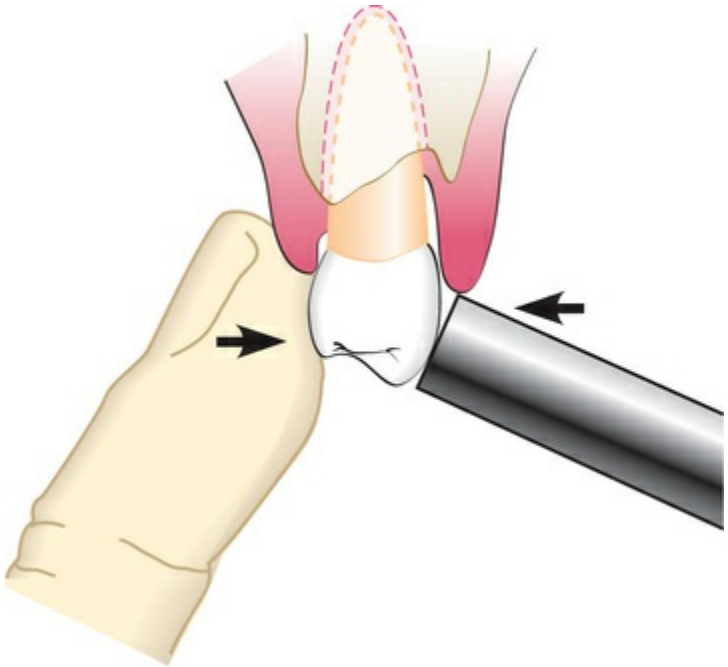

FIG. 32.20 Tooth mobility is checked with a metal instrument and one finger.

- Mobility no. 1: first distinguishable sign of movement greater than "normal"
- Mobility no. 2: movement of the crown up to 1 mm in any direction
- Mobility no. 3: movement of the crown more than 1 mm in any direction or vertical depression or rotation of the crown in its socket

Physiologic mobility is movement up to 0.2 mm horizontally and 0.02 mm axially. Mobility beyond the physiologic range is termed *abnormal* or *pathologic.* It is pathologic in that it exceeds the limits of normal mobility values; however, the periodontium is not *necessarily* diseased at the time of examination.

Increased mobility is caused by one or more of the following factors:

1. *Loss of tooth support (bone loss)* can result in mobility. The amount of mobility depends on the severity and distribution of bone loss at individual root surfaces, the length and shape of the roots, and the root size as compared with that of the crown.[55] A tooth with short, tapered roots is more likely to loosen than one with normal-size or bulbous roots with the same amount of bone loss. One should carefully evaluate postorthodontic cases for possible apical shortening of the root, which may lead to excessive mobility. Because bone loss usually results from a combination of factors and does not occur as an isolated finding, the severity of tooth mobility does not necessarily correspond to the amount of bone loss.
2. *Trauma from occlusion* (i.e., injury produced by excessive occlusal forces or incurred as a result of abnormal occlusal habits such as bruxism and clenching) is a common cause of tooth mobility. Mobility is also increased by hypofunction. Mobility produced by trauma from occlusion occurs initially as a result of resorption of the cortical layer of bone, which

leads to reduced fiber support, and later as an adaptation phenomenon that results in a widened periodontal space.

3. *Extension of inflammation* from the gingiva or the periapex into the periodontal ligament results in changes that increase mobility. The spread of inflammation from an acute periapical abscess may increase tooth mobility in the absence of periodontal disease.
4. *Periodontal surgery* temporarily increases tooth mobility immediately after the intervention and for a short period.[58-61]
5. Tooth mobility is increased during *pregnancy,* and it is sometimes associated with the *menstrual cycle* or the use of *hormonal contraceptives.* This is unrelated to periodontal disease, and it occurs presumably because of physicochemical changes in the periodontal tissues.
6. *Pathologic processes of the jaws* that destroy the alveolar bone or the roots of the teeth can also result in mobility. Osteomyelitis and tumors of the jaws belong in this category.

One study[24] has suggested that pockets around mobile teeth harbor higher proportions of *Campylobacter rectus* and *Peptostreptococcus micros* and possibly *Porphyromonas gingivalis* as compared with nonmobile teeth. This hypothesis requires further verification.

Learning Box 32.11

The three main etiologic factors of tooth mobility are periodontal inflammation, attachment loss, and occlusal trauma.

Trauma From Occlusion

Trauma from occlusion refers to *tissue injury* produced by occlusal forces rather than to the occlusal forces themselves (see Chapter 25). The criterion that determines that an occlusion is traumatic is whether it causes damage in the periodontal tissues; therefore the diagnosis of trauma from occlusion is made from the condition of the periodontal tissues. The periodontal findings are then used as a

guide for locating the responsible occlusal relationships.

Periodontal findings that suggest the presence of trauma from occlusion include excessive tooth mobility, particularly in teeth that show radiographic evidence of a widened periodontal space; vertical or angular bone destruction; infrabony pockets; and pathologic migration, especially of the anterior teeth. These are discussed in more detail in the following sections.

Pathologic Migration of the Teeth

Alterations in tooth position should be carefully noted, particularly with a view toward identifying abnormal forces, a tongue-thrusting habit, or other habits that may be contributing factors (Fig. 32.21; see Chapter 25). Premature tooth contacts in the posterior region that deflect the mandible anteriorly contribute to the destruction of the periodontium of the maxillary anterior teeth and to pathologic migration (see also Chapter 25). The loss of posterior teeth can lead to facial "flaring" of the maxillary anterior dentition. This is due to the increased trauma that the mandibular anterior dentition places against the palatal surface of the maxillary anterior dentition. Pathologic migration of the anterior teeth in young persons may be a sign of localized aggressive (juvenile) periodontitis.

FIG. 32.21 Facial flaring and supraeruption of the right central incisor and spacing between the lateral and central incisors result from pathologic migration due to chronic periodontitis. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Sensitivity to Percussion

Sensitivity to percussion is a feature of acute inflammation of the periodontal ligament. Gentle percussion of a tooth at different angles to the long axis often helps with the localization of the site of inflammatory involvement.

Dentition With the Jaws Closed

Examination of the dentition with the jaws closed can detect conditions such as irregularly aligned teeth, extruded teeth, improper proximal contacts, and areas of food impaction, all of which may favor plaque accumulation.

Excessive *overbite,* which is seen most often in the anterior region, may cause impingement of the teeth on the gingiva and food impaction, followed by gingival inflammation, gingival enlargement, and pocket formation. The real significance of the detrimental effect of an excessive anterior overbite on gingival health is still controversial.[2]

In *open-bite* relationships, abnormal vertical spaces exist between the maxillary and mandibular teeth. The condition occurs most often in the anterior region, although posterior open bite is occasionally seen. Reduced mechanical cleansing by the passage of food may lead to accumulation of plaque and debris, calculus formation, and extrusion of teeth.

With *crossbite,* the normal relationship of the mandibular teeth to the maxillary teeth is reversed, with the maxillary teeth being lingual to the mandibular teeth. Crossbite may be bilateral or unilateral, or may affect only a pair of antagonists. Trauma from occlusion, food impaction, spreading of the mandibular teeth, and associated gingival and periodontal disturbances may be caused by crossbite.

Functional Occlusal Relationships

The examination of functional occlusal relationships is an important part of the diagnostic procedure. Dentitions that appear to be normal when the jaws are closed may present marked functional abnormalities. Systematic procedures for the detection and correction of functional abnormalities are presented in Chapter 55.

Radiographic Examination

The radiographic survey should consist of a minimum of 14 intraoral films and 4 posterior bitewing films (Fig. 32.22). Panoramic radiographs are a simple and convenient method of obtaining a survey view of the dental arch and the surrounding structures (Fig. 32.23). They are helpful for the detection of developmental anomalies, pathologic lesions of the teeth and jaws, and fractures, as well as dental screening examinations of large groups. They provide an informative overall radiographic picture

of the distribution and severity of bone destruction with periodontal disease, but *a complete intraoral series is required for periodontal diagnosis and treatment planning*. Chapter 33 gives a detailed description of radiographic interpretation in periodontics.

B

FIG. 32.22 A complete intraoral radiographic is an essential adjunct to periodontal diagnosis. (A) Intraoral radiographs of a patient with gingivitis. Note the radiopaque fixed lingual orthodontic retainer. (B) Intraoral radiographs of a patient with generalized moderate to severe chronic periodontitis. Vertical bitewing radiographs are useful to evaluate crestal bone loss. (Copyright Jonathan H. Do, DDS. All rights reserved.)

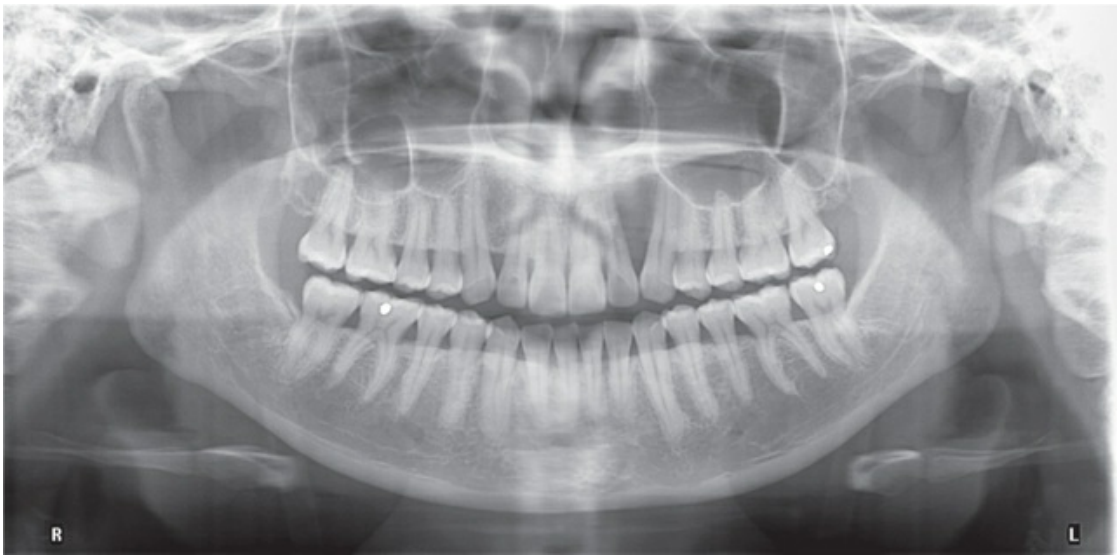

FIG. 32.23 Panoramic radiograph provides an overview of the dental arch and the surrounding structures.

Laboratory Aids to Clinical Diagnosis

When unusual gingival or periodontal problems are detected that cannot be explained by local causes, the possibility of contributing systemic factors must be explored. The signs and symptoms of oral manifestations of systemic disease have to be clearly understood and analyzed and their presence discussed with the patient's physician. Chapter 14 presents discussions of many of these problems, and the reader is also directed to standard texts that discuss medical diagnoses for more detailed descriptions of the necessary tests and their interpretation.

Numerous laboratory tests aid in the diagnosis of systemic diseases that may contribute to periodontal and oral diseases; these tests will also be needed to make treatment decisions when dealing with medically compromised patients (see Chapter 39). Analyses of blood smears, blood cell counts, white blood cell differential counts, and erythrocyte sedimentation rates are used to evaluate the presence of blood dyscrasias and generalized infections. Determinations of coagulation time, bleeding time, clot retraction time, prothrombin time, and capillary fragility as well as bone marrow studies may be required at times. The reader is referred to books about medical diagnoses for a consideration of this subject.

Periodontal Diagnosis

Once the patient history has been obtained and clinical, radiographic, and other necessary examinations have been performed, the information acquired is synthesized and interpreted to answer three basic diagnostic questions[6] to derive the periodontal diagnosis:

1. What is the disease?
2. How severe is the disease?
3. What is the extent of the disease?

Diseases that can affect the periodontium are listed in the Classification of Periodontal Diseases and Conditions. Severity of periodontal disease is classified based on a three-tier system: slight, mild, early, or initial; moderate; and severe or advanced. The extent of the disease is classified as generalized or localized. When localized, the extent can be specified to the quadrant, teeth, and even tooth surfaces.

Biofilm-induced inflammatory periodontal diseases are diagnosed based on the presence of inflammation and attachment loss (Table 32.2). In periodontal health, both inflammation and attachment loss are absent. When only inflammation is present, the diagnosis is biofilm-induced gingivitis. When both inflammation and attachment loss are present, the diagnosis is chronic periodontitis. It is possible that when both inflammation and attachment loss are present, biofilm-induced gingivitis is superimposed over a history of chronic periodontitis. However, it is prudent to diagnose the presence of both inflammation and attachment loss as chronic periodontitis due to the following reasons: progression of chronic periodontitis is sporadic, sites with previous attachment loss are susceptible to further attachment loss, and attachment loss is driven by the inflammatory response. Finally, when inflammation is absent and attachment is present, the diagnosis is healthy with a reduced periodontium or with a history of chronic periodontitis.

TABLE 32.2

Periodontal Diagnosis	Inflammation	Attachment Loss
Healthy	No	No
Biofilm-induced gingivitis	Yes	No
Chronic periodontitis	Yes	Yes
Healthy with a reduced periodontium/ with a history of chronic periodontitis	No	Yes

Learning Box 32.12

Diagnosis of biofilm-induced inflammatory periodontal diseases is based on the presence of periodontal inflammation and attachment loss.

Currently, the severity of chronic periodontitis is characterized on a three-tier system based on clinical attachment loss (CAL): slight = 1 or 2 mm CAL, moderate = 3 or 4 mm CAL, and severe ≥5 mm CAL. This system is inadequate for two reasons: (1) chronic periodontitis is diagnosed based on the presence of both inflammation and attachment loss, not attachment loss alone, and (2) the link in the relationship between periodontitis and systemic disease is inflammation, not attachment loss. Therefore an ideal classification system should take into consideration the severity of inflammation as well. Furthermore, for cases with mild attachment loss or where the cementoenamel junction is subgingival, an accurate determination of clinical attachment loss is challenging as it is difficult to accurately determine the location of the cementoenamel junction. As such, the severity of attachment loss may depend on the interpretation of radiographic bone loss. Table 32.3 correlates severity of periodontitis to clinical attachment loss and the distance from the alveolar crest to the cementoenamel junction (CEJ) on radiographs.

TABLE 32.3

Clinical and Radiographic Guidelines for Determining Severity of Periodontitis

	Distance

Severity of Periodontitis	Clinical Attachment Loss (mm)	From Alveolar Crest to CEJ (mm)	Radiographic Findings
Health	0	<2	
Mild	1–2	3–4	
Moderate	3–4	5–6	
Severe	≥5	≥7	

CEJ, Cementoenamel junction.

Learning Box 32.13

Severity of periodontitis is characterized based on clinical attachment loss.

Severity of biofilm-induced gingivitis can also be characterized based on a three-tier system of slight, moderate, and severe. However, this can be subjective.

The extent of chronic periodontitis is delineated based on the 30% threshold. Localized chronic periodontitis is defined as chronic periodontitis with a clear pattern of distribution, such as distal surfaces of second molars or ≤30% of teeth are affected.[4] Generalized chronic periodontitis is defined as periodontitis without a clear pattern of distribution or >30% of teeth are affected.[4] The extent of biofilm-induced gingivitis can also be characterized based on the 30% threshold similar to the extent of chronic periodontitis.

When biofilm-induced gingivitis and chronic periodontitis are present simultaneously, if the extent of both is generalized, the diagnosis is simply generalized chronic periodontitis, as the chronic periodontitis is the more advanced progression of the disease. Furthermore, biofilm-induced gingivitis by definition is inflammation without attachment loss, whereas chronic periodontitis is defined as inflammation with attachment loss. A diagnosis of both generalized biofilm-induced gingivitis and

generalized chronic periodontitis is contradictory. Biofilm-induced gingivitis may be diagnosed together with chronic periodontitis if the periodontitis is localized. In this situation, the diagnosis is generalized biofilm-induced gingivitis with localized chronic periodontitis. Similarly, if the extent of mild and moderate chronic periodontitis is >30%, the diagnosis is simply generalized moderate chronic periodontitis, as moderate is the more severe of the two types of disease severity.

Assessment of Biofilm Control and Patient Education

Patients presenting for periodontal consultations typically expect to find out the problems they have and the treatments they need. By the end of the periodontal consultation, it may not be possible to determine the prognosis and formulate a complete treatment plan, as a careful analysis of the information obtained, more diagnostic information, or consultation with other dental and medical professionals may be required. However, the patient should be educated on the problems in his or her mouth, the need for further diagnostics, and the etiologies and prevention of these problems. Clinical photographs, radiographs, and models may be useful to help the patient to better understand the condition of his or her mouth. The patient may be presented with a preliminary treatment plan that may include emergency and palliative treatments and nonsurgical periodontal therapy to control infections.

Although patient education and biofilm control are part of nonsurgical periodontal therapy and not the focus of this chapter, a preventive approach to oral health care demands behavior modification, which requires time, effort, and repetition. As such, every opportunity should be seized to educate patients and alter their behavior. Patients should be given personalized oral hygiene instructions to control biofilm and to improve their oral health and the conditions of the periodontium. It is not uncommon for patients to report brushing and flossing multiple times daily, while having poorly controlled periodontal disease in their mouths. For that reason, the effectiveness of the patient's biofilm control must be

evaluated. The patient should be asked to demonstrate biofilm control (toothbrushing, flossing, etc.,) in front of a mirror so that both the patient and the clinician can see his or her oral hygiene techniques. The patient should then be taught proper biofilm control techniques with a demonstration in his or her own mouth in front of a mirror. Detailed biofilm control is presented in Chapter 48.

Ideally, unless emergency treatment is required, patients should be given at least 1 or 2 weeks to improve their oral hygiene, to control biofilm and reduce periodontal inflammation, and to appreciate how they can impact their oral health with meticulous biofilm control before any periodontal treatment is rendered.

Conclusion

Periodontal examination and diagnosis begins with obtaining a thorough health and dental history. Although the periodontal examination presented in this chapter is divided into two parts, visual examination and tactile examination, in practice both visual and tactile assessments overlap and occur simultaneously, as do the evaluations of teeth and periodontium. Nevertheless, the examination should begin with an overall survey of biofilm and calculus, clinical signs of inflammation, and other obvious signs of disease to obtain insights into the patient's oral hygiene and disease status. As the examination progresses, it becomes more invasive and more specific information is acquired. Once a detailed patient history has been obtained and a thorough clinical examination has been completed, the information collected is analyzed and synthesized to arrive at a diagnosis. The periodontal examination is the basis from which the diagnosis, prognosis, and treatment plan are derived and from which treatment is ultimately rendered. Therefore a thorough and accurate periodontal examination is of the utmost importance.

Learning Box 32.14

Examination → Diagnosis → Prognosis ↔ Treatment

- Diagnosis requires thorough and careful examination.
- Prognosis is based on accurate diagnosis.
- Treatment decisions are based on prognosis.
- Treatment decisions are made to improve prognosis.
- Diagnosis and prognosis will change with treatment.

Case Scenario 32.1

Patient:

49-year-old female presented for periodontal evaluation prior to orthodontic treatment

Health History:

Patient stated she is healthy. Last physical exam was 6 months ago.
No medications.
No known drug allergy.

Dental History:

Patient did not go to the dentist for about 10 years due to a previous "bad dental experience." She did not return to the dentist until her teeth shifted.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. The distance from the cementoenamel junction (CEJ) to the alverolar crest on both mesial and distal of tooth #4, the maxillary second premolar, is 8 mm. What is the severity of bone loss on tooth #4? A. Mild B. Moderate C. Severe	**Answer:** C **Explanation:** In health, the distance between the cementoenamel junction and the alveolar crest is <2 mm. Bone loss on #4 is 6 mm (8 mm − 2 mm). Bone loss is scored as follows: mild = 1 to 2 mm, moderate = 3 to 4 mm, severe ≥5 mm.
2. Assume that the rest of the mouth has the same disease	**Answer:** C **Explanation:**

severity as the maxillary right quadrant. Based on radiographic bone loss and clinical presentation, what is the periodontal diagnosis? A. Plaque-induced gingivitis with a history of chronic periodontitis B. Generalized moderate chronic periodontitis C. Generalized severe chronic periodontitis D. Localized severe chronic periodontitis	Based on the radiographic distance between the alveolar crest and cementoenamel junction, bone loss is generalized and severe. Based on the presence of supragingival and radiographic calculus and clinical signs of inflammation, the disease is chronic periodontitis. Combining radiographic and clinical presentations, the overall diagnosis is generalized severe chronic periodontitis.

CHAPTER OUTLINE

Normal Interdental Bone
Radiographic Techniques
Bone Destruction in Periodontal Disease
Radiographic Appearance of Periodontal Disease
Digital Intraoral Radiography
Advanced Imaging Modalities
Conclusion

Radiographs are valuable for the diagnosis of periodontal disease, estimation of severity, determination of prognosis, and evaluation of treatment outcome.[6,14,19] *However, radiographs are an adjunct to the clinical examination, not a substitute for it.* Radiographs demonstrate

changes in calcified tissue; they do not reveal current cellular activity but rather reflect the effects of past cellular experience on the bone and roots.

Learning Box 33.1

Radiographs provide a static view of the current available periodontal bone. Radiographic information must be considered as one of the elements of the diagnostic workup in conjunction with clinical and historical findings.

Normal Interdental Bone

Evaluation of bone changes in periodontal disease is based mainly on the appearance of the interdental bone, because the relatively dense root structure obscures the facial and lingual bony plates. The interdental bone normally is outlined by a thin, radiopaque line adjacent to the periodontal ligament (PDL) and at the alveolar crest, referred to as the *lamina dura* (Fig. 33.1). Because the lamina dura represents the cortical bone lining the tooth socket, the shape and position of the root and changes in the angulation of the x-ray beam produce considerable variations in its appearance.

FIG. 33.1 Crest of interdental bone normally parallel to a line drawn between the cementoenamel junction of adjacent teeth *(arrow).* Note also the radiopaque

lamina dura around the roots and interdental bone.

The width and shape of the interdental bone and the angle of the crest normally vary according to the convexity of the proximal tooth surfaces and the level of the cementoenamel junction (CEJ) of the approximating teeth. The faciolingual diameter of the bone is related to the width of the proximal root surface. The angulation of the crest of the interdental septum is generally parallel to a line between the CEJs of the approximating teeth (see Fig. 33.1). When there is a difference in the level of the CEJs, the crest of the interdental bone appears angulated rather than horizontal.

Radiographic Techniques

In conventional radiographs, periapical and bitewing projections offer the most diagnostic information and are most commonly used in the evaluation of periodontal disease. To properly and accurately depict periodontal bone status, proper techniques of exposure and processing are required. The bone level, pattern of bone destruction, and PDL space width, as well as the radiodensity, trabecular pattern, and marginal contour of the interdental bone, vary by modifying exposure and development time, type of film, and x-ray angulation.[20] Standardized, reproducible techniques are required to obtain reliable radiographs for pretreatment and posttreatment comparisons.

Prichard[15] established the following four criteria to determine adequate angulation of periapical radiographs:

1. The radiograph should show the tips of molar cusps with little or none of the occlusal surface showing.
2. Enamel caps and pulp chambers should be distinct.
3. Interproximal spaces should be open.
4. Proximal contacts should not overlap unless teeth are out of line anatomically.

For periapical radiographs, the long-cone paralleling technique most accurately projects the alveolar bone level (Fig. 33.2). The bisection-of-the-angle technique elongates the projected image,

making the bone margin appear closer to the crown; the level of the facial bone is distorted more than that of the lingual. Inappropriate horizontal angulation results in tooth overlap, changes the shape of the interdental bone image, alters the radiographic width of the PDL space and the appearance of the lamina dura, and may distort the extent of furcation involvement (see Fig. 33.2).

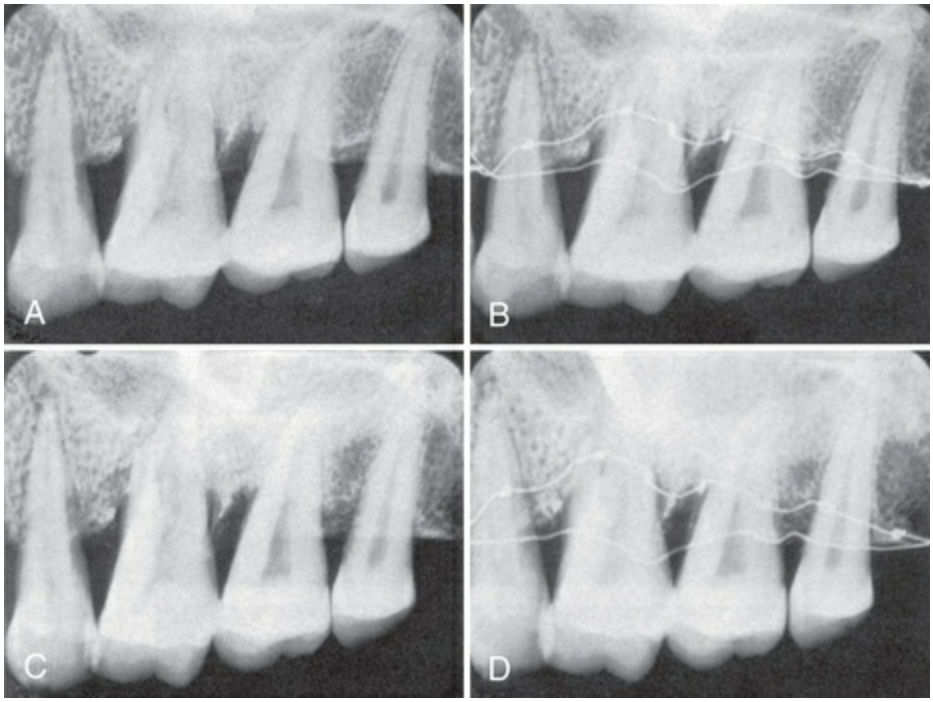

FIG. 33.2 Comparison of long-cone paralleling and bisection-of-the-angle techniques. (A) Long-cone paralleling technique, radiograph of dried specimen. (B) Long-cone paralleling technique, same specimen as shown in part A. Smooth wire is on the margin of the facial plate and knotted wire is on the lingual plate to show their relative positions. (C) Bisection-of-the-angle technique, same specimen as in parts A and B. (D) Bisection-of-the-angle technique, same specimen. Both bone margins are shifted toward the crown, the facial margin (smooth wire) more than the lingual margin (knotted wire), creating the illusion that the lingual bone margin has shifted apically. (Courtesy Dr. Benjamin Patur, Hartford, Connecticut.)

Periapical radiographs frequently do not reveal the correct relationship between the alveolar bone and the CEJ.[9] This is

particularly true in cases in which a shallow palate or floor of the mouth does not allow ideal placement of the periapical film. Bitewing projections offer an alternative method that better images periodontal bone levels. For bitewing radiographs, the film is placed behind the crowns of the upper and lower teeth parallel to the long axis of the teeth. The x-ray beam is directed through the contact areas of the teeth and perpendicular to the film. Thus the projection geometry of the bitewing films allows the evaluation of the relationship between the interproximal alveolar crest and the CEJ without distortion[17] (Figs. 33.3 and 33.4). If the periodontal bone loss is severe and the bone level cannot be visualized on regular bitewing radiographs, films can be placed vertically to cover a larger area of the jaws (Fig. 33.5). More than two vertical bitewing films might be necessary to cover all of the interproximal spaces in the area of interest.

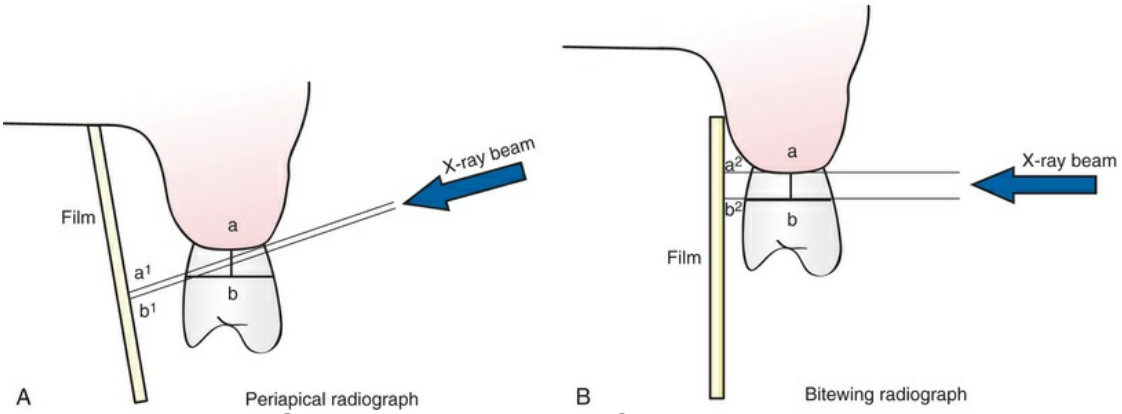

FIG. 33.3 Schematic diagram of periapical (A) and bitewing (B) radiographs. Angulation of the x-ray beam and the film on the periapical radiograph distort the distance between the alveolar crest and the cementoenamel junction (CEJ) (compare a–b versus a^1–b^1). In contrast, the projection geometry of the bitewing radiograph allows a more accurate depiction (a^2–b^2) of the distance between the alveolar crest and the CEJ (a–b).

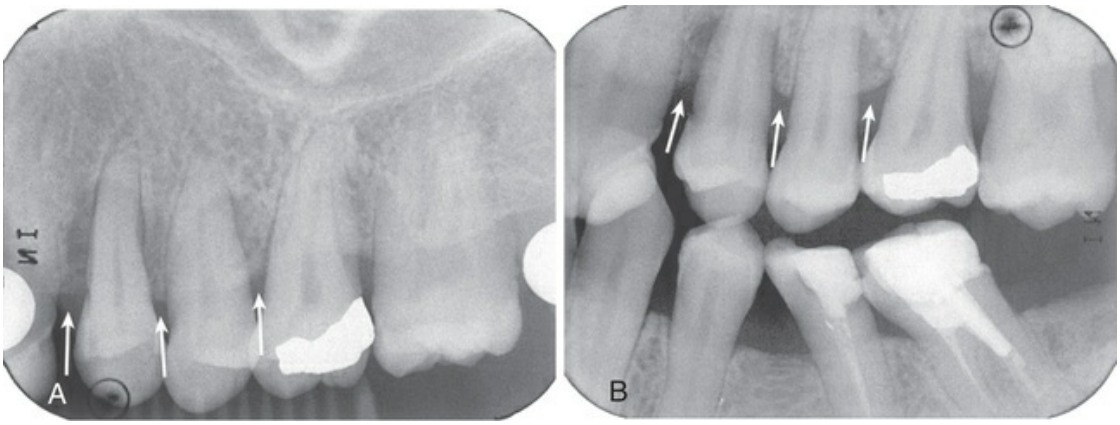

FIG. 33.4 Periapical (A) and bitewing (B) radiographs from a full-mouth series of a patient with periodontitis. The periapical film clearly underestimates the amount of bone loss *(white arrows).* Because of appropriate projection geometry, the alveolar crest height is accurately depicted on the bitewing radiograph *(white arrows).*

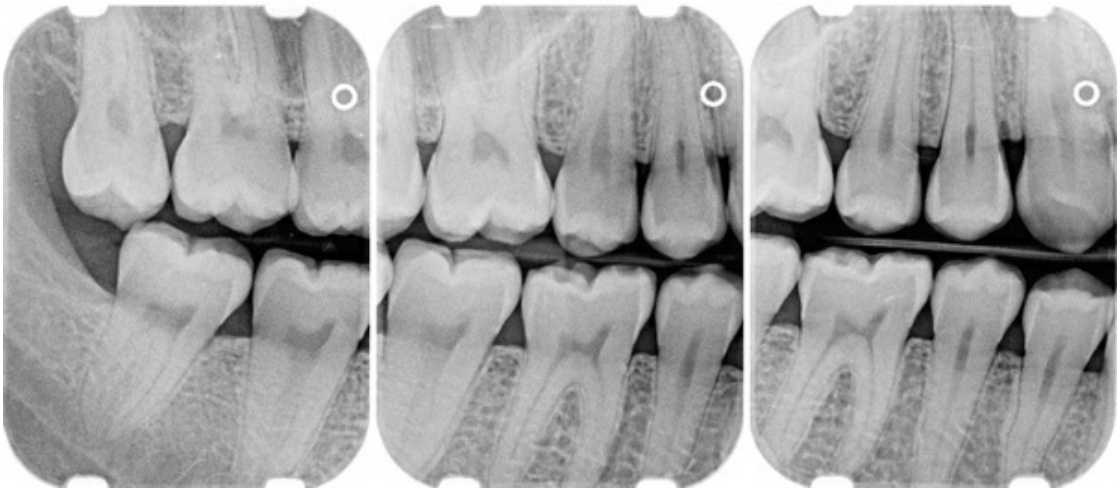

FIG. 33.5 Vertical bitewing films can be used to cover a larger area of the alveolar bone.

Learning Box 33.2

Bitewing radiography is the preferred imaging technique to depict periodontal bone levels in the posterior dentition.

Bone Destruction in Periodontal Disease

Early destructive changes of bone that do not remove sufficient mineralized tissue cannot be captured on radiographs. Therefore slight radiographic changes of the periodontal tissues suggest that the disease has progressed beyond its earliest stages.[4] The earliest signs of periodontal disease must be detected clinically.

Bone Loss

The radiographic image tends to underestimate the severity of bone loss. The difference between the alveolar crest height and the radiographic appearance ranges from 0 to 1.6 mm, mostly accounted for by x-ray angulation.

Amount

Radiographs are an indirect method for determining the amount of bone loss in periodontal disease; they show the amount of remaining bone rather than the amount lost. The amount of bone lost is estimated to be the difference between the physiologic bone level and the height of the remaining bone.

Several investigators have analyzed the distance from the CEJ to the alveolar crest.[8,11,13] Most studies, conducted in adolescents, suggest a distance of 2 mm to reflect normal periodontium; this distance may be greater in older patients.

Distribution

The distribution of bone loss is an important diagnostic sign. It points to the location of destructive local factors in different areas of the mouth and in relation to different surfaces of the same tooth.

Pattern of Bone Destruction

In periodontal disease the interdental bone undergoes changes that affect the lamina dura, crestal radiodensity, size and shape of the medullary spaces, and height and contour of the bone. The height

of interdental bone may be reduced, with the crest perpendicular to the long axis of the adjacent teeth (*horizontal* bone loss; Fig. 33.6), or angular or arcuate defects (*angular,* or *vertical,* bone loss; Fig. 33.7) could form.

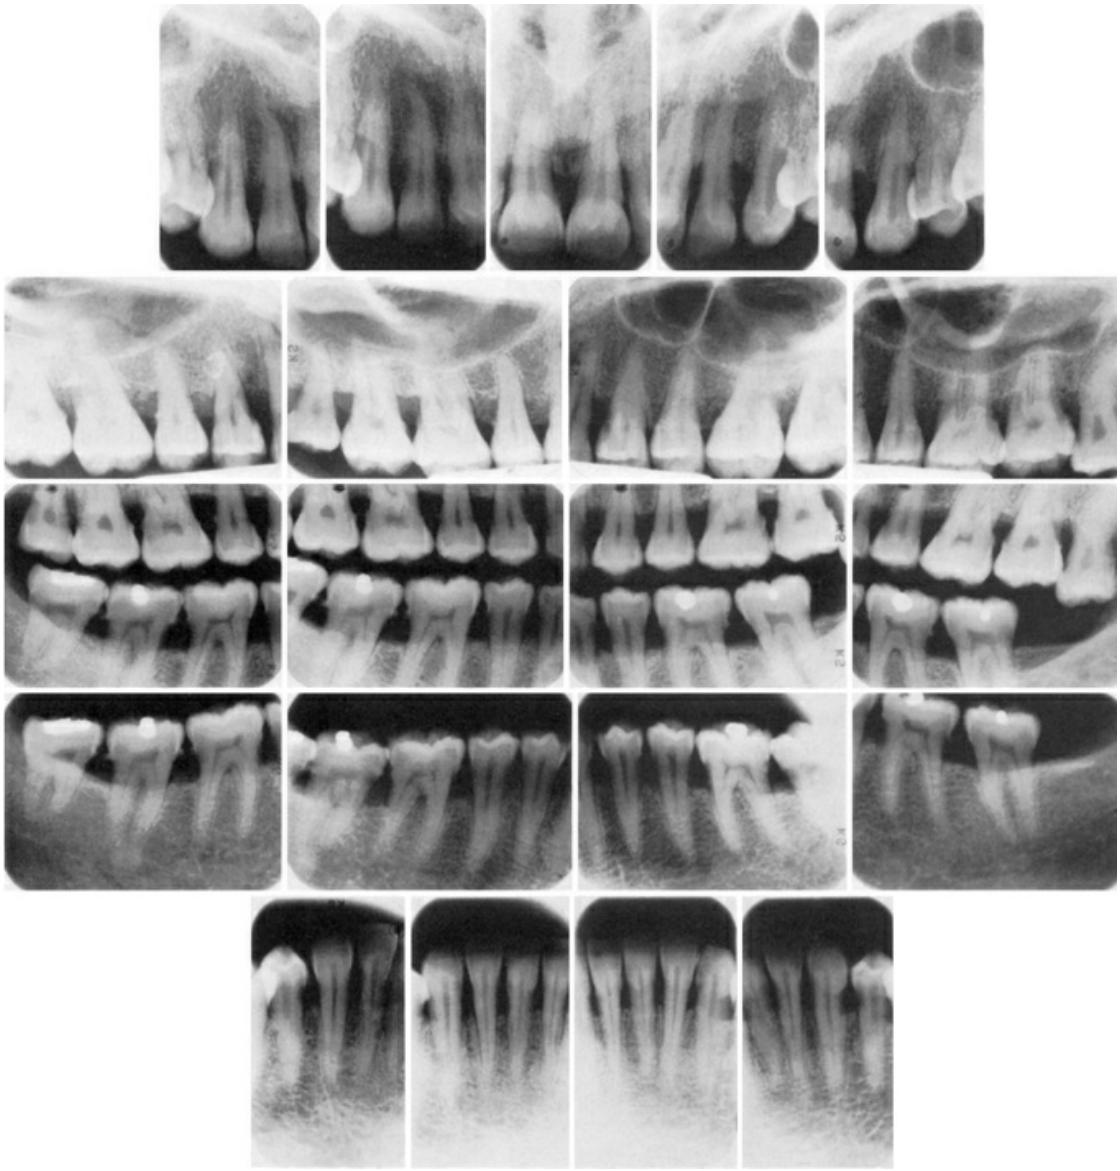

FIG. 33.6 Generalized horizontal bone loss.

FIG. 33.7 Angular bone loss on first molar with involvement of the furcation.

Radiographs do not indicate the internal morphology or depth of crater-like defects. Also, radiographs do not reveal the extent of involvement on the facial and lingual surfaces. Bone destruction of facial and lingual surfaces is masked by the dense root structure, and bone destruction on the mesial and distal root surfaces may be partially hidden by superimposed anatomy, such as a dense mylohyoid ridge (Fig. 33.8). In most cases, it can be assumed that bone loss seen interdentally continues in either the facial or lingual aspect, creating a troughlike lesion.

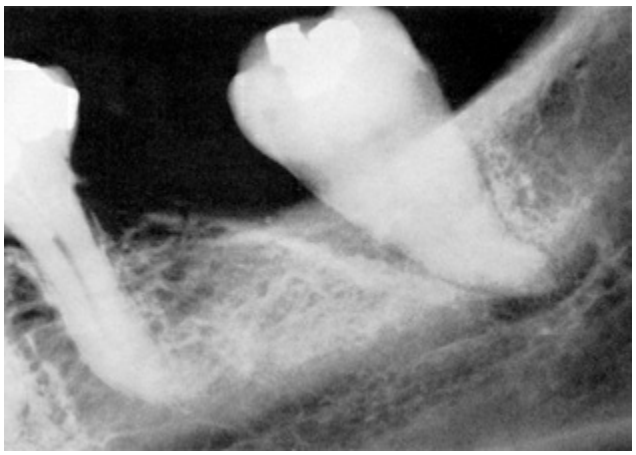

FIG. 33.8 Angular bone loss on mandibular molar partially obscured by a dense mylohyoid ridge.

Dense cortical facial and lingual plates of interdental bone

obscure destruction of the intervening cancellous bone. Thus a deep, craterlike defect between the facial and lingual plates might not be depicted on conventional radiographs. To record destruction of the interproximal cancellous bone radiographically, the cortical bone must be involved. A reduction of only 0.5 to 1 mm in the thickness of the cortical plate is sufficient to permit radiographic visualization of the destruction of the inner cancellous trabeculae.

Interdental bone loss may continue facially or lingually to form a troughlike defect that could be difficult to appreciate radiographically. These lesions may terminate on the radicular surface or may communicate with the adjacent interdental area to form one continuous lesion (Fig. 33.9).

FIG. 33.9 Interdental lesion that extends to the facial or lingual surfaces in a troughlike manner.

Fig. 33.10 shows two adjacent interdental lesions connecting on the radicular surface to form one interconnecting osseous lesion. Along with clinical probing of these lesions, the use of a radiopaque

pointer placed in these radicular defects will demonstrate the extent of the bone loss.

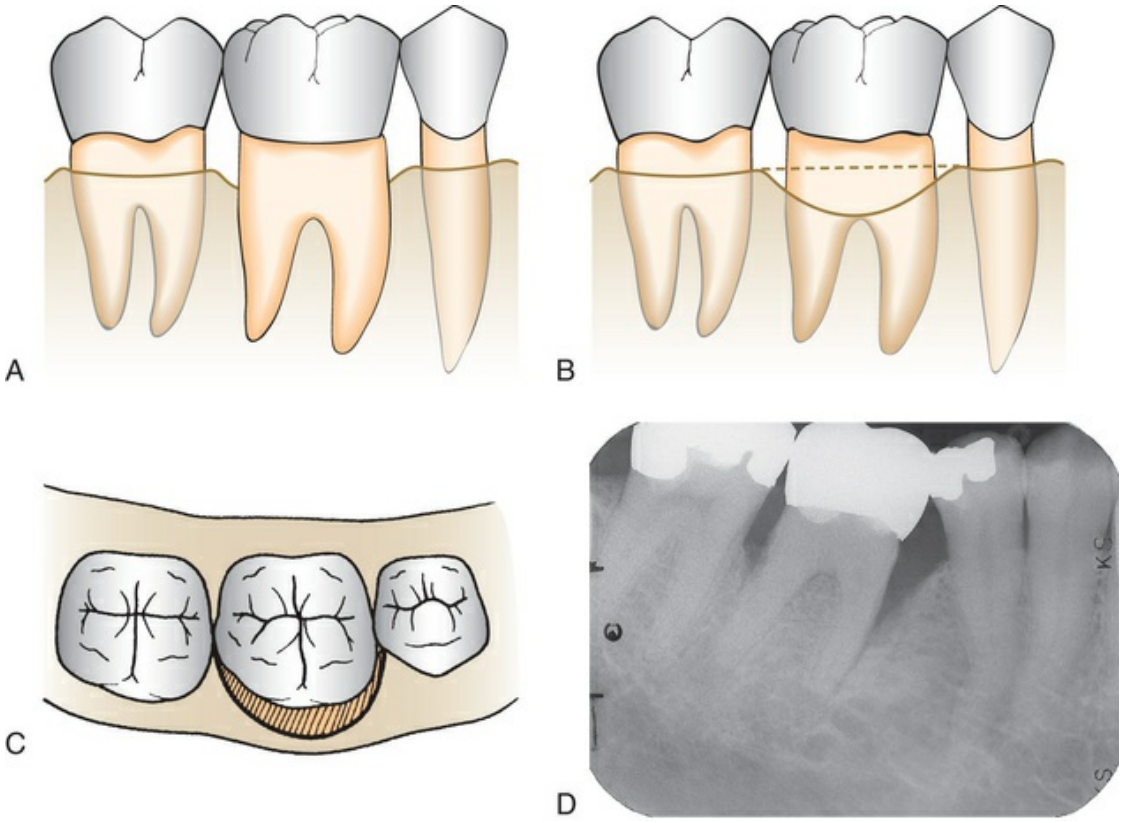

FIG. 33.10 (A) Interdental mesial and distal lesions. (B) Facial or lingual outlines of the actual lesion. (C) Occlusal view of the lesion. (D) Radiograph of mesial and facial lesions.

Periodontal bone loss should be differentiated from normal anatomy or anatomic variants that can resemble disease. For example, nutrient canals in the alveolar bone can appear as linear and circular radiolucent areas (Fig. 33.11). These canals can be seen more frequently in the anterior mandible, although they can be present throughout the alveolar ridge.

FIG. 33.11 Prominent nutrient canals in the mandible.

Finally, it should be emphasized that radiographs can only assess the amount of periodontal bone that is present and deduce the extent of bone loss. However, it is sometimes necessary to determine whether the reduced bone level is the result of periodontal disease that is no longer destructive (usually after treatment and proper maintenance) or whether destructive periodontal disease is present. Differentiation between treated versus active periodontal disease can only be achieved clinically. Radiographically detectable changes in the normal cortical outline of the interdental bone are corroborating evidence of destructive periodontal disease.

Radiographic Appearance of Periodontal Disease

Periodontitis

Radiographic changes in periodontitis follow the pathophysiology of periodontal tissue destruction and include the following:

1. *Fuzziness and disruption of lamina dura* crestal cortication continuity is the earliest radiographic change in periodontitis (Fig. 33.12A–B) and results from bone resorption activated by extension of gingival inflammation

into the periodontal bone. Depicting these early changes depends greatly on the radiographic technique, as well as on anatomic variations (thickness and density of interdental bone, position of adjoining teeth). No correlation has been found between crestal lamina dura in radiographs and the presence or absence of clinical inflammation, bleeding on probing, periodontal pockets, or loss of attachment.[16] Therefore it can be concluded that the presence of an intact crestal lamina dura may be an indicator of periodontal health, whereas its absence lacks diagnostic relevance.[1,3]

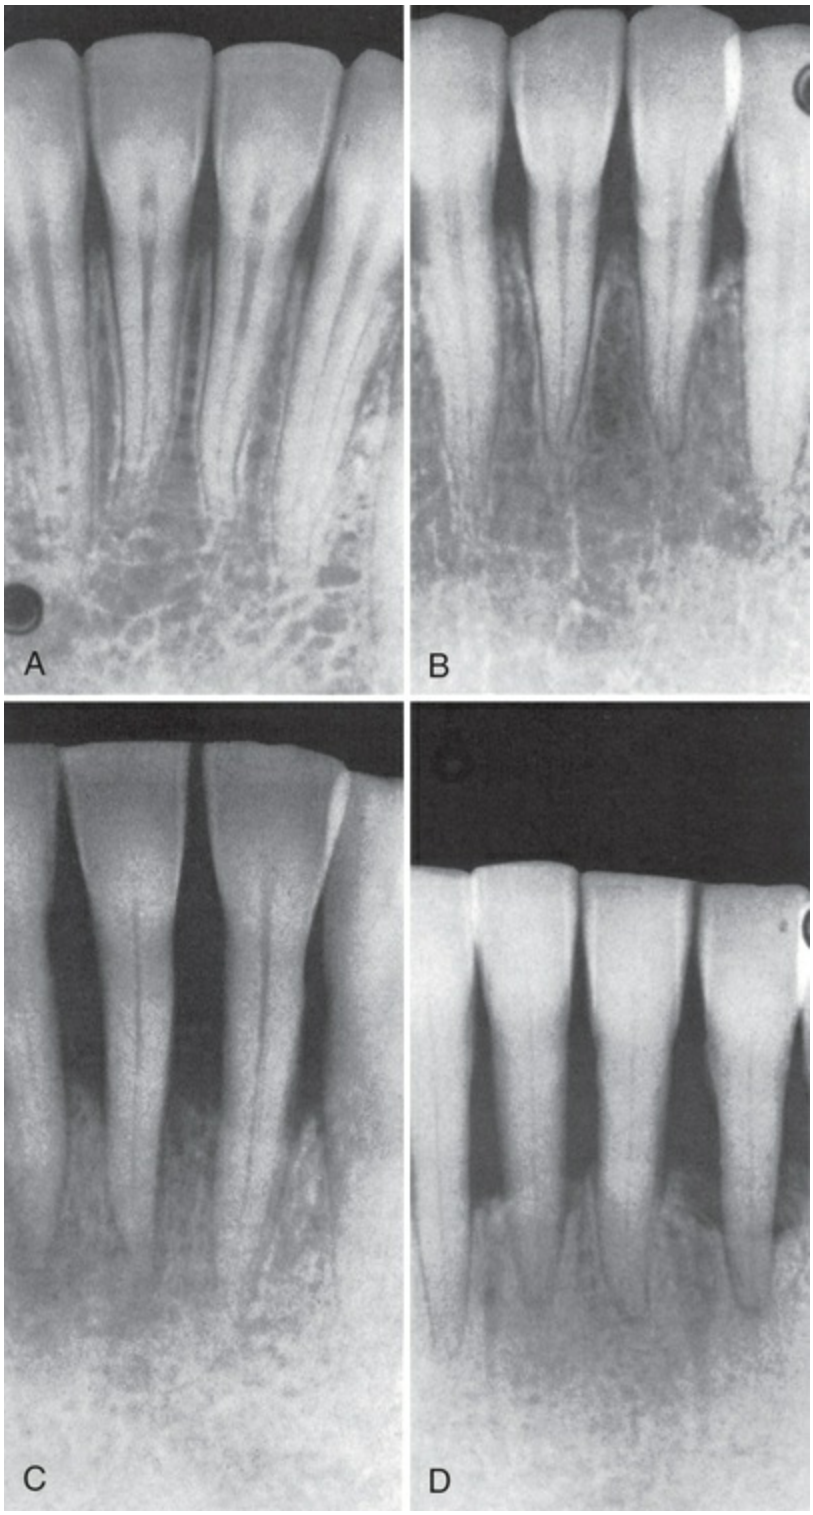

FIG. 33.12 Radiographic changes in periodontitis. (A) Normal appearance of interdental bone. (B) Fuzziness and a break in the continuity of the lamina dura at the crest of the bone distal to the central incisor *(left).* There are wedge-shaped radiolucent areas at the crest of the other interdental bone. (C) Radiolucent projections from the crest into the interdental bone indicate extension of destructive processes. (D) Severe bone loss.

2. Continued periodontal bone loss and widening of the periodontal space results in a wedge-shaped radiolucency at the mesial or distal aspect of the crest (Fig. 33.12B). The apex of the area is pointed in the direction of the root.
3. Subsequently, the destructive process extends across the alveolar crest, thus reducing the height of the interdental bone. As increased osteoclastic activity results in increased bone resorption along the endosteal margins of the medullary spaces, the remaining interdental bone can appear partially eroded (Fig. 33.12C).
4. The height of the interdental septum is progressively reduced by the extension of inflammation and the resorption of bone (Fig. 33.12D).
5. Frequently a radiopaque horizontal line can be observed across the roots of a tooth. This opaque line demarcates the portion of the root where the labial or lingual bony plate has been partially or completely destroyed from the remaining bone-supported portion (Fig. 33.13).

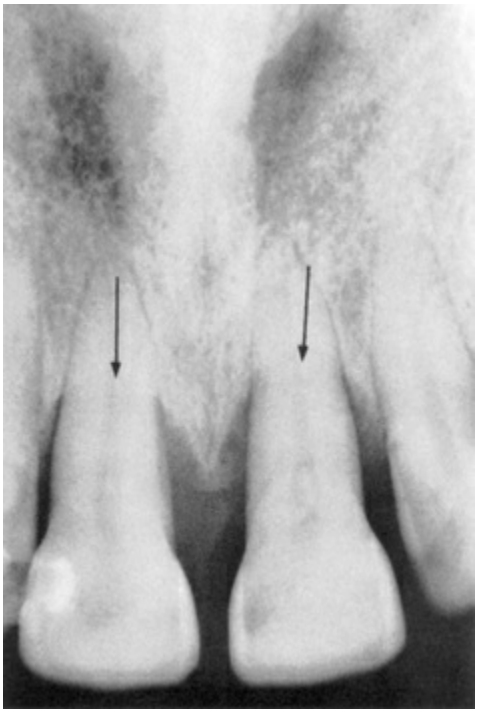

FIG. 33.13 Horizontal lines across the roots of the central incisors *(arrows).* The area of the roots below the horizontal lines is partially or completely denuded of the facial and lingual bony plates.

Learning Box 33.3

The earliest changes of periodontal disease often do not manifest on radiographs. Even when radiographic changes are evident, radiographic examination may underestimate the extent of bone loss. Thus assessment of periodontal bone level should be based on combined clinical-radiographic evaluation.

Interdental Craters

Interdental craters are seen as irregular areas of reduced density on the alveolar bone crests. Craters are generally not sharply demarcated but gradually blend with the rest of the bone. Conventional radiographs do not accurately depict the morphology or depth of interdental craters, which sometimes appear as vertical defects.

Furcation Involvement

Definitive diagnosis of furcation involvement is made by clinical examination, which includes careful probing with a specially designed probe (e.g., Nabers). Radiographs are helpful, but root superimposition, caused by anatomic variations or improper technique, can obscure radiographic representation of furcation involvement. As a general rule, bone loss is greater than it appears in the radiograph. A tooth may present marked bifurcation involvement in one film (Fig. 33.14A) but appear to be uninvolved in another (Fig. 33.14B). Radiographs should be taken at different angles to reduce the risk of missing furcation involvement.

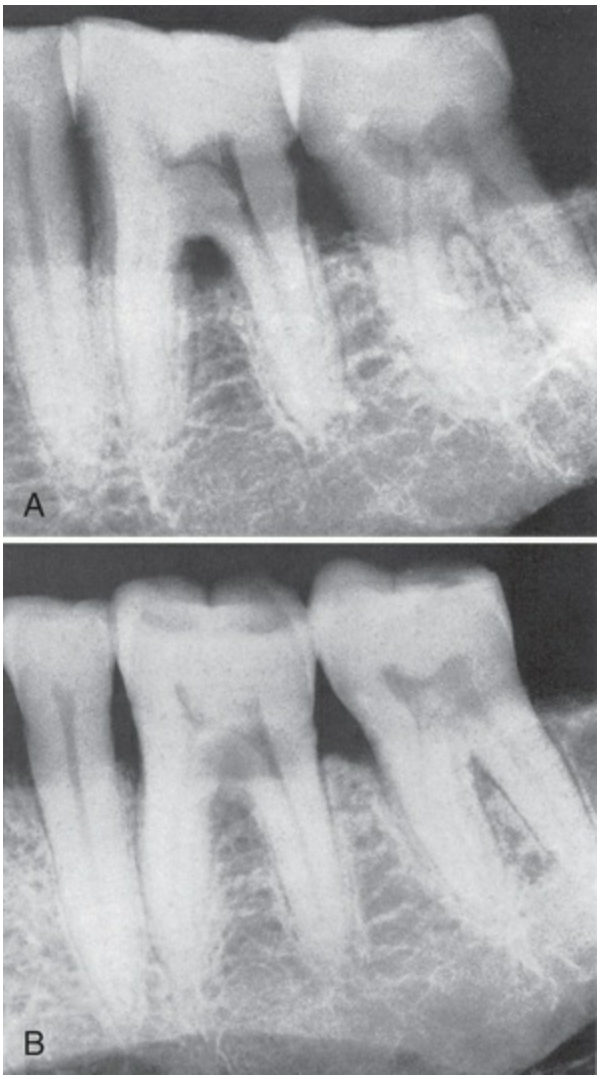

FIG. 33.14 (A) Furcation involvement indicated by triangular radiolucency in the bifurcation area of mandibular first molar. The second molar presents only a slight thickening of the periodontal space in the bifurcation area. (B) Same area as in A with different angulation. The triangular radiolucency in the bifurcation of the first molar is obliterated, and involvement of the second molar bifurcation is apparent.

A large, clearly defined radiolucency in the furcation area is easy to identify (see Fig. 33.14A), but less clearly defined radiographic changes are often overlooked. To assist in the radiographic detection of furcation involvement, the following diagnostic criteria are suggested:

1. The slightest radiographic change in the furcation area

should be investigated clinically, especially if there is bone loss on adjacent roots (Fig. 33.15).

FIG. 33.15 Early furcation involvement suggested by fuzziness in the bifurcation of the mandibular first molar, particularly when associated with bone loss on the roots.

2. Diminished radiodensity in the furcation area in which outlines of bony trabeculae are visible suggests furcation involvement (Fig. 33.16).

FIG. 33.16 Furcation involvement of mandibular first and second molars indicated by thickening of the periodontal space in the furcation area. The furcation of the third molar is also involved, but the thickening of the periodontal space is partially obscured by the external oblique line.

3. Whenever there is marked bone loss in relation to a single molar root, it may be assumed that furcation is also involved (Fig. 33.17).

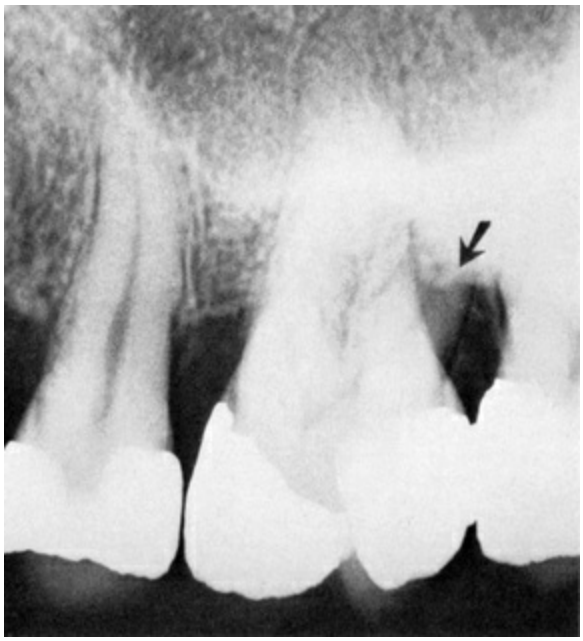

FIG. 33.17 Furcation involvement of the first molar partially obscured by the radiopaque lingual root. The horizontal line across the distobuccal root demarcates the apical portion *(arrow),* which is covered by bone, from the remainder of the root, where the bone has been destroyed.

Periodontal Abscess

The typical radiographic appearance of a periodontal abscess is a discrete area of radiolucency along the lateral aspect of the root (Figs. 33.18 and 33.19). However, the radiographic picture is often not characteristic (Fig. 33.20). This can be due to the following:

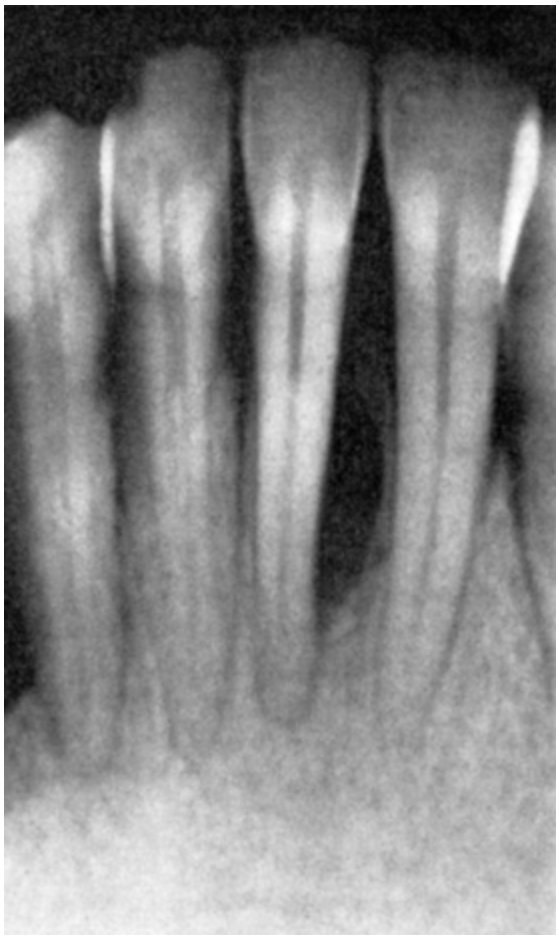

FIG. 33.18 Radiolucent area on lateral aspect of root with chronic periodontal abscess.

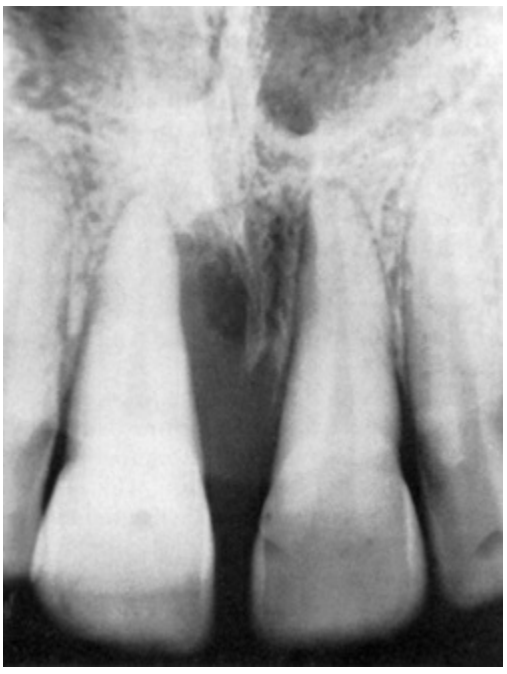

FIG. 33.19 Typical radiographic appearance of periodontal abscess on right central incisor.

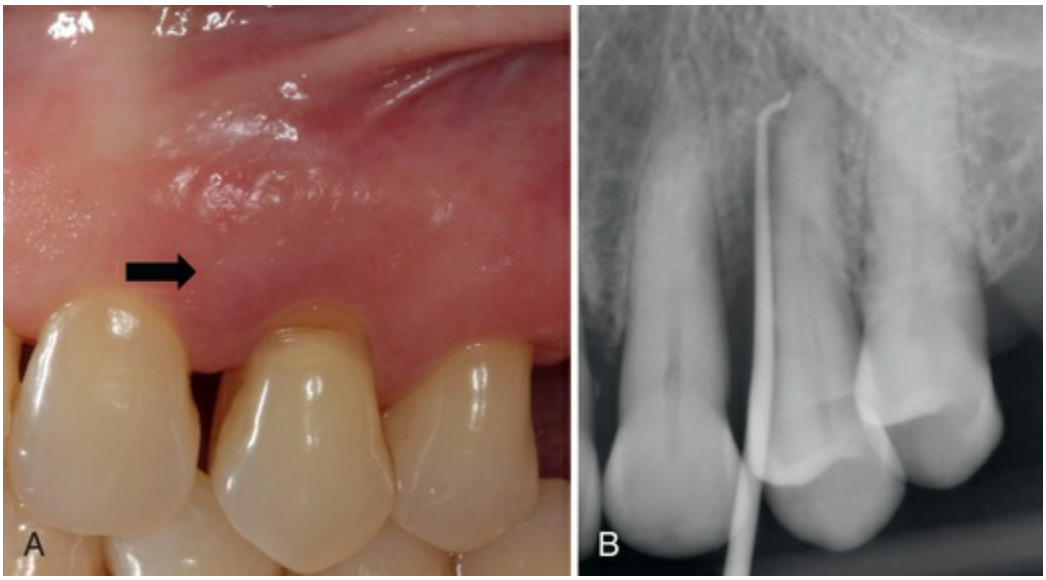

FIG. 33.20 Chronic periodontal abscess. (A) Periodontal abscess in the left maxillary first premolar area. (B) Extensive bone destruction on the mesial surface of the first premolar. Gutta-percha point traces to the root apex.

1. *The stage of the lesion.* In the early stages an acute periodontal abscess is extremely painful but presents no radiographic changes.
2. *The extent of bone destruction and the morphologic changes of the bone.*
3. *The location of the abscess.* Lesions in the soft tissue wall of a periodontal pocket are less likely to produce radiographic changes than those deep in the supporting tissues. Abscesses on the facial or lingual surface are obscured by the radiopacity of the root; interproximal lesions are more likely to be visualized radiographically.

Therefore radiographs alone cannot provide a final diagnosis of a periodontal abscess but need to be accompanied by careful clinical examination.

Clinical Probing

Regenerative and resective flap designs and incisions require prior knowledge of the underlying osseous topography. Careful probing of these pocket areas after scaling and root planing often requires local anesthesia and definitive radiographic evaluation of the osseous lesions. Radiographs taken with periodontal probes, gutta-percha points, or other indicators (e.g., Hirschfeld pointers) placed into the anesthetized pocket show the true extent of the bone lesion. As indicated previously, the attachment level on the radicular surface or interdental lesions with thick facial or lingual bone cannot be visualized in the radiograph. The use of radiopaque indicators is an efficient and necessary diagnostic aid (Fig. 33.21).

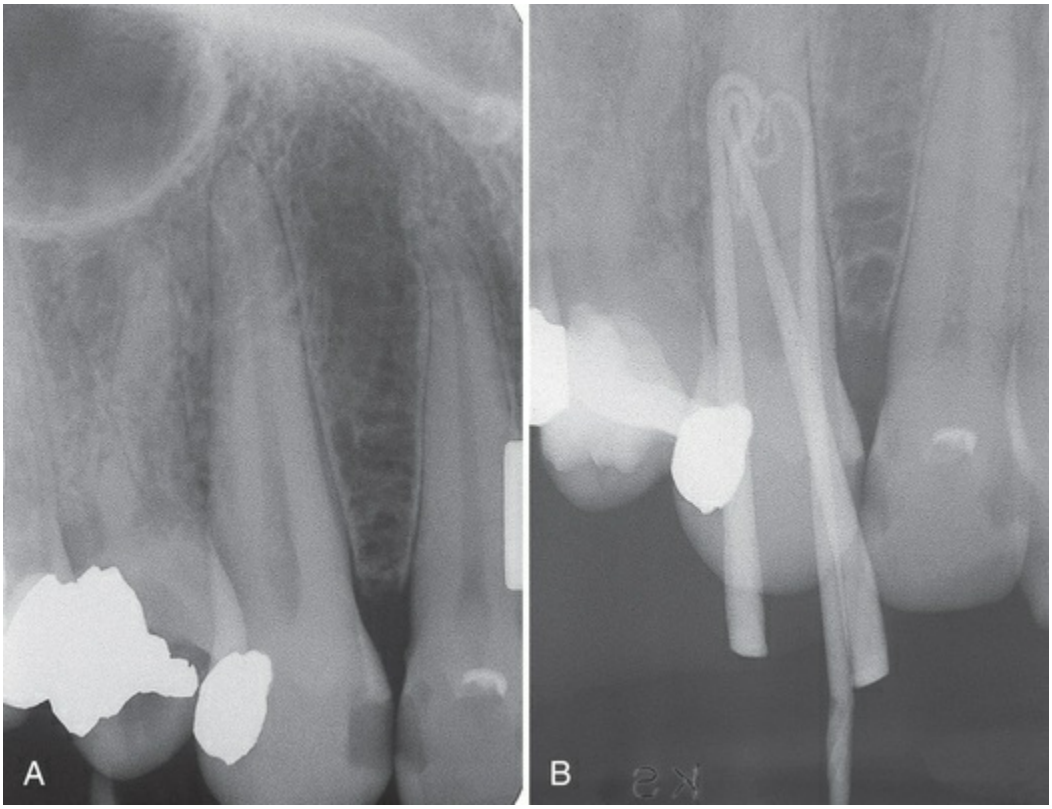

FIG. 33.21 (A) Radiograph of maxillary cuspid. This view does not show facial bone loss. (B) Radiograph of same maxillary cuspid as in part A, with gutta-percha points placed in the facial pocket to indicate bone loss.

Localized Aggressive Periodontitis

Localized aggressive (formerly “localized juvenile”) periodontitis is characterized by the following:

1. Initially, there is bone loss in the maxillary and mandibular incisor or first molar areas, usually bilaterally, resulting in a vertical, arclike destructive pattern (Fig. 33.22).

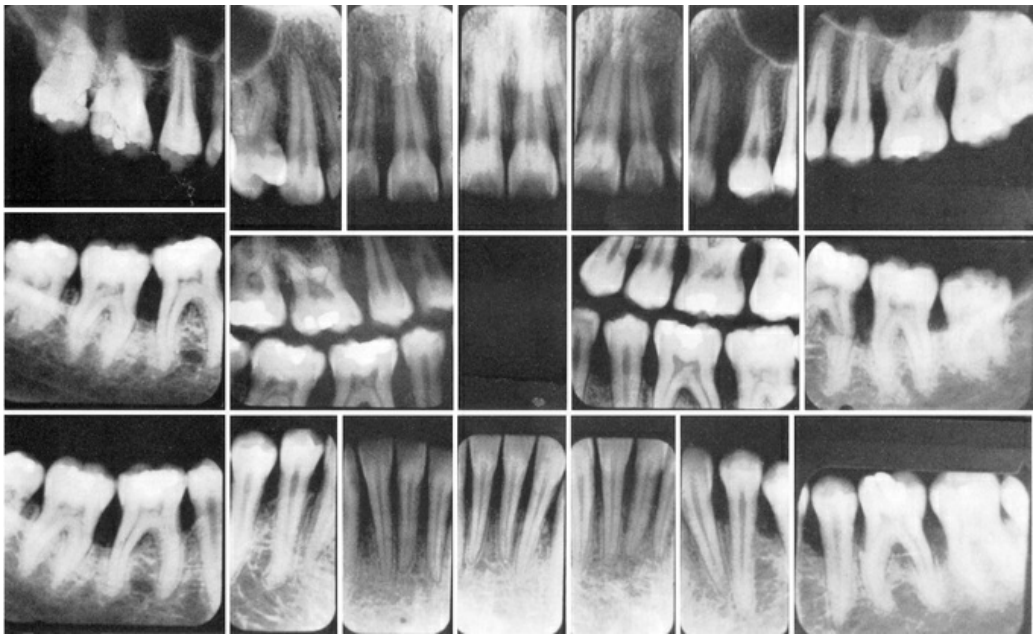

FIG. 33.22 Localized aggressive periodontitis. The accentuated bone destruction in the anterior and first molar areas is considered to be characteristic of this disease.

2. As the disease progresses, loss of alveolar bone may become generalized but remains less pronounced in the premolar areas.

Trauma From Occlusion

Trauma from occlusion can produce radiographically detectable changes in the thickness of the lamina dura, morphology of the alveolar crest, width of the PDL space, and density of the surrounding cancellous bone.[5]

Traumatic lesions manifest more clearly in faciolingual aspects because mesiodistally, the tooth has added stability provided by the contact areas with adjacent teeth. Therefore slight variations in the proximal surfaces may indicate greater changes in the facial and

lingual aspects. *The radiographic changes listed next are not pathognomonic for trauma from occlusion and must be interpreted in combination with clinical findings,* particularly tooth mobility, presence of wear facets, pocket depth, and analysis of occlusal contacts and habits.

The *injury phase* of trauma from occlusion produces a loss of the lamina dura that may be noted in apices, furcations, and marginal areas. This loss of lamina dura results in widening of the PDL space (Fig. 33.23). The *repair phase* of trauma from occlusion results in an attempt to strengthen the periodontal structures to better support the increased loads. Radiographically, this is manifested by a widening of the PDL space, which may be generalized or localized.

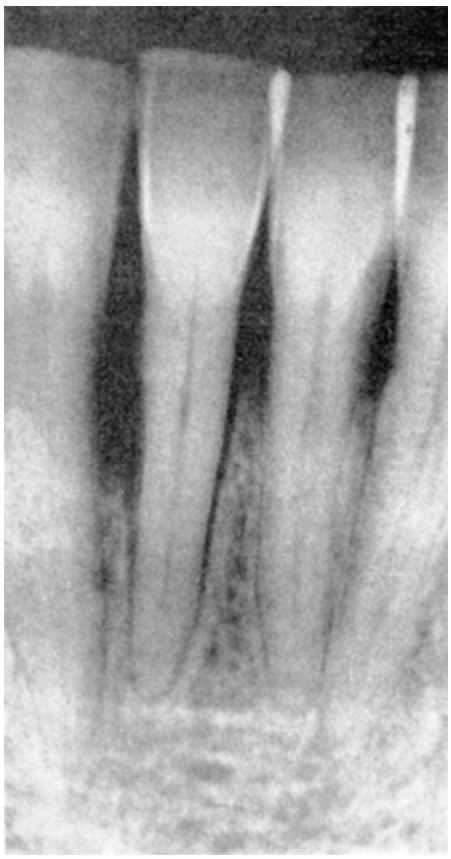

FIG. 33.23 Widened periodontal space caused by trauma from occlusion. Note the increased density of the surrounding bone caused by new bone formation in response to increased occlusal forces.

Although microscopic measurements have determined normal variations in the PDL space width along the root surface, these are

generally not detected radiographically. Thus, when seen on radiographs, variations in PDL space width suggest that the tooth is being subjected to increased forces. Successful attempts to reinforce the periodontal structures by widening the PDL space can be accompanied by increased width of the lamina dura and sometimes by condensation of the perialveolar cancellous bone.

More advanced traumatic lesions may result in deep angular bone loss, which, when combined with marginal inflammation, may lead to intrabony pocket formation. In terminal stages, these lesions extend around the root apex, producing a wide, radiolucent periapical image (cavernous lesions).

Root resorption may also result from excessive forces on the periodontium, particularly those caused by orthodontic appliances. Although trauma from occlusion produces many areas of root resorption, these areas are usually of a magnitude insufficient to be detected radiographically.

Digital Intraoral Radiography

Advances in digital imaging technology have driven rapid growth of digital intraoral radiography as a convenient alternative to conventional film-based radiography.[10,12,14,23] These technologies have been integrated into patient management systems, enabling dental offices to maintain fully electronic patient records (Fig. 33.24A). The digital records can be easily shared among dentists and other health care providers, enabling telediagnosis and facilitating transmission to third parties for reimbursement.

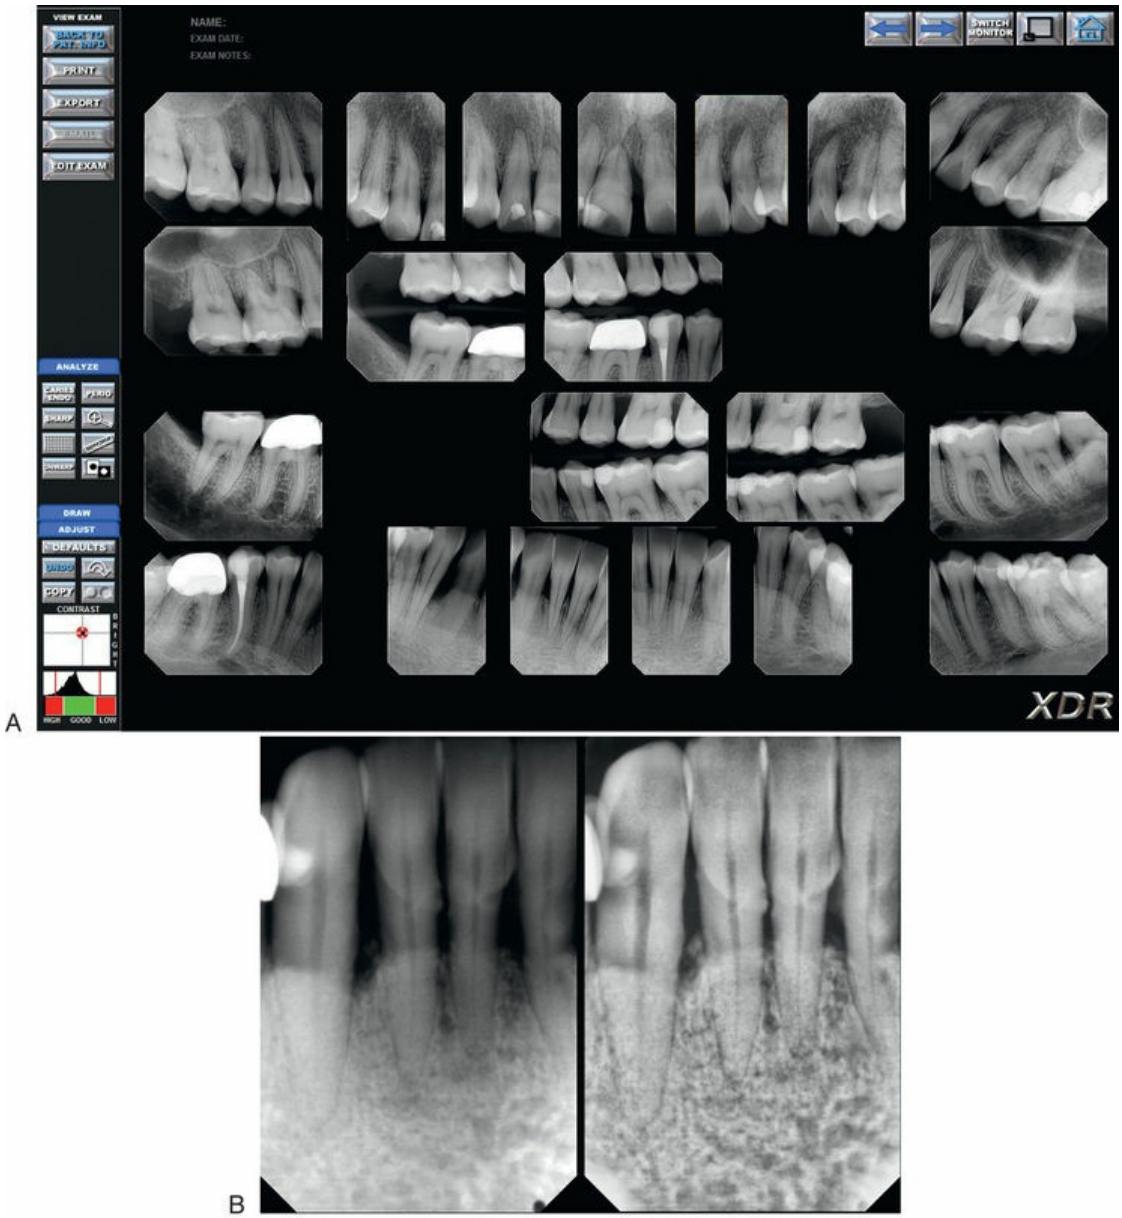

FIG. 33.24 (A) Image display of a full-mouth radiographic series acquired using complementary metal oxide semiconductor (CMOS) receptors. Specific features of the software program allow for image manipulation, measurements, and annotations. (B) The "perio" image enhancement filter applied to highlight the contrast of alveolar bone. Note the presence of calculus and better depiction of the alveolar crestal bone.

Digital intraoral radiographic systems use either solid-state detectors or photostimulable phosphor (PSP) plates.[21-23] Systems with solid-state detectors use either charge-coupled devices (CCDs) or complementary metal oxide semiconductor (CMOS) chips as

image receptors. These receptors are typically wired and connected to a computer using a Universal Serial Bus (USB) connection. Wireless sensors are also available and require the use of disposable batteries. With CCD/CMOS-based receptors, images are recorded and displayed on a computer monitor virtually in real time. These sensors are bulkier than film, and the active image-recording area is slightly smaller than that of film. A second technology for intraoral radiography is PSP plates. These receptors are the same size as intraoral radiographic film. Unlike CCD/CMOS receptors, PSP plates do not provide a real-time display of the radiographic image. On interaction with x-ray photons, PSP crystals in the plate store energy, creating a latent radiographic image. The stored energy is then released by stimulating the plate with an appropriate wavelength of light. With PSP systems, the workflow is somewhat similar to that with silver halide emulsion film. Following radiographic exposure, the PSP plate is scanned by a laser beam, converting the latent radiographic image into a digital image.

Following capture, digital radiographic images can be enhanced to augment radiographic diagnosis. The brightness and contrast of the image can be altered to highlight specific anatomic regions, depending on the diagnostic task. The images can be magnified to allow closer examination of a specific area of interest. Importantly, a variety of image enhancement filters can be applied—for example, to sharpen images (enhance edges). Some software programs have preprogrammed algorithms that can be applied for specific diagnostic tasks—for example, to enhance interproximal caries, periodontal bone, pulp canals, and so forth (Fig. 33.24B). However, it is important to recognize that such image manipulations can produce artifacts that may be misinterpreted as disease. Clinicians should be aware of such artifacts produced by digital image manipulation. In addition to the image manipulation features, digital radiographic images facilitate patient education, allow for easy storage and sharing with other health care providers, and can be easily integrated into electronic patient records.

Advanced Imaging Modalities

Cone-beam computed tomography (CBCT) has revolutionized the

field of oral and maxillofacial imaging. CBCT technology and its use in evaluating the implant patient are discussed in Chapter 76. However, CBCT finds application in almost every diagnostic task of clinical dentistry, including the evaluation of periodontal and periapical structures.[18] CBCT offers many advantages over conventional radiography, including accurate three-dimensional imaging of teeth and supporting structures. Although not recommended for every dental patient, CBCT avoids the problems of geometric superimposition and unpredictable magnification and can provide valuable diagnostic information in periodontal evaluation.

As discussed earlier, periapical and bitewing radiographs provide information mostly for interdental bone. However, a three-wall defect that preserves the buccal or lingual cortices can be difficult to diagnose, and the buccal, lingual, and furcational periodontal bone levels are hard to evaluate in conventional radiographs. When clinical examination raises concerns for such areas, CBCT imaging can add diagnostic value. Indeed, when compared to periapical radiographs, CBCT was able to depict the buccal and lingual/palatal surfaces and offered improved visualization of the morphology of the periodontal defect.[7] Furthermore, for assessment of periodontal bone loss, CBCT performed better than digital radiographs in the detection of early furcational defects, three-wall defects, fenestrations, and dehiscence, but not in advanced furcation involvement or one- or two-wall and troughlike defects.[2]

Fig. 33.25 illustrates the diagnostic advantage of CBCT in the evaluation of a three-wall defect in the distal surface of tooth #32. A periapical radiograph (Fig. 33.25A) presents normal bone height at the mesial and distal surfaces of #32. CBCT sections (Fig. 33.25A–C) clearly demonstrate a three-wall defect on the distal surface of #32. Note that the buccal and lingual cortical plates are well preserved. For this reason, the periodontal defect is not depicted in the periapical radiograph. Similarly, Fig. 33.26 depicts a vertical defect in the interproximal area between the two right maxillary premolars extending from the alveolar crest to the apical third of the roots toward the palatal aspect of the alveolar ridge. This defect cannot be appreciated on the periapical radiograph.

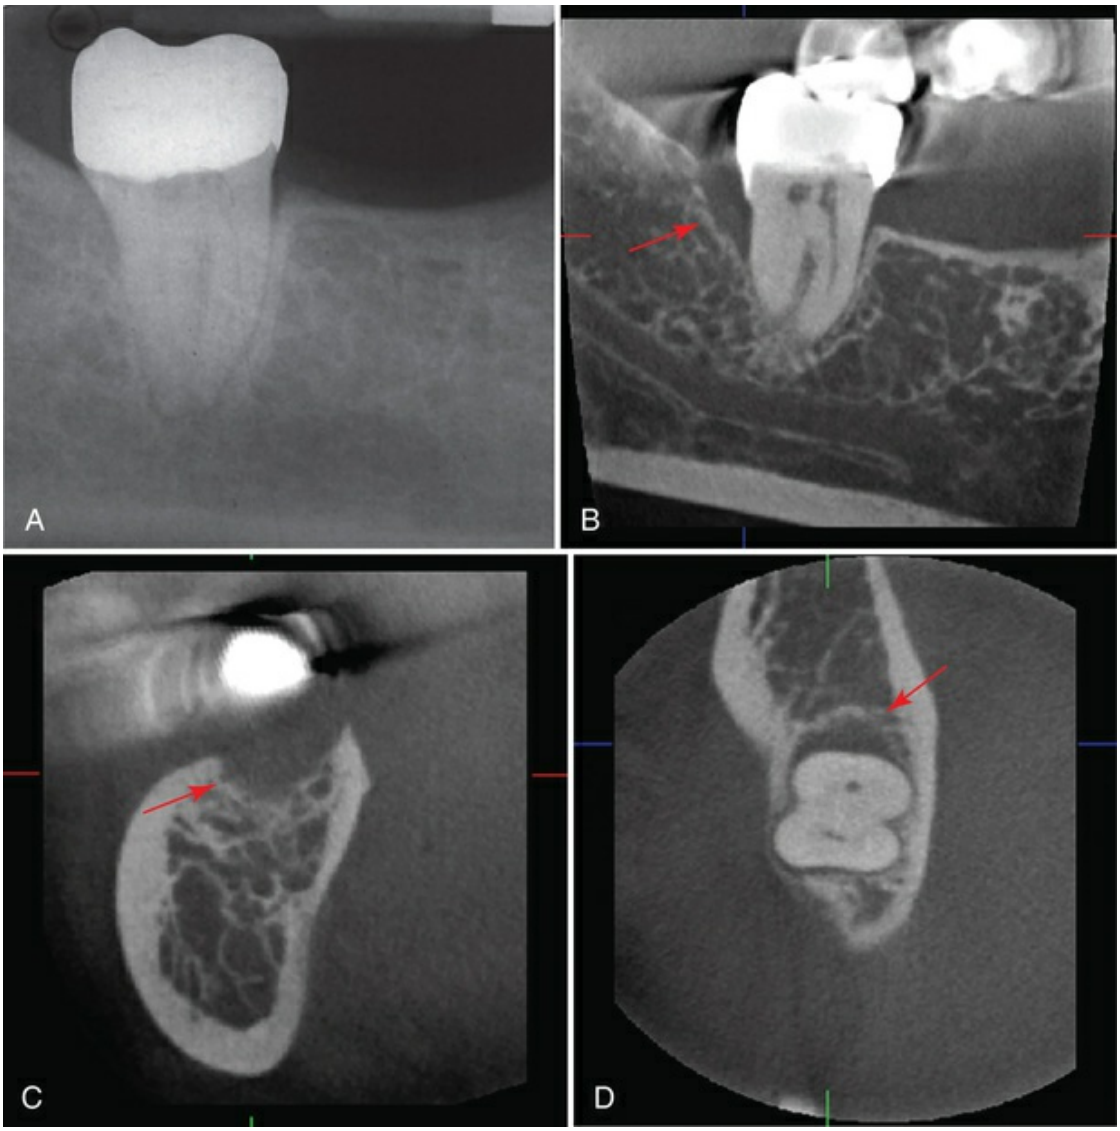

FIG. 33.25 Periapical radiograph (A) and sagittal (B), cross-sectional (C), and axial (D) cone-beam computed tomography (CBCT) sections of the mandibular right second molar. No pathology is detected on the periapical radiograph. However, CBCT images clearly illustrate a deep, vertical, three-wall defect on the distal surface of the mandibular right second molar *(red arrow).*

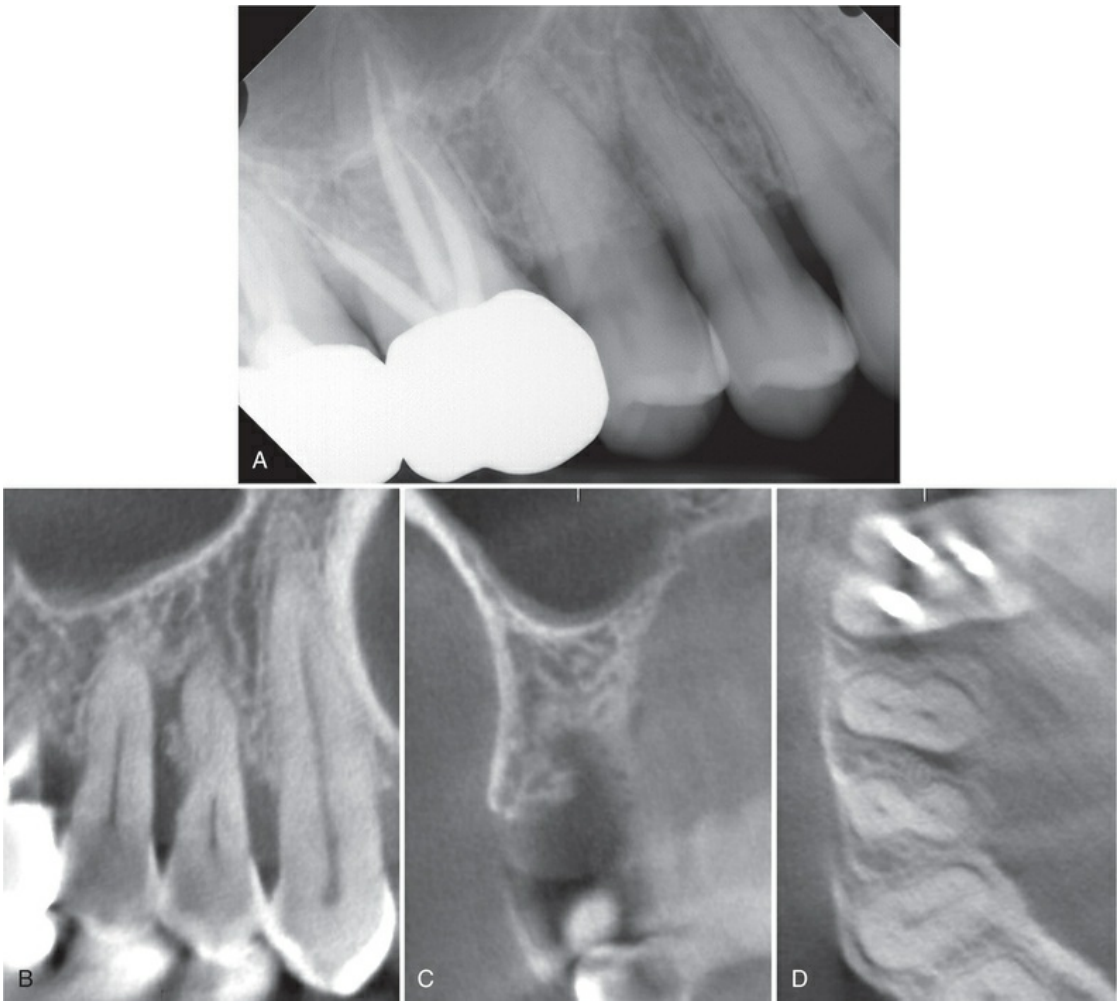

FIG. 33.26 Periapical radiograph (A) and sagittal (B), cross-sectional (C), and axial (D) cone-beam computed tomography (CBCT) sections of the maxillary premolar region. The periapical radiograph demonstrates horizontal bone loss. The CBCT images reveal the presence of a vertical defect between the premolars that extends from the palatal crest to the apical third of the roots. The extent of bone loss is underestimated on the periapical radiograph.

Learning Box 33.4

CBCT imaging provides three-dimensional information and overcomes many of the limitations of conventional two-dimensional (2D) radiography. However, CBCT imaging is a higher-dose procedure relative to bitewing radiography, and is also more expensive. CBCT imaging for periodontal bone

evaluation should be considered only for select cases where 2D information is insufficient for diagnostic or treatment planning needs, and it is not recommended for routine evaluation of periodontal bone loss.

Conclusion

Periapical radiographic examination should be part of every patient's periodontal evaluation and coupled with a detailed recording of pocket depths, gingival margin location, and bleeding on probing. Radiographic evaluation should be updated every 2 years. Periapical radiographs often underestimate the amount of periodontal bone loss, and early changes are usually not detected. Significant interdental bone loss can occur and may not be detectable on periapical radiographs because the density of the intact buccal and lingual or palatal bone plates obscure changes that occur as a result of periodontitis. Comparing periapical radiographs of the same area taken at different times will only be reliable for documenting dramatic changes in bone levels, because variations in angulation of the beam, placement of the film, and development of the image make accurate measurements taken over time difficult and unreliable.

Three-dimensional radiographic techniques with CBCT give a much more accurate picture of periodontal bone loss than two-dimensional radiographs and will be more widely used as this technology becomes available in more clinics.

Case Scenario 33.1

Patient:
52-year-old male

Current Information:
Class II mobility of endodontically treated tooth #31

Current Findings
Panoramic (A) and periapical (B) radiographs suggest altered

trabecular bone around the roots of tooth #31. No widening of the PDL space at the apical area of #31 is noted.

Case-Based Questions

Answer the following **true** or **false**. Sagittal (C), coronal (D), and axial (E) CBCT sections of #31 reveal:

1. A large carious lesion on the distal surface of tooth #30 *(arrowhead)*
2. Periradicular widening of the PDL space, most prominent along the mesial, buccal, and distal surfaces
3. Widened PDL extending to the alveolar crest and close to the periapical area
4. Horizontal root fractures at the distal and mesial roots *(thin arrows)*
5. An altered dimension of the mandibular canal that is wide anteriorly but narrows posteriorly *(thick arrows)*

Solution and Explanation

1. False. The radiolucent area represents a beam-hardening artifact due to the crown of tooth #31. Compare with the same area on the panoramic and periapical radiographs.
2. True. Extensive periradicular bone loss is noted. The amount of bone loss appears to be underestimated on the 2D images.
3. True. The pattern of bone loss is characteristic of a periodontal–endodontic lesion or vertical root fracture. Also note the close occlusion of #31 with #2, suggesting possible periodontal trauma.
4. False. Although a vertical root fracture is strongly suggested by the pattern of bone loss, no radiographic evidence of a root fracture is noted. All thin arrows point to linear artifacts due to beam-hardening adjacent to the post or endodontic restorative material.
5. False. The "altered" dimension of the mandibular canal is due to the oblique orientation of the sagittal section in relation to the canal course.

Case Scenario 33.2

Patient:
18-year-old male

Current Information:
Rapid onset of class II and III mobility of most mandibular and maxillary teeth, with rapid onset of anterior open bite (past 2–3 months). Patient feels weak, but medical history is otherwise unremarkable.

Current Findings
The most important findings on this panoramic radiograph are the following:

Case-Based Questions

Answer the following **true** or **false**:

1. Severe periodontal bone loss, particularly in the posterior mandibular teeth
2. Complete obliteration of the right and left maxillary sinuses
3. Bilateral fracture of the right and left condylar necks, probably explaining the anterior open bite *(arrows)*
4. Fracture of crowns of most of the posterior maxillary teeth *(arrowheads)*
5. Altered trabeculation of the maxillary and mandibular alveolar ridge, with loss of lamina dura around the roots of several teeth

Take a moment to consider your differential diagnosis.

Solution and Explanation

1. Partially true. What appears to be periodontal bone loss is really exfoliation of the teeth by a rapidly growing, extremely infiltrative process. Posterior tooth exfoliation explains both tooth mobility and rapid-onset open bite. However, some periodontal bone loss is also present.
2. False for the left maxillary sinus. True for the floor of the right maxillary sinus. The process that caused the changes of the periodontium eroded the cortication of the floor of the posterior wall of the right maxillary sinus.

3. False. The arrows point to the superior surface of the nasopharynx.
4. False. The arrowheads point to the dorsum of the tongue.
5. True. The trabecular architecture of the posterior mandible and posterior right maxilla is altered. Furthermore, there is a loss of normal structures, including the floor of the right maxillary sinus and the cortication of the mandibular canals.

Although one of the patient's chief complaints was tooth mobility that could be misdiagnosed as periodontal disease, the rapid onset of the symptoms strongly argues against it. The patient was finally diagnosed with Burkitt lymphoma, a type of high-grand non-Hodgkin lymphoma from B lymphocytes. Burkitt lymphoma is said to have the highest proliferation rate of all human malignancies. This is consistent with the rapid progression of clinical and bone changes in this patient.

Risk Indicators for Periodontal Disease *(e-only)*
Risk Markers/Predictors for Periodontal Disease *(e-only)*
Clinical Risk Assessment for Periodontal Disease *(e-only)*
Conclusion

Definitions

Risk assessment is defined by numerous components.[2,33] Disease risk is the probability that an individual will develop a specific disease in a given period. The risk of developing the disease will

vary from individual to individual.

Risk factors may be environmental, behavioral, or biologic factors that, when present, increase the likelihood that an individual will develop the disease. Risk factors are identified through longitudinal studies of patients with the disease of interest. Exposure to a risk factor or factors may occur at a single point in time, over multiple separate points in time, or continuously. However, to be identified as a risk factor, the exposure must occur before disease onset. Interventions often can be identified and, when implemented, can help modify risk factors.

The term *risk determinant/background characteristic*, which is sometimes substituted for the term *risk factor*, should be reserved for risk factors that cannot be modified. *Risk indicators* are *probable* or *putative* risk factors that have been identified in cross-sectional studies but not confirmed through longitudinal studies. *Risk predictors/markers,* although associated with increased risk for disease, do not cause the disease. These factors also are identified in cross-sectional and longitudinal studies. Box 34.1 lists elements of these categories of risk for periodontal disease.

Box 34.1

Categories of Risk Elements for Periodontal Disease

Risk Factors

Tobacco smoking
Diabetes
Pathogenic bacteria and microbial tooth deposits

Risk Determinants/Background Characteristics

Genetic factors
Age
Gender
Socioeconomic status

Stress

Risk Indicators

Human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS)
Osteoporosis
Infrequent dental visits

Risk Markers/Predictors

Previous history of periodontal disease
Bleeding on probing

Clinical Correlation

Lack of bleeding on probing does appear to serve as an excellent indicator of periodontal health, but the presence of bleeding on probing alone is not a good predictor of future attachment loss.

Risk Factors for Periodontal Disease

Tobacco Smoking

Tobacco smoking is a well-established risk factor for periodontitis.[2,10] A direct relationship exists between smoking and the prevalence of periodontal disease (see Chapter 12). This association is independent of other factors such as oral hygiene or age.[20] Studies comparing the response to periodontal therapy in smokers, previous smokers, and nonsmokers have shown that smoking has a negative impact on the response to therapy. However, former smokers respond similarly to nonsmokers.[3] These studies demonstrate the therapeutic impact of intervention strategies on patients who smoke (see Chapter 12).

Diabetes

Diabetes is a clear risk factor for periodontitis.[2] Epidemiologic data demonstrate that the prevalence and severity of periodontitis are significantly higher in patients with type 1 or type 2 diabetes mellitus than in those without diabetes and that the level of diabetic control is an important variable in this relationship (see Chapter 14).

Pathogenic Bacteria and Microbial Tooth Deposits

It is well documented that the accumulation of bacterial plaque at the gingival margin results in the development of gingivitis and that the gingivitis can be reversed with the implementation of oral hygiene measures.[27] These studies demonstrate a causal relationship between the accumulation of bacterial plaque and gingival inflammation. However, a causal relationship between *plaque accumulation* and *periodontitis* has been more difficult to establish. Often patients with severe loss of attachment have minimal levels of bacterial plaque on the affected teeth, indicating that the *quantity* of plaque is not of major importance in the disease process. However, although quantity may not indicate risk, there is evidence that the composition, or *quality,* of the complex plaque biofilm is important.

In terms of quality of plaque, three specific bacteria have been identified as etiologic agents for periodontitis: *Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*), *Porphyromonas gingivalis,* and *Tannerella forsythia* (formerly *Bacteroides forsythus*).[12] *Porphyromonas gingivalis* and *T. forsythia* are often found in chronic periodontitis, whereas *A. actinomycetemcomitans* is often associated with aggressive periodontitis. Cross-sectional and longitudinal studies support the delineation of these three bacteria as risk factors for periodontal disease. Additional evidence that these organisms are causal agents includes the following[17]:

1. Their elimination or suppression impacts the success of therapy.
2. There is a host response to these pathogens.

3. Virulence factors are associated with these pathogens.
4. Inoculation of these bacteria into animal models induces periodontal disease.

Although not completely supported by these criteria for causation, moderate evidence also suggests that *Campylobacter rectus*, *Eubacterium nodatum*, *Fusobacterium nucleatum*, *Prevotella intermedia, Prevotella nigrescens*, *Peptostreptococcus micros*, *Streptococcus intermedius*, and *Treponema denticola* are etiologic factors in periodontitis.[12]

It is becoming clear from investigations that the plaque composition shifts from a more symbiotic microbial community to one that is more dysbiotic (an imbalance in the relative abundance of microbes leading to disease), composed primarily of anaerobes, as we go from periodontal health to periodontal disease. Certain pathogens (termed *keystone pathogens*) such as *Porphyromonas gingivalis* play a major role in inducing such a shift, converting commensals into disease-provoking microbes (termed *pathobionts*).[18] Therefore the quantity of plaque present may not be as important as the quality of the plaque in determining risk for periodontitis.

Anatomic factors, such as furcations, root concavities, developmental grooves, cervical enamel projections, enamel pearls, and bifurcation ridges, may predispose the periodontium to disease as a result of their potential to harbor bacterial plaque and present a challenge to the clinician during instrumentation. Similarly, the presence of subgingival and overhanging margins in restorations can result in increased plaque accumulation, increased inflammation, and increased bone loss. Although not clearly defined as risk factors for periodontitis, anatomic factors and *restorative factors* that influence plaque accumulation may play a role in disease susceptibility for specific teeth.[7]

The presence of *calculus,* which serves as a reservoir of bacterial plaque, has been suggested as a risk factor for periodontitis. Although the presence of some calculus in healthy individuals receiving routine dental care does not result in a significant loss of attachment, the presence of calculus in other groups of patients, such as those not receiving regular care and those with poorly controlled diabetes, can have a negative impact on periodontal

health.[33]

Risk Determinants/Background Characteristics for Periodontal Disease

Genetic Factors

Evidence indicates that genetic differences between individuals may explain why some patients develop periodontal disease and others do not. Studies conducted in twins have shown that genetic factors influence clinical measures of gingivitis, probing pocket depth, attachment loss, and interproximal bone height.[29-31] The familial aggregation seen in localized and generalized aggressive periodontitis also indicates genetic involvement in these diseases (see Chapter 11).

Kornman and colleagues[23] demonstrated that alterations (*polymorphisms*) in specific genes encoding inflammatory cytokines such as interleukin-1α (IL-1α) and interleukin-1β (IL-1β) were associated with severe chronic periodontitis in nonsmoking subjects.[23] However, results of other studies have shown a limited association between these altered genes and the presence of periodontitis. Overall, it appears that changes in the IL-1 genes may be only one of several genetic changes involved in the risk for chronic periodontitis. Therefore, although alteration in the IL-1 genes may be a valid marker for periodontitis in defined populations, its usefulness as a genetic marker in the general population may be limited.[22]

Immunologic alterations, such as neutrophil abnormalities,[19] monocytic hyperresponsiveness to lipopolysaccharide stimulation in patients with localized aggressive periodontitis,[40] and alterations in the monocyte/macrophage receptors for the Fc portion of antibody,[22,50] also appear to be under genetic control. In addition, genetics plays a role in regulating the titer of the protective immunoglobulin G2 (IgG2) antibody response to *A. actinomycetemcomitans* in patients with aggressive periodontitis[16] (see Chapter 28).

Age

Both the prevalence and severity of periodontal disease increase with age.[8,10,35] It is possible that degenerative changes related to aging may increase susceptibility to periodontitis. However, it is also possible that the attachment loss and bone loss seen in older individuals are the result of prolonged exposure to other risk factors over a person's life, creating a cumulative effect over time. In support of this theory, studies have shown minimal loss of attachment in aging subjects enrolled in preventive programs throughout their lives.[36,37] Therefore it is suggested that periodontal disease is not an inevitable consequence of the aging process and that aging alone does not increase disease susceptibility. However, it remains to be determined whether changes related to the aging process, such as medication intake, decreased immune function, and altered nutritional status, interact with other well-defined risk factors to increase susceptibility to periodontitis.

Evidence of loss of attachment may have more consequences in younger patients. The younger the patient, the longer the time for exposure to causative factors. In addition, aggressive periodontitis in young individuals is often associated with unmodifiable risk factors, such as a genetic predisposition to disease.[10] Therefore young individuals with periodontal disease may be at greater risk for continued disease as they age.

Gender

Gender plays a role in periodontal disease.[2] Surveys conducted in the United States since 1960 demonstrate that men have more loss of attachment than women.[45,47,48] In addition, men have poorer oral hygiene than women, as evidenced by higher levels of plaque and calculus.[1,46,48] Therefore gender differences in the prevalence and severity of periodontitis appear to be related to preventive practices rather than any genetic factor.

Socioeconomic Status

Gingivitis and poor oral hygiene can be related to lower socioeconomic status (SES).[2,45,47] This most likely can be attributed to

decreased dental awareness and decreased frequency of dental visits compared with more educated individuals with higher SES. After adjusting for other risk factors, such as smoking and poor oral hygiene, lower SES alone does not result in increased risk for periodontitis (see Chapter 6).

Stress

The incidence of necrotizing ulcerative gingivitis increases during periods of emotional and physiologic stress, suggesting a link between the two.[11,41] Emotional stress may interfere with normal immune function[6,43] and may result in increased levels of circulating hormones, which can affect the periodontium.[39] Stressful life events, such as bereavement and divorce, appear to lead to a greater prevalence of periodontal disease,[14] and an apparent association exists between psychosocial factors and risk behaviors such as smoking, poor oral hygiene, and chronic periodontitis.[9] Adult patients with periodontitis who are resistant to therapy are more stressed than those who respond to therapy.[5] Individuals with financial strain, distress, depression, or inadequate coping mechanisms have more severe loss of attachment.[13] Although epidemiologic data on the relationship between stress and periodontal disease are limited, stress may be a putative risk factor for periodontitis.[10]

Clinical Correlation

The ultimate goal of performing periodontal risk assessment is to develop a more personalized treatment plan for a specific patient, taking into account the periodontal risk profile of that patient. Once an at-risk patient is identified and a diagnosis is made, the treatment plan may be modified accordingly.

Risk Indicators for Periodontal Disease

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

It has been hypothesized that the immune dysfunction associated with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) increases susceptibility to periodontal disease (see Chapter 30). Early reports on the periodontal status of patients with AIDS or those who are HIV seropositive revealed that these patients often had severe periodontal destruction characteristic of necrotizing ulcerative periodontitis.[51] More recent reports, however, have failed to demonstrate significant differences in the periodontal status of individuals with HIV infection and healthy controls.[26,44] The apparent discrepancy in these reports may have been caused by the inclusion of patients with AIDS (versus patients who were exclusively HIV seropositive) in some studies.[10]

Conflicting results also exist in studies examining the level of immunosuppression and severity of periodontal destruction. Some studies support the observation that as the degree of immunosuppression increases in adults with AIDS, periodontal pocket formation and loss of clinical attachment also increase. Results of other studies have found no relationship between periodontal diseases and HIV/AIDS status. Evidence also suggests that AIDS-affected individuals who practice good preventive oral health measures, including effective home care and seeking appropriate professional therapy, can maintain periodontal health.[42] Therefore although it seems reasonable to hypothesize that HIV infection and immunosuppression are risk factors for periodontal disease, the evidence is not conclusive.[2,10]

Osteoporosis

Osteoporosis has been suggested as another risk factor for periodontitis. Although studies in animal models indicate that osteoporosis does not initiate periodontitis, evidence indicates that the reduced bone mass seen in osteoporosis may aggravate periodontal disease progression.[4,25] However, reports in humans are conflicting. In a study of 12 women with osteoporosis and 14

healthy women, von Wowern and coworkers[49] reported that the women with osteoporosis had greater loss of attachment than the control subjects. In contrast, Kribbs[24] examined pocket depth, bleeding on probing, and gingival recession in women with and without osteoporosis. Although the two groups had significant differences in bone mass, no differences in periodontal status were noted. However, it appears that a link may exist between osteoporosis and periodontitis, and additional studies may need to be conducted to determine whether osteoporosis is a true risk factor for periodontal disease.[15,21,28]

Infrequent Dental Visits

Identifying failure to visit the dentist regularly as a risk factor for periodontitis is controversial.[33] One study demonstrated an increased risk for severe periodontitis in patients who had not visited the dentist for 3 or more years, whereas another demonstrated that there was no more loss of attachment or bone loss in individuals who did not seek dental care compared with those who did over a 6-year period. However, differences in the ages of the subjects in these two studies may explain the different results. Additional longitudinal and intervention studies are necessary to determine whether infrequency of dental visits is a risk factor for periodontal disease.

Risk Markers/Predictors for Periodontal Disease

Previous History of Periodontal Disease

A history of previous periodontal disease is a good clinical predictor of risk for future disease.[33] Patients with the most severe existing loss of attachment are at the greatest risk for future loss of attachment. Conversely, patients currently free of periodontitis have a decreased risk for developing loss of attachment compared with those who currently have periodontitis (see Chapter 6).

Bleeding on Probing

Bleeding on probing is the best clinical indicator of gingival inflammation.[33] Although this indicator alone does not serve as a predictor for loss of attachment, bleeding on probing coupled with increasing pocket depth may serve as an excellent predictor for future loss of attachment. Lack of bleeding on probing does appear to serve as an excellent indicator of periodontal health.

Clinical Risk Assessment for Periodontal Disease

Information concerning individual risk for developing periodontal disease is obtained through careful evaluation of the patient's demographic data, medical history, dental history, and clinical examination (eBox 34.1). The elements that contribute to increased risk can be identified through the collection of demographic data, including the patient's age, gender, and SES. The medical history may reveal elements such as a history of diabetes, smoking, HIV/AIDS, or osteoporosis, as well as perceived level of stress. The dental history can reveal a family history of early tooth loss (suggestive of a genetic predisposition to aggressive periodontitis), a previous history of periodontal disease, and information concerning the frequency of oral health care in the past. Important elements identified during the clinical examination can include the location and extent of bacterial plaque accumulation, presence of plaque-retentive factors (e.g., overhanging restorations, subgingival margins), presence of anatomic plaque-retentive areas (e.g., grooves, furcation involvement), presence of calculus, extent of attachment loss, and presence or absence of bleeding on probing.

eBox 34.1

Clinical Risk Assessment for Periodontal Disease

Demographic Data

Age
Duration of exposure to risk elements
Postmenopausal women
Evidence of aggressive disease
Male gender
Preventive practices
Frequency of care
Socioeconomic status
Dental awareness
Frequency of care

Medical History

Diabetes
Tobacco smoking
Human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS)
Osteoporosis
Stress

Dental History

Family history of early tooth loss
Genetic predisposition to aggressive disease
Previous history of periodontal disease
Frequency of dental care

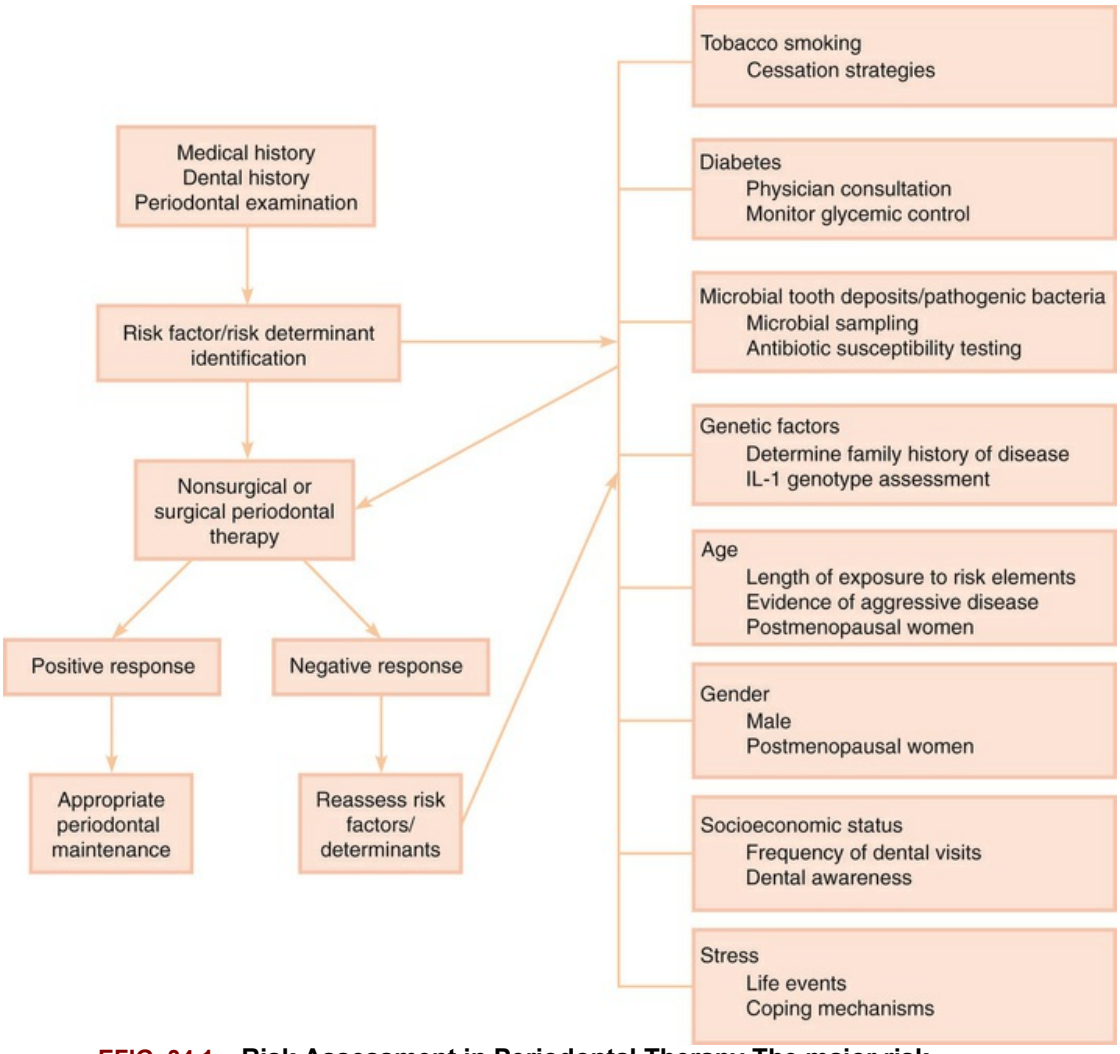
Clinical Examination

Plaque accumulation
Microbial sampling for putative periodontal pathogens
Calculus
Bleeding on probing
Extent of loss of attachment
Aggressive forms of disease
Tooth examination
Plaque retentive areas
Anatomic factors

Restorative factors

Once the social, demographic, medical history, dental history, and clinical presentation data are collected, they must be analyzed to identify whether the patient is at risk for developing periodontal disease. This analysis can be accomplished by the health care provider or through the use of a computer-based risk assessment tool. One example is the Periodontal Assessment Tool (PAT), which is one component of the PreViser Oral Health Information Suite (OHIS). The PAT utilizes input from 23 items that are part of a routine periodontal examination to generate both a quantification of current disease and a risk score for future disease. The score, which is based on an individual patient's set of risk factors and history, ranges from 1 (lowest risk) to 5 (highest risk). It has been proposed that this tool can provide a more objective, quantitative way to assess risk for periodontitis than clinical opinion.[34,38] Ultimately, a thorough risk assessment should improve clinical decision making, as well as patient outcomes.

Once an at-risk patient is identified and a diagnosis is made, the treatment plan may be modified accordingly (eFig. 34.1). For example, patients with a history of cigarette smoking should be informed of the relationship between smoking and periodontitis. They should also be informed of the impact of smoking on their prognosis and the likelihood of success of periodontal therapy if they continue to smoke. Part of their recommended treatment plan for initial therapy may include referral to a smoking cessation program or use of self-administered smoking cessation aids. As another example, a patient diagnosed with severe chronic periodontitis may be encouraged to be tested for the IL-1–positive genotype. If positive, treatment may involve the administration of systemic antimicrobial agents and host modifiers that would not be used in a patient without this genetic marker. If alterations in the host response are identified, the prognosis and treatment plan may be modified. Previously identified risk elements may also need to be reassessed at the reevaluation stage of treatment. This is especially important for patients who do not respond favorably to periodontal therapy (see eFig. 34.1).



EFIG. 34.1 Risk Assessment in Periodontal Therapy The major risk elements to be considered in the diagnosis and treatment of periodontal disease are indicated. The importance of risk assessment before initiation of therapy is highlighted, as well as the need for reassessment after a negative response to therapy.

In the era of electronic health records (EHRs), having a clinical risk assessment tool that is built into the EHR will allow clinicians to perform risk assessment and develop personalized treatment plans quickly and effectively. One investigation clearly showed that having such an electronic risk assessment tool (termed *PEMBRA*, or *periodontal risk assessment*) allows clinicians to make treatment decisions based on the best available evidence, the patient information gathered, and their clinical expertise, enabling them to consistently execute evidence-based decision making chairside.[32]

Conclusion

Risk assessment involves identifying elements that either may predispose patients to developing periodontal disease or may influence the progression of disease that already exists. In either case, these patients may require modification of their prognosis and treatment plan. In addition to an evaluation of the factors contributing to their risk, these patients should be educated concerning their risk, and, when appropriate, suitable intervention strategies should be implemented.

Case Scenario 34.1

Patient:
55-year-old male

Chief Complaint:
"I have bad breath, and my gums bleed when I brush."

Background Information
Patient has type 2 diabetes (last HbA1c level was 8) and is a past smoker. Patient takes oral hypoglycemic medication for diabetes and denies any allergies. His last dental cleaning was done 4 years ago, and he denies flossing and reports brushing once a day.

Current Findings:
Probing depths were in the range of 2 to 7 mm, bleeding on probing was 47% and poor oral hygiene.

CASE-BASED QUESTIONS	SOLUTION And EXPLANATION
1. What is the major risk factor for periodontal disease in this clinical scenario? A. Extensive restorations B. Uncontrolled diabetes	**Answer: B** **Explanation:** Uncontrolled diabetes is a significant risk factor for periodontal disease.

C. Medication usage D. Current smoking	
2. What is the effect of controlling diabetes on periodontal treatment outcome? A. Improves the outcome B. Does not change the outcome C. Worsens the outcome	**Answer: A** **Explanation:** It is clear from several studies that patients with a controlled glycemic level (HbA1c≤7) respond to periodontal therapy as well as nondiabetic patients.
3. In patients with diabetes (well controlled with medication), what common condition should the clinician anticipate and be prepared to manage chairside? A. Syncope B. Hypoglycemia C. Cardiovascular arrest D. All of the above	**Answer: B** **Explanation:** Hypoglycemia is common in patients with well-controlled diabetes. Proper history taking and questioning about meal intake are important before beginning a clinical procedure. Ready access to sugar supplements or fruit juice is critical in managing this condition.

Determination and Reassessment of Prognosis
Conclusion

Definitions

A *prognosis* is a prediction of the probable course, duration, and outcome of a disease based on a general knowledge of the pathogenesis of the disease and the presence of risk factors for the disease. It is established after the diagnosis is made and before the treatment plan is established. The prognosis is based on specific information about the disease and the manner in which it can be

treated, but it also can be influenced by the clinician's previous experience with treatment outcomes (successes and failures) as they relate to the particular case. It is important to note that determination of prognosis is a dynamic process. As such, the prognosis initially assigned should be reevaluated after completion of all phases of therapy, including periodontal maintenance.

Prognosis is often confused with the term *risk.* Risk generally deals with the likelihood that an individual will develop a disease in a specified period (see Chapter 7). *Risk factors* are characteristics that put an individual at increased risk for developing a disease (see Chapter 6). In contrast, *prognosis* is the prediction of the course or outcome of a disease. *Prognostic factors* are characteristics that predict the outcome once the disease is present. In some cases, risk factors and prognostic factors are the same. For example, patients with diabetes or patients who smoke are more at risk for acquiring periodontal disease, and once they have it, they generally have a worse prognosis.

Types of Prognosis

Although some factors may be more important than others when assigning a prognosis[34,35] (Box 35.1), it may benefit the clinician to consider each factor. Historically, prognosis classification schemes have been designed based on studies evaluating tooth mortality.[2,3,25,33,34] One scheme[25,34] assigns the following classifications:

Box 35.1

Factors to Consider When Determining a Prognosis

Overall Clinical Factors

Patient age
Disease severity
Biofilm control

Patient compliance

Systemic and Environmental Factors

Smoking
Systemic disease or condition
Genetic factors
Stress

Local Factors

Biofilm and calculus
Subgingival restorations

Anatomic Factors

Short, tapered roots
Cervical enamel projections
Enamel pearls
Bifurcation ridges
Root concavities
Developmental grooves
Root proximity
Furcation invasion
Tooth mobility
Caries
Tooth vitality
Root resorption

Prosthetic and Restorative Factors

Abutment selection

Good prognosis: Control of etiologic factors and adequate periodontal support ensure the tooth will be easy to maintain by the patient and clinician.
Fair prognosis: Approximately 25% attachment loss or grade I

furcation invasion (location and depth allow proper maintenance with good patient compliance).

Poor prognosis: 50% attachment loss, grade II furcation invasion (location and depth make maintenance possible but difficult).

Questionable prognosis: >50% attachment loss, poor crown-to-root ratio, poor root form, grade II furcation invasion (location and depth make access difficult) or grade III furcation invasion; mobility no. 2 or no. 3; root proximity.

Hopeless prognosis: Inadequate attachment to maintain health, comfort, and function.

It should be recognized that good, fair, and hopeless prognoses in this classification system can be established with a reasonable degree of accuracy. However, poor and questionable prognoses are likely to change to other categories because they depend on a large number of factors that can interact in an unpredictable number of ways.[8,14,47]

In contrast to schemes based on tooth mortality, Kwok and Caton[25] proposed a scheme based on "the probability of obtaining stability of the periodontal supporting apparatus." This scheme is based on the probability of disease progression as related to local and systemic factors (see Box 35.1). Although some of these factors may affect disease progression more than others, consideration of each factor is important in assigning a prognosis. This scheme is as follows:

Favorable prognosis: Comprehensive periodontal treatment and maintenance will stabilize the status of the tooth. Future loss of periodontal support is unlikely.

Questionable prognosis: Local or systemic factors influencing the periodontal status of the tooth may or may not be controllable. If controlled, the periodontal status can be stabilized with comprehensive periodontal treatment. If not, future periodontal breakdown may occur.

Unfavorable prognosis: Local or systemic factors influencing the periodontal status cannot be controlled. Comprehensive periodontal treatment and maintenance are unlikely to

prevent future periodontal breakdown.
Hopeless prognosis: The tooth must be extracted.

Because periodontal stability is assessed on a regular basis using clinical measures, it may be more useful in making treatment decisions and prognosis predictions than in trying to determine the likelihood that the tooth will be lost.

In many of these cases, it may be advisable to establish a *provisional prognosis* until phase I therapy is completed and evaluated. The provisional prognosis allows the clinician to initiate treatment of teeth that have a doubtful outlook in the hope that a favorable response may tip the balance and allow teeth to be retained. The reevaluation phase in the treatment sequence allows the clinician to examine the tissue response to scaling, oral hygiene, and root planing, as well as to the possible use of chemotherapeutic agents where indicated. The patient's compliance with the proposed treatment plan also can be determined.

Learning Box 35.1

A prognosis based on whether periodontal stability can be achieved with periodontal therapy and maintenance is as follows: favorable—likely, questionable—maybe, unfavorable—unlikely.

Overall Versus Individual Tooth Prognosis

Prognosis can be divided into overall prognosis and individual tooth prognosis. The *overall prognosis* is concerned with the dentition as a whole. Factors that may influence the overall prognosis include patient age; current severity of disease; systemic factors; smoking; the presence of biofilm, calculus, and other local factors; patient compliance; and prosthetic possibilities (see Box 35.1). The overall prognosis answers the following questions:

- Should treatment be undertaken?
- Is treatment likely to succeed?
- When prosthetic replacements are needed, are

the remaining teeth able to support the added burden of the prosthesis?

The *individual tooth prognosis* is determined after the overall prognosis and is affected by it.[33] For example, in a patient with a poor overall prognosis, the dentist likely would not attempt to retain a tooth that has a questionable prognosis because of local conditions. Many of the factors listed under local factors and prosthetic and restorative factors in Box 35.1 have a direct effect on the prognosis for individual teeth, in addition to any overall systemic or environmental factors that may be present.

Factors in Determination of Prognosis

Overall Clinical Factors

Patient Age

For two patients with comparable levels of remaining connective tissue attachment and alveolar bone, the prognosis is generally better for the older of the two. For the younger patient, the prognosis is not as good because of the shorter time frame in which the periodontal destruction has occurred; the younger patient may have an aggressive type of periodontitis, or disease progression may have increased because of systemic disease or smoking. In addition, although the younger patient would ordinarily be expected to have a greater reparative capacity, the occurrence of so much destruction in a relatively short period would exceed any naturally occurring periodontal repair.

Disease Severity

Studies have demonstrated that a patient's history of previous periodontal disease may be indicative of their susceptibility to future periodontal breakdown (see Chapter 6). Therefore the following variables should be carefully recorded because they are important in determining the patient's past history of periodontal disease: probing pocket depth, level of attachment, amount of bone loss, and type of bony defect. These factors are determined by

clinical and radiographic evaluation (see Chapters 32 and 33).

Determining clinical attachment loss reveals the approximate extent of root surface that is devoid of periodontal ligament; the radiographic examination shows the amount of root surface still invested in bone. Probing pocket depth is less important than level of attachment because it is not necessarily related to bone loss. In general, a tooth with deep probing depths and little attachment and bone loss has a better prognosis than one with shallow pockets and severe attachment and bone loss. However, a biofilm in deep pockets is difficult to control and may contribute to disease progression.

Prognosis is adversely affected if the base of the pocket (level of attachment) is close to the root apex. The presence of apical disease as a result of endodontic involvement also worsens the prognosis. However, surprisingly good apical and lateral bone repair can sometimes be obtained by combining endodontic and periodontal therapy (see Chapter 46).

The prognosis also can be related to the height of remaining bone. Assuming bone destruction can be arrested, is there enough bone remaining to support the teeth? The answer is readily apparent in extreme cases—that is, when there is so little bone loss that tooth support is not in jeopardy (Fig. 35.1) or when bone loss is so severe that the remaining bone is obviously insufficient for proper tooth support (Fig. 35.2). Most patients, however, do not fit into these extreme categories. The height of remaining bone is usually somewhere in between, making bone level assessment alone insufficient for determining the overall prognosis.

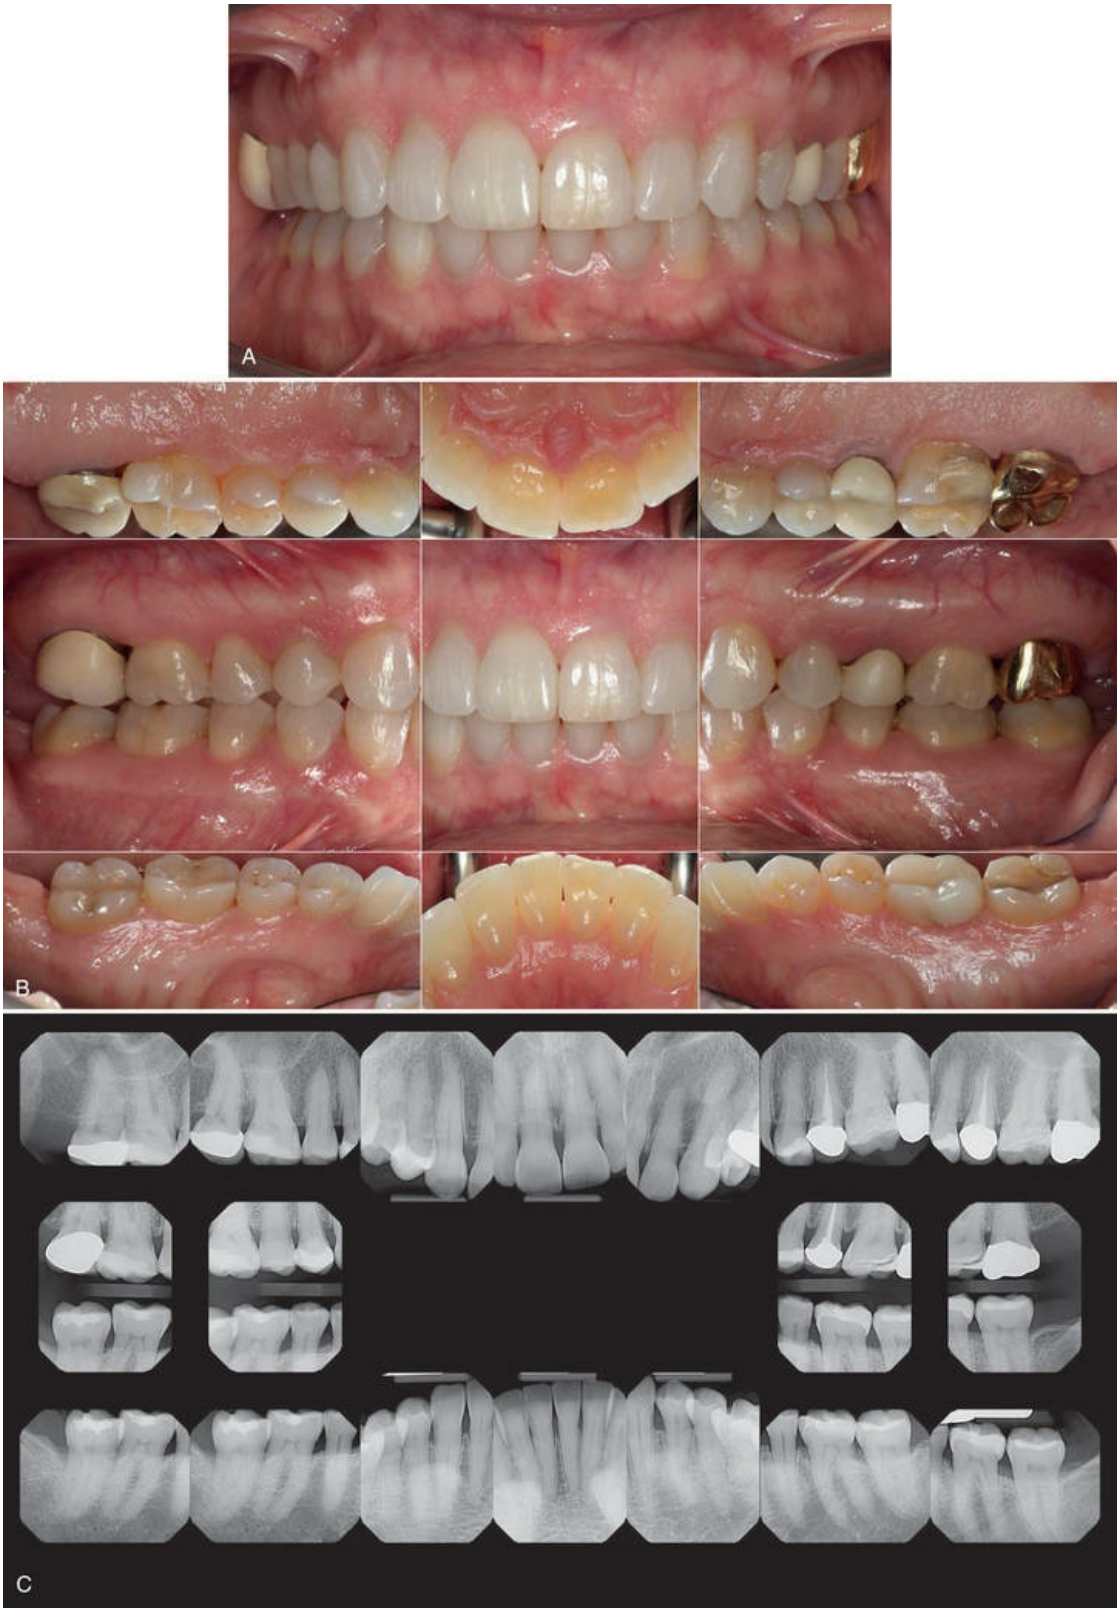

FIG. 35.1 Generalized mild chronic periodontitis in a healthy, nonsmoking 67-year-old female. Minimal clinical biofilm and gingival inflammation (A and B) and radiographic bone loss (C). Overall prognosis is

favorable. (Copyright Jonathan H. Do, DDS. All rights reserved.)

FIG. 35.2 Generalized moderate-to-severe chronic periodontitis in a healthy, nonsmoking 49-year-old female. (A and B) Moderate clinical biofilm, calculus, and gingival inflammation. (C) Moderate to severe

radiographic bone loss. Overall prognosis is questionable/unfavorable. (Copyright Jonathan H. Do, DDS. All rights reserved.)

The type of defect also must be determined. The prognosis for horizontal bone loss depends on the height of the existing bone because it is unlikely that clinically significant bone height regeneration will be induced by therapy. In the case of angular, intrabony defects, if the contour of the existing bone and the number of osseous walls are favorable, there is an excellent chance that therapy could regenerate bone to approximately the level of the alveolar crest.[45]

When greater bone loss has occurred on one surface of a tooth, the bone height on the less involved surfaces should be taken into consideration when determining the prognosis. Because of the greater height of bone in relation to other surfaces, the center of rotation of the tooth will be nearer the crown (Fig. 35.3). This results in a more favorable distribution of forces to the periodontium and less tooth mobility.[49]

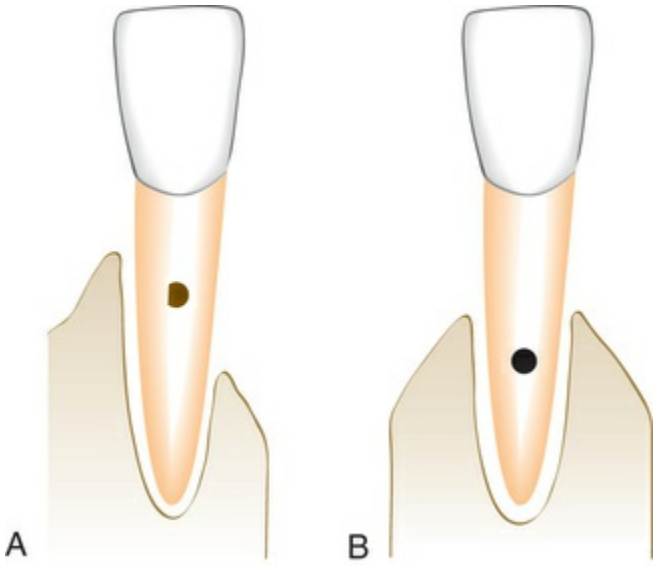

FIG. 35.3 Prognosis for tooth A is better than for tooth B, despite less bone on one of the surfaces of A. Because the center of rotation of tooth A is closer to the crown, the distribution of occlusal forces to the periodontium is more favorable than in B.

In dealing with a tooth that has a questionable prognosis, the chances of successful treatment should be weighed against any benefits that would accrue to the adjacent teeth if the tooth under consideration were extracted. Strategic extraction of teeth was first proposed as a means of improving the overall prognosis of adjacent teeth or enhancing the prosthetic treatment plan.[9] It has now been expanded to include the extraction of teeth with a questionable prognosis to enhance the likelihood of partial restoration of the bone supporting of the adjacent teeth (Fig. 35.4A–D) or successful implant placement. With the growing evidence of the long-term success of dental implants, it is proposed that a "watch and wait" approach may allow an area to deteriorate to the point that placing an implant is no longer a viable option. This means that the practitioner should weigh the potential success of one treatment option (extraction and implant placement) versus the other (periodontal therapy and maintenance) carefully when assigning a questionable prognosis to teeth.[20]

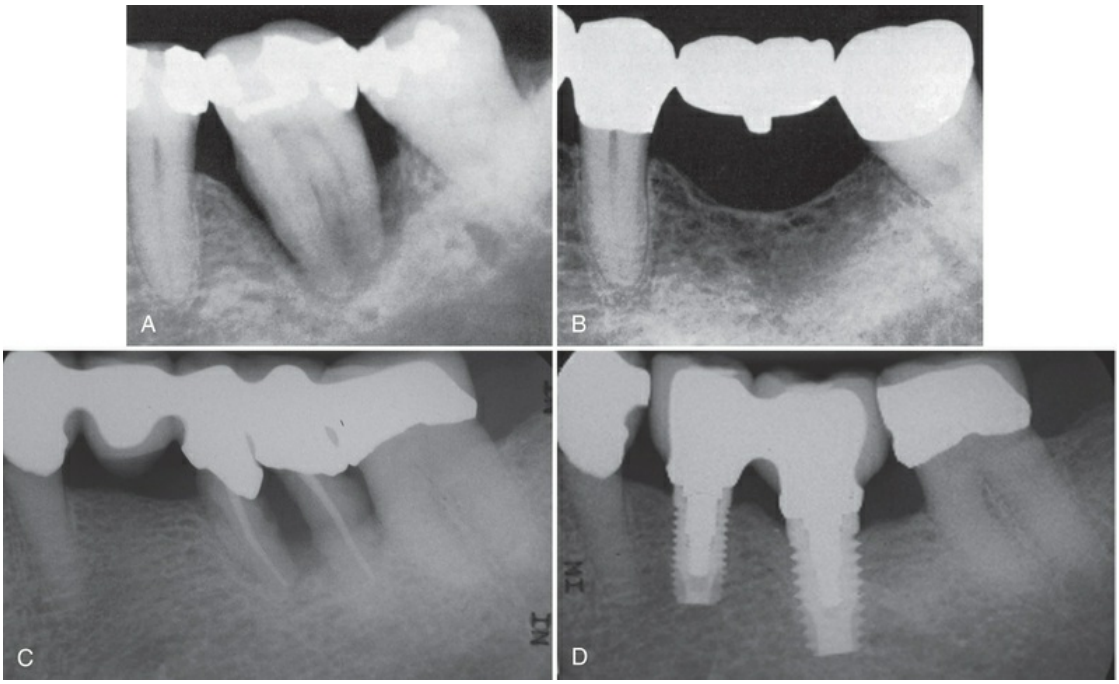

FIG. 35.4 Extraction of severely involved tooth to preserve bone on adjacent teeth. (A) Extensive bone destruction around the mandibular first molar. (B) Radiograph made years after extraction of the first molar and replacement by a prosthesis. Note the excellent bone support. (C) Extraction of periodontally

involved bicuspid and molar. (D) Implant replacement of both teeth. (Courtesy Dr. S. Angha, University of California, Los Angeles.)

Learning Box 35.2

Strategic extraction of teeth with unfavorable or questionable prognoses may improve the prognosis of adjacent teeth, enhance the prosthetic treatment, and increase the success rate of implants replacing the strategically extracted teeth.

Biofilm Control

Bacterial biofilm is the primary etiologic factor associated with periodontal disease (see Chapter 8). Therefore effective removal of biofilm on a daily basis by the patient is critical to the success of periodontal therapy and the prognosis.

Patient Compliance and Cooperation

The prognosis for patients with gingival and periodontal disease is critically dependent on the patient's attitude, desire to retain the natural teeth, and willingness and ability to effectively control biofilm. Without these, treatment cannot succeed. Patients should be educated on the etiology and prevention of dental caries and periodontal diseases, and they should be clearly informed of the important role they must play for treatment to succeed. If a patient is unwilling to perform adequate biofilm control and receive the timely periodic maintenance checkups and treatments that the dentist deems necessary, the dentist can refuse to accept the patient for treatment. The dentist should make it clear to the patient and in the patient record that further treatment is needed but will not be performed because of a lack of patient cooperation.

Systemic and Environmental Factors

Smoking

Epidemiologic evidence suggests that smoking may be the most

important environmental risk factor impacting the development and progression of periodontal disease (see Chapter 12). Therefore it should be made clear to patients that a direct relationship exists between smoking and the prevalence and incidence of periodontitis. In addition, patients should be informed that smoking affects not only the severity of periodontal destruction but also the healing potential of the periodontal tissues. As a result, patients who smoke do not respond as well to conventional periodontal therapy as patients who have never smoked.[43,44] Therefore the prognosis in patients who smoke and have slight to moderate chronic periodontitis is generally questionable. In patients with severe chronic periodontitis, the prognosis may be unfavorable or hopeless.

However, it should be emphasized that smoking cessation can affect the treatment outcome and therefore the prognosis.[5,17] As such, for patients who stop smoking, the prognosis can improve to favorable in those with slight to moderate chronic periodontitis and to questionable in those with severe chronic periodontitis.

Systemic Disease or Condition

The patient's systemic background affects the overall prognosis in several ways. For example, evidence from epidemiologic studies clearly demonstrates that the prevalence and severity of chronic periodontitis are significantly higher in patients with poorly controlled diabetes than in those whose diabetes is well controlled or those who do not have diabetes (see Chapter 6). Therefore patients at risk for diabetes should be identified as early as possible and informed of the relationship between periodontitis and diabetes. Similarly, patients diagnosed with diabetes must be informed of the impact of diabetic control on the development and progression of periodontitis. It follows that the prognosis in these cases depends on patient compliance relative to both medical and dental status. Patients with well-controlled diabetes and slight to moderate periodontitis who comply with their recommended periodontal treatment should have a favorable prognosis. Similarly, in patients with other systemic disorders that could affect disease progression, prognosis improves with correction of the systemic problem.

The prognosis is questionable when surgical periodontal treatment is required but cannot be provided because of the patient's health (see Chapter 39). Incapacitating conditions that limit the patient's performance of oral procedures (e.g., Parkinson disease) also adversely affect the prognosis. Newer "automated" oral hygiene devices, such as electric toothbrushes, may be helpful for these patients and may improve their prognosis (see Chapter 48).

Genetic Factors

Periodontal diseases represent a complex interaction between a microbial challenge and the host's response to that challenge, both of which may be influenced by environmental factors such as smoking. In addition to these external factors, evidence also indicates that genetic factors may play an important role in determining the nature of the host response.[18] Evidence for this type of genetic influence exists for patients with both chronic and aggressive periodontitis. Genetic polymorphisms in the interleukin-1 (IL-1) genes, resulting in increased production of IL-1β, have been associated with a significant increase in risk for severe, generalized, and chronic periodontitis.[24,37] It has been demonstrated that knowledge of the patient's IL-1 genotype and smoking status can aid the clinician in assigning a prognosis.[36] Genetic factors also appear to influence serum immunoglobulin G2 (IgG2) antibody titers and the expression of FcγRII receptors on neutrophils, both of which may be significant in aggressive periodontitis.[18] Other genetic disorders, such as leukocyte adhesion deficiency type 1, can influence neutrophil function, creating an additional risk factor for aggressive periodontitis.[18] Finally, the familial aggregation that is characteristic of aggressive periodontitis indicates that additional, as yet unidentified, genetic factors may be important in one's susceptibility to this form of disease (see Chapter 28).

The influence of genetic factors on prognosis is not simple. Although microbial and environmental factors can be altered through conventional periodontal therapy and patient education, genetic factors currently cannot be altered. However, detection of genetic variations linked to periodontal disease can potentially influence the prognosis in several ways. First, early detection of

patients at risk because of genetic factors can lead to early implementation of preventive and treatment measures for these patients. Second, identification of genetic risk factors later in the disease or during the course of treatment can influence treatment recommendations, such as the use of adjunctive antibiotic therapy or increased frequency of maintenance visits. Third, identification of young individuals who have not been evaluated for periodontitis but who are recognized as being at risk because of the familial aggregation seen in aggressive periodontitis can lead to the development of early intervention strategies. In each of these cases, early diagnosis, intervention, and alterations in the treatment regimen may lead to an improved prognosis for the patient.

Stress

Physical and emotional stress, as well as substance abuse, may alter the patient's ability to respond to the periodontal treatment performed (see Chapter 6). These factors must be realistically faced when attempting to establish a prognosis.

Local Factors

Biofilm and Calculus

The microbial challenge presented by bacterial biofilm and calculus is the most important local factor in periodontal diseases. Therefore in most cases, having a favorable prognosis depends on the ability of the patient and the clinician to remove these etiologic factors (see Chapters 8 and 13).

Learning Box 35.3

Periodontal prognosis depends on the ability of the patient and clinician to effectively remove bacterial biofilm and resolve inflammation.

Subgingival Restorations

Subgingival margins may contribute to increased biofilm accumulation, increased inflammation, and increased bone loss[4,40,48]

when compared with supragingival margins. Furthermore, discrepancies in these margins (e.g., overhangs) can negatively impact the periodontium (see Chapter 13). The size of these discrepancies and duration of their presence are important factors in the amount of destruction that occurs. In general, however, a tooth with a discrepancy in its subgingival margins has a worse prognosis than a tooth with well-contoured supragingival margins.

Anatomic Factors

Anatomic factors that may predispose the periodontium to disease and therefore affect the prognosis include short, tapered roots with large crowns, cervical enamel projections and enamel pearls, intermediate bifurcation ridges, root concavities, and developmental grooves. The clinician must also consider root proximity and the location and anatomy of furcations when assigning a prognosis.

Prognosis is less favorable for teeth with short, tapered roots and relatively large crowns (Fig. 35.5). Because of the disproportionate crown-to-root ratio and the reduced root surface available for periodontal support,[21] the periodontium may be more susceptible to injury by occlusal forces.

FIG. 35.5 Localized moderate-to-severe chronic periodontitis in a healthy, nonsmoking 32-year-old male. (A and B) Mild clinical biofilm and gingival inflammation. Localized moderate-to-severe radiographic bone loss and localized heavy subgingical

calculus. (C) This patient likely had localized aggressive periodontitis that became chronic periodontitis as he aged. Overall prognosis is favorable; questionable for the maxillary right first molar. (Copyright Jonathan H. Do, DDS. All rights reserved.)

Cervical enamel projections (CEPs) are flat, ectopic extensions of enamel that extend beyond the normal contours of the cementoenamel junction.[32] CEPs extend into the furcation of 28.6% of mandibular molars and 17% of maxillary molars.[32] CEPs are most likely to be found on buccal surfaces of maxillary second molars.[16,50] Enamel pearls are larger, round deposits of enamel that can be located in furcations or other areas on the root surface.[39] Enamel pearls are seen less frequently (1.1% to 5.7% of permanent molars; 75% appearing in maxillary third molars[39]) than CEPs. An intermediate bifurcation ridge has been described in 73% of mandibular first molars, crossing from the mesial to the distal root at the midpoint of the furcation.[10] The presence of these enamel projections on the root surface interferes with the attachment apparatus and may prevent regenerative procedures from achieving their maximum potential. Therefore their presence may have a negative effect on the prognosis for an individual tooth.

Scaling with root planing is a fundamental procedure in periodontal therapy. Anatomic factors that decrease the efficiency of this procedure can have a negative impact on the prognosis. Therefore the morphology of the tooth root is an important consideration when discussing prognosis. *Root concavities* exposed through loss of attachment can vary from shallow flutings to deep depressions. They appear more marked on maxillary first premolars, the mesiobuccal root of the maxillary first molar, both roots of mandibular first molars, and the mandibular incisors[6,7] (Figs. 35.6 and 35.7). Any tooth, however, can have a proximal concavity.[13] Although these concavities increase the attachment area and produce a root shape that may be more resistant to torquing forces, they also create areas that can be difficult for both the dentist and the patient to clean.

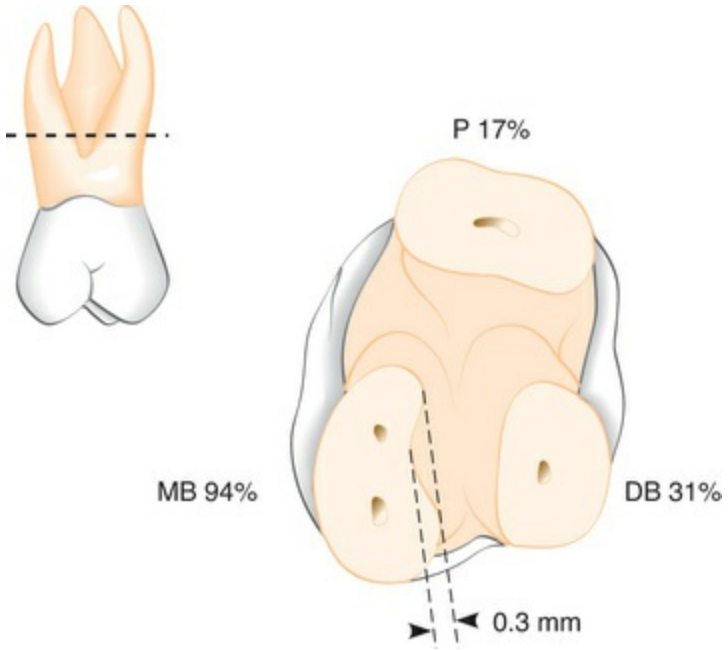

FIG. 35.6 Root concavities in maxillary first molars sectioned 2 mm apical to the furca. The furcal aspect of the root is concave in 94% of the mesiobuccal (MB) roots, 31% of the distobuccal (DB) roots, and 17% of the palatal (P) roots. The deepest concavity is found in the furcal aspects of the mesiobuccal roots (mean concavity, 0.3 mm). The furcal aspect of the buccal roots diverges toward the palate in 97% of teeth (mean divergence, 22 degrees). (Redrawn from Bower RC: Furcation morphology relative to periodontal treatment–furcation root surface anatomy. *J Periodontol* 50:366, 1979.)

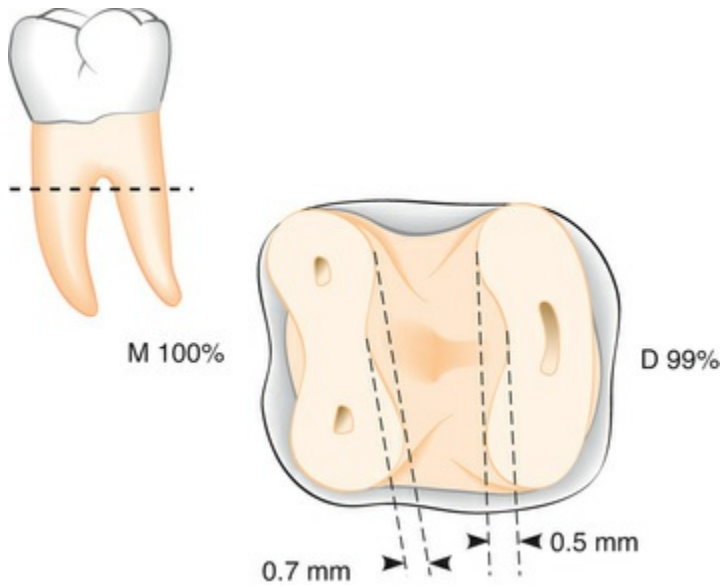

FIG. 35.7 Root concavities in mandibular first molars sectioned 2 mm apical to the furca. Concavity of the furcal aspect was found in 100% of mesial (M) roots and 99% of distal (D) roots. Deeper concavity was found in the mesial roots (mean concavity, 0.7 mm).
(Redrawn from Bower RC: Furcation morphology relative to periodontal treatment–furcation root surface anatomy. *J Periodontol* 50:366, 1979.)

Other anatomic considerations that present accessibility problems are developmental grooves, root proximity, and furcation involvement. The presence of any of these can worsen the prognosis. *Developmental grooves,* which sometimes appear in the maxillary lateral incisors (palatogingival groove[51]; Fig. 35.8) or in the lower incisors, create an accessibility problem.[11,15] They initiate on enamel and can extend a significant distance on the root surface, providing a plaque-retentive area that is difficult to instrument. These palatogingival grooves are found on 5.6% of maxillary lateral incisors and 3.4% of maxillary central incisors.[23] Similarly, *root proximity* can result in interproximal areas that are difficult for the clinician and patient to access. Finally, *access to the furcation area* is usually difficult to obtain. In 58% of maxillary and mandibular first molars, the furcation entrance diameter is narrower than the width of conventional periodontal curettes[7] (Fig. 35.9). Maxillary first premolars present the greatest difficulty, and therefore their prognosis is usually unfavorable when the lesion reaches the mesiodistal furcation. Maxillary molars also present some difficulty; sometimes their prognosis can be improved by resecting one of the buccal roots (see Chapter 64), thereby improving access to the area. When mandibular first molars or buccal furcations of maxillary molars offer good access to the furcation area, the prognosis is usually better.

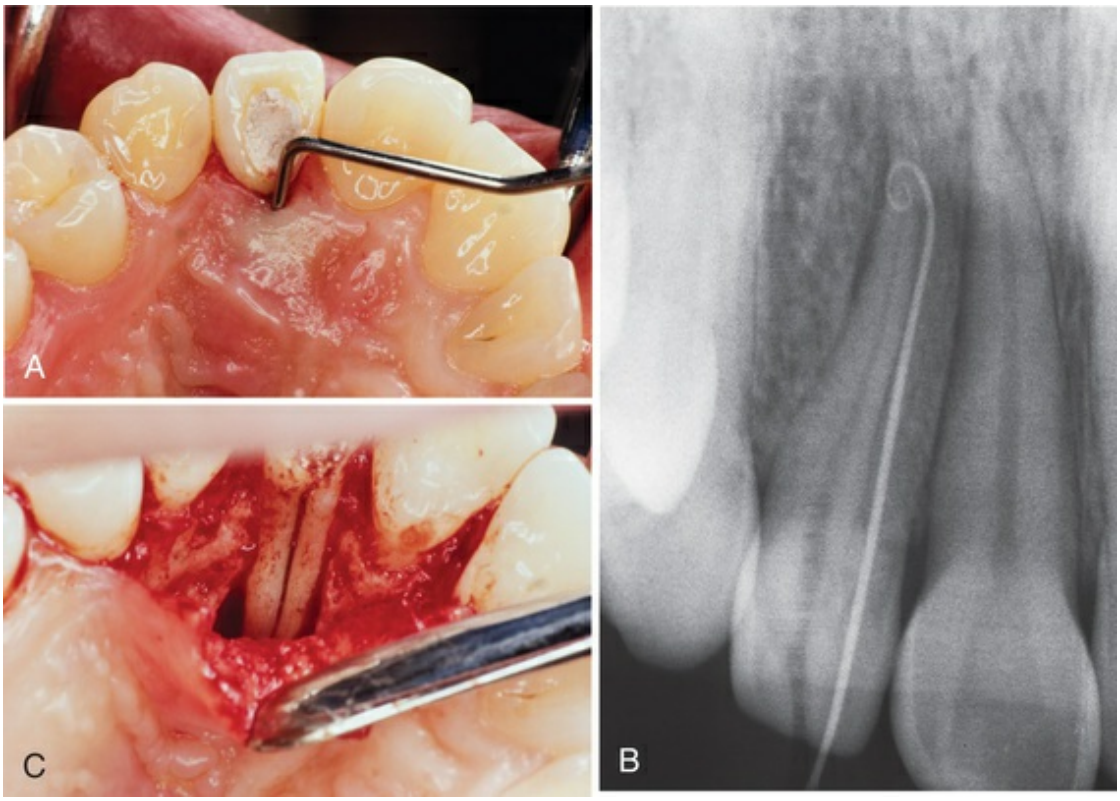

FIG. 35.8 Palatogingival groove. (A) Probe in place to indicate a deep pocket along the palatogingival groove. (B) Radiograph with a gutta-percha point placed in the pocket. (C) The area is surgically opened. Note the palatogingival groove along the entire palatal portion of the root. (Courtesy Dr. Nadia Chugal, University of California, Los Angeles.)

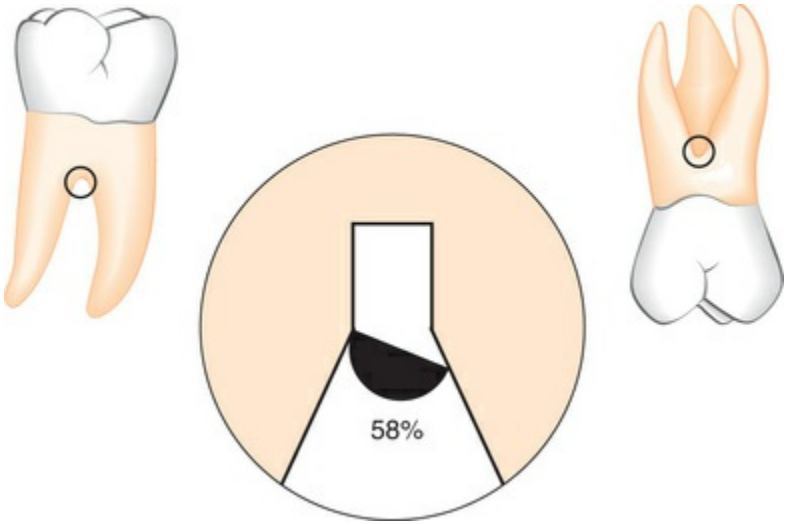

FIG. 35.9 The furcation entrance is narrower than a standard curette in 58% of first molars. (Redrawn from Bower RC: Furcation morphology relative to periodontal treatment–furcation root surface

anatomy. *J Periodontol* 50:366, 1979.)

Tooth Mobility

The principal causes of tooth mobility are loss of alveolar bone, inflammatory changes in the periodontium, and trauma from occlusion. Tooth mobility caused by inflammation and trauma from occlusion may be correctable.[38] However, tooth mobility resulting from loss of alveolar bone is not likely to be corrected. The likelihood of restoring tooth stability is inversely proportional to the extent to which mobility is caused by the loss of supporting alveolar bone. A longitudinal study of the response to treatment of teeth with different degrees of mobility revealed that pockets on clinically mobile teeth do not respond as well to periodontal therapy as pockets on nonmobile teeth exhibiting the same initial disease severity.[12] Another study, however, in which ideal plaque control was attained, found similar healing in both hypermobile and firm teeth.[45] The stabilization of tooth mobility through the use of splinting may have a beneficial impact on the overall and individual tooth prognosis.

Learning Box 35.4

Tooth mobility is often used to condemn a tooth to a prognosis of questionable, unfavorable, or hopeless. It must be recognized that, depending on the cause, mobility may be correctable. Eliminating the cause of mobility can stabilize a tooth and improve its prognosis.

Caries, Tooth Vitality, and Root Resorption

For teeth mutilated by extensive caries, the feasibility of adequate restoration and endodontic therapy should be considered before undertaking periodontal treatment. Extensive idiopathic root resorption or root resorption resulting from orthodontic therapy jeopardizes the stability of teeth and adversely affects the response to periodontal treatment. The periodontal prognosis of treated nonvital teeth does not differ from that of vital teeth. New

attachment can occur to the cementum of both nonvital and vital teeth.

Prosthetic and Restorative Factors

The overall prognosis requires a general consideration of bone levels (evaluated radiographically) and attachment levels (determined clinically) to establish whether enough teeth can be saved either to provide functional and aesthetic dentition or to serve as abutments for a useful prosthetic replacement of the missing teeth.

At this point, the overall prognosis and individual tooth prognosis overlap because the prognosis for key individual teeth may affect the overall prognosis for prosthetic rehabilitation. For example, saving or losing a key tooth may determine whether other teeth are saved or extracted or whether the prosthesis is fixed or removable (see Fig. 35.4). When few teeth remain, the prosthodontic needs become more important, and sometimes periodontally treatable teeth may have to be extracted if they are not compatible with the design of the prosthesis.

Teeth that serve as abutments are subjected to increased functional demands. More rigid standards are required when evaluating the prognosis of teeth adjacent to edentulous areas. A tooth with a post that has undergone endodontic treatment is more likely to fracture when serving as a distal abutment supporting a distal removable partial denture. Additionally, special oral hygiene measures must be instituted in these areas.

Prognosis of Specific Periodontal Diseases

Many of the criteria used in the diagnosis and classification of the different forms of periodontal disease[1] (see Chapter 5) are also used in developing a prognosis (see Box 35.1). Factors such as patient age, severity of disease, genetic susceptibility, and presence of systemic disease are important criteria in the diagnosis of the condition and in developing a prognosis. These common factors

suggest that for any given diagnosis, there should be an expected prognosis under ideal conditions. This section discusses potential prognoses for the various periodontal diseases outlined in Chapter 5.

Prognosis for Patients With Gingival Disease

Biofilm-Induced Gingival Diseases

Gingivitis Associated With Dental Plaque Only

Biofilm-induced gingivitis is a reversible disease that occurs when bacterial biofilm accumulates at the gingival margin.[29,31] This disease can occur on a periodontium that has experienced no attachment loss or on a periodontium with nonprogressing attachment loss. In either case, the prognosis is good for patients with gingivitis associated with bacterial biofilm only favorable, provided that all local irritants are eliminated, other local factors contributing to biofilm retention are eliminated, gingival contours conducive to the preservation of health are attained, and the patient cooperates by maintaining good oral hygiene.

Biofilm-Induced Gingival Diseases Modified by Systemic Factors

The inflammatory response to bacterial biofilm at the gingival margin can be influenced by systemic factors, such as endocrine-related changes associated with puberty, menstruation, pregnancy, and diabetes, and the presence of blood dyscrasias. In many cases, the frank signs of gingival inflammation that occur in these patients are seen in the presence of relatively small amounts of bacterial biofilm. Therefore the long-term prognosis for these patients depends not only on control of bacterial biofilm but also on control or correction of the systemic factors.

Biofilm-Induced Gingival Diseases Modified by Medications

Gingival diseases associated with medications include drug-influenced *gingival enlargement,* often seen with phenytoin, cyclosporine, and nifedipine and in oral contraceptive–associated gingivitis.

In drug-influenced gingival enlargement, the severity of the lesions is associated with inflammation, which is usually induced by bacterial biofilm. Inflammation may also be induced by repeated trauma (Fig. 35.10). Eliminating the source of inflammation, either trauma or biofilm, can limit the severity of the gingival overgrowth. However, surgical intervention is usually necessary to correct the alterations in gingival contour. Continued use of the drug and persistence of inflammation usually result in recurrence of the enlargement, even after surgical intervention (see Chapter 19). Therefore the long-term prognosis depends on whether the etiology of the inflammation can be completely eliminated or the patient's systemic problem can be treated with an alternative medication that does not have gingival enlargement as a side effect.

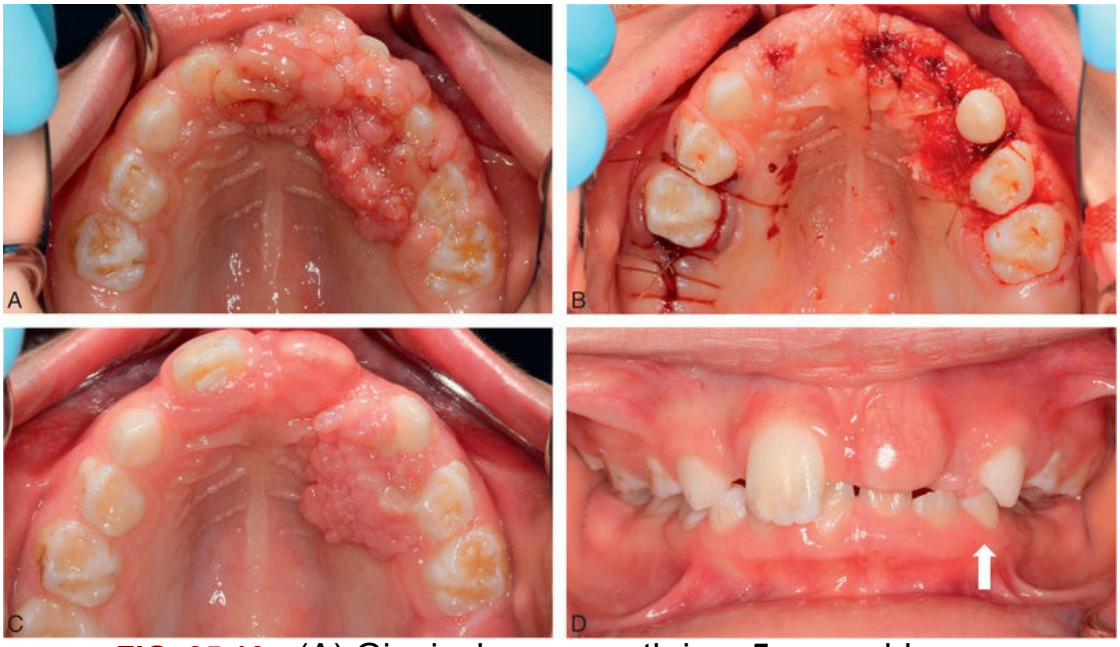

FIG. 35.10 (A) Gingival overgrowth in a 5-year-old male patient who was taking cyclosporine for the management of aplastic anemia. (B) The gingival overgrowth was resected surgically. (C) Recurrence of gingival overgrowth on the maxillary left quadrant at 1 year postop due to trauma from the opposing mandibular teeth occluding on the maxillary left palatal tissue (D). Learning Box 35.5

Inflammation may be induced by biofilm or trauma.

In oral contraceptive–associated gingivitis, frank signs of gingival inflammation can be seen in the presence of relatively little biofilm. Therefore, as seen in biofilm-induced gingival diseases modified by systemic factors, the long-term prognosis in these patients depends not only on the control of bacterial biofilm but also on the likelihood of continued use of oral contraceptives.

Gingival Diseases Modified by Malnutrition

Although malnutrition has been suspected to play a role in the development of gingival diseases, most clinical studies have not shown a relationship between the two. One possible exception is severe vitamin C deficiency. In early experimental vitamin C deficiency, gingival inflammation and bleeding on probing were independent of the biofilm levels present. The prognosis in these patients may depend on the severity and duration of the deficiency and on the likelihood of reversing the deficiency through dietary supplementation.

Non–Biofilm-Induced Gingival Lesions

Non–biofilm-induced gingivitis can be seen in patients with a variety of bacterial, fungal, and viral infections.[19] Because the gingivitis in these patients is not usually attributed to biofilm accumulation, prognosis depends on elimination of the source of the infectious agent. Dermatologic disorders such as lichen planus, pemphigoid, pemphigus vulgaris, erythema multiforme, and lupus erythematosus also can manifest in the oral cavity as atypical gingivitis (see Chapter 22). Prognosis for these patients is linked to management of the associated dermatologic disorder. Finally, allergic, toxic, and foreign-body reactions, as well as mechanical and thermal trauma, can result in gingival lesions. Prognosis for these patients depends on the elimination of the causative agent.

Prognosis for Patients With Periodontitis

Chronic Periodontitis

Chronic periodontitis is a slowly progressive disease associated with well-known local environmental factors.[27] It can present in a localized or generalized form (see Chapter 27). In cases in which the clinical attachment loss and bone loss are not advanced (slight to moderate periodontitis), the prognosis is generally favorable, provided the inflammation can be controlled through good oral hygiene and the removal of local biofilm-retentive factors (see Fig. 35.1). In patients with more severe disease, as evidenced by furcation invasion and tooth mobility, or in patients who are noncompliant with oral hygiene practices, the prognosis may be questionable or unfavorable, and even hopeless.

Aggressive Periodontitis

Aggressive periodontitis can present in a localized or generalized form.[26] Two common features of both forms are (1) rapid attachment loss and bone destruction in an otherwise clinically healthy patient and (2) a familial aggregation. These patients often present with limited microbial deposits that seem inconsistent with the severity of tissue destruction. However, the deposits that are present often have elevated levels of *Aggregatibacter actinomycetemcomitans* or *Porphyromonas gingivalis*. These patients also may present with phagocyte abnormalities and a hyperresponsive monocyte/macrophage phenotype. These clinical, microbiologic, and immunologic features would suggest that patients diagnosed with aggressive periodontitis would have an unfavorable prognosis.

However, the clinician should consider additional specific features of the localized form of disease when determining the prognosis (see Fig. 35.5). Localized aggressive periodontitis usually occurs around the age of puberty and is localized to first molars and incisors. The patient often exhibits a strong serum antibody response to the infecting agents, which may contribute to localization of the lesions (see Chapter 28). When diagnosed early, these cases can be treated conservatively with oral hygiene instruction and systemic antibiotic therapy,[42] resulting in a favorable prognosis. When more advanced disease occurs, the prognosis can still be favorable if the lesions are treated with

debridement, local and systemic antibiotics, and regenerative therapy.[30,52]

In contrast, although patients with generalized aggressive periodontitis are young (usually under age 30), they present with generalized interproximal attachment loss and a poor antibody response to infecting agents. Secondary contributing factors, such as cigarette smoking, are often present. These factors, coupled with the alterations in host defense seen in many of these patients, may result in a case that does not respond well to conventional periodontal therapy (scaling with root planing, oral hygiene instruction, and surgical intervention). Therefore these patients often have a questionable or unfavorable prognosis, and the use of systemic antibiotics should be considered to help control the disease (see Chapter 52).

Periodontitis as a Manifestation of Systemic Diseases

Periodontitis as a manifestation of systemic diseases can be divided into the following two categories[22,28]:

1. Periodontitis associated with hematologic disorders such as leukemia and acquired neutropenias
2. Periodontitis associated with genetic disorders such as familial and cyclic neutropenia, Down syndrome, Papillon-Lefèvre syndrome, and hypophosphatasia

Although the primary etiologic factor in periodontal diseases is bacterial plaque, systemic diseases that alter the ability of the host to respond to the microbial challenge may affect the progression of disease and therefore the prognosis for the case. For example, decreased numbers of circulating neutrophils (as in acquired neutropenia) may contribute to widespread destruction of the periodontium. Unless the neutropenia can be corrected, these patients present with a fair to poor prognosis. Similarly, genetic disorders that alter the way the host responds to bacterial plaque (as in leukocyte adhesion deficiency [LAD] syndrome) also can contribute to the development of periodontitis. Because these disorders generally manifest early in life, the impact on the periodontium may be clinically similar to generalized aggressive

periodontitis. The prognosis in these cases will be questionable or unfavorable.

Other genetic disorders do not affect the host's ability to combat infections but still affect the development of periodontitis. Examples include (1) hypophosphatasia, in which patients have decreased levels of circulating alkaline phosphatase, severe alveolar bone loss, and premature loss of deciduous and permanent teeth, and (2) Ehlers-Danlos syndrome, a connective tissue disorder, in which patients may present with clinical characteristics of aggressive periodontitis. In both examples the prognosis is questionable or unfavorable.

Necrotizing Periodontal Disease

Necrotizing periodontal disease can be divided into necrotic diseases that affect the gingival tissues exclusively (necrotizing ulcerative gingivitis [NUG]) and necrotic diseases that affect deeper tissues of the periodontium, resulting in a loss of connective tissue attachment and alveolar bone (necrotizing ulcerative periodontitis [NUP]).[41,46] In NUG, the primary predisposing factor is bacterial plaque. However, this disease is usually complicated by the presence of secondary factors such as acute psychologic stress, tobacco smoking, and poor nutrition, all of which can contribute to immunosuppression. Therefore superimposition of these secondary factors on preexisting gingivitis can result in the painful, necrotic lesions characteristic of NUG. With control of both the bacterial plaque and the secondary factors, the prognosis for a patient with NUG is favorable. However, the tissue destruction in these cases is not reversible, and poor control of the secondary factors may make these patients susceptible to recurrence of the disease. With repeated episodes of NUG, the prognosis may worsen to questionable.

The clinical presentation of NUP is similar to that of NUG, except the necrosis extends from the gingiva into the periodontal ligament and alveolar bone. In systemically healthy patients, this progression may have resulted from multiple episodes of NUG, or the necrotizing disease may occur at a site previously affected with periodontitis. In these patients, the prognosis depends on alleviating the biofilm and secondary factors associated with NUG.

However, many patients presenting with NUP are immunocompromised by systemic conditions such as human immunodeficiency virus (HIV) infection. In these patients the prognosis depends not only on reducing local and secondary factors but also on dealing with the systemic problem (see Chapter 43).

Determination and Reassessment of Prognosis

Determination of prognosis of a tooth or teeth requires a careful and thorough assessment of the presence of disease and its severity and extent. An accurate prognosis cannot be made without an accurate diagnosis. Once disease has been properly and accurately diagnosed, determining the prognosis can still be difficult, particularly for teeth with disease. Many factors can influence disease progression and the response to therapy, and the specific influence of any one factor is unknown and likely different from one patient to another. In addition, each patient can respond differently at different times. Moreover, the outcome of therapy significantly depends on the treatment to be rendered, the quality of the treatment, the skills and knowledge of the treating clinician, and patient home care. For these reasons, determining an accurate prognosis can be challenging.

Prognosis of teeth with minimal disease is favorable and by far the easiest to assign with accuracy and precision. As disease develops and severity increases, prognosis becomes progressively harder to assign correctly and accurately, especially for teeth with moderate to advanced disease that have a questionable or unfavorable prognosis. Once disease progresses to a point that teeth are no longer functional or treatable, the prognosis is again easy to determine. These teeth are assigned a hopeless prognosis and the treatment is extraction. However, the treatability of a tooth can be easily skewed by the skills and expertise of the treating clinician, or lack thereof. It is also easier for a clinician to make a diagnosis, determine a prognosis, and create a treatment plan that aligns with his or her expertise. For example, a prosthodontist may assign

mandibular incisors with moderate attachment loss and mobility no. 2 a hopeless prognosis and develop a treatment plan that involves replacement of these teeth with a removable partial denture or dental implants. However, with the proper periodontal treatment and effective patient biofilm control, the health and function of these mandibular anterior teeth may be restored and maintained for many years.

It is not always possible to accurately determine the prognosis prior to initiating periodontal treatment. During the periodontal examination, due to the lack of anesthesia, it may not be possible to accurately and carefully probe a tooth to determine the true extent of bone loss and severity of disease. During scaling and root planing under anesthesia, it is possible to probe to the depth of the periodontal pocket. However, the anatomy of the osseous defect may not be determined until a periodontal flap has been elevated and all the granulation tissue removed. As such, the prognosis may change as more specific diagnostic information is discovered.

Prognosis may also change and improve with periodontal treatment or disease progression. During therapy, the patient's motivation and commitment, acknowledged as critical in all forms of periodontal therapy, can be determined, as well as the host response and the healing capacity of the patient. Clearly, enhancing the host response to a microbial biofilm challenge will significantly and positively influence the periodontal prognosis. Likewise, an *inability* to enhance the host response will negatively influence the prognosis. Either outcome, however, will allow the clinician to determine a more accurate prognosis.

A frank reduction in probing depth and inflammation after therapy indicates a favorable response to treatment and may suggest a better prognosis than previously assumed (Fig. 35.11). If the inflammatory changes cannot be controlled or reduced by therapy, the overall prognosis may be unfavorable. In these patients, the prognosis can be directly related to the severity of inflammation. Given two patients with comparable bone destruction, the prognosis may be better for the patient with the greater degree of inflammation because a larger component of that patient's bone destruction may be attributable to local etiologic factors. In addition, therapy allows the clinician an opportunity to

work with the patient and the patient's physician to control systemic and environmental factors such as diabetes and smoking, which may have a positive effect on prognosis if adequately controlled.

FIG. 35.11 Prognosis changes with treatment. The maxillary left first and second molars were initially assigned an unfavorable prognosis due to advanced bone loss and deep grade II furcation invasion (A, B). The clinician contemplated extraction of both teeth. However, both teeth were vital, stable, and did not require any restorative treatment, and the patient wanted to keep them and was willing to effectively control biofilm. Both teeth were treated with periodontal surgery. After 5 years, they remain healthy and functional, and the prognosis improved to favorable (C, D). (Copyright Jonathan H. Do, DDS. All rights reserved.)

The progression of periodontitis generally occurs in an episodic manner, with alternating periods of quiescence and shorter destructive stages (see Chapter 23). No methods are available at present to accurately determine whether a given lesion is in a stage of remission or exacerbation. Advanced lesions, if active, may progress rapidly to a hopeless stage, whereas similar lesions in a quiescent stage may be maintainable for long periods. Stable lesions

in a patient in periodontal maintenance may also break down and advance due to changes in biofilm control, stress level, or systemic health. For these reasons, prognosis along with diagnosis must be carefully evaluated and reassessed throughout the course of treatment and over time during supportive maintenance therapy.

Learning Box 35.6

Due to the dynamic nature of patients and periodontal disease, prognosis must be reevaluated during all phases of treatment.

Conclusion

The periodontal prognosis plays a pivotal role in therapy, as treatment decisions are made based on prognosis and to improve prognosis. Teeth with a hopeless diagnosis are extracted, whereas teeth with more favorable prognoses are treated, with the intent of restoring health and stability and ultimately improving the prognosis. A hopeless prognosis is perhaps the easiest prognosis to assign, because hopeless teeth usually have overt and severe disease. The hopeless prognosis is also perhaps the easiest to be erroneously assigned, due to clinical bias or lack of training and expertise. Therefore the hopeless prognosis must be assigned with caution, as the consequences are irreversible. It must also be recognized that patients and diseases are dynamic. As such, a prognosis will change and must be reevaluated over time.

Learning Box 35.7

Examination → Diagnosis → Prognosis ↔ Treatment

- Diagnosis requires thorough and careful examination.
- Prognosis is based on accurate diagnosis.
- Treatment decisions are based on prognosis.
- Treatment decisions are made to improve prognosis.

- Diagnosis and prognosis will change with treatment.

CHAPTER 36

The Treatment Plan

Jonathan H. Do, Henry H. Takei, Fermin A. Carranza

CHAPTER OUTLINE

Overall Treatment Plan
Sequence of Therapy
Explaining the Treatment Plan to the Patient
Conclusion

After the diagnosis and prognosis have been established, the treatment is planned. The plan should encompass immediate, intermediate, and long-term goals.

The *immediate goals* are the elimination of all infectious and inflammatory processes that cause periodontal and other oral problems that may hinder the patient's general health. Basically, the immediate goals are to bring the oral cavity to a state of health. This may require patient education on infectious oral diseases and disease prevention, periodontal procedures, endodontics, caries control, oral surgery, and treatment of oral mucous membrane pathologies. Referral to other dental and medical specialties may be necessary.

From a periodontal viewpoint, the immediate goals are

important, because they consist of the elimination of gingival inflammation and the correction of conditions that cause and perpetuate it. These include not only elimination of root surface accretions but also pocket reduction and the establishment of good gingival contours and mucogingival relationships conducive to periodontal health. Extraction of hopeless teeth, restoration of carious lesions, and correction of poor existing restorations may be necessary.

The *intermediate goals* are the reconstruction of a healthy dentition that not only fulfills all functional and aesthetic requirements but lasts many years. Restoration of health, function, aesthetics, and longevity involves endodontic, orthodontic, periodontal, and prosthodontic considerations as well as the age, health, and desires of the patient. The financial impact of restoring the dentition to health, function, aesthetics, and longevity requires careful consideration and understanding by the patient. The intermediate goals may be quickly achieved or require treatments over months or even years, depending on the complexity of the case, the therapy involved, and the financial status of the patient.

The *long-term goal* is maintenance of health through prevention and professional supportive therapy. The long-term goal is set, and both the patient and the clinician work toward it from the very first visit. Once active disease has been controlled, all infectious and inflammatory processes have been eliminated, and health has been attained, health should be maintainable for the rest of the patient's life. Maintenance of health requires patient education on disease prevention and oral hygiene at the onset of treatment, meticulous daily home care by the patient, and patient adherence to professional recall maintenance.

Learning Box 36.1

Maintenance of health depends on disease prevention, meticulous daily patient home care, and patient adherence to professional recall maintenance at a regular interval.

The treatment plan is the blueprint for case management. It

includes all procedures required for the establishment and maintenance of oral health and involves decisions regarding the following:

- Emergency treatment (pain, acute infections)
- Removal of nonfunctional and diseased teeth, and possibly strategic extraction of healthy teeth to facilitate the prosthetic reconstruction of the patient
- Treatment of periodontal diseases (surgical or nonsurgical, regenerative or resective)
- Endodontic therapy (necessary and intentional)
- Caries removal and placement of temporary and final restorations
- Occlusal adjustment and orthodontic therapy
- Replacement of missing teeth with removable or fixed dental prostheses or dental implants
- Aesthetic demands
- Sequence of therapy

Treatment decisions are made with the diagnosis and prognosis of the individual teeth and the overall dentition in mind. The prognosis is usually established based on the diagnosis. Treatment decisions are made based on the prognosis and to improve the prognosis. As such, *diagnosis and prognosis will change with treatment*.

Unforeseen developments during treatment may necessitate modification of the initial treatment plan. However, except for emergencies, no therapy should be initiated until a treatment plan has been established.

Learning Box 36.2

Prognosis is established based on diagnosis. Treatment decisions are made based on prognosis and to improve prognosis. Diagnosis

and prognosis will change with treatment.

Overall Treatment Plan

The aim of the treatment plan is total treatment—that is, the coordination of all the immediate, intermediate, and long-term goals for the purpose of creating a well-functioning dentition in a healthy periodontal environment. The periodontal treatment encompasses different areas of therapeutic objectives for each patient according to his or her needs. It is based on the diagnosis, prognosis, disease severity, risk factors, and other factors outlined in previous chapters.

Extracting or Preserving a Tooth

Periodontal treatment requires long-range planning. Its value to the patient is measured in years of healthy functioning of the entire dentition and not by the number of teeth retained at the time of treatment. Treatment is directed to establishing and maintaining the health of the periodontium throughout the mouth rather than attempting spectacular efforts to "tighten loose teeth."

Implant replacement of missing teeth has become a predictable course of therapy. Therefore attempts to save questionable teeth may jeopardize adjacent teeth and may lead to the loss of bone needed for implant therapy. Teeth on the borderline of a hopeless prognosis do not contribute to the overall usefulness of the dentition. Such teeth become sources of recurrent problems for the patient and detract from the value of the greater service rendered by the establishment of periodontal health in the remainder of the oral cavity.

Removal, retention, or temporary (interim) retention of one or more teeth is an important part of the overall treatment plan. A tooth should be extracted under the following conditions:

- It is so mobile that function becomes painful.
- It can cause acute abscesses during therapy.
- There is no use for it in the overall treatment

plan.

In some cases, a tooth can be retained temporarily, postponing the decision to extract until after treatment is completed. A tooth in this category can be retained under the following conditions:

- It maintains posterior stops; the tooth can be removed after treatment, when it can be replaced by an implant or another type of prosthesis.
- It maintains posterior stops and may be functional after implant placement in adjacent areas. When the implant is restored, these teeth can be extracted.
- In the anterior aesthetic zone, a tooth can be retained during periodontal therapy and removed when treatment is completed and a permanent restorative procedure can be performed. The retention of this tooth should not jeopardize the adjacent teeth. This approach avoids the need for temporary appliances during therapy.
- Extraction of hopeless teeth can also be performed during periodontal surgery of the adjacent teeth. This approach reduces the number of appointments needed for surgery in the same area.

In the formulation of the treatment plan, in addition to the proper function of the dentition, aesthetic considerations play an important role. Different patients value aesthetics differently, according to their age, gender, profession, and social status. The clinician should carefully evaluate and consider a final aesthetic outcome of treatment that will be acceptable to the patient without jeopardizing the basic need of attaining health.

With the predictable use of implants, questionable teeth should be carefully evaluated as to whether their removal and replacement with an implant may be a better and more satisfactory course of therapy.

In complex cases, interdisciplinary consultation with other specialty areas is necessary before a final plan can be made. The opinions of orthodontists and prosthodontists are especially important for the final decision in these patients.

Occlusal evaluation and therapy may be necessary during treatment, which may necessitate planning for occlusal adjustment (see Chapter 55), orthodontics see Chapter 56, and splinting. The correction of bruxism and other occlusal habits may also be necessary.

Systemic conditions should be carefully evaluated because they may require special precautions during the course of periodontal treatment. The tissue response to treatment procedures may be affected, or the preservation of periodontal health may be threatened after treatment is completed. The patient's physician should always be consulted when the patient presents with medical and systemic problems that may affect the periodontal therapy.

Supportive periodontal care is also of paramount importance for case maintenance. Such care entails all procedures for maintaining periodontal health after it has been attained. It consists of instruction in oral hygiene and recall therapy at regular intervals, according to the patient's needs.

Sequence of Therapy

The periodontal treatment sequence is presented in Box 36.1, and a nonsurgical periodontal treatment decision tree is presented in Fig. 36.1. Periodontal therapy is an inseparable part of dental therapy, and all treatments must be well coordinated.

Box 36.1

Periodontal Treatment Sequence

Periodontal Evaluation

Comprehensive periodontal examination
Diagnosis and prognosis
Patient education
- Clinical findings and disease status
- Disease pathogenesis and prevention
- Personalized oral hygiene instruction

Reduction of systemic and environmental risk factors
- Physician consultation
- Smoking cessation

Periodontal treatment plan
- Oral hygiene assessment and education
- Nonsurgical therapy
- Periodontal reevaluation
- Periodontal supportive maintenance

Nonsurgical Therapy

Oral hygiene assessment and education*
Infection control
- Nonsurgical periodontal therapy
  - Supragingival and subgingival scaling and root planing
- Extraction of hopeless teeth

Reduction of local risk factors
- Removal or reshaping of overhangs and overcontoured restorations
- Restoration of carious lesions
- Restoration of open contacts

Periodontal Reevaluation

Inquiry of new concerns or problems
Inquiry of changes in patient's medical and oral health status
Oral hygiene assessment and education*
Comprehensive periodontal examination
Assessment of outcome of nonsurgical therapy

Determination of required additional nonsurgical and adjunctive therapy

Surgical Therapy

Adjunct to nonsurgical therapy
Should only occur once patient demonstrates proficient biofilm control
Objectives:
- Primary: Access for root instrumentation
- Secondary: Pocket reduction through soft tissue resection, osseous resection, or periodontal regeneration

Periodontal access surgery
- Resective
- Regenerative

Extraction of hopeless teeth
Periodontal plastic surgery
- Mucogingival surgery
- Aesthetic crown lengthening

Preprosthetic surgery
- Prosthetic crown lengthening
- Implant site preparation and implant placement

Periodontal Maintenance Therapy

Inquiry of new concerns or problems
Inquiry of changes in patient's medical and oral health status
Oral hygiene assessment and education*
Comprehensive periodontal examination
Professional maintenance care
- Supragingival and subgingival biofilm and calculus removal
- Selective scaling and root planing

Assessment of recall interval and plan for next visit

*Patient oral hygiene is critical to the overall short-term and long-term treatment

outcome. Therefore oral hygiene must be repeatedly assessed and reinforced.

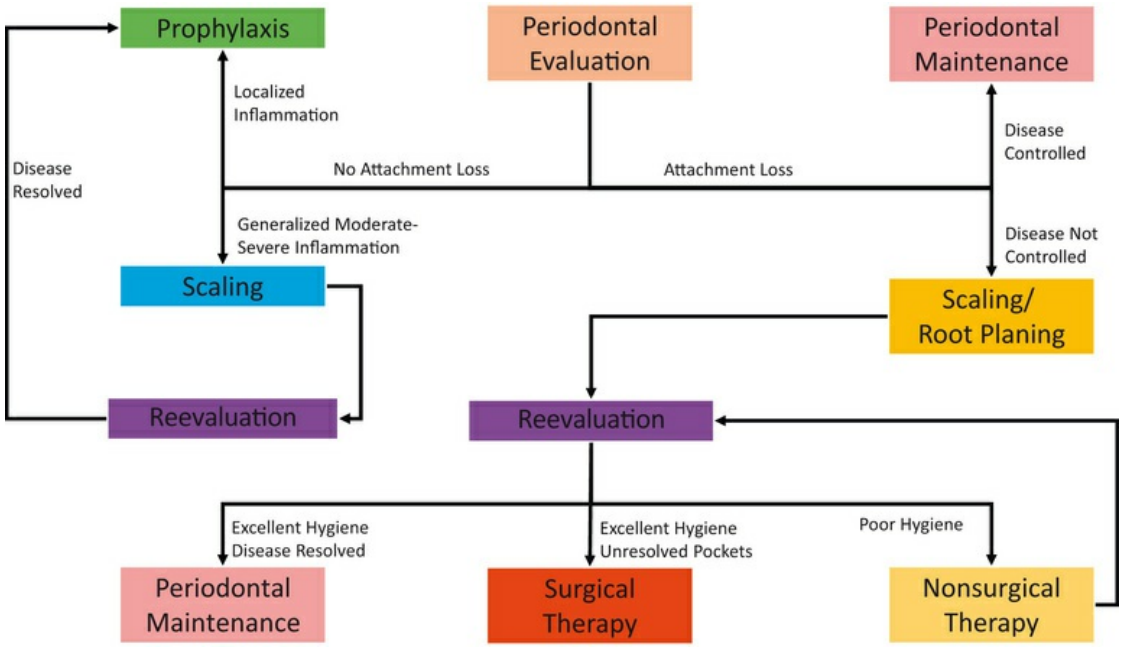

FIG. 36.1 Periodontal treatment decision tree.

Although the phases of treatment are numbered, the recommended sequence does not follow the numbers (Fig. 36.2). Phase I, or the *nonsurgical phase,* is directed to the elimination of the etiologic factors of dental, gingival, and periodontal diseases. When successfully performed, this phase stops the progression of dental and periodontal disease.

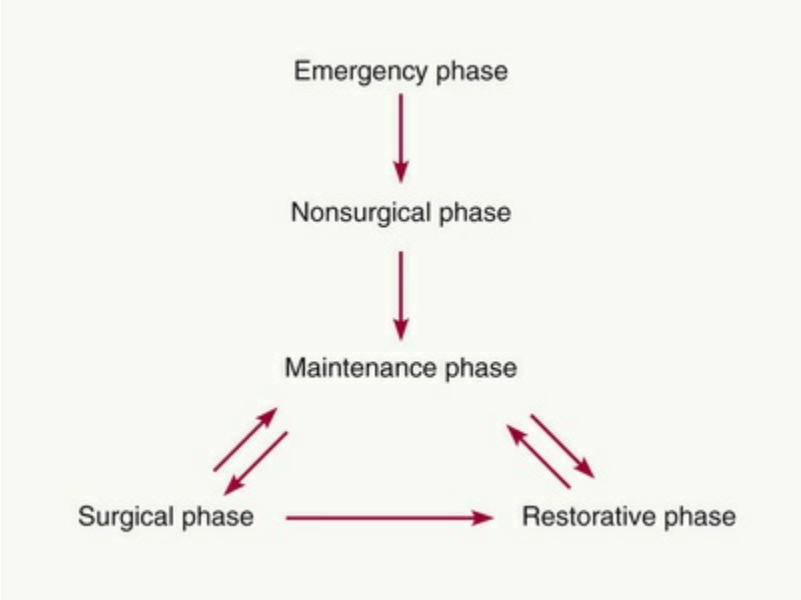

FIG. 36.2 Preferred sequence of therapy.

Immediately after completion of phase I therapy, the patient should be placed on the *maintenance phase* (phase IV) to preserve the results obtained and prevent any further deterioration and recurrence of disease. While on the maintenance phase, with its periodic evaluation, the patient enters into the *surgical phase* (phase II) and the *restorative phase* (phase III) of treatment (Fig. 36.3). These phases include periodontal surgery to treat and improve the condition of the periodontal and surrounding tissues. This may include regeneration of the gingiva and bone for function and aesthetics, placement of implants, and restorative therapy.

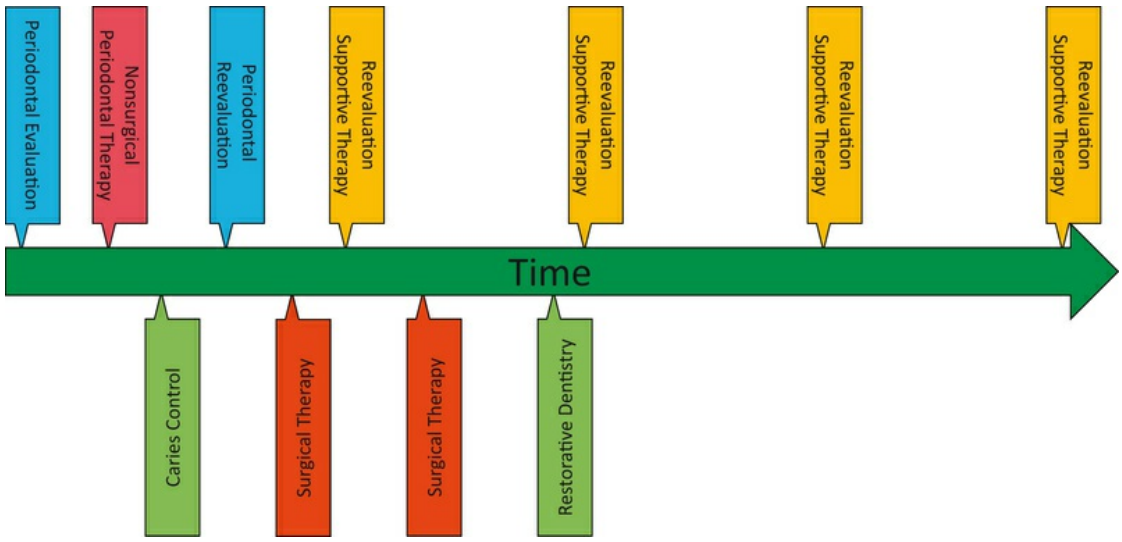

FIG. 36.3 Sample treatment timeline. Following

nonsurgical periodontal therapy, the patient is placed on periodontal maintenance at regular intervals. Surgical and restorative treatments are scheduled between periodontal recalls.

Learning Box 36.3

Immediately after the completion of phase I therapy, the patient should be placed on the maintenance phase.

Explaining the Treatment Plan to the Patient

The following discussion includes suggestions for explaining the treatment plan to the patient.

Be specific. Tell your patient, "You have gingivitis" or "You have periodontitis," then explain exactly what the condition is.

Avoid vague statements. Do not use statements such as "You have trouble with your gums" or "Something should be done about your gums." The patient may not understand the significance of such statements and may disregard them.

Begin your discussion on a positive note. Talk about the teeth that can be retained and the long-term service they can be expected to render. Do not begin your discussion with the statement "The following teeth have to be extracted." This creates a negative impression, which adds to the erroneous attitude of hopelessness the patient may already have regarding his or her mouth. Make it clear that every effort will be made to retain as many teeth as possible, but do not dwell on the patient's loose teeth. Emphasize that the important purpose of the treatment is to prevent the other teeth from becoming as severely diseased as the loose teeth.

Present the entire treatment plan as a unit. Avoid creating the impression that treatment consists of separate procedures,

some or all of which may be selected by the patient. Make it clear that dental restorations and prostheses contribute as much to the health of the gingiva as the elimination of inflammation and periodontal pockets. Do not speak in terms of "having the gums treated and then taking care of the necessary restorations later" as if these were unrelated treatments.

Patients often seek guidance from the dentist with questions such as the following:

- "Are my teeth worth treating?"
- "Would you have them treated if you had my problem?"
- "Why don't I just go along the way I am until the teeth really bother me and then have them all extracted?"

Explain that "doing nothing" or holding onto hopelessly diseased teeth as long as possible is inadvisable for the following reasons:

1. Periodontal disease is a microbial infection, and research has clearly shown it to be an important risk factor for severe life-threatening diseases such as stroke, cardiovascular disease, pulmonary disease, and diabetes, as well as for premature low-birth-weight babies in women of childbearing age. Correcting the periodontal condition eliminates a serious potential risk of systemic disease, which in some cases ranks as high on the danger list as smoking.
2. It is not feasible to place restorations or fixed bridges on teeth with untreated periodontal disease because the usefulness of the restoration would be limited by the uncertain condition of the supporting structures.
3. Failure to eliminate periodontal disease not only results in the loss of teeth already severely involved, but also shortens the life span of other teeth. With proper treatment, these teeth can serve as the foundation for a healthy, functioning

dentition.

Therefore the dentist should make it clear to the patient that if the periodontal condition is treatable, the best results are obtained by prompt treatment. If the condition is not treatable, the teeth should be extracted.

It is the dentist's responsibility to advise the patient of the importance of periodontal treatment. However, if treatment is to be successful, the patient must be sufficiently interested in retaining his or her natural teeth and to maintain the necessary oral hygiene. Individuals who are not particularly perturbed by the thought of losing their teeth are generally not good candidates for periodontal treatment.

Conclusion

The ultimate goal for every patient is to bring his or her mouth to a state of health and maintain it long term. This begins with educating the patient on the problems in his or her mouth and the etiologies, treatment, and prevention of these problems. A properly formulated treatment plan is paramount to achieving this goal. A treatment plan is a plan for therapy formulated only after a thorough examination has been completed, diagnosis and prognosis have been determined, and the needs and desires of the patient have been taken into consideration. It must be recognized that as diagnosis and prognosis will change with treatment, therapeutic needs may also change. As such, the treatment plan must be changed accordingly.

Learning Box 36.4

Examination → Diagnosis → Prognosis ↔ Treatment

- Diagnosis requires thorough and careful examination.
- Prognosis is based on accurate diagnosis.
- Treatment decisions are based on the the prognosis.

- Treatment decisions are made to improve the prognosis.
- Diagnosis and prognosis will change with treatment.

CHAPTER 37

Electronic Dental Records and Decision Support Systems

Thankam P. Thyvalikakath, Corey Stein, Titus Schleyer

CHAPTER OUTLINE

Functionalities and Components Available in Electronic Dental Records
Electronic Dental Record Use in Dental Practices
Future of Electronic Dental Records and Decision Support Systems in Dentistry

Dental practices are using electronic dental records (EDRs) for patient care to a significant and rapidly rising degree.[14] Early on, computers primarily automated administrative and financial functions, but they now increasingly support clinical patient documentation, digital radiographs, intraoral photos, and oral disease risk assessments. This shift in EDR use is generating vast

amounts of patient data that could provide significant benefits to clinicians and researchers. Until now, clinicians could track individual patient outcomes only through paper-based records, and they typically spent considerable time transcribing that information into an electronic form so that they could analyze the data.

Digitization of patient data creates opportunities to dissect and analyze data in ways not possible before. Clinicians are able to track their patients' treatment progress and risks for various diseases at the individual, group, and practice levels. Analyzing electronic data can generate new knowledge in real time. This chapter discusses the current functions available in EDRs; EDR use by dental practices in the United States, Europe, and other locations throughout the world; commonly used EDRs in the United States and Europe; and the drawbacks and advantages of using EDRs in practice. Finally, the chapter explores the decision support systems available in dentistry, focusing specifically on periodontal disease, and closes with a discussion of the future of EDRs.

Functionalities and Components Available in Electronic Dental Records

An EDR typically includes components such as patient registration, medical and medication history, extraoral and intraoral exams, hard and soft tissue charting, treatment planning, patient education, visit documentation, imaging, and scheduling. This section reviews selected examples of these functions.

Patient Registration

The data captured in patient registration include the patient's name, gender, birth date, identification numbers (such as Social Security and driver's license numbers), and address and contact information. Typically, offices with more than one clinician assign a provider. That makes it easy to list all patients for a particular provider.

Registration also includes an unobtrusive but important data field, the chart number that a patient is assigned automatically as

soon as the record is saved. This chart number is the identifier that links together all parts of the electronic record for a particular patient; it is a unique internal identifier with which all information items for one patient are "stamped."

Another feature of an EDR is that most information on the registration screen is stored in separate fields, called "structured data." Structured data fields can be summarized and analyzed on their own or in combination, enabling some of the powerful reporting and analysis functions found in EDRs.

Periodontal Chart

The sample periodontal chart shown in Fig. 37.1 not only shows the pocket depth and clinical attachment loss but is also a graphical presentation of periodontal changes over time. This presentation is difficult to achieve using paper-based periodontal charts.

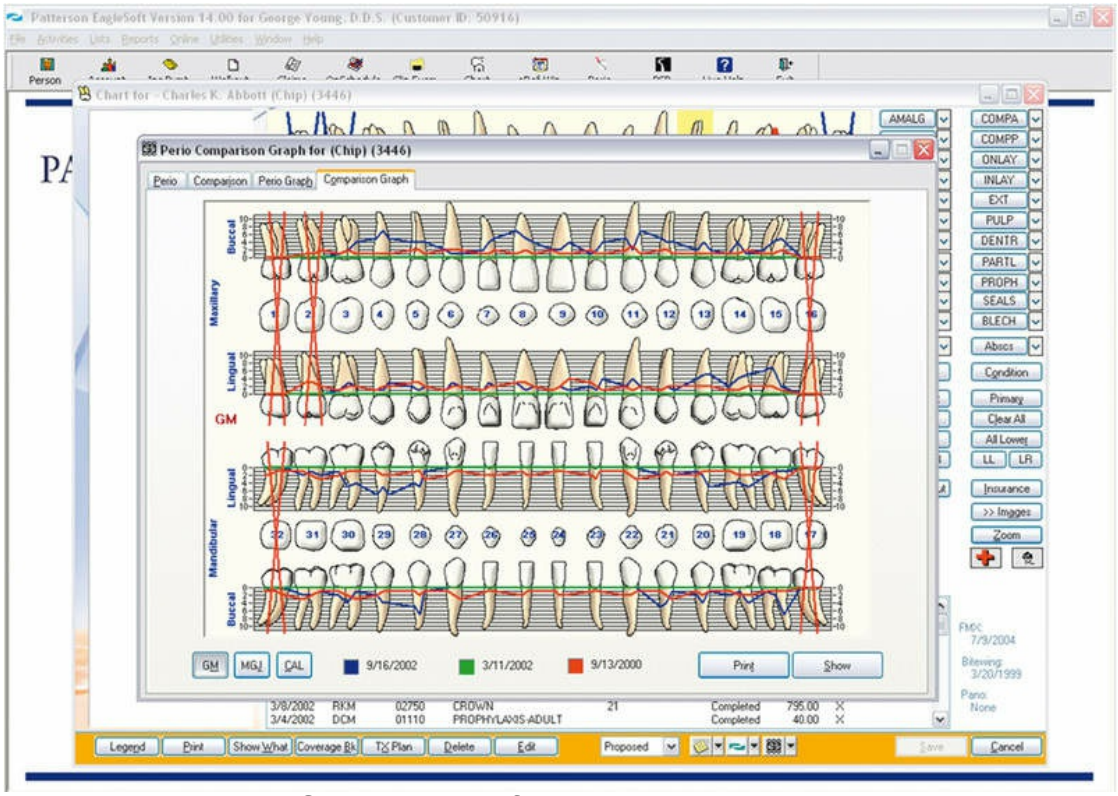

FIG. 37.1 Screenshot of the periodontal chart in EagleSoft. (Courtesy Patterson Technology.)

Electronic Dental Record Use in Dental Practices

Since the late 1990s, the use of EDRs in dental practices has risen significantly worldwide, especially in the United States.[13,26] Early on, dental practices used computerized systems primarily for administrative functions, such as patient accounting and billing (94%), insurance processing (90.9%), and patient scheduling (83%).[6] Only 37% of dental practices reported using a computer to maintain patient records at that time. Studies on EDR use in England and Sweden reported similar figures.[28,26,19]

More recent studies have pointed to a marked increase in EDR use for clinical documentation.[14,13,6] In 2010, US dental practices used EDRs to acquire and store radiographs (68%), intraoral photos and videos (67%), examination forms (54%), progress notes (54%), and dental charts (50%).[6] Most practices maintained a hybrid system of patient records, with some information spread across paper and the EDR. Compared to 2% in 2006, in 2012 about 15% of practices maintained completely paperless records.[1]

Figs. 37.2, 37.3, and 37.4 illustrate how clinical information is stored in US solo and group practices, as well as in Scandinavian group dental practices.[14] These figures clearly show that more dental practices in Scandinavian countries stored clinical information on computers than in the United States. Meanwhile, nearly all dental schools in the United States and Europe use (primarily commercial) EDR systems in some capacity.[15,7] However, few studies exist on how these systems are used in academic settings.

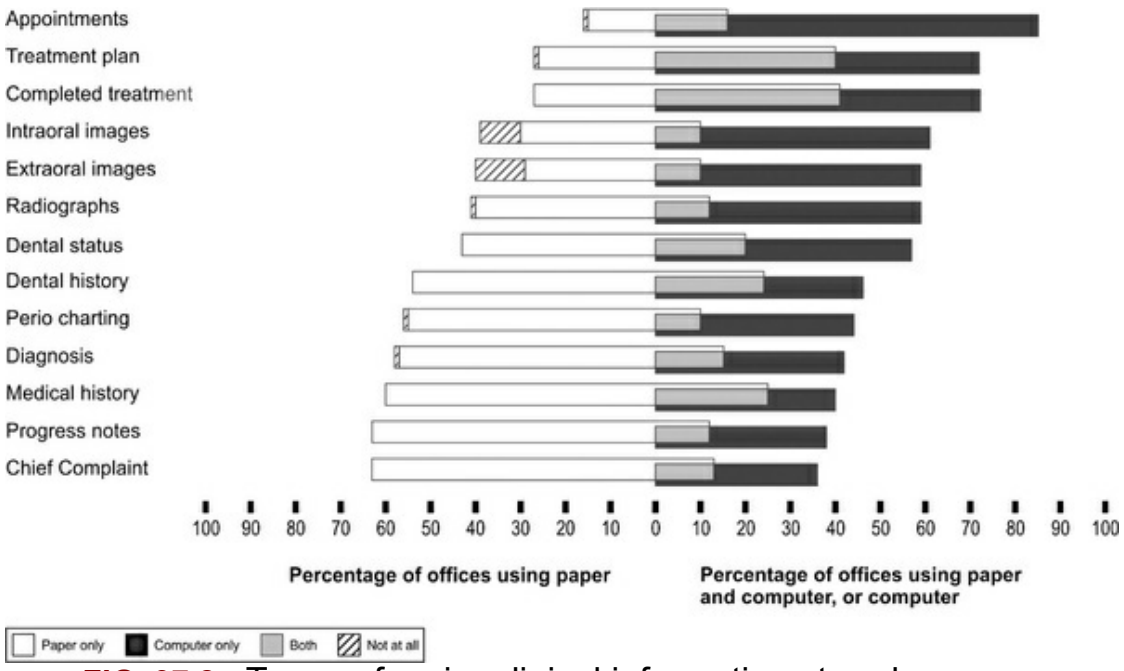

FIG. 37.2 Types of major clinical information stored on paper, a computer, or both by US solo practices.

Commonly Used Electronic Dental Records

Four systems currently hold about 75% of the market in EDRs in the United States. They are Dentrix Dental Systems (Henry Schein; 37%), EagleSoft (Patterson Dental; 18%), and SoftDent and PracticeWorks (Carestream; 20%).[14,13,6] About 100 other companies, most of them fairly small, develop and market EDR systems in the United States. Notable among them are the Windows-based MOGO and the web-based Curve Dental and Dental Symphony. Although no general reports on EDRs commonly used in Europe exist, Al Dente (Nordenta, Horning, Denmark), Dental Suite (Plandent, Helsinki), and Opus (Planmeca, Helsinki) appear to dominate in

Scandinavian countries.

Barriers to Using Electronic Dental Records

In spite of the rapid adoption of EDRs, several barriers exist to using them effectively for patient care. These include limited functionality, suboptimal usability and a steep learning curve, insufficient operational reliability, and cost and infection control issues.

Limited Functionality for Communication and Collaboration

Dental personnel collaborate extensively during patient care.[9] However, existing EDRs provide limited support for collaboration and communication among dental team members. In addition, breakdowns related to technology interrupt the workflow, cause rework, and increase the number of steps in work processes.[8]

Suboptimal Usability and Steep Learning Curve

Several studies have reported on the poor usability of existing EDRs.[13,28,15,7,3,16] Two examples of usability problems are the separation of patient information across multiple screens and the frequent mismatch between system design and task flow. As a result, users have to shift their attention from patients to EDRs to navigate through the information and avoid making mistakes. Users believed they spent more time interacting with EDRs than with paper records, resulting in less face time with their patients.

Insufficient Reliability of Electronic Dental Records and Infection Control Issues

System crashes during patient care that lead to loss of patient data and time[13,15] are an example of the insufficient operational reliability of EDRs. Infection control issues are primarily due to the fact that the keyboard and mouse are the primary mechanisms for interacting with a computer. Many practices use auxiliary personnel to control the EDR. Although this workaround is effective, it reduces efficiency and increases the chance of errors.

Challenges to Realizing the Full Potential of Electronic Dental Records

Standards for the Information Content of Electronic Dental Records

As expressed by the adage "dentists and patients forget, but good records remember," complete and comprehensive patient records are essential to support effective decision-making and outcomes research.[27] Currently, no standards exist on what clinical information dental records should or must contain. As more and more dentists adopt EDRs to deliver patient care,[14] it is essential that we address the question of what patient information should be documented and how it should be structured.[25] Since the late 1980s, state, national, and international dental organizations have produced many guidelines or standards for essential components of the dental record. Common information categories recommended include personal and demographic information, reason for visit, dental history, medical history, clinical examination information, diagnosis, treatment plan, and informed consent information. However, these recommendations are very general, and dental records vary significantly in the degree to which they meet them.[13] Currently, major work is being pursued toward developing a standard information model for EDRs.[25,4]

Data Representation and Interoperability

Dentistry lacks a standard terminology for documenting and describing dental findings and diagnoses. The World Health Organization's International Classification of Diseases coding system, or ICD, is limited with regard to oral and dental diagnoses. Several terminologies, such as the Systematized Nomenclature of Dentistry (SNODENT)[24] and EZCodes,[20] are being developed and evaluated as standard diagnostic codes for dentistry. However, standard terminologies alone will not solve the problem of data representation and interoperability. We need to consider how dental data in their totality can be represented on the computer so they can be easily stored, exchanged, and analyzed. Patient records typically consist of free text; numbers; standardized codes; and

radiographic, histologic, and clinical images. Although structured data can be represented and analyzed unambiguously, that is not true for free text data and images. Concepts in dental records must be represented to facilitate semantic interoperability and exchange of information across different systems. Ontologies are a powerful way to create computer-based representations that fulfill that goal.[12]

Benefits of Using Electronic Dental Records

In spite of barriers and challenges to using EDRs, tremendous opportunities exist for using them to improve patient care. As mentioned in the introduction, EDRs can provide significant benefits for clinicians and researchers. Using EDRs, clinicians are able to track their patients' treatment progress and risks for various diseases. Other benefits include timely access to patient records, access to patient records regardless of geographic location, simultaneous access to patient records by multiple users, and the ability to generate the best evidence from patient data and built-in decision support systems to reduce errors such as those involving medications and drug–drug interactions. For researchers, digitization creates opportunities to dissect and analyze patient data in ways that were not possible before.[22] Reuse of electronic patient data for dental research is in a nascent stage, but it provides a significant opportunity to help build a "learning health care system." Advantages of using EDR data for research include the ability to conduct studies of significant statistical power due to large sample sizes, obtain well-matched controls, ascertain important potential confounders, identify patients with rare diseases, save study time, collect data in real time, and generate systematic data documentation. We discuss a few of these benefits next.

Reusing Electronic Dental Records Data for Research Purposes

EDR data can be a strong alternative or synergistic to traditional research methods. They can be used for many types of studies, including epidemiology, outcomes, and comparative effectiveness.[22] Using EDRs for research allows the study of patient populations

instead of research study populations, thus generating study results that are applicable to real-world clinical settings and patients. However, using electronic patient data for research is significantly more common in medicine than in dentistry.[22] Limitations such as the poor quality of clinical data, lack of standards for clinical findings and diagnoses, and lack of interoperability of EDRs hamper our ability to synthesize patient data for research in dentistry. More research is needed on reusing clinical data to generate knowledge that impacts research and clinical care.

Clinical Decision Support Systems

Clinical decision support systems (CDSSs) are "information systems that improve clinical decision-making."[19] They are designed to provide relevant and current evidence to clinicians to improve patient care and reduce errors in practice. CDSSs analyze patient characteristics against a computerized knowledge base and generate patient-specific recommendations. Required patient data are either entered by clinicians or patients or retrieved from the electronic health record. Patient-specific recommendations are delivered to clinicians through the electronic health records, email communications, text messages, or printouts placed in the patient charts. As Garg et al[6] found, many CDSSs demonstrably improve practitioner performance.

Decision Support System Types

Both the theoretic foundations and the applications of decision support have been extensively studied in medicine.[23] Research on medical decision support has included studies on human diagnostic problem solving, the development of several types of algorithms to encode decision-support processes (e.g., rule-based systems, Bayesian belief systems, and neural networks), and the evaluation of their performance in clinics. These systems could be of two types: open-loop system or closed-loop system. Open-loop systems provide recommendations but do not take action on their own. For example, alerts and reminders are part of open-loop systems. Closed-loop systems take action on their own without the clinicians' intervention. Since the late 1980s, dentistry also saw the

development of many decision support systems,[2] but their use is not common. These systems addressed topics such as dental emergencies and trauma, radiographic interpretation of lesions, analysis of cephalograms in orthodontics, pulpal diagnosis, and design of partial dentures in restorative dentistry.

Risk-Based Decision Support Systems for Periodontal Disease

In periodontology, risk-based decision support systems are the most common type of CDSS. The PreViser Risk Calculator (PRC) (PreViser Corp., Mount Vernon, Washington) developed by Page et al,[18] UniFe developed by Trombelli et al,[25a] and DentoRisk (DentoSystem Scandinavia AB, Stockholm, Sweden) developed by Lindskog et al[13a] are examples of risk assessment tools for periodontal disease. The PRC is a web-based tool developed based on the scientific evidence of the importance of risk factors for periodontal disease. The tool calculates the patient's disease score and risk score based on a mathematical algorithm that assigns relative weights to 11 factors: patient age, smoking history, diagnosis of diabetes, history of periodontal surgery, bleeding on probing, pocket depth, furcation involvement, subgingival restorations, root calculus, vertical bone defects, and radiographic bone loss.[5] The disease score ranges from 0 (no disease) to 100 (severe periodontitis), and the risk score ranges from 1 (lowest) to 5 (highest).

Barriers to the Adoption of Clinical Decision Support Systems

There are several reasons for the slow implementation of CDSSs: stand-alone systems that are not integrated with the clinicians' workflow, lack of formal evaluation, challenges in developing standards for representing data, lack of studies on the clinicians' decision-making process, and the clinicians' skepticism regarding the value of CDSSs for patient care. Investigators emphasize the need for vigorous studies to integrate decision support systems into clinicians' clinical workflow to improve patient care.[2,18,10,11]

Factors That Improve the Adoption of Clinical Decision Support Systems

Several important lessons on the implementation of CDSSs are available from the extensive literature in medical informatics. In syntheses of research on decision support, Bates et al[3] and Kawamato et al[12] identified several factors that facilitate the adoption of decision support systems by practitioners. They include delivering decision support to the individual making the decision at the time the decision is made, fitting the system into the user's workflow, focusing on usability for the clinician, and not requiring additional data entry unless absolutely necessary. It is also important to evaluate the impact of these systems during the early phases of development and keep their knowledge bases up to date.

To summarize, CDSSs have the potential to improve clinical care and patient outcomes by delivering the best evidence to the clinician at the point of care. However, most systems are developed in isolation, with limited impact on patient care. It is important that these systems are implemented in electronic patient records to improve patient care. Finally, more studies are needed to learn how best to influence clinician behavior through use of these systems.

Future of Electronic Dental Records and Decision Support Systems in Dentistry

The adoption of EDRs has the potential not just to support clinical care but also to advance research and improve patient outcomes. In addition, EDRs offer the opportunity to move from a reparative to a preventive approach to treating oral diseases. Many dental diseases, including periodontal disease, are currently being managed using a reparative model, under which dentists and hygienists concentrate on the clinically obvious items that require immediate intervention, focusing less attention on preventing future disease.[17,21] Using this model, the treatment is essentially the same for all patients with identical clinical presentation. EDRs with integrated decision support systems can help with identifying

patients at high risk and with providing individualized recommendations. Despite emerging evidence of the validity and clinical utility of these systems for treatment in dentistry and, specifically, periodontology, little evidence suggests that these approaches are adopted broadly in general practice.[11] Leveraging the full functionalities of these systems will require significant work and trained informatics personnel. Dental informatics is an interdisciplinary field that applies computer and information science knowledge and methods to improve information management during clinical care, research, and dental education. Until now, the challenge for dentistry was to transition from paper to EDRs in a very basic fashion. Often, EDRs were designed as close or exact replicas of paper records.

Going forward, this approach will be insufficient. Dentistry now faces the challenge of making sense of electronic data, facilitating clinical care and research, and improving outcomes. It is important that trained dental informaticians, clinicians, educators, and researchers collaborate to accomplish this goal. Dentistry, just like other health care disciplines, is an information-intensive domain. The future success of dentistry depends on how we best use information technology to make sense of data and improve patient care. Informatics holds the key to that success.

Moderate Sedation *(e-only)*
Sedation Failures
Emergency Preparedness
Conclusions

Periodontal and implant surgery should be performed painlessly and with minimal or no apprehension. The patient should be assured at the initial consultation. The most reliable means of providing painless surgery is effective administration of local anesthesia. However, patients who are apprehensive may require treatment under mild or moderate sedation. The use of sedation can

help make patients more comfortable during periodontal and implant surgery, especially when the procedure is expected to continue for 2 hours or more. Routes of administration for sedation agents include inhalation, oral, intramuscular, and intravenous. The specific agents and modality of administration are based on the desired level of sedation, anticipated length of the procedure, overall condition of the patient, and training of the clinician and staff. This chapter reviews the rationale, definitions, techniques, and guidelines for the use of mild to moderate conscious sedation in the dental office for periodontal and implant surgical procedures.

Rationale for Sedation During Periodontal and Implant Surgical Procedures

Many patients delay or avoid having needed dental treatment because of fear and anxiety. This avoidance behavior often results in compromised health and quality of life. In a study of 174 patients referred for dental implant therapy, only 40.8% proceeded with therapy, and 24% listed dental fear as the reason for refusing to accept treatment.[33,41] Those who proceeded with therapy had low anxiety ratings as measured by the Modified Dental Anxiety Scale.[33]

Anxiety about dental therapy has not changed significantly during the past 50 years; publications report that about 30% to 50% of patients are at least somewhat fearful of dental procedures.[6,13–15,41,61,70] Evidence suggests that genetic variations are associated with anxiety related to dental care, which could help to explain the consistent avoidance patterns despite improved treatment methods.[7] According to a national survey of the Canadian population, more than 68% of patients would prefer to have sedation or general anesthesia for periodontal surgery[8] (Fig. 38.1). Anxiety reduction that includes moderate sedation is an important part of delivering advanced periodontal services.[1,53,65]

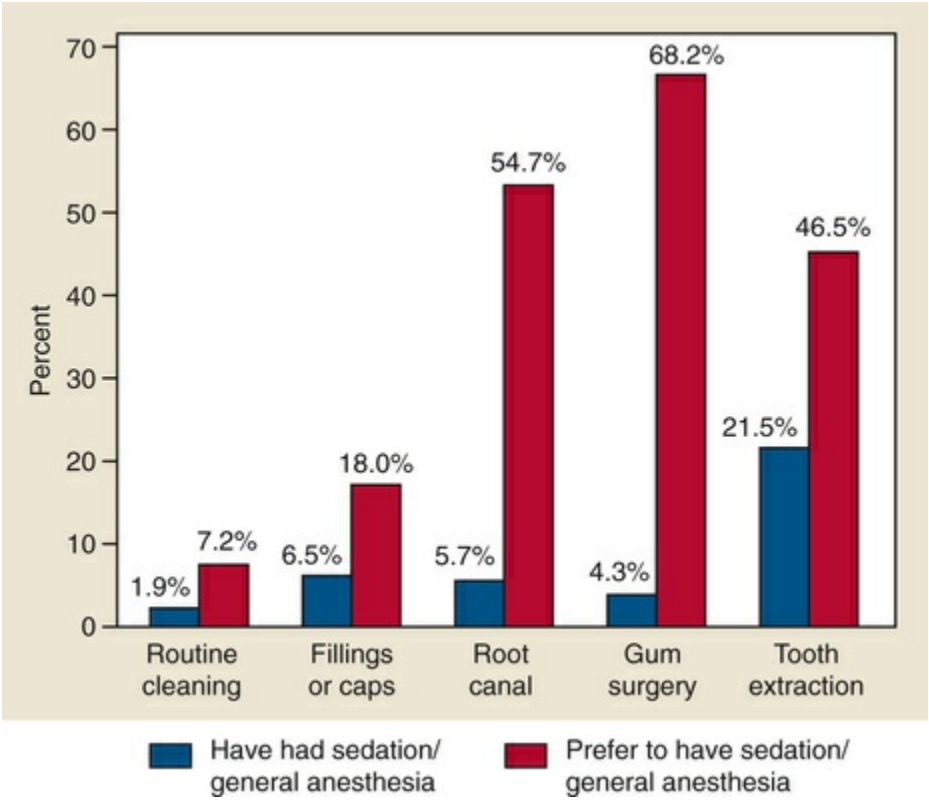

FIG. 38.1 Patient preferences for sedation or general anesthesia by dental procedure. (From Chanpong B, Haas DA, Locker D: Need and demand for sedation or general anesthesia in dentistry: a national survey of the Canadian population, *Anesth Prog* 52:3–11, 2005.)

Because dental anxiety results in avoidance behavior and is associated with more dental and periodontal problems,[19,43,70] it is likely that disproportionate numbers of patients referred to periodontal specialists have dental anxiety. There appears to be a close relationship between anxiety and postoperative pain, and preoperative anxiety can be a predictor of postoperative pain.[22,25] High levels of anxiety (i.e., stress) can affect wound healing after periodontal treatment[37,40,68] (see Chapter 14). Sedation techniques have been effective in reducing physiologic markers of stress.[58] For these reasons, it is important for clinicians who provide advanced periodontal and implant therapy to be knowledgeable and skilled in providing sedation to reduce anxiety in their patients.

American Dental Association Policy Statement and Guidelines for

Conscious Sedation

The American Dental Association (ADA) released three documents related to the use of sedation and general anesthesia in dentistry: the ADA Policy Statement on the Use of Sedation and General Anesthesia by Dentists,[2] the ADA Guidelines for the Use of Sedation and General Anesthesia by Dentists,[3] and the ADA Guidelines for Teaching Pain Control and Sedation to Dentists and Dental Students.[4] The policy statement and guidelines provide educational and practice standards for anxiety control in dental practice. The ADA Committee on Anesthesiology, consisting of representatives from dental organizations involved with sedation and anesthesia, produced these documents after reviewing the relevant scientific evidence, expert opinions, and comments by all communities of interest. The following sections describe the important elements of these documents as they relate to treating anxious periodontal patients.

Use of Sedation and General Anesthesia by Dentists

The dental profession's continued ability to effectively control anxiety and pain depends on a strong educational foundation in the discipline. Training to competency in minimal and moderate sedation techniques may be acquired at the predoctoral, postgraduate, graduate, or continuing education level. Dentists who wish to use minimal or moderate sedation are expected to successfully complete formal training, which is structured in accordance with the ADA Guidelines for Teaching Pain Control and Sedation for Dentists and Dental Students.

The knowledge and skills required for administration of deep sedation and general anesthesia are beyond the scope of predoctoral and continuing education. Only dentists who have completed an advanced education program accredited by the Commission on Dental Accreditation (CODA) that provides training in deep sedation and general anesthesia are considered educationally qualified to use these modalities in practice.

Use of Sedation and General Anesthesia by Dentists

The 2016 ADA guidelines refer to the effects of sedation on the central nervous system and do not depend on the route of administration. The purpose of the guidelines is to assist dentists in the delivery of safe and effective sedation and anesthesia. The ADA adopted the American Society of Anesthesiologists (ASA) definitions for levels of sedation (Fig. 38.2) and expanded and commented on them as they relate to treating adult dental patients.[5]

CONTINUUM OF DEPTH OF SEDATION: DEFINITION OF GENERAL ANESTHESIA AND LEVELS OF SEDATION/ANALGESIA*
Committee of Origin: Quality Management and Departmental Administration (Approved by the ASA House of Delegates on October 13, 1999, and amended on October 27, 2004)

	Minimal Sedation/ Analgesia	Moderate Sedation/ "Conscious Sedation"	Deep Sedation/Anxiolysis	General Anesthesia/ Analgesia
Responsiveness	Normal response to verbal stimulation	Purposeful† response to verbal and tactile stimulation	Purposeful† response following repeated and painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

Minimal Sedation (Anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate Sedation/Analgesia ("Conscious Sedation") is a drug-induced depression of consciousness during which patients respond purposefully† to verbal commands, either alone and accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

Deep Sedation/Analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully† following repeated and painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General Anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Because sedation is a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to rescue†† patients whose level of sedation becomes deeper than initially intended. Individuals administering Moderate Sedation/Analgesia ("Conscious Sedation") should be able to rescue†† patients who enter a state of Deep Sedation/Analgesia, while those administering Deep Sedation/Analgesia should be able to rescue†† patients who enter a state of General Anesthesia.

*Monitored anesthesia care does not describe the continuum of depth of sedation, rather it describes "a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure."
†Reflex withdrawal from a painful stimulus is NOT considered a purposeful response.
††Rescue of a patient from a deeper level of sedation than intended is an intervention by a practitioner proficient in airway management and advanced life support. The qualified practitioner corrects adverse physiologic consequences of the deeper-than-intended level of sedation (such as hypoventilation, hypoxia, or hypotension) and returns the patient to the originally intended level of sedation.

FIG. 38.2 Continuum of depth of sedation: definitions of general anesthesia and levels of sedation or analgesia. The information was approved by the ASA House of Delegates on October 13, 1999, and it was last amended on October 15, 2014. (From American Society of Anesthesiologists: Continuum of depth of sedation: definition of general anesthesia and levels of sedation/analgesia, 2014. http://www.asahq.org/quality-and-practice-

management/standards-guidelines-and-related-resources/continuum-of-depth-of-sedation-definition-of-general-anesthesia-and-levels-of-sedation-analgesia.)

For children, the ADA supports the use of the American Academy of Pediatric Dentistry (AAPD) series of Guidelines for Monitoring and Management of Pediatric Patients During and After Sedation for Diagnostic and Therapeutic Procedures.[11]

Definitions and Levels of Sedation

Pediatric Sedation

The definition of *child* is not discussed in the ADA guidelines but has been defined in other sources. The end of childhood can be defined by age, size, and development.[11,12,20,54] With normal size and development, an individual becomes an adolescent between the ages of 11 and 13 years.[20]

Sedation is often administered to children to control behavior, which often requires deeper levels of sedation. Children can become moderately sedated despite an intended level of minimal sedation. Except in extraordinary situations, the use of preoperative sedatives for children must be avoided because of the risk of unobserved respiratory obstruction during transport by untrained individuals. The management of conscious sedation in children is beyond the scope of this chapter but is addressed by the American Academy of Pediatrics/American Academy of Pediatric Dentists (APA/AAPD) Guidelines for Monitoring and Management of Pediatric Patients During and After Sedation for Diagnostic and Therapeutic Procedures.[11]

Adult Sedation

Minimal Sedation

Minimal sedation is defined as a minimally depressed level of consciousness produced by a pharmacologic method that retains the patient's ability to independently and continuously maintain an airway and respond normally to tactile stimulation and verbal commands. Although cognitive function and coordination can be

modestly impaired, respiratory and cardiovascular functions are unaffected. Minimal sedation can be achieved by the administration of a drug (singly or in divided doses) by the enteral route to achieve the desired clinical effect, not to exceed the maximum recommended dose as printed in U.S. Food and Drug Administration (FDA)–approved labeling for unmonitored home use. The administration of enteral drugs exceeding the FDA-recommended dose during an appointment is considered moderate sedation, and the moderate sedation guidelines apply.

Inhalation sedation with nitrous oxide and oxygen (N_2O/O_2) can be used in combination with a single enteral drug for minimal sedation. When used in combination with one or more sedative agents, N_2O/O_2 can produce sedation that is minimal, moderate, or deep, and in some cases it can produce general anesthesia. If more than one enteral drug is administered to achieve the desired sedation effect, with or without the concomitant use of N_2O, the guidelines for moderate sedation apply.

Maximum Recommended Dose

The *maximum recommended dose* (MRD) is the maximum FDA-recommended dose of a drug as printed in FDA-approved labeling for unmonitored home use.

Key Fact

Minimal sedation is a drug-induced minimally depressed level of consciousness. The ability to independently and continuously maintain an airway and respond to tactile stimulation and verbal commands is maintained. Respiratory and cardiovascular functions are unaffected.

Moderate Sedation

Moderate sedation is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous

ventilations are adequate. Cardiovascular function is usually maintained.

In accord with this definition, the drugs and techniques used should carry a margin of safety wide enough to render unintended loss of consciousness unlikely. Repeated dosing of an agent before the effects of previous dosing can be fully appreciated may result in greater alteration of the state of consciousness than intended by the dentist. A patient whose only response is reflex withdrawal from a painful stimulus is not considered to be in a state of moderate sedation.

Titration

Titration is the administration of incremental doses of an intravenous or inhalation drug until a desired effect is reached. Knowledge about each drug's time of onset, peak response, and duration of action is essential to avoid oversedation. The concept of titration to effect is critical for patient safety, and when the intent is moderate sedation, the clinician must know whether the previous dose has taken full effect before administering an additional drug increment.

Key Fact

Moderate sedation is a drug-induced depression of consciousness. Patients respond purposefully to verbal commands, possibly requiring light tactile stimulation. A patent airway is maintained, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

Deep Sedation

Deep sedation is drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully to repeated or painful stimulation. The ability to independently maintain respiratory function can be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

Key Fact

Deep sedation is a drug-induced depression of consciousness. Patients may not be easily aroused but respond purposefully to repeated or painful stimulation. Respiratory function may be impaired, and assistance may be necessary to maintain a patent airway. Spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General Anesthesia

General anesthesia is drug-induced loss of consciousness during which patients are not aroused, even by painful stimulation. The ability to independently maintain respiratory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function can be impaired.

Clinical Guidelines for Minimal and Moderate Sedation

The following clinical guidelines apply to minimal and moderate sedation[3]: (1) patient evaluation, (2) preoperative preparation, (3) personnel and equipment, (4) monitoring and documentation, and (5) recovery and discharge. Differences between guidelines for minimal and moderate sedation are indicated.

Patient History and Evaluation

The patient's health status is assessed before any sedation procedure. Evaluation includes determination of the ASA physical status (ASA) (Table 38.1). For healthy or medically stable individuals (i.e., ASA 1 or 2), a review of the medical history and medication use may be adequate. For patients with significant medical considerations (i.e., ASA 3 or 4), a consultation with the primary care physician or consulting medical specialist is indicated. The evaluation must include a focused physical examination,

including baseline vital signs and a focused examination of alertness, respiratory function, airway, and appearance, as well as a specific evaluation of identified medical conditions (Box 38.1 and Fig. 38.3). Assessment of body mass index (BMI) should be considered for patients undergoing moderate sedation.

TABLE 38.1

American Society of Anesthesiologists Physical Status Classification System

Class	Definition	Examples
ASA 1	A normal, healthy patient	No disease, nonsmoking, no or minimal alcohol use
ASA 2	A patient with mild systemic disease	Mild conditions or diseases without substantive functional limitations, such as current tobacco use, social drinking, pregnancy, obesity (BMI = 30–40), well-controlled DM or HTN, mild lung disease
ASA 3	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases, such as poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis, premature infant (PCA < 60 wk), history (>3 mo) of MI, CVA, TIA, or CAD/stents
ASA 4	A patient with severe systemic disease that is a constant threat to life	Recent (<3 mo) MI, CVA, TIA, or CAD/stents; ongoing cardiac ischemia or severe valve dysfunction; severe reduction of ejection fraction; sepsis, DIC, or ARD or ESRD not undergoing regularly scheduled dialysis
ASA 5	A moribund patient who is not expected to survive without the operation	Ruptured abdominal or thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the setting of significant cardiac pathology or multiple organ or system dysfunction
ASA 6	A declared brain-dead patient whose organs are being removed for donation purposes	

ARD, Acute renal disease; *BMI*, body mass index; *CAD*, coronary artery disease; *COPD*, chronic obstructive pulmonary disease; *CVA*, cardiovascular accident; *DIC*, disseminated intravascular coagulation; *DM*, diabetes mellitus; *ESRD*, end-stage renal disease; *HTN*, hypertension; *MI*, myocardial infarction; *PCA*, postconceptional age; *TIA*, transient ischemic attack.

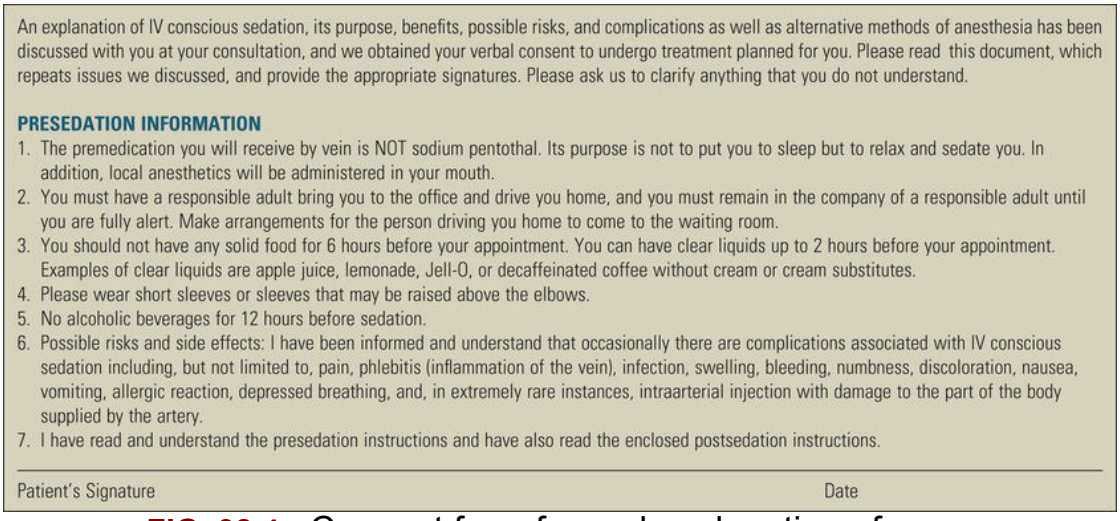
Class 2: soft palate, fauces, portion of uvula
Class 3: soft palate, base of uvula
Class 4: hard palate only

FIG. 38.3 Mallampati classifications used to predict difficult tracheal intubations. (Modified from Mallampati SR, Gatt SP, Gugino LD, et al: A clinical sign to predict difficult tracheal intubation: a prospective study. *Can Anaesth Soc J* 32:429–434, 1985.)

Preoperative Preparation

The patient, or a parent, guardian, or caregiver if the patient is a minor, must be informed about the planned procedure that will occur while under sedation, including benefits, risks, and instructions for sedation (Fig. 38.4). Informed consent for the

proposed procedure and sedation must be obtained.



An explanation of IV conscious sedation, its purpose, benefits, possible risks, and complications as well as alternative methods of anesthesia has been discussed with you at your consultation, and we obtained your verbal consent to undergo treatment planned for you. Please read this document, which repeats issues we discussed, and provide the appropriate signatures. Please ask us to clarify anything that you do not understand.

PRESEDATION INFORMATION

1. The premedication you will receive by vein is NOT sodium pentothal. Its purpose is not to put you to sleep but to relax and sedate you. In addition, local anesthetics will be administered in your mouth.
2. You must have a responsible adult bring you to the office and drive you home, and you must remain in the company of a responsible adult until you are fully alert. Make arrangements for the person driving you home to come to the waiting room.
3. You should not have any solid food for 6 hours before your appointment. You can have clear liquids up to 2 hours before your appointment. Examples of clear liquids are apple juice, lemonade, Jell-O, or decaffeinated coffee without cream or cream substitutes.
4. Please wear short sleeves or sleeves that may be raised above the elbows.
5. No alcoholic beverages for 12 hours before sedation.
6. Possible risks and side effects: I have been informed and understand that occasionally there are complications associated with IV conscious sedation including, but not limited to, pain, phlebitis (inflammation of the vein), infection, swelling, bleeding, numbness, discoloration, nausea, vomiting, allergic reaction, depressed breathing, and, in extremely rare instances, intraarterial injection with damage to the part of the body supplied by the artery.
7. I have read and understand the presedation instructions and have also read the enclosed postsedation instructions.

Patient's Signature Date

FIG. 38.4 Consent form for and explanation of intravenous conscious sedation.

Determination of an adequate oxygen supply and the equipment necessary to deliver oxygen under positive pressure must be completed. Baseline vital signs, including weight, height, blood pressure, pulse rate, and respiration rate, must be obtained. For moderate-sedation patients, blood oxygen saturation must be obtained by pulse oximetry. Body temperature should be measured when clinically indicated. Preoperative verbal or written instructions must be given to the patient, parent, escort, legal guardian, or caregiver. For moderate sedation, this includes preoperative fasting instructions based on the ASA summary of fasting and pharmacologic recommendations.

Preoperative dietary restrictions are based on the sedation technique prescribed (Boxes 38.2 and 38.3). For moderate sedation, NPO (nothing by mouth) status should be confirmed.

Box 38.2

Mild Sedation: Protocol for the Use of Adult Oral Sedative Premedication for Anxious or Fearful Dental Patients

1. The dentist determines the extent of dental treatment, evaluates the patient's medical history, researches potential drug interactions, consults with the patient's physician if appropriate, and obtains informed consent.
2. The patient must have a responsible adult companion for travel to and from the dental office. The patient must be escorted by this companion to and from the parking lot to prevent stumbling.
3. The patient should take the prescribed medication according to directions and is instructed to have a light meal such as toast and a beverage without caffeine.
4. A patient who has received oral sedative is monitored visually and never left alone.
5. After treatment is complete, postoperative directions are given to the patient and a responsible adult, and the patient is released into the care of his or her companion for travel home. The companion is informed that the patient may have psychomotor and cognitive impairment for the rest of the day.

From Merin RL: Adult oral sedation in California: what can a dentist do without a special permit or certificate from the Dental Board of California? *J Calif Dent Assoc* 34:959–968, 2006.

Box 38.3

Mild Sedation: Suggested Patient Pretreatment Instructions

1. The sedative _____ (name of medication) is being prescribed to help reduce your anxiety before and during your dental procedure.
2. The medication may make you sleepy and impair your thinking and coordination. You must have a responsible adult companion for travel to and from the dental office.
3. You must be escorted by this companion to and from the parking lot to prevent stumbling.
4. You should take the prescribed medication according to

directions. You can have a light meal (no fat) such as toast without butter or margarine and a beverage without caffeine. No grapefruit juice is allowed.

5. After the treatment is complete, a responsible adult must escort you out of the office and take you home. Because the sedative effects may linger for the rest of the day, you should not plan to do anything, and it is advisable to have a responsible adult stay until you are able to take care of yourself.

From Merin RL: Adult oral sedation in California: what can a dentist do without a special permit or certificate from the Dental Board of California? *J Calif Dent Assoc* 34:959–968, 2006.

Personnel and Equipment

At least one person trained in basic life support (BLS) for health care providers must be present in addition to the dentist. Monitoring equipment includes a sphygmomanometer, positive-pressure oxygen delivery system, suction, and, if inhalation sedation is used, a fail-safe and scavenging system. In the case of moderate sedation, a pulse oximeter, equipment for monitoring end-tidal carbon dioxide (CO_2), a precordial or pretracheal stethoscope, equipment for intravenous or intraosseous access, and reversal agents for drugs used must be available (Table 38.2).

TABLE 38.2

Equipment Required for Mild or Moderate Sedation

Mild or Moderate Sedation	Moderate Sedation
Sphygmomanometer	Pulse oximeter
Positive-pressure oxygen delivery system	Equipment for establishing intravenous access
Suction equipment	Reversal agents for drugs used
Inhalation equipment with a fail-safe system and scavenging system	End-tidal CO_2 monitor (i.e., capnography)

A positive-pressure oxygen delivery system suitable for the patient being treated must be immediately available. Documentation of compliance with the manufacturer's recommended maintenance of monitors, anesthesia delivery

systems, and other anesthesia-related equipment should be maintained. A preprocedural check of equipment and a preoperative review of the patient's records and physical status are performed immediately before each administration of sedation (Box 38.4). When inhalation equipment is used, it must have a fail-safe system that is appropriately checked and calibrated. The equipment must also have a functioning device that prohibits the delivery of less than 30% oxygen or an appropriately calibrated and functioning in-line oxygen analyzer with an audible alarm. An appropriate scavenging system must be available if gases other than oxygen or air are used.

Box 38.4

Safety Checklist for Office-Based Sedation

Check Before Patient Is Brought to the Procedure Room

1. Ensure functional monitors
    - Pulse oximeter
    - Capnograph
    - Blood pressure monitor
    - Printer
    - Bluetooth pretracheal stethoscope
    - Electrocardiograph if required
2. Oxygen source and delivery
3. Dinitrogen dioxide (N_2O) scavenger and fail-safe system
4. Suction functioning
5. Emergency equipment and medications
    - Positive-pressure oxygen delivery system
    - Airway adjuncts
    - Laryngeal suction device
    - Reversal agents
    - Emergency medications
6. Fire hazard precautions with oxygen if laser, electrosurgery, flame sources, or burs and drills are used
7. Necessary instruments and devices for procedure

Preoperative Encounter With the Patient

1. Sedation record available
2. Correct patient chart
3. Recent radiographs
4. Correct procedure listed
5. Informed consent signed
6. Review of medical history, including allergies, adverse drug reactions, and changes in health
7. Medications taken
8. American Society of Anesthesiologists (ASA) score, Mallampati classification
9. NPO status (no oral intake)
10. Name of responsible adult escort
11. Preoperative vital signs

For moderate sedation, the equipment necessary to establish intravascular or intraosseous access should be available until the patient meets the discharge criteria. This includes a catheter or butterfly needle, an intravenous drip line, a solution bag (i.e., saline or dextrose), a tourniquet, and appropriate antiseptic or dermal disinfectant (Fig. 38.5). For moderate sedation, the equipment necessary for monitoring end-tidal CO_2 and auscultation of breath sounds must be immediately available.

(A) A tourniquet, indwelling catheter, appropriate antiseptic or dermal disinfectant wipes, tape, and adhesive bandage. (B) An IV line with drip chamber and administration ports. (C) Saline solution. (D) A tourniquet is placed proximal to the antecubital fossa, and veins are visualized and palpated. (E) The skin is prepared with an antiseptic wipe. (F) The indwelling catheter is directed toward a vein with the bevel of the needle facing up. (G) The**

needle with catheter is advanced into the vein (notice the blood flashback). (H) The catheter is advanced, and the needle is removed. (I) The IV line is connected, the tourniquet is removed, and the IV line is opened to check fluid flow and then secured with tape.

Monitoring

For minimal sedation, a dentist or, at the dentist's direction, an appropriately trained individual must remain in the operating room during active dental treatment to monitor the patient continuously until he or she meets the criteria for discharge to the recovery area. The appropriately trained individual must be familiar with monitoring techniques and equipment.

In the case of moderate sedation, a dentist administering moderate sedation must remain in the room to monitor the patient continuously until he or she meets the criteria for recovery. When active treatment concludes and the patient recovers to a minimally sedated level, a qualified auxiliary may be directed by the dentist to remain with the patient and continue to monitor him or her as explained in the guidelines until discharged from the facility. The dentist must not leave the facility until the patient meets the criteria for discharge and is discharged to go home with a responsible adult (Box 38.5).

Box 38.5

Discharge Criteria

Alertness: patient able to answer three simple questions
- Who is driving you home?
- Where are you?
- What day is it?

Breathing
- Normal oxygen saturation on room air
- Able to breathe deeply and cough

Circulation
- Systolic blood pressure within 20% of baseline

Ambulation

	Able to walk with minimal assistance
Color	
	Normal skin color and appearance

Key Fact

For moderate sedation, a dentist administering moderate sedation must remain in the operation room to monitor the patient continuously until he or she meets the criteria for recovery. When the patient recovers to a minimally sedated level, a qualified auxiliary person may be directed by the dentist to remain and monitor the patient until he or she meets the criteria for discharge. The dentist must not leave the facility until the patient meets the criteria for discharge and is discharged to home with a responsible adult.

Vital signs, level of sedation, and oxygen perfusion must be continuously monitored throughout the conscious sedation procedure. There are many methods of monitoring.

Circulation

For minimal sedation, blood pressure and heart rate should be evaluated preoperatively, postoperatively, and intraoperatively as necessary. For moderate sedation, the dentist must continually evaluate blood pressure and heart rate unless invalidated by the nature of the patient, procedure, or equipment, and this information is noted in the time-oriented anesthesia record. Continuous electrocardiographic monitoring should be considered for patients with significant cardiovascular disease. All-in-one monitors with printers can efficiently perform these functions.

Consciousness

The level of consciousness or sedation (e.g., responsiveness to verbal command) must be continually assessed. In 1990, Chernik and colleagues[8a] developed the Observer's Assessment of Alertness/Sedation Scale (Table 38.3), which has been used in many studies to evaluate the degree of alertness of patients undergoing

sedation. The method developed by Dr. Katherine Wilson and coworkers in 2011 at the Newcastle University School of Dental Sciences is also an efficient method for assessing the level of sedation.[71]

TABLE 38.3
Observer's Assessment of the Alertness/Sedation Scale

Category	Observation	Score[a]
Responsiveness	Responds readily to name spoken in normal tone	5
	Lethargic response to name spoken in normal tone	4
	Responds only after name is called loudly and/or repeatedly	3
	Responds only after mild prodding or shaking	2
	Does not respond to mild prodding or shaking	1
Speech	Normal	5
	Mild slowing or thickening	4
	Slurring or prominent slowing	3
	Few recognizable words	2
Facial expression	Normal	5
	Mild relaxation	4
	Marked relaxation (slack jaw)	3
Eyes	Clear, no ptosis	5
	Glazed or mild ptosis (less than half of the eye)	4
	Glazed and marked ptosis (half of the eye or more)	3

[a]This scored is used to evaluate the level of sedation.

Modified from Chernik DA, Gillings D, Laine H, et al: Validity and reliability of the Observer's Assessment of Alertness/Sedation Scale: study with intravenous midazolam, *J Clin Psychopharmacol* 10:244–251, 1990.

Ventilation and Oxygenation

For minimal sedation, the dentist or appropriately trained individual must observe chest movements and verify respirations. Oxygen saturation by pulse oximetry may be clinically useful and should be considered. For moderate sedation, the dentist must observe chest movements continuously, and oxygen saturation must be evaluated continuously by pulse oximetry. Ventilation or breathing can also be assessed by monitoring end-tidal CO_2 (i.e., capnography). Ventilation should be monitored by continual observation of qualitative signs, including auscultation of breath sounds with a precordial or pretracheal stethoscope.

The color of the mucosa, skin, or blood must be evaluated continuously to assess oxygenation. Oxygen saturation by pulse

oximetry is clinically useful and should be considered for minimal sedation. For moderate sedation, oxygen saturation must be continuously evaluated by pulse oximetry. Approximately 98% to 99% of the total oxygen content in arterial blood is bound to hemoglobin in red blood cells. The pulse oximeter measures the degree to which hemoglobin is saturated with oxygen (SpO_2). The remaining 1% to 2% of oxygen is dissolved in plasma and produces a gas pressure referred to as arterial oxygen tension (PaO_2). The PaO_2 level is what determines how much oxygen is entering the body tissues and is referred to as *oxygenation*. Normally, the SpO_2 level is at 98% to 99% and sustains a PaO_2 level of about 95%. Normal oxygenation is defined as a PaO_2 of 80 to 100 mm Hg. There is a nonlinear relationship between SpO_2 and PaO_2. SpO_2 readings of 95% and higher maintain PaO_2 at or above 80 mm Hg and prevent hypoxemia (Table 38.4).

TABLE 38.4

Arterial Oxyhemoglobin Saturation and Oxygen Tension Values for Monitoring Tissue Oxygenation

Oximeter Arterial Oxyhemoglobin Saturation (Spo_2)	Arterial Oxygen Tension (Pao_2)	Interpretation
95%–99%	80–100 mm Hg	Normal oxygenation
90%	60 mm Hg	Alarm goes off; patient is hypoxemic
80%	45–50 mm Hg	Severe hypoxemia

Capnography

Adequate ventilation and respiration can be monitored by assessing end-tidal CO_2 using capnography. This method monitors CO_2 concentrations in exhaled respiratory gases. A capnography monitor provides a graphic representation of the partial pressure of CO_2 and is more effective than other clinical assessments of ventilation.[62] A report of a randomized controlled clinical trial of patients undergoing moderate sedation demonstrated that capnography improved patient monitoring, with earlier detection of respiratory compromise prompting intervention to minimize

hypoxemia compared with other care methods.[42]

Clinical Correlation

A capnography monitor provides a measure of exhaled CO_2 that is more effective than pulse oximetry. It provides an immediate alarm for life-threatening breathing problems during moderate sedation. Pulse oximeters, which have been the standard of care, take much longer to register respiratory distress because oxygen levels in the blood can remain normal for several minutes after a patient stops breathing. Capnography provides earlier detection.

Documentation

An appropriate, time-oriented anesthetic record (Fig. 38.6) must be maintained with the names of all administered drugs (including local anesthetics) along with dosages, times administered, and routes of administration. Physiologic parameters, including heart rate, respiratory rate, blood pressure, and level of consciousness, must be recorded. For moderate sedation, oxygen saturation (i.e., pulse oximetry) must be monitored and recorded continually. The anesthesia record should also include BMI, Mallampati classification, and capnography information.

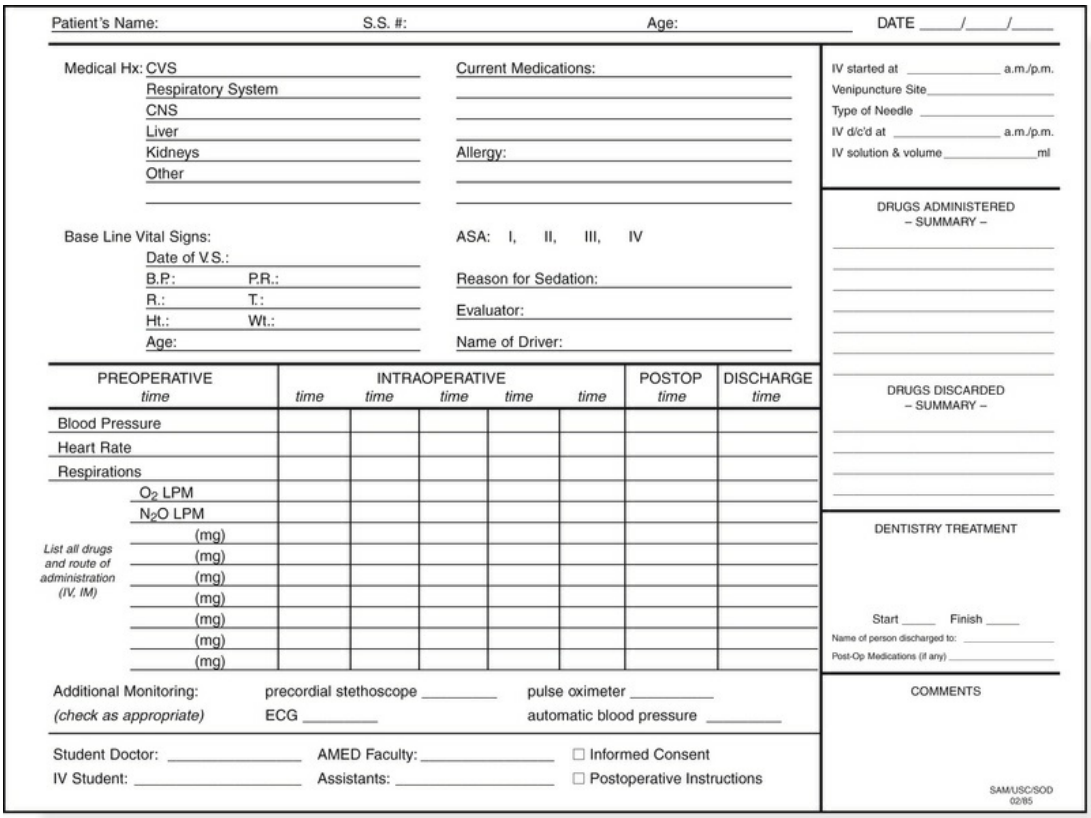

FIG. 38.6 Example of a moderate sedation record. (From Malamed SF: *Sedation: a guide to patient management,* 5th ed, St. Louis, 2010, Elsevier.)

Recovery and Discharge

Oxygen and suction equipment must be immediately available in the treatment room and the recovery room (if a separate recovery area is used). The qualified dentist or appropriately trained clinical staff must continually monitor the patient's blood pressure, heart rate, and respiration. In cases of moderate sedation, oxygen saturation and level of consciousness must be evaluated continuously. The qualified dentist must determine and document that the levels of consciousness, oxygenation, ventilation, and circulation are satisfactory before discharge (see Box 38.5). Postoperative verbal and written instruction must be given to the patient and a responsible adult (e.g., parent, escort, guardian, or caregiver).

If a reversal agent is administered before discharge criteria have been met, the patient must be monitored until recovery is ensured. A potential problem when using reversal agents is the possibility

that the duration of action of the reversal agent can be shorter than the sedative agent used, and the patient can become sedated again. It is critical for the clinician to understand and appreciate the duration of action of all sedative and reversal agents used.

Minimal Sedation and Anxiolysis

Oral Sedation

Oral sedation can help reduce anesthetic failures and decrease anxiety in a large percentage of dental patients.[21,51] Oral premedication is cost-effective, has few complications, and requires minimal monitoring when correct doses are used.[14,15,55,59] Most states do not require special permits for dentists who are prescribing sedatives to achieve mild sedation or anxiolysis in adults. Because state laws vary, dentists need to check with their dental board.

Minimal sedation dosages are defined as less than or equal to the single MRD that can be prescribed for home use. MRDs can be found in references such as https://dailymed.nlm.nih.gov, package inserts, pharmaceutical websites, articles in the dental literature,[55] and frequently updated sources such as Lexicomp Online for Dentistry (http://webstore.lexi.com).

The use of oral sedation premedication is an art and a science. It is wise for dentists to become familiar with a small number of oral sedative regimens, which ensures a better chance of accurately predicting the correct dose for each patient and understanding the precautions and side effects of each agent.

Although there are a large number of oral sedative agents available by prescription, dental articles have concentrated on the use of zaleplon, diazepam, triazolam, and lorazepam.[17,23,24,28,29,59,73] Although diazepam has been recommended for dental anxiety in several sources,[9,36,59,72] its duration of action is 6 to 8 hours. It has a primary half-life of 20 to 80 hours and a 40- to 120-hour half-life for active secondary metabolites. Two head-to-head comparisons of diazepam and triazolam found triazolam to be a more effective anxiolytic agent.[18,50] The remainder of this section discusses guidelines and protocols for the use of zaleplon, triazolam, and lorazepam..

Zaleplon is a short-acting hypnotic in the pyrazolopyrimidine class. Its onset of action is usually within 30 minutes, and it is rapidly eliminated, with a half-life of approximately 1 hour. Zaleplon is a relatively new agent, and there are few articles on its use in dentistry. Triazolam and lorazepam are benzodiazepines, and the main difference is the effective time of sedation. The duration of action of triazolam is 2 to 4 hours, compared with 4 to 8 hours for lorazepam (eTable 38.1). The dentist should carefully review the patient's medical history to rule out contraindications to these medications before the treatment appointment.

eTABLE 38.1
Comparison of Zaleplon, Triazolam, and Lorazepam

Characteristic	Zaleplon	Triazolam	Lorazepam
Available dosages	5- and 10-mg capsules	0.125- and 0.25-mg tablets	0.5-, 1-, and 2-mg tablets
Onset of hypnotic effect	15–30 min	30 min	30–60 min
Peak plasma concentration	1 hr	<2 hr	1–6 hr
Duration of action	1 hr	2–4 hr	4–8 hr
Mean half-life	1 hr	2–5 hours	12–16 hr

Data from Donaldson M, Goodchild JH: Maximum cumulative doses of sedation medications for in-office use. *Gen Dent* 55:143–148; quiz 149, 167–48, 2007; Ganzberg SI, Dietrich T, Valerin M, et al: Zaleplon (Sonata) oral sedation for outpatient third molar extraction surgery. *Anesth Prog* 52:128–131, 2005; Goodchild JH, Donaldson M: Calculating and justifying total anxiolytic doses of medications for in-office use. *Gen Dent* 54:54–57; quiz 58, 2006; Wynn RL, Meiller TF, Crossley HI: *Drug information handbook for dentistry,* Hudson, OH, 2009, Lexi-Comp.

Suggested patient pretreatment instructions are provided in Box 38.3. Patients must understand that they will need a responsible adult to escort them home when they take a sedative medication. *Patients who are not reliable about following directions are not good candidates for oral sedative premedication.*

Guidelines for Minimal Sedation With Oral Medications

This section provides guidelines for the mild sedation and anxiolytic doses of these medications, but these recommendations should not be a substitute for good clinical judgment and direct patient assessment. Patient factors such as diminished liver enzyme function, extremes of age, and drug tolerance as the result of past

drug use can alter the proposed protocol. Precautions and drug interactions for zaleplon, triazolam, and lorazepam are presented in eBoxes 38.1, 38.2, and 38.3, respectively.

eBOX 38.1

Zaleplon Precautions and Drug Interactions[a]

- Relative and absolute contraindications: pregnancy, liver impairment, severe renal disease, respiratory disease, mental depression, pediatric patients
- Drug interactions that may increase effects: imipramine, thioridazine, cimetidine, erythromycin, ketoconazole, other central nervous system depressants
- Drug interactions that may decrease effects: hepatic cytochrome P450 enzyme inducers such as carbamazepine, phenobarbital, phenytoin, rifampin
- Foods and supplements that may increase effects: alcohol, valerian, kava, gotu kola
- Foods and supplements that may decrease effects: St. John's wort, caffeine; a high-fat or heavy meal can reduce peak blood levels by 35% and time to peak plasma levels by 2 hours

[a]For this relatively new drug, many potential drug interactions have not been studied.

eBOX 38.2

Triazolam Precautions and Drug Interactions

- Relative and absolute contraindications: acute narrow-angle glaucoma; uncorrected open-angle glaucoma; myasthenia gravis; respiratory diseases, including severe sleep apnea and

severe chronic obstructive pulmonary disease; pregnancy; lactation; severe liver impairment; renal impairment; pediatric patients; mental depression; hypersensitivity to this drug or other benzodiazepines

- Drug interactions that may increase effects: other central nervous system depressants, isoniazid, oral contraceptives, ranitidine, CYP3A4 inhibitors such as macrolide antibiotics (e.g., erythromycin, clarithromycin), azole antifungals, doxycycline, some calcium channel blockers
- Drug interactions that may decrease effects: theophylline, CYP3A4 inducers such as aminoglutethimide, carbamazepine, nafcillin, nevirapine, phenobarbital, phenytoin, and rifamycins
- Foods and supplements that may increase effects: grapefruit juice, alcohol, kava, gotu kola, starfruit, melatonin, valerian, chamomile
- Foods and supplements that may decrease effects: St. John's wort, caffeine

eBOX 38.3

Lorazepam Precautions and Drug Interactions

- Relative and absolute contraindications: acute narrow-angle glaucoma; uncorrected open-angle glaucoma; myasthenia gravis; respiratory diseases, including severe sleep apnea and severe chronic obstructive pulmonary disease; pregnancy; lactation; severe liver impairment; renal impairment; pediatric patients; mental depression, hypersensitivity to this drug or other benzodiazepines
- Drug interactions that may increase effects: other central nervous system depressants, probenecid (used for gout); drugs that inhibit the oxidative metabolism of triazolam are less likely to affect lorazepam, which undergoes direct glucuronide conjugation
- Drug interactions that may decrease effects: theophylline;

drugs that induce the oxidative metabolism of triazolam are less likely to affect lorazepam, which undergoes direct glucuronide conjugation

- Foods and supplements that may increase effects: alcohol, valerian, St. John's wort, kava, gotu kola
- Foods that may decrease the effect: caffeine

If the calculated amount of medication is ineffective, the dentist can choose to terminate the dental appointment or continue if the patient is willing. If the patient's anxiety is not sufficiently diminished, the dentist must follow all normal dismissal procedures, including releasing the patient to a responsible adult because the sedative agent may impair motor activity even when not relieving dental anxiety. A failure to produce anxiolysis may require changing future prescriptions, using the services of a dental anesthesiologist in the office, or referring the patient to an office that provides moderate (conscious) sedation or general anesthesia.

Anxiolytic dosing guidelines for zaleplon, triazolam, and lorazepam are given in eTable 38.2. A review of the dental literature suggests a maximum dose of 0.625 mg of triazolam or 2.5 mg of lorazepam for anxiolysis.[29] However, individual tolerance and responses vary, and maximum and average doses are not appropriate for all patients. It is necessary to adjust dosages according to weight, age, health status, and other prescribed medications, taking into account the patient's previous experience with sedative agents. The literature shows that age-related changes can impair benzodiazepine metabolism, and the maximum anxiolytic dose for elderly patients should be reduced by 50% for triazolam and 30% to 50% for lorazepam.[30] The opposite is true for younger adult patients (<40 years of age), who may need a 25% increase in their weight-related anxiolytic dose. Sample prescriptions for zaleplon, triazolam, and lorazepam are presented in eFigs. 38.1, 38.2, and 38.3, respectively.

eTABLE 38.2

Total Anxiolytic Dosing Guidelines for Zaleplon, Triazolam, and Lorazepam

Characteristic	Zaleplon[a]	Triazolam[b]	Lorazepam[c]
Weight (lb):	Age 41–64 yr	Age 41–64 yr	Age 41–64 yr
<100	5 mg	0.250 mg	1.0 mg
150	10 mg	0.375 mg	1.5 mg
200+	10–15 mg	0.500 mg	2.0 mg
Notes	Elderly and debilitated patients are more sensitive to hypnotics; recommended dose for these patients is 5 mg. Doses >10 mg in elderly and debilitated patients are not recommended. Maximum dose in package insert is 20 mg for sleep.	Dose for debilitated or elderly patients should be reduced by 50%. Doses for healthy adults <40 yr can be increased by 25%. With sublingual administration, systemic availability is approximately 27% higher than for the same dose taken by the conventional oral route. Maximum single dose listed in the package insert is 0.5 mg for sleep.	Dose for debilitated or elderly patients should be reduced by 30%–50%. Doses for healthy adults <40 yr can be increased by 25%. Maximum single dose listed in the package insert is 4.0 mg.

When using a very short-acting agent such as zaleplon, there is a risk that recovery of psychomotor functions may take longer than 1 hour after the onset of action despite the reported duration of action. When using triazolam in anxiolytic doses (usually higher than the hypnotic dose), there is a risk that full recovery to a normal state of consciousness may take longer than 4 hours. Ganzberg and colleagues found that 28.5% of zaleplon-sedated patients and 78.5% of triazolam-sedated patients thought that the sedation effects

lingered for the rest of the day.[28] Consequently, zaleplon and triazolam patients must be accompanied by a responsible adult and not resume normal activities for the remainder of the day.

The opposite problem can occur when using short-acting sedative agents. The sedation effects of the short-acting agents can wear off quickly. For this reason, the dentist must prevent delays or interruptions so that treatment can be completed in a timely manner. If the procedure is expected to last longer than 2 hours, it may be best to use a longer-acting agent such as lorazepam.

Inhalation Sedation

This section provides a general description of the N_2O technique. To be competent in N_2O sedation, the ADA recommends a minimum course of 14 hours, including a clinical component.[4]

In 1844, Dr. Horace Wells of Hartford, Connecticut, was the first to recognize and introduce the use of N_2O as an analgesic-sedative agent for performing dental surgical procedures. Since that time, use of N_2O has accrued a long safety record in numerous dental procedures. Advantages of N_2O are rapid onset of action and rapid recovery. There are few contraindications (e.g., chronic obstructive pulmonary disease, severe emotional disturbance, early pregnancy). Obstacles to the use of N_2O include the initial cost of equipment, the need for effective scavenging equipment, periodic maintenance, and the concern that long-term exposure to trace amounts of N_2O can be hazardous to dental personnel.

N_2O/O_2 inhalation sedation is divided into three phases.[46] The technique begins with an induction phase, which leads to a treatment phase and ends with a recovery phase.

Induction Phase

1. A flow rate of 100% oxygen is started, and a nasal hood is placed on the patient and adjusted.
2. The correct flow rate is established while the patient is breathing 100% oxygen.
3. The scavenging system is adjusted and checked for function.

4. The N_2O flow is started, usually at 20%, and titrated in 10% increments every 60 seconds until the patient states that he or she feels relaxed and displays the signs of relaxation.

Treatment Phase

1. After the ideal level of sedation is achieved, local anesthetic can be given and the dental procedure can be started.
2. The flow of N_2O can be reduced when the patient is comfortable with the procedure or increased if more local anesthetic is required (and the patient has not been given any other sedative).

Recovery Phase

1. When the patient no longer requires sedation, the N_2O flow is terminated and the patient is given 100% oxygen for 5 minutes or until he or she is recovered from the sedation.
2. The patient can leave the office unescorted if he or she is completely recovered from the sedative effects of the N_2O.

Moderate Sedation

The ADA recognizes that moderate sedation requires more training and knowledge than minimal sedation and recommends that moderate sedation providers of moderate sedation have current certification in BLS for health care providers and advanced cardiac life support (ACLS) or appropriate training in a dental sedation and anesthesia emergency management course on the same recertification cycle that is required for ACLS.[3] Guidelines for course content and adult case experiences recommended for teaching moderate sedation are summarized in eBox 38.4.

eBOX 38.4

2016 American Dental Association

Guidelines for Teaching Moderate Enteral and Moderate Parental Sedation

The course must include the following:

1. Minimum of 60 hours of instruction plus administration of sedation for at least 20 individually managed patients
2. Certification of competence in moderate sedation techniques
3. Certification of competence in rescuing patients from a deeper level of sedation than intended, including managing the airway, intravascular or intraosseous access, and reversal medications
4. Provision of a course director or faculty of additional clinical experience if participant competency has not been achieved in time allotted
5. Records of instruction and clinical experiences (i.e., number of patients managed by each participant in each modality or route) that are maintained and available for participant review

Before performing any moderate sedation technique, practitioners must satisfy all state laws and regulations for the provision of this service. The following discussion is meant to be an overview of some of the popular moderate sedation techniques used to treat periodontal and implant patients. Practitioners must follow the clinical and educational guidelines previously presented in this chapter.

Oral Moderate Sedation

Most medications available for moderate enteral sedation are used in an off-label manner and have no determined MRD for that purpose.[17] The most frequently used agent is triazolam. A typical regimen includes a dose of triazolam 1 hour before a dental appointment, followed by an incremental dose to achieve an adequate level of sedation.[17] Because it takes 30 to 90 minutes to reach maximum serum levels, dentists cannot accurately titrate sedation levels with oral or sublingual administration. Donaldson and Goodchild calculated 24-hour maximum cumulative doses

(MCDs) for triazolam to be 2.0 mg for a young healthy 200-pound patient.[17] This dosage needs to be adjusted for patients by weight and health status. For healthy ASA PS 1 patients, the weight is divided by 100 to calculate the MCD of triazolam.

In a study of the effects of multidose sublingual triazolam in 10 healthy volunteers, subjects were given 0.25 mg, followed by additional doses after 60 minutes (0.5 mg) and 90 minutes (0.25 mg), for a total dose of 1.0 mg. Plasma concentrations of triazolam, sedation scores, and bispectral index scores were greatest at the end of the 3-hour observation period.[35] Although all subjects maintained a patent airway independently, eight had Observer's Assessment of Alertness/Sedation scores (see Table 38.3) consistent with the definition of deep sedation or general anesthesia. Incremental dosing of this short-acting benzodiazepine results in long-lasting sedation, which is dose-dependent.

The sedation produced by supplemental dosing of triazolam cannot be reversed by a single submucosal injection of the reversal agent, flumazenil.[32] Supplemental doses should follow an observation period sufficient to assess the drug's effects, and the decision to administer additional doses of oral sedatives should be based on direct patient observation.

Combined Oral and Inhalation Sedation

Combining oral benzodiazepines with N_2O/O_2 inhalation in human and animal studies produced safe and effective sedation.[31,34,38,66] The technique is to prescribe a minimal sedation dose of an appropriate benzodiazepine and then titrate N_2O/O_2 to the appropriate level of moderate sedation. Most published studies used triazolam as the sedative agent.

N_2O/O_2, when used in combination with sedative agents, can produce sedation that is minimal, moderate, or deep, and in some cases, it can produce general anesthesia. Patients should be monitored carefully to avoid going beyond the intended level of sedation.

Intravenous Sedation

There are differences in the moderate intravenous sedation protocols taught in dental specialty programs, even at the same university,[57] but the goal is the same. The desired endpoint of intravenous sedation is drowsiness, tranquility, and loss of anxiety. The classic sign of drooping eyelids can represent unnecessarily deep sedation.[60] The correct level of sedation is achieved when the patient rests with his or her eyes closed, responds to verbal commands or mild physical stimulation, and shows signs of relaxation.

Single Benzodiazepine Intravenous Sedation Techniques

Midazolam Technique

An initial test dose of 0.2 mg is given, and then midazolam is titrated at a rate of 0.5 mg per minute until the desired level of sedation is achieved.[16,63] The effective loading dose (ELD) is defined as the dose required to reach the level of moderate sedation. Additional intravenous midazolam can be administered as needed during the surgical procedure up to a maximum dose of 10 mg (eTable 38.3). In a study of 401 patients given midazolam at a faster rate of 1 mg/min, there was a 3% complication rate, with 11 minor complications (e.g., fainting, respiratory depression) not requiring a reversal agent and one moderate complication (i.e., oversedation), which required reversal with flumazenil.[71]

eTABLE 38.3

Intravenous Midazolam and Diazepam

Characteristic	Midazolam	Diazepam
Average dose, periodontal patients[63]	3.3 mg	12.1 mg
Average dose, dental patients[47,71]	2.5–7.6 mg	10 mg
Maximum dose	10 mg	20 mg
Duration of action	20–45 min	30–60 min
Half-life	1.7-2.4 hr	31.3 hr
Active metabolites	No	Yes
Anterograde amnesia	Good	Fair
Ease of titration	Good	Very good
Recovery	Abrupt	Slow/smoother
Phlebitis potential	Minimal/water soluble	High/not water soluble

Diazepam Technique

An initial test dose of 1.0 mg is given to determine whether there is unusual drug sensitivity, and then diazepam is titrated at a rate of 2.5 mg/min until the desired level of sedation is achieved.[46,63] Additional intravenous diazepam can be administered as needed during the surgical procedure up to a maximum of 20 mg (see eTable 38.3).

Combination Intravenous Sedation

When little clinical effect is produced with the usual maximum safe dose of a single sedative agent, further administration of the same drug is unlikely to provide acceptable sedation until an extremely large dose is given.[67,69] To help prevent sedation failure, combination techniques are required. Administration of two or more sedative agents increases the likelihood of drug synergism and reduces the dose required to render 50% of patients unconscious (ED_{50}).

When using a combination technique, the clinician must carefully monitor the patient for increased depth of sedation beyond that which is desired and be prepared to stop the periodontal procedure until the patient is returned to the appropriate level of sedation. Opioids are frequently combined with benzodiazepines to produce analgesia, drowsiness, changes in mood, and mental clouding. All opioids produce dose-related respiratory depression, which is a major factor in morbidity and mortality related to intravenous sedation.

Meperidine Combined With Diazepam or Midazolam

The benzodiazepine is titrated in the usual manner until the desired (minimal to moderate) sedation is produced. A small test dose of meperidine is given initially to see whether there is an unusual reaction. Meperidine is titrated at a rate of 5 mg/min until moderate sedation is produced (up to a maximum dose of 50 mg). The dose can be estimated on the basis of the effective loading dose of the benzodiazepine given. The clinical effects of meperidine are exhibited 2 to 4 minutes after intravenous administration, which may lead to excessive sedation if administered too rapidly.[46] For

this reason, all narcotics should be administered slowly when the goal is moderate sedation to avoid deep sedation or general anesthesia. The rate of administration determines the initial depth of anesthesia.

Fentanyl Combined With Midazolam

Fentanyl is a rapid-onset, short-acting opioid agonist. After intravenous administration, the onset of analgesia and sedation occurs in less than 1 minute, although the maximum analgesic and respiratory depressant effects do not develop for several minutes. The respiratory depressant effects of fentanyl last longer than its analgesic and sedative properties, and this can be a problem for patients dismissed from the office.[45] Fentanyl techniques usually recommend that fentanyl be administered before midazolam.[16,63]

Fentanyl is administered first in a fixed dose of 0.001 mg/kg by slow intravenous infusion over 2 minutes.[46] The time between injection and clinical effect is the lead time for that patient. Later in the procedure, knowledge of the lead time is useful in timing the administration of subsequent doses. Midazolam is then administered at a rate of 0.5 mg/min until the appropriate level of sedation is produced.[46]

Combined Oral and Intravenous Sedation

The dental literature has five reports of combining oral and intravenous sedation or general anesthesia in dental patients.[44,48,49,64] All of the studies found that oral sedation reduced preoperative anxiety and improved overall patient comfort.

Patients are prescribed a minimal sedation dose of lorazepam (described earlier) to be taken at home. As patients walk into the procedure room, they are assessed in terms of how sedated they are from the oral lorazepam, which is interpreted as their sensitivity to benzodiazepines.

Vital signs are measured, and an intravenous drip is started. Midazolam is titrated to the level of moderate sedation. The amount of intravenous midazolam required is usually small (1 to 2 mg) because the patient is already sedated from the oral lorazepam. Midazolam typically produces good amnesia, but sometimes the

patient can be talkative and not feel sleepy. Small amounts of intravenous pentobarbital (12.5 to 50 mg) can be titrated to provide the patient with a feeling of more profound sedation.

Rationale for Technique

Merin has been using combined oral and intravenous sedation for more than 10 years and found it to be very effective. Lorazepam was selected for oral premedication for several reasons. The duration of action is appropriate for periodontal procedures, and several studies have shown that it works well to relieve anxiety before surgical procedures.[10,26,27,52] When anxious patients are sedated without oral premedication, slow titration usually is not possible. They need to be given a slightly larger dose and put into a deeper level of sedation temporarily to overcome their initial anxiety. With effective oral premedication, the dose can be slowly titrated to produce the desired level of sedation.

Although midazolam produces good amnesia, it has been our and others' experience that it is sometimes difficult to smoothly titrate to produce a light sedation level.[63] This process is sometimes referred to as *reading the patient*. After administering intravenous midazolam, many patients become talkative and say, "I don't feel sedated," even though the dentist knows they are already affected by the midazolam and will probably not remember what they are saying. After a small amount of sodium pentobarbital is added, patients state that they feel the effects of sedation and are slightly sleepy. Only small amounts of pentobarbital are required because barbiturates increase the affinity of benzodiazepine receptors to midazolam and are supra-additive in producing increased sedation.[39] Although pentobarbital has no reversal agent, it has been used safely for many years as a dental sedative.[46]

Sedation Failures

When performing outpatient mild or moderate sedation, the clinician must realize that sedation will not be 100% effective for all patients. A certain percentage of patients will not respond appropriately to minimal or moderate sedation protocols (Table 38.5). If a patient is not responding to the sedation procedure, it is

extremely hazardous to go beyond dose limits or to attempt putting the patient into a deeper level of sedation. It is best to abort the procedure and reschedule the appointment for another day, with a different technique or with a dental anesthesiologist.

TABLE 38.5

Sedation Failure in Dentistry by Route of Administration

Technique	Expected Failure Rate (%)
Oral (child, older)	40–50
Oral (child, younger)	50–65
Oral (adult)	20–50
Inhalation	15–20
Oral + inhalation	5–10
Intravenous	4.3–5
Oral + intravenous	2–3
Deep sedation/general anesthesia	1.6

Data from Malamed SF: Sedation and safety: 36 years of perspective *Alpha Omegan* 99:70–74, 2006; Senel FC, Buchanan JM Jr, Senel AC, et al: Evaluation of sedation failure in the outpatient oral and maxillofacial surgery clinic. *J Oral Maxillofac Surg* 65:645–650, 2007; Skehan SJ, Malone DE, Buckley N, et al: Sedation and analgesia in adult patients: evaluation of a staged-dose system based on body weight for use in abdominal interventional radiology. *Radiology* 216:653–659, 2000; Wilson KE, Thorpe RJ, McCabe JF, Girdler NM: Complications associated with intravenous midazolam sedation in anxious dental patients. *Primary Dental Care* 18:161–166, 2011.

Emergency Preparedness

Because sedation and general anesthesia are on a continuum of drug-induced depression of consciousness to loss of consciousness, it is not always possible to predict how an individual patient will respond. Practitioners intending to produce a given level of sedation should be able to diagnose and manage the physiologic consequences for patients whose level of sedation becomes deeper than initially intended (i.e., rescue). For all levels of sedation, the practitioner must have the training, skills, drugs, and equipment to identify and manage such an occurrence until assistance arrives (i.e., emergency medical service) or the patient returns to the intended level of sedation without airway or cardiovascular complications. The qualified dentist is responsible for sedation

management, adequacy of the facility, competence of the staff, diagnosis and treatment of emergencies related to the administration of sedation, and providing and maintaining the equipment and protocols for patient rescue.

If a patient enters a deeper level of sedation than the dentist is qualified to provide, the dentist must stop the procedure and focus attention on the patient until his or her condition returns to the intended level of sedation. This can involve monitoring the patient, providing airway management and support, administering reversal agents, or activating the emergency medical service. The qualified dentist is responsible for sedative management, adequacy of the facility and staff, diagnosis and treatment of emergencies related to the administration of minimal or moderate sedation, and providing the equipment, drugs, and protocol for patient rescue.

Conclusions

As periodontal procedures become more complex, there is an increased need for the use of conscious sedation techniques for patients with fear and anxiety. The ADA guidelines and policy are outlined in documents that need to be followed. Mild sedation with N_2O inhalation techniques must be used with appropriate patient monitoring. The doctor should have a minimum of 14 hours of instruction, including a clinical component.

After appropriate recovery, patients usually can be allowed to function normally and do not need another adult to monitor them. Mild sedation using oral agents, such as triazolam in one dose, should not exceed the MRD for home use, but after recovery, these patients cannot drive and need another adult to supervise them. Moderate to deep sedation should be performed only by practitioners with appropriate postdoctoral training in an accredited advanced education program, which carries additional responsibilities for patient monitoring, restrictions on food and liquid intake, recovery, and additional trained support staff.

Patients with systemic problems should get preoperative evaluations from a physician, and elderly patients frequently need downward adjustments of normal dosage. Children require special care from trained doctors, and preoperative sedation in children

younger than 12 years of age should be carried out by specialists in pediatric anesthesia. Patients with significant systemic problems are best treated in a hospital environment rather than in an outpatient surgical center.

Case Scenario 38.1

Patient:
45-year-old male

Chief Complaint:
Dental phobia

Background Information
Patient had a bad experience with dental treatment. He is fearful and has avoided taking care of his oral health. He has periodontal disease that requires surgical treatment.

Current Findings:
Before beginning treatment, the patient was given moderate sedation with an average dose of the sedative typically used. Although all vital signs (e.g., pulse oximeter, breathing, color, blood pressure) are normal, the patient has fallen asleep and is not responsive to verbal commands.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
What do you do? A. Continue treatment as long as all the vital signs are normal. B. Immediately start positive-pressure oxygen delivery. C. Stop the procedure and facilitate the process to bring the patient to the moderate sedation level. D. Immediately give reversal agents.	**Answer: D** **Explanation:** The patient should be responsive to verbal or physical stimulus while undergoing moderate sedation. The sedation level is too deep. Attention must be focused on bringing the sedation back up to a moderate level with patient responsiveness.

Case Scenario 38.2

Patient:
36-year-old female

Chief Complaint:
"I would like to improve the appearance of my smile. I don't like the long appearance of my teeth. I am afraid of surgery and would like to be asleep."

Background Information
Patient has gingival recession with a high smile. The gingival recession is Miller class I, which can be corrected with a connective tissue graft.

Current Findings:
The young, healthy patient is administered moderate sedation with supplemental oxygen through a nasal cannula. She stops breathing.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
How long will it take for the pulse oximeter value to drop below 90% arterial oxyhemoglobin saturation? A. One minute B. Two minutes C. Three minutes D. Four minutes or more	**Answer: D** **Explanation:** For a well-oxygenated healthy patient, it could take as long as 7 or 8 minutes for the pulse oximeter value to drop below 90%. Capnography can detect breathing cessation in seconds.

Pulmonary Diseases *(e-only)*
Medications and Cancer Therapies
Prosthetic Joint Replacement

Pregnancy *(e-only)*
Infectious Diseases *(e-only)*

Many patients seeking dental care have significant medical conditions that can alter the course of their oral disease and the therapy provided. Older periodontal patients are more likely to have underlying disease. The therapeutic responsibility of the clinician includes identification of the patient's medical problems to formulate a proper treatment plan. A thorough medical history is paramount.[81] If significant findings are unveiled, consultation with or referral of the patient to an appropriate physician is indicated. This ensures correct management and provides medicolegal coverage for the clinician.

This chapter covers common medical conditions and associated periodontal management. The review of each topic area can be supplemented by consulting other references for more detailed coverage of specific disorders. Understanding these conditions enables the clinician to treat the total patient, not merely the periodontal reflection of underlying disease.

Cardiovascular Diseases

Cardiovascular diseases are the most prevalent category of systemic disease in the United States and many other countries, and they are more common with increasing age.[113] Health histories should be closely scrutinized for cardiovascular problems, including hypertension, angina pectoris, myocardial infarction (MI), cardiac bypass surgery, cerebrovascular accident (CVA), congestive heart failure (CHF), infective endocarditis (IE), and implanted cardiac pacemakers or automatic cardioverter-defibrillators.

In most cases, the patient's physician should be consulted, especially if stressful or prolonged treatment is anticipated. Short appointments and a calm, relaxing environment help minimize stress and maintain hemodynamic stability.

Hypertension

Hypertension, the most common cardiovascular disease, affects more than 50 million American adults, many of whom are undiagnosed.[37] In 2003, the National Heart, Lung, and Blood Institute issued revised guidelines for evaluation and management of hypertension.[18,38,47] The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7 guidelines[18]) simplified the classification of blood pressure (Table 39.1).

TABLE 39.1

Classification of Adult Blood Pressure

Classification	Systolic (mm Hg)	Diastolic (mm Hg)	Dental Treatment Modifications
Normal	<120	<80	No changes in dental treatment
Prehypertension	120–139	80–89	No changes in dental treatment
			Monitor BP at each appointment
Stage 1 hypertension	140–159	90–99	Inform patient of findings
			Medical consultation or referral
			Monitor BP at each appointment
			No changes in dental treatment; minimize stress
Stage 2 hypertension	≥160	≥100	Inform patient
			Medical consultation or referral
			Monitor BP at each appointment
			If systolic BP is <180 mm Hg and diastolic is <110 mm Hg, perform selective dental care (i.e., routine examination, prophylaxis, restorative nonsurgical endodontics and periodontics); minimize stress
			If systolic BP ≥180 mm Hg or diastolic ≥100 mm Hg, give immediate medical consultation or referral and perform emergency dental care only (to alleviate pain, bleeding, infection),[a] minimize stress
			Consider stress-reduction protocol

[a]Risk of providing emergency dental care must outweigh risk of possible hypertensive complications.[18,38,47]

BP, Blood pressure.

Compared with previous classification schemes[43,44] that focused on diastolic blood pressure (BP), the JNC-7 guidelines[18] emphasize the importance of systolic BP. Systolic BP greater than 140 mm Hg is considered a greater risk factor for cardiovascular disease than elevated diastolic pressure. JNC-7 also introduced a category

known as *prehypertension* to replace the more innocuous terms *high normal* and *borderline* hypertension. People with systolic BP between 120 and 139 mm Hg or diastolic BP between 80 and 89 mm Hg are classified as prehypertensive. It is not considered a disease category or diagnosis; it is instead a term used to describe a condition and identify individuals who are at high risk for hypertension.

The JNC-7 guidelines classify hypertension into two categories, versus the three under the previous classification schemes, for simplicity and because treatment for categories 2 and 3 was essentially the same. *Stage 1 hypertension* is defined as a systolic BP of 140 to 159 mm Hg or diastolic pressure of 90 to 99 mm Hg. *Stage 2 hypertension* is defined as a systolic pressure greater than 160 mm Hg or diastolic pressure greater than 100 mm Hg.

Hypertension is not diagnosed from a single elevated BP recording. Rather, classification is usually based on the average value of two or more BP readings taken at two or more appointments. The higher systolic or diastolic pressure determines the patient's classification. Patients with hypertension enter dental practices every day, and hypertension is particularly common among the older population seen in most periodontal practices. Evidence from the Framingham Heart Study revealed that people with normal BP at age 55 still have a 90% risk of becoming hypertensive later in life.[115]

Hypertension is divided into primary and secondary types. *Primary* (i.e., essential) *hypertension* occurs when no underlying pathologic abnormality can be found to explain the disease. Approximately 95% of hypertensive patients have primary hypertension. The remaining 5% have *secondary hypertension,* in which an underlying cause can be found and is often treated. Conditions responsible for secondary hypertension include renal disease, endocrinologic changes, and neurogenic disorders.

In early hypertension, the patient may be asymptomatic. If not identified, diagnosed, and treated, hypertension can persist and increase in severity, leading eventually to coronary artery disease, angina, MI, CHF, CVA, or kidney failure.[55] The dental office can play a vital role in the detection of hypertension and maintenance care of the patient with hypertensive disease. The first dental office visit should include two BP readings spaced at least 10 minutes

apart, which are averaged and used as a baseline. Before the clinician refers a patient to a physician because of elevated BP, readings should be taken at a minimum of two appointments, unless the measurements are extremely high (i.e., systolic pressure >180 mm Hg or diastolic pressure >100 mm Hg).

The periodontal recall system is an ideal method for hypertension detection and monitoring. Almost three of every four adult patients with hypertension in the United States do not control their BP well enough to attain the goal of systolic pressure less than 140 mm Hg and diastolic pressure less than 90 mm Hg.[14] Lack of compliance with antihypertensive therapy is the primary reason for this failure. Dentists can help achieve greater success in managing hypertension by taking BP readings at each periodontal recall visit.

Periodontal procedures should not be performed until accurate BP measurements and histories have been taken to identify patients with significant hypertensive disease. The time of day should be recorded because BP varies significantly throughout the day.[73] Table 39.1 outlines appropriate medical referral or consultation and dental treatment modifications, depending on the patient's stage of hypertension.

Dental treatment for hypertensive patients is safe as long as stress is minimized.[55,61] If a patient is receiving antihypertensive therapy, consultation with the physician may be warranted regarding the current medical status, medications, periodontal treatment plan, and patient care. Many physicians are not knowledgeable about the specific details of dental or periodontal procedures. The dentist must inform the physician regarding the estimated degree of stress, length of the procedures, and complexity of the individualized treatment plan. Morning dental appointments were once suggested for hypertensive patients, but evidence indicates that BP usually increases around awakening and peaks at midmorning.[10,73,103] Because lower BP levels occur in the afternoon, afternoon dental appointments may be preferred.

No routine periodontal treatment should be given to a patient who is hypertensive and not under medical management. For patients with systolic BP greater than 180 mm Hg or diastolic BP greater than 110 mm Hg, treatment should be limited to emergency care until hypertension is controlled. Analgesics are prescribed for

pain and antibiotics for infection. Acute infections may require surgical incision and drainage, although the surgical field should be limited because excessive bleeding can occur with elevated BP.

When treating hypertensive patients, the clinician should not use a local anesthetic containing an epinephrine concentration greater than 1 : 100,000 or a vasopressor to control local bleeding. Local anesthesia without epinephrine can be used for short procedures (<30 minutes). In a patient with hypertensive disease, however, it is important to minimize pain by providing profound local anesthesia to avoid an increase in endogenous epinephrine secretion.[55,61]

The benefits of the small doses of epinephrine used in dentistry far outweigh the potential for hemodynamic compromise. The smallest possible dose of epinephrine should be used, and aspiration before injection of local anesthetics is critical. Intraligamentary injection is usually contraindicated because hemodynamic changes are similar to intravascular injection.[102] If the hypertensive patient exhibits anxiety, use of conscious sedation in conjunction with periodontal procedures may be warranted[111] (see Chapter 38).

β-adrenergic receptor antagonists (i.e., β-blockers) are typically used to treat hypertension (Table 39.2). The β-blockers are *cardioselective,* blocking only β1 cardiac receptors (i.e., β1 receptors), or *nonselective,* blocking both β1 cardiac receptors and β2 peripheral receptors (i.e., β2 receptors). Epinephrine, an α-adrenergic and β-adrenergic agonist, increases heart rate through direct stimulation of cardiac β1 receptors. Epinephrine also stimulates α-adrenergic receptors, producing vasoconstriction of arteries, and β2 receptors, causing vasodilation of skeletal muscle arterioles.

TABLE 39.2

Nonselective and Selective β-Adrenergic Receptor Antagonists

Generic Name	Trade Name
Nonselective β-Blockers	
Carvedilol	Coreg
Carteolol hydrochloride	Cartrol
Nadolol	Corgard
Penbutolol sulfate	Levatol
Pindolol	Visken
Propranolol hydrochloride	Inderal; Inderal LA

Timolol maleate	Blocadren
Selective β-Blockers	
Acebutolol hydrochloride	Sectral
Atenolol	Tenormin
Betaxolol hydrochloride	Kerlone
Bisoprolol fumarate	Zebeta
Metoprolol tartrate	Lopressor
Metoprolol succinate	Toprol-XL

Administration of local anesthetics containing epinephrine to patients taking nonselective β-blockers (e.g., propranolol, nadolol) can elevate BP.[127] Epinephrine-induced α-adrenergic stimulation results in vasoconstriction and increased BP. Because the patient's nonselective medication has blocked the β2 receptors, epinephrine cannot stimulate the normal compensatory β2 receptor–induced vasodilation. This can result in dramatically increased BP, followed by reflex bradycardia mediated by the vagus nerve and carotid baroreceptors. The end result is a patient with severe hypertension and bradycardia, producing a dangerous decrease in vascular perfusion and possibly causing death. Because of this potential complication, epinephrine-containing local anesthetics should be used cautiously and only in very small amounts in patients taking nonselective β-blockers, with careful monitoring of vital signs.[55,127]

The clinician should be aware of the many side effects of antihypertensive medications. *Postural hypotension* is common and can be minimized by slow positional changes in the dental chair.[55] *Depression* is a side effect of which many patients are unaware. Nausea, sedation, oral dryness, lichenoid drug reactions, and gingival overgrowth are associated with certain classes of antihypertensive agents.[61]

Clinical Correlation

Hypertension, the most common cardiovascular disease, affects more than 50 million American adults, many of whom are undiagnosed. Almost three of every four adults with hypertension do not control their blood pressure well enough. The dental office can play a vital role in the detection of undiagnosed hypertension and the compliance of patients being treated for hypertension. Blood pressure should be taken at the initial visit and at each recall

visit.

Ischemic Heart Diseases

Ischemic heart disease (Fig. 39.1) includes disorders such as angina pectoris and MI. Angina pectoris occurs when myocardial oxygen demand exceeds supply, resulting in temporary myocardial ischemia.[38] Patients with a history of unstable angina pectoris (i.e., angina that occurs irregularly or on multiple occasions without predisposing factors) should be treated only for emergencies and then in consultation with their physician. Patients with stable angina (i.e., angina that occurs infrequently, is associated with exertion or stress, and is easily controlled with medication and rest) can undergo elective dental procedures. Because stress often induces an acute anginal attack, stress reduction is important. Profound local anesthesia is vital, and conscious sedation may be indicated for anxious patients[111] (see Chapter 38). Supplemental oxygen delivered by nasal cannula can help prevent intraoperative anginal attacks.

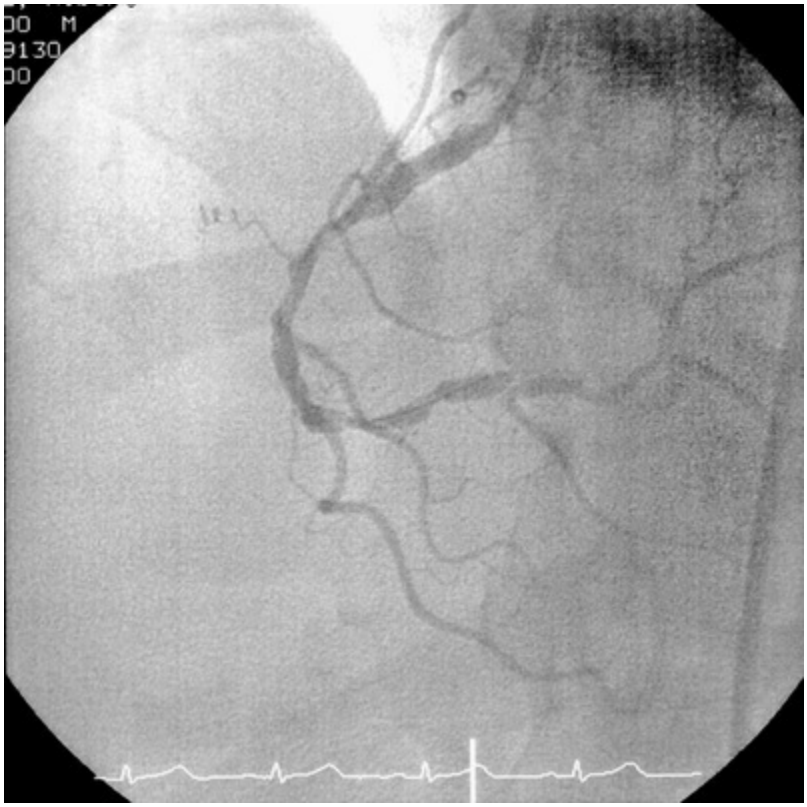

FIG. 39.1 As seen on a coronary angiogram,

atherosclerosis can result in narrowing of the coronary arteries, producing signs and symptoms of ischemic heart disease.

Patients who manage acute anginal attacks with nitroglycerin should be instructed to bring their medication to dental appointments. Nitroglycerin should also be kept in the office medical emergency kit. For particularly stressful procedures, the patient may take a nitroglycerin tablet preoperatively to prevent angina, although this usually is not necessary. The patient's nitroglycerin should be readily accessible on the dental tray in case it is needed during treatment. Because the shelf life of nitroglycerin is relatively short, the expiration date of the patient's nitroglycerin and that of the nitroglycerin in the office's medical emergency kit should be noted.

Patients with angina may be taking longer-acting forms of nitroglycerin (e.g., tablet, patch), β-blockers, or calcium channel blockers (also used for treating hypertension) for prevention of angina. Restrictions on the use of local anesthetics containing epinephrine are similar to those for the patient with hypertension. Intraosseous injection with epinephrine-containing local anesthetics using special systems (e.g., Stabident, Fairfax Dental) should be done cautiously in patients with ischemic heart disease because it results in transient increases in heart rate and myocardial oxygen demand.[78]

If the patient becomes fatigued or uncomfortable or has a sudden change in heart rhythm or rate during a periodontal procedure, the procedure should be discontinued as soon as possible. A patient who has an anginal episode in the dental chair should receive the following emergency medical treatment:

1. Discontinue the periodontal procedure.
2. Administer 1 tablet (0.3 to 0.6 mg) of nitroglycerin sublingually.
3. Reassure the patient, and loosen restrictive garments.
4. Administer oxygen with the patient in a reclined position.
5. If the signs and symptoms cease within 3 minutes, complete the periodontal procedure if possible, making sure that the patient is comfortable. Terminate the procedure at the

earliest convenient time.

6. If the anginal signs and symptoms do not resolve with this treatment within 5 minutes, administer another dose of nitroglycerin, monitor the patient's vital signs, call the patient's physician, and be ready to accompany the patient to the emergency department.
7. A third nitroglycerin tablet can be given 5 minutes after the second. Chest pain that is not relieved by three tablets of nitroglycerin indicates likely MI. The patient should be transported to the nearest emergency medical facility immediately.

Nitroglycerin lingual spray formulations have been popular in hospital pharmacies because of the increased shelf life compared with nitroglycerin tablets.[72] The lingual spray can provide greater and more rapid vasodilation with a longer duration of action.[25,86] The convenience and advantages of a nitroglycerin lingual spray are appealing, but the accuracy of dose delivery has been questioned and warrants additional studies before the spray can be recommended to replace the known tablet regimen.[72]

MI is the other category of ischemic heart disease encountered in dental practice. Dental treatment is usually deferred for at least 6 months after MI because the peak mortality rate occurs during this time.[30] After 6 months, MI patients can usually be treated using techniques similar to those for stable angina patients.

Cardiac (aortocoronary) bypass, femoral artery bypass, angioplasty, and endarterectomy have become common surgical procedures in patients with ischemic heart disease. If one of these procedures was performed recently, the physician should be consulted before elective dental therapy to determine the degree of heart damage or arterial occlusive disease, the stability of the patient's condition, and the potential for infective endocarditis or graft rejection. Prophylactic antibiotics are not usually necessary for cardiac bypass patients unless recommended by the cardiologist.

Congestive Heart Failure

CHF is a condition in which the pump function of the heart is

unable to supply sufficient amounts of oxygenated blood to meet the body's needs.[30] CHF usually begins with left ventricular failure caused by a disproportion between the hemodynamic load and the capacity to handle that load. CHF can be caused by a chronic increase in workload (as in hypertension or aortic, mitral, pulmonary, or tricuspid valvular disease), direct damage to the myocardium (as in MI or rheumatic fever), or an increase in the body's oxygen requirements (as in anemia, thyrotoxicosis, or pregnancy).

Patients with poorly controlled or untreated CHF are not candidates for elective dental procedures. These individuals are at risk for sudden death, usually from ventricular arrhythmias.[29] For patients with treated CHF, the clinician should consult with the physician regarding the severity of CHF, underlying cause, and current medical management. Medical management of CHF can include the use of calcium channel blockers, direct vasodilators, diuretics, angiotensin-converting enzyme (ACE) inhibitors, α-receptor blockers, or cardiotonic agents such as digoxin.[27,46] Each medication has potential side effects that can affect periodontal therapy. Because of orthopnea (i.e., inability to breathe unless in an upright position) in some CHF patients, the dental chair should be adjusted to a comfortable level for the patient rather than placed in a supine position. Short appointments, stress reduction with profound local anesthesia and possibly conscious sedation, and use of supplemental oxygen should be considered.[30,55]

Cardiac Pacemakers and Implantable Cardioverter-Defibrillators

Cardiac arrhythmias are most often treated with medications, but some are also treated with implantable pacemakers or automatic cardioverter-defibrillators.[29,55,80] Pacemakers are usually implanted in the chest wall and enter the heart transvenously. Automatic cardioverter-defibrillators are more often implanted subcutaneously near the umbilicus and have electrodes passing into the heart transvenously or directly attached to the epicardium. Consultation with the patient's physician allows determination of the underlying cardiac status, the type of pacemaker or automatic

cardioverter-defibrillator, and any precautionary measures to be taken.

Older pacemakers were unipolar and could be disrupted by dental equipment that generated electromagnetic fields, such as ultrasonic and electrocautery units. Newer units are bipolar and are usually not affected by dental equipment. Automatic cardioverter-defibrillators activate without warning when certain arrhythmias occur. This can endanger the patient during dental treatment because activation often causes sudden patient movement. Stabilization of the operating field during periodontal treatment with bite blocks or other devices can prevent unexpected trauma.

Infective Endocarditis

Infective endocarditis (IE) is a disease in which microorganisms colonize damaged endocardium or heart valves.[32] Although the incidence of IE is low, it is a serious disease with a poor prognosis despite modern therapy. The term *infective endocarditis* is preferred to the previous term *bacterial endocarditis* because the disease can also be caused by fungi and viruses. The organisms most often encountered in IE are α-hemolytic streptococci (e.g., *Streptococcus viridans*). However, nonstreptococcal organisms often found in the periodontal pocket have been increasingly implicated, including *Eikenella corrodens, Aggregatibacter actinomycetemcomitans, Capnocytophaga,* and *Lactobacillus* species.[8]

IE has been divided into acute and subacute forms. The acute form involves virulent organisms, usually nonhemolytic streptococci and strains of staphylococci, which invade normal cardiac tissue, produce septic emboli, and cause infections that run a rapid, usually fatal course. The subacute form results from colony formation on damaged endocardium or heart valves by low-grade pathogenic organisms. The classic example is rheumatic carditis from rheumatic fever.

Since the last American Heart Association (AHA) publication on prevention of IE in 1997,[22] many have questioned the efficacy of antimicrobial prophylaxis to prevent IE in patients who undergo dental or other procedures and have suggested that the AHA guidelines should be revised.[26,105] Members of the Rheumatic Fever,

Endocarditis, and Kawasaki Disease Committee of the AHA Council on Cardiovascular Disease in the Young and a national and international group of experts on IE extensively reviewed data published on the prevention of IE. The committee concluded that only an extremely small number of IE cases might be prevented by antibiotic prophylaxis for dental procedures (even if such therapy were 100% effective). Consequently, the guidelines were changed and published in a 2008 report.[125] The new guidelines advise that IE prophylaxis should be recommended only for cardiac conditions with the highest risk of adverse outcome from IE (Box 39.1). For these patients, antibiotic prophylaxis is recommended for all dental procedures that involve manipulation of the gingival or periapical tissues, or perforation of the oral mucosa. Antibiotic prophylaxis is not indicated for individuals on the basis of an increased lifetime risk of contracting IE.

Box 39.1

Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Infective Endocarditis for Which Prophylaxis With Dental Procedures Is Recommended[a]

Previous history of infective endocarditis
Prosthetic cardiac valves or prosthetic material used for cardiac valve repair
Congenital heart disease (CHD), with the following conditions:

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after the procedure
- Repaired CHD with residual defects at or adjacent to the site of a prosthetic patch or prosthetic device

(which inhibits endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

[a]American Heart Association recommendations.[125]

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis: guidelines from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*, 116:1736–1754, 2007.

The practice of periodontics is intimately concerned with the prevention of IE. However, bacteremia may occur even in the absence of dental procedures, especially in individuals with poor oral hygiene and significant periodontal inflammation. IE is much more likely to result from frequent exposure to random bacteremias associated with daily activities than be caused by a dental procedure.[125] Prevention of periodontal inflammation is paramount. The AHA states that patients who are at risk for IE should "establish and maintain the best possible oral health to reduce potential sources of bacterial seeding." To provide adequate preventive measures for IE, the clinician's major concern should be to reduce the microbial population in the oral cavity to minimize soft tissue inflammation and bacteremia.

Key Fact

The updated American Heart Association (AHA) guidelines on the prevention of infective endocarditis (IE) were published in a 2008 report. The guidelines recommend that prophylaxis should be provided only for cardiac conditions with the highest risk of adverse outcomes from IE (see Box 39.1).

Preventive measures to reduce the risk of IE consist of the following:

1. *Define the susceptible patient.* A careful medical history can disclose a susceptible patient. Health questioning should cover the history in all categories of risk. If any doubt exists, the patient's physician should be consulted.
2. *Provide oral hygiene instruction.* Oral hygiene should be practiced with methods that improve gingival health. In patients with significant gingival inflammation, oral hygiene should initially be limited to gentle procedures (i.e., oral rinses and gentle toothbrushing with a soft brush) to minimize bleeding. As gingival health improves, more aggressive oral hygiene can be initiated. Oral irrigators are usually not recommended because their use can induce bacteremia.[67] Susceptible patients should be encouraged to maintain the highest level of oral hygiene after soft tissue inflammation is controlled.
3. *Recommended antibiotic prophylactic regimens should be practiced with all high-risk patients during periodontal treatment* (Table 39.3). If any doubt regarding susceptibility exists, the patient's physician should be consulted. In patients who have been receiving continuous oral penicillin for secondary prevention of rheumatic fever, penicillin-resistant α-hemolytic streptococci are occasionally found in the oral cavity. An alternate regimen is recommended instead. If the periodontal patient is taking a systemic antibiotic as part of periodontal therapy, changes in the IE prophylaxis regimen may be indicated. For example, a patient taking a penicillin agent after regenerative therapy can be placed on azithromycin before the next periodontal procedure. Patients with early-onset forms of periodontitis often have high levels of *A. actinomycetemcomitans* in the subgingival plaque. This organism has been associated with IE and is often resistant to penicillins. In patients with aggressive periodontitis who should be given prophylaxis, Slots and colleagues[101] suggested using tetracycline (250 mg four times daily for 14 days) to eliminate or reduce *A. actinomycetemcomitans*, followed by the conventional prophylaxis protocol at the time of dental treatment.

TABLE 39.3

Recommended Antibiotic Prophylaxis Regimens for Periodontal Procedures in Adults at Risk for Infective Endocarditis

Regimen	Antibiotic	Dosage[a]
Standard oral regimen	Amoxicillin	2.0 g 30–60 min before procedure
Alternate regimen for patients allergic to amoxicillin or penicillin	Clindamycin	600 mg 30–60 min before procedure
	Azithromycin or clarithromycin	500 mg 30–60 min before procedure
	or	
	Cephalexin or cefadroxil[b]	2.0 g 30–60 min before procedure
Regimen for patients unable to take oral medications	Ampicillin	2.0 g intramuscularly or intravenously within 30 min before procedure
Regimen for patients unable to take oral medications and allergic to penicillin	Clindamycin	600 mg intravenously within 30 min before procedure (must be diluted and injected slowly)
	or	
	Cefazolin[b]	1.0 g intramuscularly or intravenously within 30 min before procedure

[a]Adult dosages are listed. Children's dosages are lower.

[b]Cephalosporins should not be used in patients with immediate-type hypersensitivity reactions to penicillins (e.g., urticaria, angioedema, anaphylaxis).

4. *Periodontal treatment should be designed for susceptible patients to accommodate their degree of periodontal involvement.* The nature of periodontal therapy enhances the problems related to the prophylaxis of subacute IE. Patients are faced with long-term therapy, healing periods that extend beyond a 1-day antibiotic regimen, multiple visits, and procedures that easily elicit gingival bleeding.

The following guidelines can aid in the development of periodontal treatment plans for patients susceptible to IE:

- Periodontal disease is an infection with potentially wide-ranging systemic effects. For patients at risk for IE, every effort should be made to eliminate this infection. Teeth with severe periodontitis and a poor prognosis may require

extraction. Teeth with less severe involvement in a motivated patient should be retained, treated, and maintained closely.

- All periodontal treatment procedures (including probing) require antibiotic prophylaxis; gentle oral hygiene methods are excluded. Pretreatment chlorhexidine rinses are recommended before all procedures, including periodontal probing, because these oral rinses significantly reduce the bacteria on mucosal surfaces.[22]
- To reduce the number of visits required and thereby minimize the risk of developing resistant bacteria, numerous procedures can be accomplished at each appointment, depending on the patient's needs and ability to tolerate dental treatment.[55]
- When possible, allow at least 7 days between appointments (preferably 10 to 14 days). If this is not possible, select an alternative antibiotic regimen for appointments within a 7-day period.
- Evidence does not support or refute a need to place patients at risk for IE on extended antibiotic regimens after treatment.[55] Patients who have had periodontal surgery are not usually placed on antibiotics for the first week of healing unless there are specific indications to do so. If patients are placed on these regimens, the dosages are inadequate to prevent endocarditis during ensuing appointments. The standard prophylactic antibiotic dose is still needed. For example, if a

patient was placed on 250 mg of amoxicillin three times a day for 10 days after periodontal surgery and was to return to the office for more treatment on the seventh day, the patient would require a full 2.0-g dose of amoxicillin before that treatment. Alternatively, clindamycin or azithromycin could be used at the second appointment.

- Regular recall appointments, with an emphasis on oral hygiene reinforcement and maintenance of periodontal health, are extremely important for patients susceptible to IE.

Cerebrovascular Accident

A CVA (i.e., stroke) results from ischemic changes (e.g., cerebral thrombosis caused by an embolus) or hemorrhagic phenomena. Hypertension and atherosclerosis are predisposing factors for CVA and should alert the clinician to evaluate the patient's medical history carefully for the possibility of early cerebrovascular insufficiency and to be aware of symptoms of the disease. A physician's referral should precede periodontal therapy if the signs and symptoms of early cerebrovascular insufficiency are evident.

To prevent a repeat stroke, active infections should be treated aggressively, because even a minor infection can alter blood coagulation and trigger thrombus formation and ensuing cerebral infarction. The clinician should counsel the patient about the importance of thorough oral hygiene.[82] Post-stroke weakness of the facial area or paralysis of extremities can make oral hygiene procedures extremely difficult.[66] The clinician may need to modify oral hygiene instruments for ease of use, perhaps in consultation with an occupational therapist. Long-term chlorhexidine rinses greatly aid in plaque control.

Dental clinicians should treat post-CVA patients with the following guidelines in mind:

1. No periodontal therapy (except for an emergency) should be

performed for 6 months because of the high risk of recurrence during this period.

2. After 6 months, periodontal therapy can be performed during short appointments with an emphasis on minimizing stress. Profound local anesthesia should be obtained, using the minimal effective dose of local anesthetic agents. Concentrations of epinephrine greater than 1 : 100,000 are contraindicated.
3. Light conscious sedation (i.e., inhalation, oral, or parenteral) can be used for anxious patients. Supplemental oxygen is indicated to maintain thorough cerebral oxygenation.
4. Stroke patients are frequently placed on oral anticoagulants. Previously, it was thought that for procedures entailing significant bleeding, such as periodontal surgery or tooth extraction, the anticoagulant regimen might need adjustment, depending on the level of anticoagulation at which the patient is maintained. However, evidence regarding the risks of altering anticoagulation therapy suggests that it may be prudent to provide treatment without changing it (see Anticoagulant Medications). Any changes in anticoagulant therapy regimens for a stroke patient should be done in consultation with the patient's physician.
5. BP should be monitored carefully. Recurrence rates for CVAs are high, as are rates of associated functional deficits.

Endocrine Disorders

Diabetes

The diabetic patient requires special precautions before periodontal therapy. Type 1 diabetes was formerly known as insulin-dependent diabetes, and type 2 diabetes was referred to as non–insulin-dependent diabetes.[59] During the past decade, the medical management of diabetes has changed significantly in an effort to minimize the debilitating complications associated with this disease.[108,114] Blood glucose (i.e., glycemia) levels are more tightly managed through diet, oral agents, and insulin therapy.[56]

If the clinician detects intraoral signs of undiagnosed or poorly controlled diabetes, a thorough history is indicated.[77] The classic signs of diabetes include *polydipsia* (i.e., excessive thirst), *polyuria* (i.e., excessive urination), and *polyphagia* (i.e., excessive hunger, often with unexplained concurrent weight loss). If the patient has any of these signs or symptoms or the clinician suspects diabetes, further investigation with laboratory studies and physician consultation is indicated. Periodontal therapy has limited success in the setting of undiagnosed or poorly controlled diabetes.

If a patient is suspected of having undiagnosed diabetes, the following procedures should be performed:

1. Consult the patient's physician.
2. Analyze laboratory tests (Box 39.2), including fasting blood glucose and casual glucose test results.[5]

Box 39.2

Diagnostic Criteria for Diabetes Mellitus

Diabetes mellitus can be diagnosed by any one of the following laboratory methods. Initial results using any method must be confirmed on a subsequent day.

1. Fasting plasma glucose level ≥126 mg/dL (≥7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours. The normal fasting glucose level is 70 to 100 mg/dL.
2. Two-hour postprandial glucose level ≥200 mg/dL (≥11.1 mmol/L) during an oral glucose tolerance test. The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water. The normal 2-hour postprandial glucose level is <140 mg/dL.
3. Glycated hemoglobin (HbA1c) value ≥6.5% (≥48 mmol/L). The test should be performed in a laboratory using a method that is certified by the National Glycohemoglobin Standardization Program (NGSP) and standardized according to the Diabetes Control and Complications Trial (DCCT) assay.[a]
4. Random plasma glucose level ≥200 mg/dL (≥11.1 mmol/L) for a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, which include polyuria, polydipsia, and unexplained weight loss. Blood for casual glucose testing can be drawn without regard to the time since the last meal.

[a]In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.

Data from American Diabetes Association: 2. Classification and diagnosis of diabetes. *Diabetes Care* 40(Suppl. 1):S11–S24, 2017.

3. Rule out acute orofacial infection or severe dental infection; if present, provide emergency care immediately.
4. Establish the best possible oral health through nonsurgical debridement of plaque and calculus. Institute oral hygiene instruction. Limit more advanced care until the diagnosis has been established and good glycemic control obtained.

If a patient is known to have diabetes, it is critical that the level of glycemic control be established before initiating periodontal treatment. The fasting glucose and casual glucose tests provide snapshots of the blood glucose concentration at the time the blood was drawn; these tests reveal nothing about long-term glycemic control. The primary test used to assess glycemic control in a known diabetic individual is the glycated hemoglobin (Hb) assay (Box 39.3). Two tests are available, the HbA1 and HbA1c assays; the HbA1c is used more often.[56] This assay has been shown by a large international study to provide an accurate measure of the average blood glucose concentrations over the preceding 2 to 3 months.[64] Fig. 39.2 is a simplified graphic representation of the data from that study depicting the average blood glucose concentrations for HbA1c values.

Box 39.3

Laboratory Evaluation of Diabetes Control by Glycated Hemoglobin (HbA1c) Assay Values

Normal	4%–6%
Good diabetes control	<7%
Moderate diabetes control	7%–8%
Action suggested to improve diabetes control	>8%

Data from American Diabetes Association: 2. Classification and diagnosis of diabetes. *Diabetes Care* 40(Suppl. 1):S11–S24, 2017.

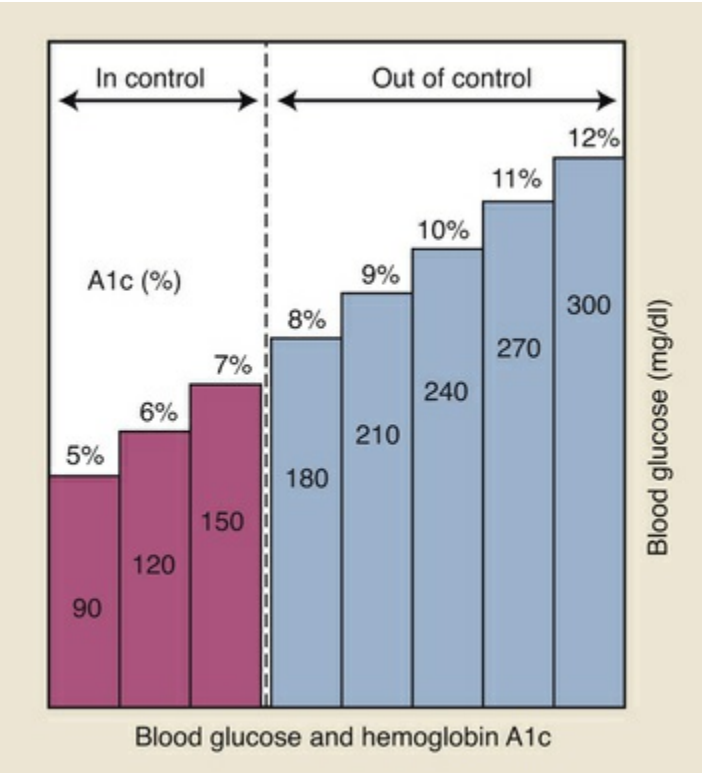

FIG. 39.2 Graphic representation of glycated hemoglobin (HbA1c) values that correspond to estimated average blood glucose levels.

The therapeutic goal for many patients is to achieve and maintain an HbA1c below 8%. Patients with relatively well-controlled diabetes (HbA1c <8%) usually respond to therapy in a manner similar to nondiabetic individuals.[19,107,124] Poorly controlled patients (HbA1c >10%) often have a poor response to treatment, with more postoperative complications and less favorable long-term results[59,107] (see Fig. 14.3 in Chapter 14). Improvements in HBA1c values after periodontal therapy may provide an indication of the potential response.

As discussed in Chapter 14, periodontal infection can worsen glycemic control and should be managed aggressively. Diabetic patients with periodontitis should receive oral hygiene instructions, mechanical debridement to remove local factors, and regular maintenance. When possible, an HbA1c of less than 10% should be established before surgical treatment is performed. Systemic antibiotics are not needed routinely, although evidence indicates that tetracycline antibiotics in combination with scaling and root planing may positively influence glycemic control. If the patient has

poor glycemic control and surgery is absolutely needed, prophylactic antibiotics can be given; penicillins are most often used for this purpose. Frequent reevaluation after active therapy is needed to assess treatment response and prevent recurrence of periodontitis.

Almost all diabetic patients use a glucometer for blood glucose self-monitoring. These devices use capillary blood from a fingerstick to provide blood glucose readings in seconds. Diabetic patients should be asked whether they have a glucometer and how often they use it. Because these devices provide instantaneous assessment of blood glucose, they are highly beneficial in the dental office environment. The following guidelines should be observed:

1. Patients should be asked to bring their glucometer to the dental office at each appointment.
2. Patients should check their blood glucose before any long procedure to obtain a baseline level. Patients with a blood glucose level at or below the lower end of normal before the procedure may become hypoglycemic intraoperatively. It is advisable to have the patient consume some carbohydrate before starting treatment. For example, if a 2-hour procedure is planned and the pretreatment glucose level is 70 mg/dL (i.e., lower end of normal range), providing 4 ounces of juice preoperatively may help prevent hypoglycemia during treatment. If the pretreatment glucose level is excessively high, the clinician should determine whether the patient's glycemic control has been poor recently. This can be done with thorough patient questioning and by determining the most recent HbA1c values. If glycemic control has been poor over the preceding few months, the procedure may need to be postponed until better glycemic control is established. If glycemic control has been good and the current high glucometer reading is a fairly isolated event, the surgical procedure may proceed.
3. If the procedure lasts several hours, it is often beneficial to check the glucose level during the procedure to ensure that the patient does not become hypoglycemic.
4. After the procedure, the blood glucose can be checked again

to assess fluctuations over time.

5. Any time the patient feels the symptoms of hypoglycemia, the blood glucose level should be checked immediately. This may prevent the onset of severe hypoglycemia, a medical emergency.

The most common dental office complication seen in diabetic patients taking insulin is a symptomatic low blood glucose level (i.e., hypoglycemia) (Box 39.4). Hypoglycemia is also associated with the use of numerous oral agents (Table 39.4). In patients receiving conscious sedation, the warning signs of an impending hypoglycemic episode can be masked, making the patient's glucometer one of the best diagnostic aids. Hypoglycemia does not usually occur until the blood glucose level falls below 60 mg/dL. However, in patients with poor glycemic control who have prolonged hyperglycemia (i.e., high blood glucose levels), a rapid drop in glucose can precipitate signs and symptoms of hypoglycemia at levels well above 60 mg/dL.

Box 39.4

Signs and Symptoms of Hypoglycemia

Shakiness or tremors
Confusion
Agitation and anxiety
Sweating
Tachycardia
Dizziness
Feeling of impending doom
Unconsciousness
Seizures

TABLE 39.4

Oral Agents Used for the Management of Diabetes

					Risk of

		Hypoglycemia[a]
Sulfonylureas (1st gen): Chlorpropamide Tolbutamide Tolazamide	Stimulate pancreatic insulin secretion	++
Sulfonylureas (2nd gen): Glyburide Glipizide	Stimulate pancreatic insulin secretion	+++
Sulfonylureas (3rd gen): Glimepiride	Stimulate pancreatic insulin secretion	+
Meglitinides: Repaglinide Nateglinide	Stimulate rapid pancreatic insulin secretion (different mechanism from sulfonylureas)	+
Biguanides: Metformin	Block production of glucose by liver; improve tissue sensitivity to insulin	−
Thiazolidinediones: Rosiglitazone Pioglitazone	Improve tissue sensitivity to insulin	−
α-Glucosidase inhibitors: Acarbose Miglitol	Slow absorption of some carbohydrates from gut, decreasing postprandial peaks in glycemia	−
Dipeptidyl peptidase-4 (DPP-4) inhibitors: Sitagliptin Saxagliptin	Inhibit the enzyme DPP-4; enable the pancreas to produce more insulin but only after food ingestion	−
Combination agents	Combine two different oral agents into single drug	Risk depends on which drugs are combined

[a]Hypoglycemia risk: +++, high; ++, moderate; +, low; −, none.

As medical management of diabetes has intensified over the past decade, the incidence of severe hypoglycemia has risen.[109] The clinician should question diabetic patients about past episodes of hypoglycemia. Hypoglycemia is more common in patients with better glycemic control. When planning dental treatment, it is best to schedule appointments before or after periods of peak insulin activity. This requires knowledge of the pharmacodynamics of the drugs being taken by the diabetic patient. Patients taking insulin are at greatest risk, followed by those taking sulfonylurea agents. Metformin and thiazolidinediones usually do not cause hypoglycemia (see Table 39.4).

Insulins are classified as rapid-acting, short-acting, intermediate-acting, or long-acting agents (Table 39.5). The categories vary in onset, peak, and duration of activity. It is important that the

clinician establish exactly which insulin the diabetic patient takes, the amount, the number of times per day, and the time of the last dose. Periodontal treatment often can be timed to avoid peak insulin activity. Many diabetic patients take multiple injections each day, in which case it is difficult, if not impossible, to avoid peak insulin activity. Checking the pretreatment glucose with the patient's glucometer, checking again during a long procedure, and checking again at the end of the procedure provides a better understanding of the patient's insulin pharmacodynamics and can help prevent hypoglycemia.

TABLE 39.5
Types of Insulin

Type	Classification	ACTIVITY		
		Onset	Peak	Duration
Lispro (Humalog), aspart (Novolog), glulisine (Apidra)	Rapid-acting	15 min	30–90 min	<5 hr
Regular R or Novolin R, Velosulin (used in insulin pump)	Short-acting	30–60 min	2–3 hr	3–6 hr
			1–2 hr	2–3 hr
NPH (N), Humulin N, Novolin N	Intermediate-acting	2–4 hr	4–12 hr	14–18 hr
Insulin determir (Levemir)	Long-acting	1–2 hr	Relatively flat (fairly even over 24 hr)	up to 24 hr
Glargine (Lantus)	Long-acting	6–8 hr	There is no peak	20–24+ hr

If hypoglycemia occurs during dental treatment, therapy should be immediately terminated. If a glucometer is available, the blood glucose level should be checked. Treatment guidelines include the following[56]:

1. Provide approximately 15 g of oral carbohydrate to the patient
    - 4 to 6 ounces of juice or soda
    - 3 or 4 teaspoons of table sugar
    - Hard candy with 15 g of sugar
2. If the patient is unable to take food or drink by mouth or if the patient is sedated
    - Give 25 to 30 mL of 50% dextrose intravenously, which provides 12.5 to 15.0 g of dextrose, or
    - Give 1 mg of glucagon intravenously (i.e.,

glucagon results in rapid release of stored glucose from the liver), or

- Give 1 mg of glucagon intramuscularly or subcutaneously (if no intravenous access).

Emergencies resulting from hyperglycemia are rare in the dental office. They usually take days to weeks to develop. However, the glucometer may be used to rule out hyperglycemic emergencies such as diabetic ketoacidosis, a life-threatening event.

Key Fact

The most common dental office complication seen in diabetic patients taking insulin is a symptomatic low blood glucose level, or hypoglycemia. It does not usually occur until blood glucose level falls below 60 mg/dL. However, in patients with poor glycemic control who have prolonged hyperglycemia, a rapid drop in glucose can precipitate signs and symptoms of hypoglycemia at higher levels. Clinicians must recognize the signs of hypoglycemia and be prepared to manage it. Hypoglycemia is more common in individuals with well-controlled glucose levels.

Because periodontal therapy can render the patient unable to eat for some time, adjustment in insulin or oral agent dosages may be required. It is critical that patients eat a normal meal before dental treatment. Taking insulin without eating is the primary cause of hypoglycemia. If the patient is restricted from eating before treatment (e.g., for conscious sedation), normal insulin doses need to be reduced. As a general guideline, *well-controlled diabetic patients having routine periodontal treatment may take their normal insulin doses as long as they also eat their normal meal.* If the procedure is going to be particularly long, the insulin dose before treatment may need to be reduced. Likewise, if the patient will have dietary restrictions after treatment, insulin or sulfonylurea dosages may need to be reduced.

Consultation with the patient's physician is prudent and allows both practitioners to review the proposed treatment plan and

determine whether modifications are needed. When periodontal surgery is indicated, it is usually best to limit the size of the surgical field so that the patient will be comfortable enough to resume a normal diet immediately.

Thyroid and Parathyroid Disorders

Periodontal therapy requires minimal alterations for the patient with adequately managed thyroid disease.[71,97] Patients with *thyrotoxicosis* and those with inadequate medical management should not receive periodontal therapy until their condition is stabilized. Patients with a history of *hyperthyroidism* should be carefully evaluated to determine the level of medical management, and they should be treated in a way that limits stress and infection. Hyperthyroidism can cause tachycardia and other arrhythmias, increased cardiac output, and myocardial ischemia. Medications such as epinephrine and other vasopressor amines should be given with caution to patients with treated hyperthyroidism, although the small amounts used in dental anesthetics rarely cause problems.[97,127] These drugs should not be given to patients with thyrotoxicosis or poorly controlled thyroid disorders. Patients with *hypothyroidism* require careful administration of sedatives and narcotics because of the potential for excessive sedation.

Routine periodontal therapy can be provided to patients with parathyroid disease after the disorder has been identified and the proper medical treatment given. However, patients who have not received medical care may have significant renal disease, uremia, and hypertension. If hypercalcemia or hypocalcemia exists, the patient may be more prone to cardiac arrhythmias.

Adrenal Insufficiency

Acute adrenal insufficiency is associated with significant morbidity and mortality rates as a result of peripheral vascular collapse and cardiac arrest. The periodontist should be aware of the clinical manifestations (eBox 39.1) and ways of preventing acute adrenal insufficiency in patients with a history of *primary* adrenal insufficiency (i.e., Addison disease) or *secondary* adrenal insufficiency (i.e., most often caused by use of exogenous

glucocorticosteroids).

eBox 39.1

Adrenal Crisis: Manifestations of Acute Adrenal Insufficiency

Mental confusion, fatigue, and weakness
Nausea and vomiting
Hypertension
Syncope
Intense abdominal pain, lower back pain, and leg pain
Loss of consciousness
Coma

The use of systemic corticosteroids is common in patients with allergic, endocrine, respiratory, joint, intestinal, neurologic, renal, liver, skin, or connective tissue disorders. Significant complications associated with corticosteroid use include alterations in glucose metabolism (i.e., steroid-induced diabetes), increased risk of infection, altered wound healing, osteoporosis, skin disorders, cataracts, glaucoma, and suppression of the hypothalamic-pituitary-adrenal (HPA) axis.[34,55] In the normal healthy patient, stress activates the HPA axis, stimulating increased endogenous cortisol production by the adrenal glands. Exogenous steroids may suppress the HPA axis and impair the patient's ability to respond to stress with increased endogenous cortisol production, leading to the potential for acute adrenal crisis (see eBox 39.1). The degree of adrenal suppression depends on the drugs used, dose, duration of administration, time elapsed since steroid therapy was terminated, and route of administration.

It was common practice in the past to administer prophylactic systemic steroids before dental treatment for patients who were taking or had recently taken exogenous steroids. However, steroid supplementation may not be required for many periodontal procedures.[37] *Adrenal crisis* is rare in dentistry, especially when associated with secondary adrenal suppression caused by steroid

use.[60] Shapiro and associates[96] found that patients taking 5 to 20 mg/day of prednisone maintained at least some adrenal reserve after immediate termination of steroid therapy. Higher doses can suppress the adrenal glands to a greater degree. Although exogenous steroids can suppress normal adrenal cortisol secretion for an extended period, the ability of the adrenal gland to respond to stress can return quickly after termination of steroid therapy.

Despite its rarity, the severe consequences of adrenal crisis suggest caution in patient care. Before providing extensive dental treatment to a patient with a history of recent or current steroid use, physician consultation is indicated to determine whether the patient's treatment needs warrant supplemental steroids. Use of a stress-reduction protocol and profound local anesthesia helps minimize the physical and psychologic stress associated with therapy and reduce the risk of acute adrenal crisis.

Most individuals with adrenal insufficiency can receive routine dental treatment without the need for supplemental glucocorticosteroids.[13,48] Patients currently taking corticosteroids usually have enough exogenous and endogenous cortisol to handle routine dental procedures if their usual dose is taken within 2 hours of the planned procedure. For most patients, supplemental corticosteroid administration is not required when uncomplicated minor surgical procedures, including periodontal surgery, are performed with local anesthesia with or without sedation.[48]

Individuals at risk for adrenal crisis requiring supplementation include those who are undergoing lengthy major surgical procedures, those expected to have significant blood loss, and those who have extremely low adrenal function. For these individuals, consultation with their physician and steroid supplementation is indicated. Low adrenal function can be identified with an adrenocorticotropic hormone (ACTH) stimulation test. A rapid assay is also available to determine the degree of adrenal reserve by measurement of serum cortisol levels 30 and 60 minutes after intravenous administration of synthetic corticotropin.[96]

For the patient who is identified as being at risk, the need for corticosteroid prophylaxis depends on the drug used because of the variance in equivalent therapeutic doses (eTable 39.1).

eTABLE 39.1

Equivalent Doses of Corticosteroids

Corticosteroid	Equivalent Dose (mg)
Cortisone	25
Hydrocortisone	20
Prednisone	5
Prednisolone	5
Methyl prednisone	5
Methylprednisolone	4
Triamcinolone	4
Dexamethasone	0.75
Betamethasone	0.6

Glucocorticosteroid coverage regimens vary, but most provide a twofold to fourfold increase in coverage, depending on the stress produced by the procedure. In an emergency situation, when testing is not possible, increasing the steroid dose before the procedure can decrease the chances of acute adrenal crisis.

Management of the patient in an acute adrenal insufficiency crisis is as follows:

1. Terminate periodontal treatment.
2. Summon medical assistance.
3. Give oxygen.
4. Monitor vital signs.
5. Place the patient in a supine position.
6. Administer 100 mg of hydrocortisone sodium succinate (Solu-Cortef) intravenously over 30 seconds or intramuscularly.

Hemorrhagic Disorders

Patients with a history of bleeding problems caused by disease or drugs should be managed to minimize the risks of hemorrhage. Identification of these patients through the health history, clinical examination, and clinical laboratory tests is paramount. Health questioning should cover (1) the history of bleeding after previous surgery or trauma, (2) past and current drug history, (3) history of bleeding problems among relatives, and (4) illnesses associated with potential bleeding problems.

Clinical examination can detect jaundice, ecchymosis, spider telangiectasia, hemarthrosis, petechiae, hemorrhagic vesicles, spontaneous gingival bleeding, and gingival hyperplasia. Laboratory tests include methods to measure the hemostatic, coagulation, or lytic phase of the clotting mechanism, depending on clues regarding which phase is involved (Table 39.6). These tests include bleeding time, tourniquet test, complete blood cell count, prothrombin time (PT), partial thromboplastin time (PTT), and coagulation time. Bleeding disorders are classified as coagulation disorders, thrombocytopenic purpuras, or nonthrombocytopenic purpuras.

TABLE 39.6
Laboratory Tests for Bleeding Disorders

HEMOSTATIC TESTS			
Vascular	**Platelet**	**Coagulation**	**Lysis**
1. Tourniquet test *N:* 10 petechiae *Abn:* >10 petechiae	1. Platelet count *N:* 150,000-300,000/mm^3 *Abn:* Thrombocytopenia occurs at <100,000/mm^3; clinical bleeding occurs at <80,000/mm^3; spontaneous bleeding occurs at <20,000/mm^3	1. PT measures extrinsic and common pathways: factors I, II, V, VII, and X. *N:* 11–14 sec (depending on laboratory) measured against control PT reported as international normalized ratio (INR): *N:* INR = 1.0 *Abn:* INR >1.5	1. Euglobin clot lysis time *N:* <90 min *Abn:* >90 min
2. Bleeding time *N:* 1–6 min *Abn:* >6 min	2. Bleeding time 3. Clot retraction 4. Complete blood cell count	2. PTT measures intrinsic and common pathways: factors III, IX, XI, and low levels of factors I, II, V, X, and XII. *N:* 25–40 sec (depending on laboratory) measured against control *Abn:* >1.5 times normal 3. Clotting (coagulation) time *N:* 30–40 min *Abn:* >1 hr

Coagulation Disorders

The main inherited coagulation disorders include hemophilia A, hemophilia B, and von Willebrand disease[77,88] (Table 39.7). *Hemophilia A* results in a deficiency of coagulation factor VIII, and the clinical severity of the disorder depends on the level of factor VIII remaining.[68] Patients with severe hemophilia who have less than 1% of normal factor VIII levels can have severe bleeding on the slightest provocation, whereas those with more moderate hemophilia (i.e., 1% to 5% of factor VIII) have less frequent spontaneous hemorrhage but still bleed with minimal trauma.[55] Patients with mild hemophilia (i.e., 6% to 30% of factor VIII) rarely bleed spontaneously but may still hemorrhage after severe trauma or during surgical procedures.

TABLE 39.7
Inherited Coagulation Disorders

Type	Prolonged	Normal	Treatment
Hemophilia A	PTT	PT Bleeding time	DDAVP factor VIII concentrate or cryoprecipitate Fresh frozen plasma Fresh whole blood ε-Aminocaproic acid (Amicar) Tranexamic acid

Hemophilia B	PTT	PT Bleeding time	Purified prothrombin complex concentrate Factor IX concentrates Fresh-frozen plasma
Von Willebrand disease	Bleeding time PTT Variable factor VIII deficiency	PT Platelet count	DDAVP factor VIII concentrate or cryoprecipitate

DDAVP, 1-deamino-8-D-arginine vasopressin (desmopressin); *PT,* prothrombin time; *PTT,* partial thromboplastin time.

The clinician should consult the patient's physician before dental treatment to determine the risk of bleeding and treatment modifications required. To prevent surgical hemorrhage, a factor VIII level of at least 30% is needed.[55,68] Parenteral 1-deamino-8-D-arginine vasopressin (DDAVP; desmopressin) can be used to raise factor VIII levels twofold to threefold in patients with mild or moderate hemophilia. DDAVP has the significant advantage of avoiding the risk of viral disease transmission from factor VIII infusion and is considered the drug of choice in responsive patients. Most patients with moderate or severe hemophilia require infusion of factor VIII concentrate before surgical procedures. Before 1985, the risk of viral disease transmission from these infusions was high. Since then, virally safe, highly purified monoclonal antibody or recombinant DNA factor VIII products have come into widespread use.

Hemophilia B (i.e., Christmas disease) results in a deficiency of factor IX. The severity of the disorder depends on the relative amount of existing factor IX. Surgical therapy requires a factor IX level of 30% to 50%, which is usually achieved by administration of purified prothrombin complex concentrate or factor IX concentrate.[68]

Von Willebrand disease results from a deficiency of von Willebrand factor, which mediates adhesion of platelets to the injured vessel walls and is required for primary hemostasis. Von Willebrand factor also carries the coagulant portion of factor VIII in the plasma. The disorder has three major subtypes, with a wide range of clinical severity. Many cases of von Willebrand disease go undiagnosed, and bleeding during dental treatment may be the first sign of the underlying disease. More severe forms require preoperative factor VIII concentrate or cryoprecipitate infusion. Patients with milder

forms respond favorably to administration of DDAVP before periodontal surgery or tooth extraction.[68,69]

Periodontal treatment can be performed in patients with these coagulation disorders, provided that sufficient precautions are taken. Probing, scaling, and prophylaxis can usually be done without medical modification. More invasive treatment, such as local block anesthesia, root planing, or surgery, dictates prior physician consultation.

During treatment, local measures to ensure clot formation and stability are of major importance. Complete wound closure and application of pressure can reduce hemorrhage. Antihemostatic agents, such as oxidized cellulose or purified bovine collagen, can be placed over surgical sites or into extraction sockets. The antifibrinolytic agent *ε-aminocaproic acid* (Amicar), given orally or intravenously, is a potent inhibitor of initial clot dissolution.[42] *Tranexamic acid* is a more potent antifibrinolytic agent than Amicar and can prevent excessive oral hemorrhage after periodontal surgery and tooth extraction.[76] It is available as an oral rinse and may be used alone or in combination with systemic tranexamic acid for several days after surgery.[99]

Not all coagulation disorders are hereditary. Liver disease affects all phases of blood clotting because most coagulation factors are synthesized and removed by the liver. Long-term alcohol abusers or chronic hepatitis patients often demonstrate inadequate coagulation. Coagulation can be impaired by vitamin K deficiency, often caused by malabsorption syndromes, or by prolonged antibiotic administration, which alters the intestinal microflora that produces vitamin K. Dental treatment planning for patients with liver disease should include the following:

1. Physician consultation
2. Laboratory evaluations: PT, bleeding time, platelet count, and PTT (for patients in later stages of liver disease)
3. Conservative, nonsurgical periodontal therapy whenever possible
4. When surgery is required (may require hospitalization)
    - International normalized ratio (INR; PT) should be less than 2.0; for simple surgical procedures, an

INR of less than 2.5 is usually safe.[39]

- Platelet count should be more than 80,000/mm^3.

Key Fact

Periodontal treatment can be performed in patients with coagulation disorders, provided that sufficient precautions are taken. Probing, scaling, and prophylaxis usually can be done without medical modification. However, more invasive treatment, such as local block anesthesia, root planing, or surgery, should be considered only after consultation with a physician.

Anticoagulant Medications

The most common cause of abnormal coagulation may be drug therapy. Patients with a prosthetic heart valve or a history of MI, CVA, or thromboembolism are frequently placed on anticoagulant therapy using coumarin derivatives such as dicumarol and warfarin.[39,51] These drugs are vitamin K antagonists that decrease production of vitamin K–dependent coagulation factors II, VII, IX, and X. The effectiveness of anticoagulation therapy is monitored by a PT laboratory test. The recommended level of therapeutic anticoagulation for most patients is an INR of 2.0 to 3.0, with prosthetic heart valve patients usually in the 2.5 to 3.5 range.[39] Traditional recommendations for periodontal treatment are as follows:

1. Consult the patient's physician to determine the nature of the underlying medical problem and the degree of required anticoagulation.
2. The procedure to be done determines the acceptable INR. Infiltration anesthesia, scaling, and root planing can be done safely in patients with an INR of less than 3.0. Block anesthesia, minor periodontal surgery, and simple extractions usually require an INR of less than 2.0 to 2.5. Complex surgery or multiple extractions may require an INR of less than 1.5 to 2.0.
3. The physician must be consulted about any changes (i.e.,

discontinuing or reducing) in anticoagulant dosage until the desired INR is achieved. The dentist must inform the physician what degree of intraoperative and postoperative bleeding is usually expected with the planned procedure. If the INR is higher than the level at which significant bleeding is likely to accompany a particular procedure, the physician may elect to change anticoagulant therapy. Often, the anticoagulant is discontinued for 2 to 3 days before periodontal treatment (i.e., clearance half-life of warfarin is 36 to 42 hours), and the INR is checked on the day of therapy. If the INR is within the acceptable target range, the procedure is done and the anticoagulant resumed immediately after treatment.

4. Careful technique and complete wound closure are paramount. For all procedures, application of pressure can minimize hemorrhage. Use of oxidized cellulose, microfibrillar collagen, topical thrombin, and tranexamic acid should be considered for persistent bleeding.

Discontinuing anticoagulant therapy before dental surgery was common in the past. However, many clinicians no longer recommend discontinuing anticoagulation for many procedures because it poses significant risks for patient health.[41,90] Evidence related to the risks of altering anticoagulant therapy and the lack of evidence for bleeding complications suggest that treating patients without reducing or discontinuing medications may be more prudent. Details of anticoagulant or antiplatelet therapy are discussed in the next section.

Heparin typically is used for short-term anticoagulation and is given intravenously and usually in a hospital environment. It is a powerful anticoagulant with a duration of action of 4 to 8 hours. Periodontal treatment is rarely required while a patient is taking heparin.

Antiplatelet Medications

Aspirin interferes with normal platelet aggregation and can result in prolonged bleeding. Because it binds irreversibly to platelets, the effects of aspirin last at least 4 to 7 days. Aspirin typically is used in

small doses of 325 mg or less per day, which usually does not alter bleeding time. Patients taking low doses of aspirin daily usually do not need to discontinue aspirin therapy before periodontal procedures.[90] However, higher doses can increase bleeding time and predispose the patient to postoperative bleeding.[55] For patients taking more than 325 mg of aspirin per day, it may need to be discontinued 7 to 10 days before surgical therapy that could result in significant bleeding; this should be done in consultation with the physician.

Nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen also inhibit platelet function. Because NSAIDs bind reversibly, the effect is transitory, lasting only a short time after the last drug dose. The bleeding time is used when questions arise about the potential effect of aspirin or NSAIDs. Aspirin should not be prescribed for patients who are receiving anticoagulation therapy or who have an illness related to bleeding tendency.

Key Fact

Discontinuing anticoagulant therapy before an oral surgical procedure was common in the past. Many clinicians no longer recommend discontinuing anticoagulation for many procedures because it can pose significant risks for patient health. Evidence related to the risks of altering anticoagulant therapy and the lack of evidence for bleeding complications in these patients suggest that treating them without discontinuing medications may be more prudent.

Thrombocytopenic Purpuras

Thrombocytopenia is defined as a platelet count of less than 100,000/mm^3. Bleeding caused by thrombocytopenia can be seen with idiopathic thrombocytopenic purpuras, radiation therapy, myelosuppressive drug therapy (e.g., chemotherapy), leukemia, or infections. Purpuras are hemorrhagic diseases characterized by extravasation of blood into the tissues under the skin or mucosa, producing spontaneous petechiae (i.e., small red patches) or ecchymoses (i.e., bruises).

Periodontal therapy for patients with thrombocytopenia should be directed toward reducing inflammation by removing local irritants to avoid the need for more aggressive therapy.[55,68] Oral hygiene instructions and frequent maintenance visits are paramount. Physician referral is indicated for a definitive diagnosis and to determine alterations in planned therapy. Scaling and root planing are usually safe unless the platelet count is less than 60,000/mm^3. No surgical procedure should be performed unless the platelet count is greater than 80,000/mm^3. Platelet transfusion may be required before surgery. Surgical technique should be as atraumatic as possible, and local hemostatic measures should be applied.

Nonthrombocytopenic Purpuras

Nonthrombocytopenic purpuras result from vascular wall fragility or thrombasthenia (i.e., impaired platelet aggregation). Vascular wall fragility can result from hypersensitivity reactions, scurvy, infections, chemicals (e.g., phenacetin, aspirin), dysproteinemia, and other causes. Thrombasthenia occurs in uremia, Glanzmann disease, aspirin ingestion, and von Willebrand disease.[68] Both types of nonthrombocytopenic purpura can cause immediate bleeding after gingival injury. Treatment consists primarily of direct pressure applied for at least 15 minutes. This initial pressure should control the bleeding unless coagulation times are abnormal or reinjury occurs. Surgical therapy should be avoided until the qualitative and quantitative platelet problems are resolved.

Blood Dyscrasias

Numerous disorders of red and white blood cells can affect the course of periodontal therapy. Alterations in wound healing, bleeding, tissue appearance, and susceptibility to infection can occur. Clinicians should be aware of the clinical signs and symptoms of blood dyscrasias, availability of screening laboratory tests, and need for physician referral.

Leukemia

Altered periodontal treatment for patients with leukemia is based on their enhanced susceptibility to infections, bleeding tendency, and effects of chemotherapy.[55] The treatment plan for leukemia patients is as follows:

1. Refer the patient for medical evaluation and treatment. Close cooperation with the physician is required.
2. Before chemotherapy, a complete periodontal treatment plan should be developed with a physician (discussed in the previous discussion).
    - Monitor hematologic laboratory values daily: bleeding time, coagulation time, PT, and platelet count.
    - Administer antibiotic coverage before periodontal treatment because infection is a major concern.
    - If systemic conditions allow, extract all hopeless, nonmaintainable, or potentially infectious teeth at least 10 days before the initiation of chemotherapy.
    - Periodontal debridement (i.e., scaling and root planing) should be performed and thorough oral hygiene instructions given if the patient's condition allows. Twice-daily rinsing with 0.12% chlorhexidine gluconate is recommended after oral hygiene procedures. Recognize the potential for bleeding caused by thrombocytopenia. Use pressure and topical hemostatic agents as indicated.
3. During the acute phases of leukemia, patients should receive only emergency periodontal care. Any source of potential infection must be eliminated to prevent systemic dissemination. Antibiotic therapy is frequently the treatment of choice, combined with nonsurgical or surgical debridement as indicated.
4. Oral ulcerations and mucositis are treated palliatively with agents such as viscous lidocaine. Systemic antibiotics may be indicated to prevent secondary infection.
5. Oral candidiasis is common in leukemic patients and can be

treated with nystatin suspension (400,000–600,000 U/mL four times daily) or clotrimazole vaginal suppositories (10 mg four or five times daily).[57]

6. For patients with chronic leukemia and those in remission, scaling and root planing can be performed without complication, but periodontal surgery should be avoided if possible. Platelet count and bleeding time should be measured on the day of the procedure. If either is low, postpone the appointment and refer the patient to a physician.

Agranulocytosis

Patients with agranulocytosis (i.e., cyclic neutropenia and granulocytopenia) have an increased susceptibility to infection. The total white blood cell count is reduced, and granular leukocytes (i.e., neutrophils, eosinophils, and basophils) are reduced in number or disappear. These disorders are often marked by early, severe periodontal destruction.[122] When possible, periodontal treatment should be done during periods of disease remission. At such times, treatment should be as conservative as possible while reducing potential sources of systemic infection. After physician consultation, severely affected teeth should be extracted. Oral hygiene instruction should include chlorhexidine rinses twice daily. Scaling and root planing should be performed carefully under antibiotic protection.

Renal Diseases

The most common causes of renal failure are glomerulonephritis, pyelonephritis, kidney cystic disease, renovascular disease, drug nephropathy, obstructive uropathy, and hypertension.[36,45] Renal failure can result in severe electrolyte imbalance, cardiac arrhythmias, pulmonary congestion, CHF, and prolonged bleeding.[55] Because the dental management of patients with renal disease may need to be drastically altered, physician consultation is necessary to determine the stage of renal disease, regimen for medical management, and alterations in periodontal therapy. The

patient in chronic renal failure has a progressive disease that ultimately may require kidney transplantation or dialysis. It is preferable to treat the patient before transplantation or dialysis.

The following treatment modifications should be made:

1. Consult the patient's physician.
2. Monitor BP; patients in end-stage renal failure are usually hypertensive.
3. Check laboratory values: PTT, PT, bleeding time, and platelet count; hematocrit; blood urea nitrogen (do not treat if <60 mg/dL); and serum creatinine (do not treat if <1.5 mg/dL).
4. Eliminate areas of oral infection to prevent systemic infection.
    - Good oral hygiene should be established.
    - Periodontal treatment should aim at eliminating inflammation or infection and providing easy maintenance. Questionable teeth should be extracted if medical parameters permit.
    - Frequent recall appointments should be scheduled.
5. Drugs that are nephrotoxic or metabolized by the kidney should not be given (e.g., phenacetin, tetracycline, aminoglycoside antibiotics). Acetaminophen may be used for analgesia and diazepam for sedation. Local anesthetics such as lidocaine are usually safe.[55,79]

The patient who is receiving dialysis requires modifications in treatment planning.[36,47] The three modes of dialysis are intermittent peritoneal dialysis (IPD), chronic ambulatory peritoneal dialysis (CAPD), and hemodialysis. Only hemodialysis patients require special precautions. They have a high incidence of viral hepatitis, anemia, and prolonged hemorrhage. The risk of hemorrhage is related to anticoagulation during dialysis, platelet trauma from dialysis, and the uremia that develops with renal failure.[55] Hemodialysis patients have an internal arteriovenous fistula or an external arteriovenous shunt. The shunt is often located in the arm and must be protected from trauma. In addition to guidelines for

patients with chronic renal disease, the following recommendations are made for those receiving hemodialysis:

1. Screen for hepatitis B and hepatitis C antigens and antibodies before any treatment.
2. Provide antibiotic prophylaxis to prevent endarteritis of the arteriovenous fistula or shunt. IPD and CAPD patients do not usually require prophylactic antibiotics.
3. Patients receive heparin anticoagulation on the day of hemodialysis. Periodontal treatment should be provided on the day *after* dialysis, when the effects of heparinization have subsided. Hemodialysis treatments are usually performed three or four times per week. (IPD and CAPD patients are not systemically heparinized; they usually do not have the potential bleeding problems associated with hemodialysis.)
4. The hemodialysis shunt or fistula must be protected when the patient is in the dental chair. If the shunt or fistula is placed in the arm, do not cramp the limb; *BP readings should be taken from the other arm.* Do not use the limb for the injection of medication. Patients with leg shunts should avoid sitting with the leg dependent for longer than 1 hour. If the appointment lasts longer, allow the patient to walk about for a few minutes, then resume therapy.
5. Refer the patient to the physician if uremic problems develop, such as uremic stomatitis. To prevent systemic dissemination, refer to the physician if oral infections do not resolve promptly.

The renal transplant patient's greatest foe is infection. Transplant recipients take immunosuppressive drugs that greatly reduce resistance to infection.[79] Excessive bleeding can occur during or after periodontal treatment because of drug-induced thrombocytopenia or anticoagulation, or both. A periodontal abscess is a potentially life-threatening situation, and a dental team approach should be used *before* transplantation to determine which teeth can be easily maintained. Many organ transplantation centers include dental examination in their standard protocols. Teeth with

severe bone and attachment loss, furcation invasion, periodontal abscesses, or extensive surgical requirements should be extracted, leaving an easily maintainable dentition. In addition to the recommendations for patients with chronic renal failure, the following should be considered for the renal transplant recipient:

1. Hepatitis B and C screening
2. Determination of the level of immune system compromise resulting from antirejection drug therapy
3. Prophylactic antibiotics using AHA recommendations or a specific regimen based on physician consultation; not all transplant recipients require antibiotic coverage, and physician consultation is warranted before prescribing

Liver Diseases

Liver diseases range from mild conditions to complete liver failure. Major causes of liver disease include drug toxicity, cirrhosis, viral infections (e.g., hepatitis B, hepatitis C), neoplasms, and biliary tract disorders.[130] Because the liver is the site of production of most clotting factors, excessive bleeding during or after periodontal treatment can occur in patients with severe liver disease. Many drugs are metabolized in the liver, and liver disease alters normal drug metabolism. Treatment recommendations for patients with liver disease include the following:

1. Consultation with the physician concerning the current stage of disease, risk of bleeding, potential drugs to be prescribed during treatment, and required alterations to periodontal therapy
2. Screening for hepatitis B and C
3. Laboratory values for PT and PTT
4. Laboratory values for INR

For the liver transplant recipient, as with kidney and other organ transplantation, infection is a major concern. Patients take immunosuppressive drugs that greatly reduce resistance to infection.[79] Excessive bleeding can occur during or after periodontal

treatment because of drug-induced thrombocytopenia or anticoagulation, or both. Dental or periodontal infections are potentially life-threatening. A pretransplantation evaluation is recommended to determine which teeth can be maintained without risk of infection. Teeth with severe bone and attachment loss, furcation invasion, periodontal abscesses, or extensive surgical requirements should be extracted.

Pulmonary Diseases

The periodontal treatment of a patient with pulmonary disease may require alteration, depending on the nature and severity of the respiratory problem. Pulmonary diseases range from obstructive lung diseases (e.g., asthma, emphysema, bronchitis, acute obstruction) to restrictive ventilatory disorders caused by muscle weakness, scarring, obesity, or any condition that can interfere with effective lung ventilation.[70,87] Combined restrictive-obstructive lung disease may also develop.

The clinician should be aware of the signs and symptoms of pulmonary disease, such as increased respiratory rate, cyanosis, clubbing of the fingers, chronic cough, chest pain, hemoptysis, dyspnea or orthopnea, and wheezing. Patients with any of these problems should be referred for medical evaluation and treatment. Most patients with chronic lung disease can undergo routine periodontal therapy if they are receiving adequate medical management. Caution should be practiced in relation to any treatment that may depress respiratory function.

Acute respiratory distress can be caused by slight airway obstruction or depression of respiratory function. Because of limited vital lung capacity, patients also have decreased cough effectiveness.[87] They must continually deal with the mental anxiety caused by air hunger and alter their position in attempts to improve their ventilatory efficiency.

The following guidelines should be used during periodontal therapy:

1. Identify and refer patients with signs and symptoms of pulmonary disease to their physician.

2. For patients with known pulmonary disease, consult with their physician regarding medications (e.g., antibiotics, steroids, chemotherapeutic agents) and the degree and severity of pulmonary disease.
3. Avoid elicitation of respiratory depression or distress:
    - Minimize the stress of a periodontal appointment. The patient with emphysema should be treated in the afternoon, several hours after sleep, to allow for airway clearance.
    - Avoid medications that could cause respiratory depression (e.g., narcotics, sedatives, general anesthetics).
    - Avoid bilateral mandibular block anesthesia, which could cause increased airway obstruction.
    - Position the patient to allow maximal ventilatory efficiency, be careful to prevent physical airway obstruction, keep the patient's throat clear, and avoid excess periodontal packing.
4. For a person with a history of asthma, especially if asthma attacks are frequent, make sure the patient's medication (inhaler) is available. The inhaler should be readily accessible on the countertop in the dental treatment room.
5. Patients with active fungal or bacterial respiratory diseases should not be treated unless the periodontal procedure is an emergency.

Medications and Cancer Therapies

Some medications prescribed to cure, manage, or prevent diseases have effects on periodontal tissues, wound healing, or the host immune response that sometimes require modification of treatment. Bisphosphonates, anticoagulation medications, antiplatelet medications, steroids, chemotherapy, and radiation therapy are briefly addressed in this chapter, and additional information and advice can be found in other sources.

Bisphosphonates

Bisphosphonate medications are primarily used to treat cancer (i.e., intravenous administration) and osteoporosis (i.e., oral administration). They act by inhibiting osteoclastic activity, which leads to less bone resorption, remodeling, and turnover.[83] Bisphosphonates are used in cancer treatment to prevent the often lethal imbalance of osteoclastic activity. In the treatment of osteoporosis, the goal is to harness osteoclastic activity to minimize or prevent bone loss. The major difference between these applications is the potency and route of administration. Potency is influenced by the chemical properties and pharmacokinetics of these agents in bone. Chapter 14 describes the chemical structure, activity, and role of bisphosphonates in the development of bisphosphonate-related osteonecrosis of the jaw (BRONJ).

Clinically, BRONJ manifests as exposed alveolar bone occurring spontaneously or after a dental procedure (see Figs. 14.20 and 14.21 in Chapter 14). Individuals treated with high-potency, nitrogen-containing bisphosphonates, especially those administered intravenously for cancer treatment (e.g., zoledronate), appear to be at greater risk for BRONJ than individuals taking oral bisphosphonates for prevention and treatment of osteoporosis. For patients treated for cancer, the incidence ranges from 2.5% to 5.4%.[121] Estimating the incidence for patients taking oral bisphosphonates for osteoporosis is more difficult but appears to range from 0.007% to 0.04%.[118] Even if this is an underestimation of the actual risk for individuals taking oral bisphosphonates, the incidence appears to be low. The risk for individuals treated with oral bisphosphonates for a period of less than 3 years appears to be minimal or zero.[52] Regular use of oral bisphosphonates for a period greater than 3 years suggests a risk profile that increases with time and length of use.[52]

As with many multifactorial diseases and conditions, it is likely that factors in addition to bisphosphonate therapy contribute to the individual risk of BRONJ. Potential risk factors include systemic corticosteroid therapy, smoking, alcohol, poor oral hygiene, chemotherapy, radiotherapy, diabetes, and hematologic disease.[25] Reported factors for BRONJ include extractions, root canal treatment, periodontal infections, periodontal surgery, and dental implant surgery.[54] Periodontal disease and treatment (especially

surgery) poses a risk for patients treated with bisphosphonates. The bacteria-induced inflammatory process of periodontitis that causes bone resorption can lead to bone necrosis. Likewise, periodontal treatment can cause bone necrosis in the setting of bisphosphonates. Caution is warranted for all patients treated with bisphosphonates.

Health care providers need to evaluate patients carefully, communicate with other medical health care providers, inform patients, and consider treatment options and risks carefully. A careful intraoral examination is prudent for all patients treated with intravenous or oral bisphosphonate therapy to determine whether bone exposure exists and to assess local conditions that may predispose them to BRONJ. A thorough medical history should be reviewed, evaluated, and annotated with details about bisphosphonate treatment, including medication type, dose, route of administration, and duration. Comorbidities, such as previous and current medications, treatments, and existing disease or pathology, should be considered. Radiographs should be carefully evaluated for signs of bisphosphonate toxicity.

Marx suggested that a laboratory blood test for the serum C-terminal telopeptide fragment of type I collagen (CTX) could be used to assess an individual's risk of developing BRONJ.[52] Marx reported that lower CTX values were associated with greater risk (eTable 39.2). It is important to recognize that these values are based on retrospective evaluation of patients with osteonecrosis of the jaws and that prospective studies to validate these findings have not been done. The CTX laboratory test is a measure of the specific C-terminal fragment of type I collagen cleaved by osteoclasts and indicates bone resorption activity. However, its use as a measure of the risk for BRONJ is controversial and not confirmed by prospective studies.

eTABLE 39.2

C-Terminal Telopeptide Laboratory Risk Assessment for Bisphosphonate Therapy

C-Terminal Telopeptide (CTX) Value	Risk of BRONJ
300–600 pg/mL (normal)	None
150–299 pg/mL	None or minimal
101–149 pg/mL	Moderate
≤100 pg/mL	High

BRONJ, Bisphosphonate-related osteonecrosis of the jaw.

Data from Marx RE: *Oral and intravenous bisphosphonate-induced osteonecrosis of the jaws,* Hanover Park, MD, 2007, Quintessence.

Optimal periodontal and oral health should be achieved and maintained for all patients. For individuals treated with intravenous bisphosphonates, invasive treatment, such as extractions, periodontal surgery, implant surgery, and bone augmentation procedures, should be avoided. Risks must be considered before treatment of individuals with a history of taking oral bisphosphonates for longer than 3 years. This area of research will continue to evolve as the pathophysiology becomes better understood. Providers are encouraged to consult other sources for updates on this important topic.

Key Fact

Bisphosphonate therapy and one or more comorbidity factors contribute to the individual risk of bisphosphonate-related osteonecrosis of the jaw (BRONJ). Potential risk factors include systemic corticosteroid therapy, smoking, alcohol, poor oral hygiene, chemotherapy, radiotherapy, diabetes, and hematologic disease.

Anticoagulant or Antiplatelet Therapy

Many patients with a variety of conditions are placed on anticoagulant or antiplatelet medications to prevent thrombosis (i.e., blood clotting) or thromboembolism. Patients at risk who may be on anticoagulant or antiplatelet therapy include those with heart valve replacements, heart rhythm disorders, congenital heart defects, or a history or risk of MI, stroke, or deep vein thrombosis. These medications, although effective in reducing the risk of thrombosis, may increase the risk for bleeding complications, especially in patients undergoing surgical procedures.

The traditional approach to patients on anticoagulant or antiplatelet therapy was to discontinue therapy about 3 to 5 days (antiplatelet therapy) or 7 to 10 days (anticoagulant therapy) before a planned surgical procedure. Evidence and theories about the care

of patients on anticoagulant or antiplatelet therapy suggest that treating them (e.g., with periodontal surgery or extractions) without altering their anticoagulant or antiplatelet medications is safe and does not lead to intraoperative or postoperative bleeding complications. The increased risk of morbidity and mortality for those discontinuing the anticoagulant or antiplatelet therapy may be significant.

Controlled clinical studies have demonstrated that intraoperative bleeding is not likely to be a problem with simple extractions or periodontal surgery if antiplatelet therapy (e.g., aspirin) is continued.[6,50] In these studies, there were no episodes of uncontrolled bleeding, all bleeding was controlled with local measures, and there were no cases of postoperative bleeding problems. Conversely, the risk of stopping antiplatelet therapy may be serious. In a retrospective evaluation of 52 patients undergoing cataract surgery, 1 in 10 whose antiplatelet therapy was stopped or reduced suffered a stroke.[85]

Clinical studies of patients on anticoagulant therapy undergoing extractions and other oral surgical procedures have demonstrated minimal bleeding problems when therapy is continued.[12,15,119,120,129] In a review of the literature, Wahl and colleagues[120] reported that only 12 (<1.3%) of 950 patients receiving continuous anticoagulant therapy required more than local measures to control hemorrhage after 2400 minor oral surgical procedures. Most of the 950 patients had anticoagulation levels that were well above currently recommended therapeutic levels. Only three patients (<0.31%) had anticoagulation levels within or below currently recommended therapeutic levels. In contrast, 5 (0.95%) of 526 patients who experienced 575 interruptions of continuous anticoagulant therapy suffered serious embolic complications; 4 patients died.

In a prospective study of 131 patients undergoing 511 extractions, those whose oral anticoagulant therapy was reduced 72 hours before surgery to achieve an INR of 1.5 to 2.0 (target, 1.8) had postoperative bleeding that warranted subsequent local intervention in 10 (15.1%) of 66 patients.[84] Postoperative bleeding occurred in only 6 (9.2%) of 65 patients in the group that continued the regular dosage of oral anticoagulant therapy (mean INR, 2.9).

These studies suggest that the risk of serious morbidity

associated with discontinuing anticoagulant or antiplatelet therapy should be avoided and that the risk of bleeding while maintaining this therapy is minimal.

Corticosteroids

Approximately 5% of the adults in the United States habitually take corticosteroids for the treatment of various conditions, potentially putting them at risk for secondary adrenal insufficiency.[48] Patients who habitually use corticosteroids have an increased likelihood of developing hypertension, osteoporosis, and peptic ulcer disease. Care should be taken to minimize the risk of adverse outcomes in these patients. BP should be monitored, and medications that may exacerbate peptic ulceration (e.g., aspirin, NSAIDs) should be avoided.

Stressful events, such as trauma, illness, surgery, emotional upset, or athletic events, normally increase circulating endogenous cortisol levels through stimulation of the HPA axis. Pain appears to increase the requirement for cortisol release.[75] There is concern that the normal release of cortisol in response to a stressful event, such as a dental procedure may be impaired in patients exposed to habitual corticosteroid use. The concern is about whether these patients require perioperative supplementation for dental procedures. Historically, recommendations were based on the type, amount, and duration of corticosteroid use. However, current thinking about the need for perioperative corticosteroid supplementation has been adjusted.

Studies investigating the stress response to minor general and oral surgical procedures concluded that significant increases in cortisol were usually not seen until 1 to 5 hours after surgery and appeared to be associated more with postoperative pain and the loss of local anesthesia than with the preoperative and intraoperative stress of the procedure.[7,94,95] Administration of adequate analgesics in the postoperative period can diminish the release (requirement) of cortisol.[7]

Most individuals with adrenal insufficiency can receive routine dental treatment without the need for supplemental glucocorticosteroids.[13,48] Patients taking corticosteroids usually have

enough exogenous and endogenous cortisol to handle routine dental procedures if the usual dose is taken within 2 hours of the planned procedure. For most patients, supplemental corticosteroid administration is not required when uncomplicated minor surgical procedures, including periodontal surgery, are performed with local anesthesia with or without sedation.[48] Topical corticosteroids usually have minimal HPA effect, and steroid supplementation is not required for these patients.

Individuals at risk for adrenal crisis who require supplementation include those undergoing lengthy major surgical procedures, those expected to have significant blood loss, and those who have extremely low adrenal function. Low adrenal function can be identified with an ACTH stimulation test. For these individuals, consultation with the physician and steroid supplementation are indicated.

Immunosuppression and Chemotherapy

Immunosuppressed patients have an impaired host defense as a result of an underlying immunodeficiency or use of drugs (primarily related to organ transplantation or cancer chemotherapy).[58,91] Because chemotherapy is often cytotoxic to bone marrow, destruction of platelets and red and white blood cells results in thrombocytopenia, anemia, and leukopenia. Immunosuppressed individuals are at greatly increased risk for infection, and even minor periodontal infections can become life-threatening if immunosuppression is severe.[74,77] Bacterial, viral, and fungal infections can manifest intraorally. Patients undergoing bone marrow transplantation require special attention because they receive extremely high-dose chemotherapy and are particularly susceptible to dissemination of oral infections.

Treatment should be directed toward prevention of oral complications that can be life-threatening. The greatest potential for infection occurs during periods of extreme immunosuppression; treatment should be conservative and palliative. It is always preferable to evaluate the patient before initiation of chemotherapy.[58,91] Teeth with a poor prognosis should be extracted, with thorough debridement of remaining teeth to minimize the

microbial load. The clinician must teach and emphasize the importance of good oral hygiene. Antimicrobial rinses, such as chlorhexidine, are recommended, especially for patients with chemotherapy-induced mucositis, to prevent secondary infection.

Chemotherapy is usually performed in cycles, with each cycle lasting several days, followed by intervening periods of myelosuppression and recovery. If periodontal therapy is needed during chemotherapy, it is best done the day *before* chemotherapy is given, when white blood cell counts are relatively high. Coordination with the oncologist is critical. Dental treatment should be done when the white blood cell count is above 2000/mm^3, with an absolute granulocyte count of 1000 to 1500/mm^3.[55]

Radiation Therapy

The use of radiotherapy, alone or in conjunction with surgical resection, is common in the treatment of head and neck tumors. The side effects of ionizing radiation include dramatic perioral changes of significant concern to dental health personnel.[38,57,92] The extent and severity of mucositis, dermatitis, xerostomia, dysphagia, gustatory alteration, radiation caries (Fig. 39.3), vascular changes, trismus, temporomandibular joint degeneration, and periodontal changes depend on the type of radiation used, field of irradiation, number of ports, type of tissue in the field, and dosage.

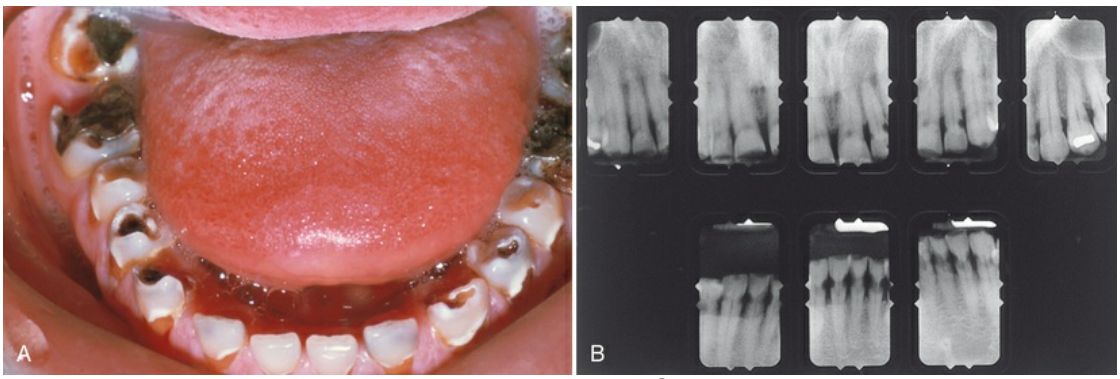

FIG. 39.3 (A) In a clinical view of a patient with radiation caries, notice how the caries primarily affected the smooth tooth surfaces, especially cervical areas and cusp tips. (B) Radiographs of anterior teeth of 52-year-old man with postradiation caries. The

patient received a dose of 6000 cGy for radiation treatment of the posterior mandible and base of the tongue for squamous cell carcinoma. Radiation caries developed within 1 year after radiation treatment, affecting the cervical areas and incisal edges of the anterior teeth. (A, courtesy Dr. Eric Sung, Hospital Dentistry, University of California Los Angeles.)

Patients scheduled to receive head and neck radiation therapy require dental consultation *at the earliest possible time* to reduce the morbidity of known perioral side effects.[89] Preirradiation treatment depends on the patient's prognosis, compliance, and residual dentition in addition to the field, ports, dose, and immediacy of radiotherapy. The initial visit should include panoramic and intraoral radiographs, a clinical dental examination, a periodontal evaluation, and a physician consultation. The physician should be asked about the amount of radiation to be administered, extent and location of the lesion, nature of surgical procedures already performed or to be performed, number of radiation ports, exact fields to be irradiated, mode of radiation therapy, and patient's prognosis (i.e., likelihood of metastasis). Preirradiation treatment should commence immediately after the physician consultation. The first decision should involve possible extractions because radiation can cause side effects that interfere with healing.

For head and neck squamous cell carcinomas, the radiation dose is usually 5000 to 7000 cGy (1 cGy = 1 rad) delivered in a fractionated method (150 to 200 cGy/day over a 6- to 7-week course).[11,57] This is considered full-course radiation treatment, and the degree of perioral side effects depends on which tissues are irradiated (i.e., radiation fields). If the radiation is administered to the salivary gland tissues, xerostomia will ensue. The parotid is the most radiosensitive of the salivary glands; saliva may become extremely viscous or nonexistent, depending on the dose delivered to the particular gland. Xerostomia causes a decrease in the normal salivary cleansing mechanisms, buffering capacity of saliva, and pH of oral fluids.[57] Oral bacterial populations shift to a preponderance of cariogenic forms (e.g., *Streptococcus mutans, Actinomyces* spp., *Lactobacillus* spp.). Radiation-induced caries may progress rapidly, and they primarily affect smooth tooth surfaces (see Fig. 39.3).

High-dose radiation therapy results in hypovascularity of irradiated tissues, with a reduction in wound-healing capacity.[66,116,117] Most severe among the resulting oral complications is osteoradionecrosis (ORN). Decreased vascularity renders the bone less capable of resolving trauma or infection. These events can cause severe destruction of bone. The risk of ORN continues for the remainder of the patient's life and does not decrease with time.[53]

Periodontal disease can be a precipitating factor in ORN.[16,31] Tooth extraction after radiation treatment involves a high risk of developing ORN, and surgical flap procedures are usually discouraged after radiation therapy. For these reasons, it is important that the clinician address the patient's periodontal disease *before* radiation begins, when possible. Teeth that are nonrestorable or severely periodontally diseased should be extracted, ideally at least 2 weeks before radiation therapy.[57] Extractions should be performed in a manner that allows primary closure. Mucoperiosteal flaps should be gently elevated; teeth should be extracted in segments; alveolectomy should be performed, allowing no rough bony spicules to remain; and primary closure should be provided without tension. It is not necessary to extract teeth that can be retained with conservative restorative, endodontic, or periodontal therapy. However, prudence dictates extraction of questionable teeth because periodontal treatment after irradiation may be limited to nonsurgical forms of therapy. Flap surgery or extraction of teeth after radiation can lead to ORN. Management of ORN is often difficult and costly, involving progressively more aggressive treatment if bone does not respond to conservative therapy. Costly hyperbaric oxygen therapy is frequently required for complete resolution.

During radiation therapy, patients should receive weekly prophylaxis, oral hygiene instruction, and professionally applied fluoride treatments, unless mucositis prevents treatment. Patients should be instructed to brush daily with a 0.4% stannous or 1.0% sodium fluoride gel. Custom gel trays allow optimal fluoride application.[116] All remaining teeth should receive thorough debridement (i.e., scaling and root planing).

Postirradiation follow-up consists of palliative treatment given as indicated. Viscous lidocaine can be prescribed for painful mucositis,

and salivary substitutes can be given for xerostomia. Daily topical fluoride application and oral hygiene are the best means of preventing radiation caries over time. A long-term, 3-month recall interval is ideal.

Prosthetic Joint Replacement

The main treatment consideration for patients with prosthetic joint replacement is the potential need for antibiotic prophylaxis before periodontal therapy. No scientific evidence indicates that prophylactic antibiotics prevent late prosthetic joint infections, which can occur from transient bacteremia induced by dental treatment.[23,55,93] Although dental-induced bacteremia can theoretically cause prosthetic joint infection, scant reports demonstrate dental treatment as a source of joint infection, and none actually documents a cause-and-effect relationship.[19,81,112]

Reports of the American Dental Association (ADA), American Academy of Orthopedic Surgeons (AAOS), American Academy of Oral Medicine (AAOM), and British Society for Antimicrobial Chemotherapy (BSAC) agree that routine antibiotic prophylaxis before dental treatment is not indicated for most patients with prosthetic joint replacement.[2,3,21,28,110] However, antibiotic prophylaxis is indicated for almost all patients within the first 2 years after joint replacement and for high-risk patients, including those with previous prosthetic joint infections, immunosuppression, rheumatoid arthritis, systemic lupus erythematosus, type 1 diabetes, hemophilia, and malnourishment.[2] Many investigators consider patients with severe periodontal disease or other potential dental infections to be at high risk, and antibiotic prophylaxis may be indicated for them before dental treatment.[65,110]

Between 2009 and 2014, there was controversy and debate among experts, with a complete shift toward recommending prophylactic antibiotics before dental treatment for all patients with prosthetic joint replacement for life. After further review of the evidence and consensus among experts, new recommendations were published that did not recommend prophylactic antibiotics for dental procedures in patients with prosthetic joint replacement to prevent

prosthetic joint infection. A historical description of the changes that were implemented from 2009 to 2012 can be found online (www.ada.org/en/member-center/oral-health-topics/antibiotic-prophylaxis).

In February 2009, the AAOS released an information statement regarding antibiotic prophylaxis for bacteremia in patients with joint replacements.[1] Their earlier information statement, developed jointly with the ADA, was published in 1997[2] and revised in 2003.[3] It was intended to reduce the risk to patients from unnecessary use of antibiotics. The 2009 information statement, which was not developed collaboratively with the ADA, greatly increased the number of patients exposed to antibiotics because it stated that all patients with prosthetic joint replacements should be given antibiotic prophylaxis before invasive procedures. Commentaries that challenged the statement were published in the *Journal of the American Dental Association*[35] and the *Journal of the Canadian Dental Association*.[63]

In December 2012, the AAOS and ADA released new joint recommendations for the routine use of antibiotics for joint replacement patients. According to this document, there is insufficient evidence to recommend the routine use of antibiotics for patients with orthopedic implants to prevent infection before dental procedures. The following sections list the 2012 evidence-based recommendations along with qualifications about the strength of evidence.

Recommendation 1

The practitioner might consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic implants undergoing dental procedures.

The strength of evidence for this recommendation was classified as *limited*, meaning that the quality of the supporting evidence that exists is unconvincing or that well-conducted studies show little clear advantage of one approach over another. The guidelines also state that "practitioners should be cautious in deciding whether to follow a recommendation classified as *limited* and should exercise judgment and be alert for emerging publications that report

evidence. Patient preference should have a substantial influencing role."

Recommendation 2

The work group was unable to recommend for or against the use of topical oral antimicrobials in patients with prosthetic joint implants or other orthopaedic implants undergoing dental procedures.

The strength of evidence for this recommendation was classified as *inconclusive*, meaning that there is a lack of compelling evidence, resulting in an unclear balance between benefits and potential harm. The guidelines also state that practitioners should feel little constraint in deciding whether to "follow a recommendation labeled as *inconclusive* and should exercise judgment and be alert to future publications that clarify existing evidence for determining balance of benefits versus potential harm. Patient preference should have a substantial influencing role."

Recommendation 3

In the absence of reliable evidence linking poor oral health to prosthetic joint infection, it is the opinion of the work group that patients with prosthetic joint implants or other orthopaedic implants maintain appropriate oral hygiene.

The strength of evidence for this recommendation was classified as *consensus*, meaning that expert opinion supports the guideline recommendation even though there is no available empiric evidence that meets the inclusion criteria. The guidelines also state that "practitioners should be flexible in deciding whether to follow a recommendation classified as *consensus*, although they may set boundaries on alternatives. Patient preference should have a substantial influencing role."

Although the evidence demonstrated no need for antibiotic prophylaxis in most patients, many orthopedic surgeons still preferred such treatment,[98] most likely because of the high morbidity and potential mortality associated with prosthetic joint infections. Consultation with the patient's orthopedic surgeon before periodontal treatment is in the patient's best interest and may help assess the risk for joint infection relative to current dental

status and type of periodontal treatment planned. Because individuals with significant periodontal disease are considered high risk, antibiotic prophylaxis before treatment is common in periodontal practice (eTable 39.3).[2]

eTABLE 39.3

Antibiotic Regimens for Prevention of Prosthetic Joint Infections[a]

Patient Characteristics	Drug Regimen
Patients not allergic to penicillins	Cephalexin, cephradine, or amoxicillin 2 g orally 1 hour before dental procedure
Patients allergic to penicillins	Clindamycin 600 mg orally 1 hr before dental procedure
Patients not allergic to penicillins but unable to take oral medication	Cefazolin 1 g or ampicillin 2 g intramuscularly or intravenously 1 hr before dental procedure
Patients allergic to penicillins and unable to take oral medications	Clindamycin 600 mg intravenously 1 hr before dental procedure (must be diluted and injected slowly)

[a]No second doses were recommended.

Data from American Dental Association and American Academy of Orthopedic Surgeons: Advisory statement. Antibiotic prophylaxis for dental patients with total joint replacements. *Am Dent Assoc J* 128:1004–1008, 1997.

Current advice for patients with orthopedic joint replacement stresses the importance of maintaining good dental health and hygiene and seeking prompt attention and treatment for oral infections when they occur. Dental procedures have not been associated with an increased risk of prosthetic joint infection, and the use of prophylactic antibiotics before dental procedures does not reduce the risk of infection.[9,100,128] Given the lack of evidence to support the need for prophylactic antibiotics, the AAOM, ADA, AAOS, and BSAC advise against universal use of antibiotic prophylaxis before dental procedures for the prevention of prosthetic joint infections.

In 2013, the ADA in conjunction with the AAOS published a joint guideline on the prevention of orthopedic implant infections in patients undergoing dental procedures. The publication stated that there was no convincing evidence to support the routine use of prophylactic antibiotics for patients with prosthetic joints.[123] In 2015, the ADA Council on Scientific Affairs published a clinical practice guideline to clearly state the findings of the 2013 ADA/AAOS joint guideline. The clinical practice guideline states that prophylactic antibiotics are not recommended before dental

procedures for patients with prosthetic joint implants to prevent prosthetic joint infections.[104]

Key Fact

In 2015, the American Dental Association (ADA) Council on Scientific Affairs published a clinical practice guideline to clearly state the findings published in the 2013 ADA and American Association of Orthopedic Surgeons (AAOS) joint guideline. The clinical practice guideline states that prophylactic antibiotics are *not* recommended before dental procedures for patients with prosthetic joint implants to prevent prosthetic joint infections.

Pregnancy

The aim of periodontal therapy for the pregnant patient is to minimize the exaggerated inflammatory response related to pregnancy-associated hormonal alterations. Meticulous plaque control, scaling, root planing, and polishing should be the only nonemergency periodontal procedures performed.

The second trimester is the safest time to perform treatment. However, long, stressful appointments and periodontal surgical procedures should be delayed until the postpartum period. As the uterus increases in size during the second and third trimesters, obstruction of the vena cava and aorta can occur if the patient is placed in a supine position. The reduction in return cardiac blood supply can cause *supine hypotensive syndrome,* with decreased placental perfusion.[106] Decreasing BP, syncope, and loss of consciousness can occur. This can be prevented by placing the patient on her left side or by elevating the right hip 5 to 6 inches during treatment. Appointments should be short, and the patient should be allowed to change positions frequently. A fully reclined position should be avoided if possible.

Other precautions during pregnancy relate to the potential toxic or teratogenic effects of therapy on the fetus. Ideally, no medications should be prescribed. However, analgesics, antibiotics, local anesthetics, and other drugs may be required during

pregnancy, depending on the patient's needs. Before being prescribed, all drugs should be reviewed for potential adverse effects on the fetus.[55,106]

As for any patients, use of dental radiographs during pregnancy should be kept to a minimum. The small amount of radiation exposure during diagnostic dental radiography poses little or no risk to the fetus as long as the mother is properly shielded.[4,21] The ADA has stated that "normal radiographic guidelines do not need to be altered because of pregnancy."[4] Use of a properly positioned lead apron is an absolute requirement. Chapter 41 includes a detailed discussion of the care of the female patient, including pregnancy.

Infectious Diseases

Because many infectious diseases are occult in nature and medical histories are often inaccurate or incomplete, all periodontal patients should be treated as though they have an infectious disease.[24] Protection of patients, clinicians, and office staff requires use of universal (standard) precautions for all patients, maximizing prevention of infection and cross-contamination. This section provides a brief discussion of hepatitis, human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), and tuberculosis in relation to the precautions required in periodontal therapy.

Hepatitis

Six distinct viruses that cause viral hepatitis have been identified: hepatitis A, B, C, D, E, and G viruses.[20,33,49] A single-stranded deoxyribonucleic acid (DNA) virus known as *transfusion-transmitted virus* has been identified in cases of acute and chronic hepatitis[49,126]; its role as an etiologic agent is undetermined. These forms of hepatitis differ in their virology, epidemiology, and prophylaxis (eTable 39.4). Because most hepatitis infections are undiagnosed, the clinician must be aware of high-risk groups such as renal dialysis patients, health care workers, immunosuppressed patients, patients who have received multiple blood transfusions,

homosexuals, drug users, and institutionalized patients.

eTABLE 39.4
Comparison of Hepatitis Viruses

Characteristic	VIRUS					
	HAV	HBV	HCV	HDV	HEV	HGV
Source	Feces	Blood and body fluids	Blood and body fluids	Blood and body fluids	Feces	Blood
Primary modes of transmission	Fecal-oral	Percutaneous, permucosal, sexual	Percutaneous, permucosal	Percutaneous, permucosal (occurs only after previous infection with HBV or as coinfection with HBV)	Fecal-oral	Percutaneo (usually occurs as coinfection with other hepatitis viruses)
Incubation period	15–50 days	50–160 days	15–150 days	15–150 days	15–60 days	Unknown
Risk of chronic infection	No chronic infection	Varies with age: adults 5%–10%; children 25%–50%; infants >85%	Very high (>85%)	5% when acquired as coinfection with HBV; >70% when acquired as a second infection in chronic HBV carrier	No chronic infection	Unknown whether chronic infection occurs
Protective immunity after infection?	Yes; anti-HAV antibody	Usually; antibodies to core antigen, e antigen, and HBsAg are produced; anti-HBsAg is most protective; chronic carrier state exists	No; anti-HCV antibody is produced but is usually not protective	Because HDV infection requires previous infection or coinfection with HBV, protective immunity is similar to hepatitis B	Unknown	Unknown
Vaccine available?	Yes	Yes	No	Yes (HBV vaccine protects against HDV)	No	No

HAV, Hepatitis A virus; *HBsAg*, hepatitis B surface antigen; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HDV*, hepatitis D virus; *HEV*, hepatitis E virus; *HGV*, hepatitis G virus; *TTV*, transfusion-transmitted virus.

Hepatitis A virus (HAV) and *hepatitis E virus* (HEV) produce self-limited infections with no associated chronic liver disease. These

viruses are primarily transmitted by the fecal-oral route. HAV transmission in the United States usually results from close personal household, sexual, or day care center contact. HEV is transmitted mainly through feces-contaminated drinking water and is relatively uncommon in the United States. A vaccination is available to protect against HAV infection but not HEV infection.

Hepatitis B virus (HBV) infection can result in chronic liver disease and a chronic carrier state. Chronic HBV infection develops in about 5% to 10% of infected individuals, with much higher rates among infants and children. Because it is transmitted primarily through a hematogenous route, HBV is a major concern for health care workers; the highest rates of HBV infection are found among dentists and oral surgeons.[33] Percutaneous or permucosal injury with contaminated instruments or needles is the most common route of infection in the dental office. The HBV vaccine is recommended for all health care workers.

Hepatitis D virus (HDV) is a defective virus that requires the presence of HBV for its survival, replication, and infectivity. The HDV genetic material is packaged in the HBV surface-antigen coating. Prevention of HDV infection is similar to prevention of HBV and relies strongly on HBV vaccination. After antibody titers to HBV are elevated to a protective level, the patient is also protected against HDV infection.

Hepatitis C virus (HCV) is probably the most serious of all viral hepatitis infections because of its high chronic infection rate. Only 15% of patients infected with HCV recover completely; 85% develop chronic HCV infection, which dramatically increases the risk of cirrhosis, hepatocellular carcinoma, and liver failure. HCV infection is the leading cause of liver transplantation in the United States. Unfortunately, no vaccine is available for HCV. Because HCV is transmitted primarily through a percutaneous or permucosal route, health care workers are at risk from injury with contaminated instruments.

Hepatitis G virus (HGV) is a ribonucleic acid (RNA) virus, and its epidemiology and virology are not fully understood. HGV rarely occurs as a solitary infection, instead usually appearing as a coinfection with hepatitis A, B, or C. HGV is transmitted through the blood and has frequently been associated with transfusions.

Transfusion-transmitted virus (TTV) was first identified in 1997 and is common in the general population.[49,62] The virus is often present in patients with hepatitis and chronic liver disease. Similar to HGV, TTV may not cause a specific form of hepatitis. Patients infected with TTV can develop a chronic carrier state without having clinically evident disease, or they can develop frank disease. Evidence indicates that TTV can be transmitted through the blood (e.g., transfusions), by a fecal-oral route, and from mother to child. As with HGV, TTV is often associated with HCV.

The following guidelines are offered for treating hepatitis patients:

1. If the disease, regardless of type, is active, do not provide periodontal therapy unless the situation is an emergency. In an emergency case, follow the protocol for patients testing positive for hepatitis B surface antigen (HBsAg).
2. For patients with a history of hepatitis, consult the physician to determine the type of hepatitis, course and length of the disease, mode of transmission, and any chronic liver disease or viral carrier state.
3. For recovered HAV and HEV patients, perform routine periodontal care.
4. For recovered HBV and HDV patients, consult with the physician and order HBsAg and anti-HBs (i.e., antibody to HBV surface antigen) laboratory tests.
    - If HBsAg and anti-HBs test results are negative but HBV is suspected, order another HBs determination.
    - Patients who are HBsAg positive are probably infective (i.e., chronic carriers); the degree of infectivity is measured by an HBsAg determination.
    - Patients who are anti-HBs positive may be treated routinely because they have antibody to HBsAg.
    - Patients who are HBsAg negative may be treated routinely.
5. For HCV patients, consult with the physician to determine the patient's risk for transmissibility and current status of

chronic liver disease.

6. If a patient with active hepatitis, positive-HBsAg (i.e., HBV carrier) status, or positive-HCV carrier status requires emergency treatment, use the following precautions:
    - Consult the patient's physician regarding status.
    - If bleeding is likely during or after treatment, measure the PT and bleeding time. Hepatitis can alter coagulation; change the treatment accordingly.
    - All personnel in clinical contact with the patient should use full barrier techniques, including masks, gloves, glasses or eye shields, and disposable gowns.
    - Use as many disposable covers as possible, covering light handles, drawer handles, and bracket trays. Headrest covers should also be used.
    - All disposable items (e.g., gauze, floss, saliva ejectors, masks, gowns, gloves) should be placed in one lined wastebasket. After treatment, these items and all disposable covers should be bagged, labeled, and disposed of following proper guidelines for biohazardous waste.
    - Aseptic technique should be followed at all times. Minimize aerosol production by not using ultrasonic instrumentation, air syringe, or high-speed handpieces; remember that saliva contains a distillate of the virus. Prerinsing with chlorhexidine gluconate for 30 seconds is highly recommended.
    - When the procedure is completed, all equipment should be scrubbed and sterilized. If an item cannot be sterilized or disposed of, it should not be used.

If a percutaneous or permucosal injury occurs during dental treatment of an HBV carrier, Centers for Disease Control and Prevention (CDC) guidelines recommend administration of *hepatitis*

B immune globulin (HBIG).[40] The HBV vaccine should also be administered if the injured individual has not previously received it. Unfortunately, postexposure prophylaxis with immune globulin or antiviral agents is usually ineffective if a percutaneous injury occurs during treatment of a hepatitis C carrier.[17,20]

HIV and AIDS

Since the beginning of the AIDS epidemic, a wide range of oral lesions has been associated with HIV infection; these lesions are discussed in Chapter 30. As with hepatitis, not all HIV-infected patients know that they are infected when they present for dental treatment. Individuals with known HIV infection may not admit their status on the medical history. Every patient receiving dental treatment should be managed as a potentially infected person, using universal precautions for all therapy.

Extensive periodontal treatment plans must be considered in regard to the patient's systemic health, prognosis, and survival time.[55] Large variations in progression of HIV disease exist among individuals, and selecting an appropriate treatment plan depends on the state of the patient's overall health. Although there appear to be few contraindications to routine dental treatment for many HIV-infected patients, the periodontal treatment plan is influenced by the patient's overall systemic health and coincident oral infections or diseases. An awareness of oral disorders associated with HIV infection may allow the clinician to recognize previously undiagnosed disease or modify treatment protocols appropriately.

Tuberculosis

The patient with tuberculosis should receive only emergency care, following the guidelines listed in the section on hepatitis. If the patient has completed chemotherapy, the patient's physician should be consulted regarding infectivity and the results of sputum cultures for *Mycobacterium tuberculosis*. When medical clearance has been given and sputum culture results are negative, the patient can be treated normally. Any patient who gives a history of poor medical follow-up (e.g., lack of yearly chest radiographs) or shows signs or symptoms indicative of tuberculosis should be referred for

evaluation. Adequate treatment of tuberculosis requires a minimum of 18 months, and thorough posttreatment follow-up should include chest radiographs, sputum cultures, and a review of the patient's symptoms by the physician at least every 12 months.

Case Scenario 39.1

Patient:
45-year-old female

Chief Complaint:
"My upper right tooth is loose, and it has been hurting the last few days. My gum is also very swollen in that area. I rinsed with salt water, but it did not get better."

Background Information:
Diabetes mellitus was diagnosed 4 years ago. The patient has been taking metformin as prescribed by her primary care physician. The last glycated hemoglobin (HbA1c) value, taken 2 weeks ago, was 10.2%. She has no other systemic conditions, such as nonketotic diabetic acidosis. She does not smoke, drink, or use illicit substances. Patient never had scaling and root planing. She does not see a dentist regularly but had a cleaning done at a community dental clinic 10 days ago.

Current Findings:
Generalized 3- to 6-mm probing depths were identified, with a localized 12-mm depth at #3M, 9 mm at #3B, 7 mm at #14D, and 4- to 7-mm probing depths around #19. Grade II furcation involvement at #19 was found. Generalized bleeding was elicited on probing. Gingival tissue appeared to be inflamed, erythematous, and edematous. There was an abscess on the buccal surface of #3, and there was generalized moderate plaque and calculus accumulation. Radiographs revealed generalized mild to moderate horizontal bone loss with localized moderate to severe vertical bone loss at #3M and #14D. Patient had inadequate oral hygiene (i.e., biofilm control).

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Tooth #3 needs to be extracted to relieve pain. The fasting glucose level on the day of extraction was 120 mg/dL. What does this value mean? A. A fasting glucose level of 120 mg/dL indicates that diabetes is well controlled. B. The fasting glucose level determined on the day of extraction is more important than the HbA1c value because the latter test result is 2 weeks old. C. A fasting glucose level of 120 mg/dL on the day of extraction means that the patient is safe and stable for extraction. D. The HbA1c value is a more important indication of the patient's long-term glycemic control than the fasting glucose level.	**Answer: D** **Explanation:** HbA1c is a test that reflects glycemic control over the past 2 to 3 months. The fasting blood glucose level is a measure of glycemic control at that moment. The latter test fluctuates greatly. It does not indicate that the blood glucose level has been stable over weeks or months.
1. Although the patient has poor glycemic control, extraction of #3 is deemed necessary to relieve pain. Giving the patient prophylactic antibiotics as premedication should be considered. A. True B. False	**Answer: A** **Explanation:** Patients with poorly controlled diabetes are much more susceptible to infection and poor wound healing. Use of antibiotics is an appropriate preventive measure. Consultation with the patient's primary care physician is prudent. It is important to follow up after an invasive procedure to ensure proper healing and assess for signs of infection.
1. All of the following are important aspects to consider when any patient with diabetes undergoes a surgical procedure *except*: A. Limit the size of the surgical field so the patient is comfortable enough to resume a normal diet immediately and avoid hypoglycemia. B. Schedule the patient early in the morning. C. Routinely give prophylactic	**Answer: C** **Explanation:** Antibiotics are not routinely given to patients with diabetes as a prophylactic measure.

antibiotics. D. Life-threatening hypoglycemia is the most common dental complication in diabetic patients.

CHAPTER 40

Sleep-Disordered Breathing

Adrian K. Zacher, Michael J. McDevitt

CHAPTER OUTLINE

New and Evolving Role of the Dentist
Sleep-Related Breathing Disorders and the Periodontium
Dental Identification of Signs and Symptoms
Sleep, Breathing, and Apnea
Diagnosis of Obstructive Sleep Apnea
Treatment Options for Obstructive Sleep Apnea
Oral Devices for Mandibular Repositioning
Device Design and Compliance *(e-only)*
Conclusions

New and Evolving Role of the Dentist

Everyone sleeps, and no one thinks much about sleep until something goes wrong. When sleep does go wrong—and it can in

many ways—the effects can be more than just feeling a little tired in the morning. This chapter explores the exciting and evolving role of the dentist with an interest in sleep-disordered breathing (SDB) who helps patients to breathe, sleep, and ultimately function better each day.

Snoring and sleep apnea (i.e., cessation of breathing) are points along a spectrum that extends from benign or simple snoring with no sleep disturbance to obstructive sleep apnea (OSA) with excessive daytime sleepiness and the physiologic consequences of recurrent asphyxia.[21] Over the years, there have been many dubious claims made regarding snoring cures. However, knowledge has greatly improved,[13] and much can be done to manage OSA and its associated consequences. It is in the provision of oral devices for OSA that a key role for suitably trained dentists is developing.

Sleep apnea can be caused by the lack of a central drive to breathe. The central, mixed, and complex types of apnea are reviewed later in this chapter.

Professor Colin Sullivan invented the mainstay therapy for sleep apnea: positive airway pressure (PAP) therapy. He was also an internationally renowned key opinion leader, and he advocated[5] for dentists, as part of a multidisciplinary team, to play a critical role in four areas:

1. Treating adults with oral devices for snoring and mild to moderate OSA to slow the progression of the disease
2. Identifying at-risk children and adults by looking at their upper airway on a regular basis
3. Treating children with rapid maxillary expansion and avoiding deleterious orthodontic treatments
4. Recognizing the need for bimaxillary osteotomy in young adults requiring maxillofacial correction

Sleep-Related Breathing Disorders and the Periodontium

The prevalence of impaired breathing in patients who are also susceptible to periodontal disease and whose periodontitis

experience may be affected by a sleep-related breathing disorder is sufficient to compel dentists and their teams to develop recognition strategies.

Whereas diagnosing OSA is the responsibility of a qualified physician, the dentist is capable of identifying and differentiating clinical signs of possible airway issues, often before the patient becomes suspicious of the health risk. Information shared by the patient regarding his or her overall health status should be reviewed and correlated with clinical observations of oral indicators of attempted compensation by the patient for a significant degree of airway obstruction or resistance.

The value of early recognition and intervention cannot be overstated. The deleterious effects of sleep-related breathing disorders and resultant periods of asphyxia on cardiovascular health, endocrine function, neurologic function, and masticatory system integrity add to the urgency for dentists to include recognition protocols during initial and recurring evaluations of their patients. A multidisciplinary team approach[25] that incorporates respect for each team member's professional role is essential to make an accurate diagnosis and facilitate provision of the most appropriate treatment.

The following sections discuss sleep, apnea, and the dentist's role in the provision of oral devices, which is one of the increasingly favored OSA treatment options.

Dental Identification of Signs and Symptoms

Review of Health Status and Systems

The frequency with which dentists see their patients places them in a unique position to recognize the symptoms of OSA. At the beginning of every dental appointment, the dentist or a member of the dental team should conduct an effective review and record the patient's health status. In addition to addressing specific items that might have been discussed previously, the inclusion of questions about breathing issues can alert the dentist to look for clinical indicators of sleep-related breathing disorders. Identification of

clinical signs can reframe future discussions of the patient's overall health to prevent overlooking possible correlations with observations. For example, snoring or gasping reported to the patient by his or her bed partner may correlate with unexpected mobility of occluding anterior teeth. Important conditions or factors that may be reported by a patient include the following:

- Hypertension
- Gastroesophageal reflux disease
- Excessive daytime sleepiness
- Cardiovascular disease, including arrhythmias
- Type 2 diabetes
- Hypothyroidism
- Obesity
- Sudden onset of snoring
- Awareness of snoring or SDB
- Use of a snore appliance from a dentist or another source

Dental Signs and Symptoms of Obstructed Breathing

Neither the clinical indicators nor the health or breathing status reported by the patient can define the degree or implications of a sleep-related breathing disorder for the dentist. Developing a list of observations to discuss with the patient allows him or her to confirm the possibility of a breathing disorder and communicate the signs to the physician for further assessment and diagnosis.

Sleep Bruxism

Although patients commonly report SDB and sleep bruxism, there is only a suspected association because no evidence-based clinical trial has established a specific relationship. The bruxing patient's repeated patterns of mandibular movement are primarily mediated by the central nervous system. It has been hypothesized that the

advancement of the mandible opens the oropharynx, relieving some of the consequences of SDB.[27,28]

Clinical Signs and Symptoms

- Wear patterns on opposing incisors can suggest that the patient positions the mandible anteriorly to open the airway.[42,43]
- The mobility of the anterior teeth may be in excess of that estimated on the basis of the patient's health and the support available from periodontal structures.
- In the periodontitis-susceptible patient, progressive bone loss may be located or exaggerated in sites of unusual wear or mobility. The possible role of occlusal trauma in the amplification of the consequences of periodontitis is described in the online version of Chapter 55 of this textbook (www.expertconsult.com).
- Tongue crenulations (i.e., scalloped borders) suggest that the patient is depressing the tongue forward against the mandibular teeth regularly to open the oral airway.
- Development of an anterior or lateral open-bite relationship of the opposing teeth may result from tongue posturing.
- Sleep bruxism may develop or increase.
- Dimpling of the cusps and lingual surfaces of the teeth can indicate related gastroesophageal reflux.
- The development of orofacial pain,

temporomandibular joint (TMJ) dysfunction symptoms, masticatory muscle fatigue noticed on awakening, or morning headache can be related to the positioning of the mandible to open the patient's airway. This topic is addressed in the online version of Chapter 26 of this textbook (www.expertconsult.com), where comprehensive diagnostic references can also be found.

- During evaluation of the oropharynx, prominent tonsils, a large uvula, or a narrow or tongue-obstructed airway may be seen. The patient's age can contribute to the loss of tone of the pharyngeal muscles.
- Mouth breathing while sleeping can manifest as drying of the surface of the gingiva.

Sleep, Breathing, and Apnea

A basic understanding of sleep physiology, normal sleep cycles, and the variety of sleep disorders can provide the dentist with the means for effective communication with patients and their physicians.

Sleep is classically defined as a cyclic, temporary, and physiologic loss of consciousness that is readily, promptly, and completely reversed with appropriate stimuli. Not being able to breathe would seem to qualify as an appropriate stimulus, but affected individuals are rarely aware of any difficulty. Normal sleep progresses through different stages that are typically depicted on a hypnogram (Fig. 40.1).

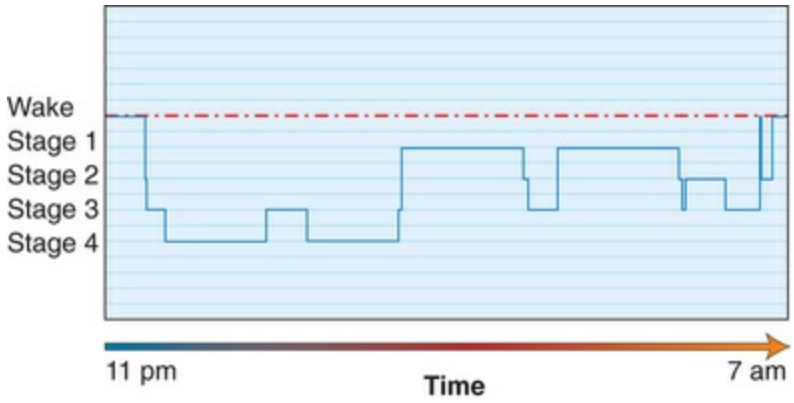

FIG. 40.1 Simplified hypnogram of a normal adult's sleep. (Courtesy Adrian Zacher, 2013. Snorer.com.)

Snoring is a vibratory noise that is generated by the back of the relaxed tongue, pharynx, and soft palate. Further loss of tone or narrowing produces louder snoring and labored inspiration. Still further narrowing can cause complete collapse of the airway. This obstruction is known as an *apneic episode.*

There comes a point at which the increased inspiratory effort or oxygen desaturation that may accompany the apneic episode is sensed by the sleeping brain and a transient arousal is provoked. This is a brief awakening to breathe before the individual returns to sleep. These arousals can be seen in Fig. 40.2 as decreased-duration periods and increasingly frequent interruptions in the descent into deeper, more refreshing sleep. Disregarding complaints about the snoring noise, these repetitive arousals occur for the most part without the individual being aware, sometimes several hundred times a night.

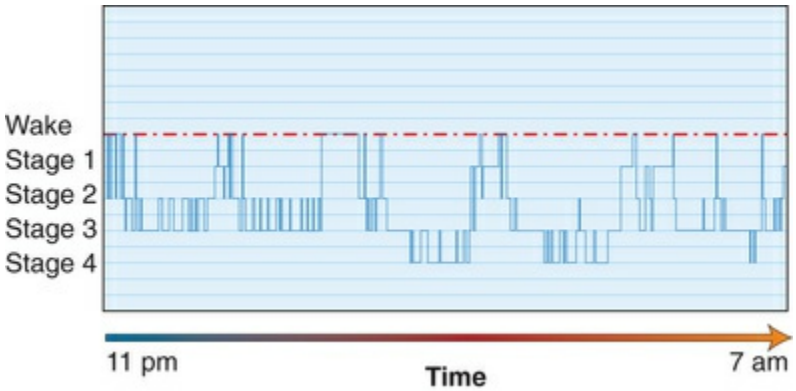

FIG. 40.2 Simplified hypnogram of an adult's fragmented sleep. (Courtesy Adrian Zacher, 2013. Snorer.com.)

Each apneic episode can last from a few seconds to approximately 2 minutes. The individual's descent into the deeper and more restorative slow-wave stages of sleep is interrupted because he or she has partially awakened to restore the airway. Sleep becomes highly fragmented, and the consequent daytime sleepiness known as *hypersomnolence* increases the individual's risk of accidents at home, at work, and on the road.[50]

OSA has a significant impact on an individual's quality of life.[10] If left untreated, it has neurologic and physiologic consequences,[37] including increased morbidity and mortality[35] and, particularly for men, impaired cardiovascular[51] and metabolic[18] function.

Prevalence of Obstructive Sleep Apnea

Sleep apnea affects a large number of people, but it continues to be largely unrecognized. Estimates suggest that 24% of men and 9% of women who are 30 to 60 years old with an average body mass index of 25 to 28 kg/m^2 are affected.[49] When considered in the context of the concurrent metabolic dysfunction epidemic (which is manifested in obesity, cardiovascular disease,[31,26] and type 2 diabetes in men[12,40,39]), the prevalence of sleep apnea becomes alarming. The International Diabetes Federation urges health care professionals to ensure that a person diagnosed with OSA is evaluated for type 2 diabetes and vice versa.[41]

Central, Mixed, and Complex Apnea

In contrast to OSA, central sleep apnea (CSA) occurs without physical obstruction of the airway. CSA is caused by disorders that are characterized by the intermittent loss of the respiratory drive. Fig. 40.3 shows the lack of chest wall movement in a patient with CSA. Cheyne–Stokes respirations as a form of CSA are most often seen in patients with heart failure. Mixed apnea is a combination of OSA and CSA. Complex apnea occurs when CSA events emerge in response to PAP therapy for OSA.[17]

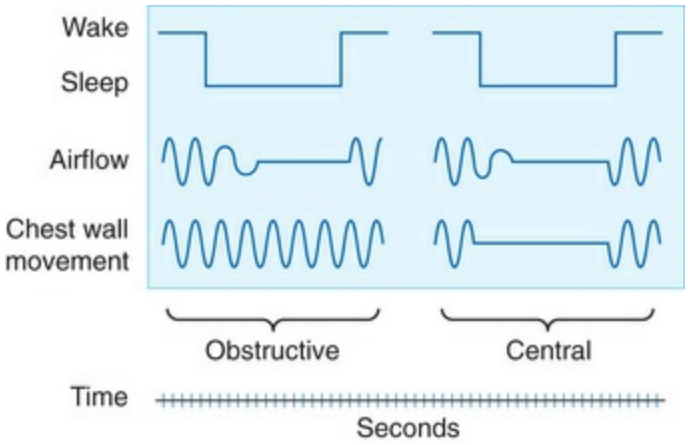

FIG. 40.3 Obstructive versus central apnea. (Courtesy Learning Center, ResMed, San Diego, CA.)

This chapter is confined to OSA because it is by far the most common form of apnea, and it is in the provision of oral devices, also known as *mandibular repositioning devices* (MRDs), for OSA that the suitably trained dentist can play a role.[22]

Chronic Disease

The maintenance of a separate silo approach and viewing one aspect of an individual's symptomatology in isolation can be considered flawed thinking. OSA in isolation and as a potential component of metabolic syndrome (i.e., syndrome Z[47]) requires a multidisciplinary approach to chronic disease management. The World Health Organization[48] states that chronic diseases are projected to be the leading cause of disability; if they are not successfully prevented and managed by 2020, they will become the most expensive problems for health care systems.

Diagnosis of Obstructive Sleep Apnea

Snoring is a symptom of a partially impeded airway, the walls of which are vibrating as the air passes. How frequently the walls of the airway vibrate (i.e., snoring noise) or collapse (i.e., apnea events of varying duration) indicates the severity of OSA.

A multidisciplinary team approach is necessary for the diagnosis and treatment of OSA. Dentists are experts when it comes to the mouth and should be recognized as such. For OSA treatment,

dentists need to build relationships with physicians so they can provide an appropriate dental solution for a medical condition. However, it is important to recognize that the diagnosis of OSA is not within the purview of dentistry.[7]

The closest thing to internationally accepted practice parameters, which are those issued by the American Academy of Sleep Medicine,[14] state that the "presence or absence and severity of OSA must be determined before initiating treatment." In practice, this means that a dentist must not initiate treatment with an oral device unless the patient has been assessed, medically diagnosed, and then referred to the dentist (Fig. 40.4).

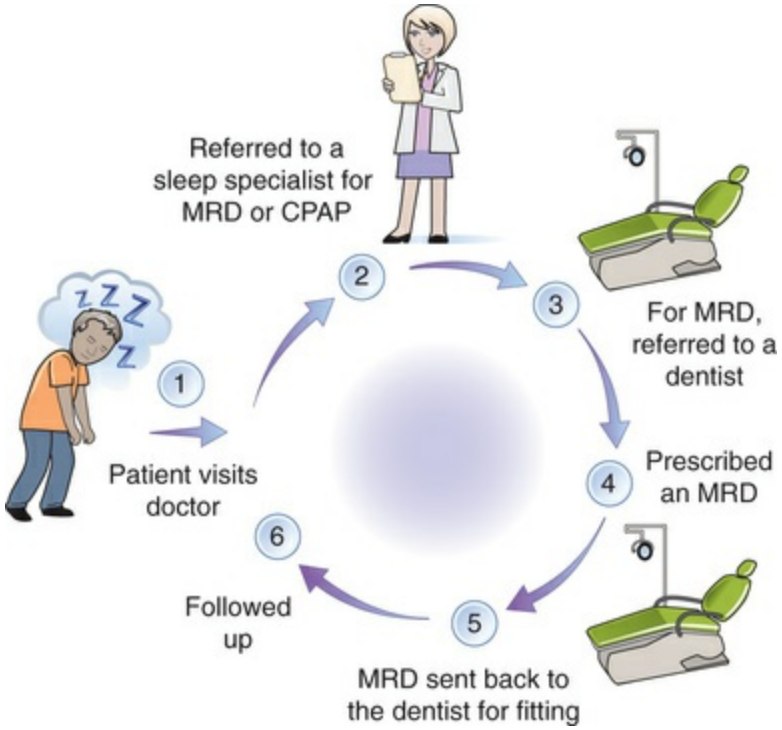

FIG. 40.4 Obstructive sleep apnea diagnosis and treatment route. *CPAP*, Continuous positive airway pressure; *MRD*, mandibular repositioning device.
(Courtesy ResMed, San Diego, CA, 2011.)

If OSA is suspected, a referral is made for a sleep study. This can involve spending a night in a sleep laboratory or at home with an electronic monitoring device to wear while sleeping. A sleep laboratory is essentially a bedroom with monitoring equipment.

In a sleep laboratory, the patient undergoes *polysomnography*

(PSG), during which multiple parameters are monitored while the patient is asleep. These parameters include, but are not limited to, sound, video, oxygen saturation, respiratory effort, electrocardiography, electroencephalography, and body position. Attended overnight PSG is an expensive assessment to perform, and availability and access vary based on geography.

Several screening protocols have been proposed over the years.[24,20] In January 2012, the California Dental Association[8] determined that it was appropriate for dentists to screen patients for the signs and symptoms of SDB and to work with physicians to diagnose and treat it. The association also stated that SDB is a medical condition and that its diagnosis is outside of the scope of the practice of dentistry.

Whether a PSG is essential to diagnose OSA is being questioned.[36] Since 2009 in the United Kingdom, a general dental practitioner working as part of a multidisciplinary team (including a sleep medicine specialist) can, in certain defined circumstances, screen, recognize the need for, and initiate treatment with an MRD without a prior medical diagnosis.[45] Currently in the United States, PSG and home study monitor results need to be interpreted by a physician.

The role of home sleep testing and who should interpret the data that it produces are points of contention that fuel the debate surrounding PSG. The need for mandatory PSG may be questioned in response to the following:

- Increasingly valid and competitively priced home sleep testing equipment
- Increase in the number of patients requiring assessment
- Perception that PSG is the point of contention in the treatment process
- Realization that oral devices are appropriate for milder forms of OSA and that dentists are uniquely positioned to provide them because they may see patients more frequently than sleep

medicine specialists
- Realization that a trained dentist, as part of a multidisciplinary team, can filter referrals to the sleep medicine specialist

A sleep laboratory's main function is to diagnose OSA and then offer treatment to those who are likely to benefit from it. If the symptoms are fairly disabling and the diagnosis is confirmed by a sleep study, PAP therapy is routinely offered. Increasingly, around the world, oral devices are becoming a first-line treatment for mild to moderate OSA when they can be prescribed and monitored by a multidisciplinary team. Fig. 40.5 provides definitions and diagnostic criteria for SDB.[44]

Apnea	Cessation of airflow > 10 seconds
Hypopnea	> 50% reduction in airflow for > 10 seconds
Apnea hypopnea index (AHI)	Number of apneas and hypopneas per hour of sleep
Severity	Normal: AHI < 5 Mild: AHI 5–15 Moderate: AHI 15–30 Severe: AHI > 30
Sleep apnea syndrome (SAS)	AHI > 5 with symptoms
Cheyne–Stokes respiration	> 3 consecutive cyclical crescendo-decrescendo changes in breathing apmplitude during 10 consecutive minutes and/or an AHI > 5

FIG. 40.5 Sleep-related disorders in adults: definitions and diagnostic criteria.

Treatment Options for Obstructive Sleep Apnea

Otolaryngology or Oromaxillofacial Surgery

Surgical options for snoring and OSA are largely outside of the scope of this text. However, when physical obstructions to the airway (e.g., tonsils, deviated septum, nasal polyps) are present, surgical correction may improve breathing. For example, if adenotonsillar hypertrophy exists, childhood correction is considered advantageous.[30]

Limited evidence for adult palatal surgery, which is known as *uvulopalatopharyngoplasty,* exists; this surgery should be considered only after PAP therapy has failed.[6] Maxillary or bimaxillary orthognathic surgery is rarely considered, whereas tracheotomy is an effective option of last resort because it completely bypasses the affected area.

Positive Airway Pressure

PAP (Fig. 40.6) is considered the first-line treatment for OSA, and it is very effective in helping the patient to overcome daytime sleepiness symptoms. Individuals with severe sleep apnea do well with this therapy, despite the forbidding appearance. Possibly considered an arduous therapy, it involves wearing a mask over the nose (and sometimes the mouth and nose) at night while being connected to a quiet blower. It works by slightly pressurizing the upper airway, thereby pneumatically splinting it open and preventing it from collapsing. PAP is particularly useful when there is a need for rapid control of OSA.

FIG. 40.6 Positive airway pressure therapy. (Courtesy ResMed, San Diego, CA, 2011.)

The sleep laboratory may also suggest that oral device therapy is appropriate. This depends on the severity of the OSA and the existence of other comorbidities. Oral devices can be used to provide therapy for sleep apnea of any severity; however, effective results are considered less certain with increasing severity.[19] PAP and MRD therapies are complementary; in patients with moderate OSA, the two modalities in some circumstances can be considered equally appropriate. Fig. 40.7 illustrates this point in broad terms. Treatment of severe sleep apnea with an oral device necessitates careful patient monitoring, because things such as small weight changes can negate the effect.[34]

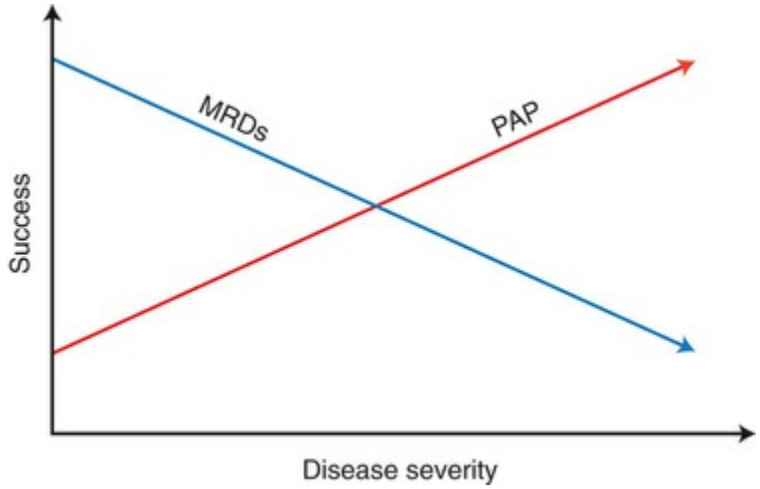

FIG. 40.7 Complementary therapies. *MRD*, Mandibular repositioning device; *PAP*, positive airway pressure. (Courtesy Adrian Zacher, 2013, Snorer.com.)

The technology of PAP and oral devices is fast developing, with particular focus on improving the patient's ability to tolerate their use and minimize their side effects. PAP development focuses on better mask design, the inclusion of air humidifiers, and the sensitive electronically controlled variation of air pressure in response to inspiration and expiration. Oral devices have become increasingly adjustable and thinner, and they can be designed to minimize some common side effects, such as hypersalivation and incisor sensitivity. Future developments in oral devices may focus

on objective compliance monitoring and treatment efficacy.

Oral Devices for Mandibular Repositioning

The developing role of dentistry in the provision of oral devices for snoring and OSA has given rise to concerns about training and professional indemnity. Dentists may be asked to place antisnoring devices; consequently, state boards of dentistry (and insurance providers) are issuing position statements regarding whether the provision of these devices falls within the practice of dentistry. These statements will determine whether the devices are within the scope of the assistance normally provided.

Dentists should check with their state boards of dentistry and professional indemnity insurers to clarify the situation. Most insurers suggest that dentists are well placed to construct oral devices, provided that they have appropriate training to do so. However, the treatment of snoring and OSA does not routinely fall within the definition of the practice of dentistry and therefore would fall outside of the scope of assistance normally provided by the insurer.

Dentists should undergo a documented training course in the provision of antisnoring devices that includes training in appropriate screening for OSA. Candidates for oral devices should be properly assessed for the signs and symptoms of OSA in accordance with contemporary standards, and the assessment should be documented. If the patient exhibits signs or symptoms of OSA, there must be a referral for a medical assessment. Patients should be advised about the risks and benefits of antisnoring devices, including the potential impact on the occlusion, periodontium, and TMJs. Documentary evidence of the consent process must be retained. When OSA exists, an antisnoring device should be supplied only as part of an integrated treatment plan provided by a multidisciplinary team that includes the dentist.

Devices Pertinent to the Dentist

Oral devices for snoring and OSA aim to maintain the upper airway during sleep. Tongue-retaining devices and MRDs do this either directly, by acting on the tongue and holding it in a forward position, or indirectly, by forward repositioning of the mandible, which maintains upper airway patency (Fig. 40.8). MRDs are the most researched type of oral device for OSA, and they are the focus of this chapter.

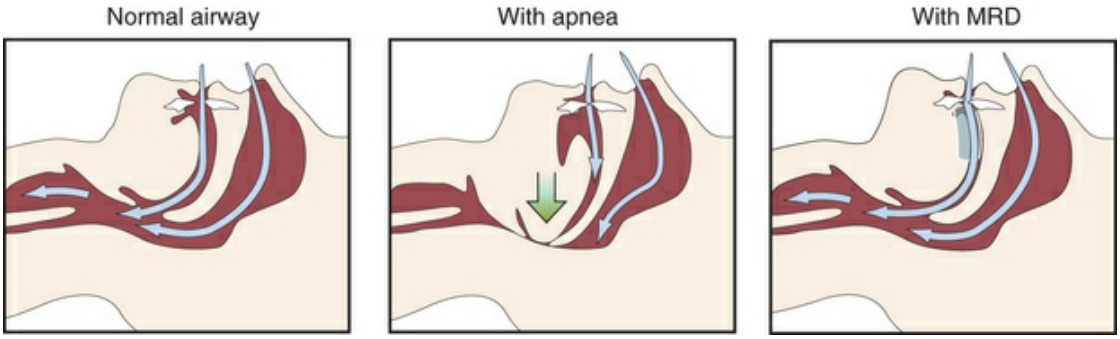

FIG. 40.8 Airway status: healthy and apneic, with a mandibular repositioning device (MRD). (Courtesy ResMed, San Diego, CA, 2011.)

Custom-made adjustable devices typically are associated with better treatment outcomes[46] compared with universal "boil and bite" MRDs. Adjustable MRDs are more likely to provide successful therapy in patients with moderate to severe OSA than nonadjustable MRDs.[29]

Predictor Devices

Sleep medicine specialists charged with caring for patients with OSA understandably desire certainty that the patient has been effectively treated. This has historically represented a legitimate concern when considering an MRD for a patient with OSA and has resulted in MRDs being confined to use for mild to moderate OSA. Predictor devices, which are sometimes known as *titration devices,*[11] are intended to do the following:

- Establish whether the patient can tolerate an intraoral device and whether it is subjectively

effective
• Objectively determine whether mandibular repositioning delivers adequate therapy
• Provide a prescription jaw relationship for custom MRD manufacture if the outcome is positive

The use of predictor devices has been an area of MRD technologic innovation during recent years. In this role, it is important that predictor devices not be confused with thermoplastic universal treatment devices. Predictor devices are expressly designed for use for a limited number of nights; their use is self-limited, and they sacrifice patient convenience for functionality. Basic taxonomy for the oral devices of MRDs is shown in Fig. 40.9.

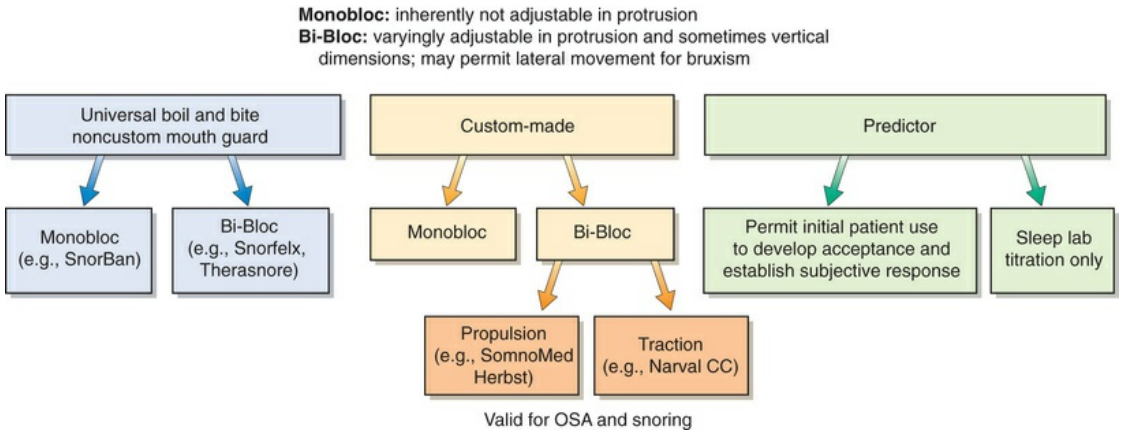

FIG. 40.9 Mandibular repositioning device taxonomy.
(Courtesy Adrian Zacher, 2013, Snorer.com.)

Characteristics of the Ideal Oral Device

From an individual wearer's perspective, any intraoral device feels foreign and invasive. The individual may seek treatment largely to please his or her partner and may perceive little or no personal benefit because hypersomnolence symptoms correlate poorly with OSA severity.[10] Affected individuals may have forgotten what it feels like to be fully awake.

Side effects of early devices included hypersalivation or dry mouth when worn, dental sensitivity, and perhaps a claustrophobic locking of the jaws in a protrusive position and a morning postwear TMJ ache. For these reasons, early oral devices required development. Some MRD manufacturers have reduced or eliminated these side effects, but there is no single perfect device.[2] Knowledge of a range of MRDs to suit different individuals is necessary. The characteristics of the ideal MRD vary for each patient, and some characteristics may preclude others. Table 40.1 presents several options.

TABLE 40.1

Characteristics of the Ideal Mandibular Repositioning Device

Acceptance, Adherence, and Efficacy	Mitigation of Side Effects	Practical Considerations
Constructed of two separate pieces; to give the patient time to accept wearing the device, one half is worn alone before the complete device is worn	Metal-free; no parts that can fatigue, fracture, and then be inhaled or ingested to create a galvanic reaction with other dental restorations	Low cost
Enables titration anteroposteriorly for tolerability and effect	Minimal bulk for less impact on phonetic function and reduced hypersalivation	East to fit for the patient and dental practitioner
Enables starting titration from zero protrusion to improve comfort throughout the titration process	Does not dictate a protrusive path or final protruded position for the temporomandibular joints	Can be titrated in the sleep laboratory without waking the patient
Encourages the mouth to close and prevents the mouth from falling open at sleep onset	No unwanted orthodontic effects (e.g., incisor tilting)	Instant device; no impressions or laboratory work required
Permits lip seal and encourages nasal breathing		Minimal follow-up appointments
Enables titration of the vertical opening (i.e., <5 mm measured at the incisors) considered optimal for acceptance and adherence[38]		Easy to modify
Easy to clean		Does not necessitate a remake if a dental restoration is necessary
Permits lateral movement where there is evidence of parafunction		
Does not encroach on tongue space or		

impede forward movement of the tongue		
Includes compliance and efficacy monitoring		
Is it worn and does it work?		

From Adrian Zacher, 2013. https://snorer.com/snorer-training-for-dentists-who-want-to-help-snorers/.

Recognizing that a child may benefit from an SDB investigation is important. MRDs are *not* recommended for children unless they are under the supervision of an orthodontist who is working as part of a multidisciplinary team.

Communication

Effective communication among the referring sleep laboratory, the patient, and the patient's general dental practitioner is essential and should begin before the patient is seen (Box 40.1).

Box 40.1

The Take-Home Message

1. Has the presence (and severity) or absence of obstructive sleep apnea been established?
2. Is the patient at least partially dentate? Does he or she have sufficient alveolar bone to withstand lateral loads?
3. Are you satisfied that there is no severe periodontal condition that the device would prejudice? Does the patient possess the competence to maintain his or her oral hygiene?
4. Are you satisfied there is no gross temporomandibular disorder?
5. Have you ensured that there is no pronounced gag reflex?
6. Does the patient have a competent nasal airway?
7. Does the patient comprehend the costs of therapy?
8. Have the patient's expectations of therapy been managed appropriately?

Sleep Laboratory and Primary Care Physician

Communication

The OSA diagnosis and the requirement for revaluation should be confirmed. Relevant medical history information should be exchanged. The existence of positional apnea (i.e., apnea that worsens when sleeping supine) should also be documented.

Patient Communication

Valid informed consent for treatment (including a risk-benefit analysis, information about side effects, and therapy limitations) and permission to obtain dental records from the general dental practitioner should be obtained.

General Dental Practitioner

With reference to the patient's existing dental records, a recent orthopantomogram may be valuable.

General Indications and Contraindications

When a patient who has been diagnosed with OSA is referred to a dentist, assessment to determine the suitability of MRD therapy is based on an individual analysis of indications and contraindications. It is essential to obtain valid informed consent and baseline records and to retain pre-MRD therapy casts. Uncontrolled epilepsy is an absolute contraindication.

All MRDs, which are also known as *mandibular advancement devices* (MADs) or *oral appliances,* protrude the mandible, but each MRD has a unique feature set. In 2010, Ahrens stated that "no [one] MAD design most effectively influences subjectively perceived treatment efficacy, but efficacy depends on many factors, including materials and method used for fabrication, type of MAD (monobloc or twin block [bi-bloc]), and the degree of protrusion."[1] Understanding the differences among these devices enables the dentist to prescribe appropriately, with knowledge of the indications, features, and design limitations, allowing him or her to maximize treatment efficacy and minimize unwanted side effects.

Temporomandibular Joint Dysfunction

Severe TMJ dysfunction, limited opening, and reports of jaw locking should be considered contraindications. A limited protrusive range (i.e., <5 mm) suggests a low likelihood of OSA treatment efficacy with an MRD.

Although basic assessment for TMJ dysfunction is essential, consideration of the validity of certain TMJ theories and diagnostic tools is necessary. Thorough record-keeping is advised. Referral to a dental practitioner who has advanced training in the diagnosis and management of TMJ dysfunction may be indicated if symptoms are identified at the initial evaluation or if they develop at any time during treatment. Reports of diffuse tenderness, ear canal stuffiness, clicks, significant deviation with opening or protruding, or pain associated with these movements necessitate referral to an expert.

Dentate State

The individual must have sound teeth. Edentulous patients are unable to use MRDs because they function by retaining the teeth, and retention is used to reposition the mandible anteriorly. The minimum number and distribution of teeth varies by device. Placement of the adjustment mechanism routinely needs to be on the teeth and not in an edentulous area. To avoid excessive lateral load, the 8 to 10 teeth distributed around the arch serve as a general guide. The shape and inclination of the teeth can affect retention of the MRD and the dentist's ability to provide effective MRD therapy; the presence of no teeth or grossly undercut teeth can be problematic. Difficulty taking impressions in the setting of a pronounced gag reflex suggests that the patient will have difficulty adhering to MRD therapy.

Periodontal Condition and Tooth Mobility

A healthy periodontium with evidence of adequate oral hygiene is essential before therapy with an MRD commences. Anything worn in the mouth can compromise oral hygiene if it is not kept clean.

Bruxism

Management of sleep bruxism is an important role for the dentist.

Bruxism is not necessarily a contraindication to MRD therapy. An assessment for TMJ dysfunction is recommended. The bruxing individual should be advised that their parafunction will both limit their choice of MRD and negatively affect the life expectancy of the MRD.

Gastroesophageal Reflux Disease

Dentinal pooling that results from gastroesophageal reflux disease can be a symptom of OSA, and it is one that a dentist is ideally positioned to recognize.

Mandibular Repositioning Device Therapy

Long-term complications of MRD therapy are not well documented. Given the intricacies of determining which device is most likely to be successful, the role of titration, and the management of complications, the dentist should seek advanced training before supplying MRDs.

Complete periodontal assessment should precede the decision to fit a patient with an MRD. Management of inflammation can be more difficult with an MRD, which the patient must use consistently when sleeping. Bacterial biofilm formation and retention are likely to be encouraged on the tissues and the device, and additional instruction and encouragement regarding effective bacterial biofilm removal are often necessary. Careful and frequent monitoring of the periodontal status with ongoing use of the MRD is essential to confirm sustained health and tooth stability, to recognize negative changes, and to recommend intervention and consideration of an alternative treatment modality.

Device Design and Compliance

Application Considerations

eTable 40.1 proposes factors to consider when selecting an adjustable custom-made MRD for a patient, and eBox 40.1 provides definitions of terms.

eTABLE 40.1

Factors to Consider When Selecting a Mandibular Repositioning Device

Features	Benefits
Discreet	Reduces hypersalivation and improves acceptance
Permits full lip seal	Eliminates dry mouth or dribbling when worn
Adjustable from zero protrusion and over a wide range	Time to adapt to wearing the device and ability to titrate for maximum effect
Does not load the incisor teeth	Low dental morbidity
Retentive	Stays in place as it works
Controls vertical opening	Does not permit the effect of protrusion to be lost by mouth opening
Permits lateral movement	Useful for patients with bruxism
Does not invade the tongue space	Ability to tolerate the device and to speak discernibly
Easy for the dental clinician	Improves chance of success
Long life and robust	Value for money
Biocompatible and without metal components	Avoids allergic and galvanic reaction (bad taste when worn)
Easy to keep clean	Useful life
Compliance and obstructive sleep apnea efficacy monitoring	Evidence of device wear and effect

From Adrian Zacher, 2013. https://snorer.com/snorer-training-for-dentists-who-want-to-help-snorers/.

eBox 40.1

Glossary

Apneic (ap-nee-ic) episode A period of not breathing while asleep that usually lasts for more than 10 seconds.

Hypercapnia (high-per-cap-nee-ah) A raised level of carbon dioxide in the blood. Carbon dioxide is the gas that is normally breathed out, but its blood level rises if breathing is inadequate. It is usually measured by taking an arterial blood sample.

Hypersomnolence (high-per-som-no-lence) Excessive daytime sleepiness.

Hypnogram (hip-no-gram) The final printout of the all-night sleep stages (i.e., rapid eye movement and non–rapid eye movement) after an overnight study.

Hypopnea (high-pop-nee-ah) A period of underbreathing that

usually lasts for more than 10 seconds.

Hypothyroidism (high-po-thy-royd-ism) Also known as *myxedema* (mix-si-dee-ma), hypothyroidism occurs when the thyroid gland fails to make enough thyroid hormone, and it can manifest as obstructive sleep apnea.

Hypoxia (high-pox-ee-a) The state in which the body is short of oxygen and therefore the level in the blood falls.

Hypoxic (high-pox-ic) dips Decreases in oxygen levels seen on the oximeter that usually accompany apneas. They are also known as *desaturations*, because when it is not hypoxic, the blood is described as fully saturated with oxygen.

Insomnia (in-som-nee-ah) The state of being awake when a person wants to be asleep. Although often thought of as a problem, it may not be.

Mandibular repositioning device (MRD) An intraoral device that is used to maintain upper airway patency during sleep. It is also known as a mandibular advancement device, an oral appliance, or a splint.

Manometer (ma-nom-i-ter) A device used to measure the pressure being delivered by a continuous positive airway pressure machine, which is usually measured in centimeters of water (cm H_2O). A common pressure is about 10 cm H_2O.

Microarousals Very brief awakenings that can be identified only when the brain waves are being monitored by encephalography.

Movement arousals Short awakenings that involve minor body movements of which the sleeper is unaware.

Narcolepsy (nar-co-lep-see) A cause of daytime sleepiness that results from an inherited disorder of the control of dreaming sleep. Narcolepsy must be differentiated from sleep apnea, periodic leg movements, and other uncommon causes of daytime sleepiness.

Obstructive sleep apnea (ap-nee-ah) This syndrome is commonly referred to as obstructive sleep apnea (OSA) or obstructive sleep apnea syndrome (OSAS). It usually involves 30 or more periods of not breathing when asleep. Each period or apneic episode lasts for more than 10 seconds.

Positive airway pressure (PAP) The process of delivering a

continuously raised airway pressure via a mask worn on the face to pneumatically splint open the airway.

Sleep-disordered breathing (SDB) The collective term for a group of disorders that are characterized by abnormalities of the respiratory pattern (i.e., pauses in breathing) or the quantity of ventilation during sleep.

Bulk, Xerostomia, and Hypersalivation

Logically, the least presence in the mouth the MRD represents, the easier the patient will tolerate it. Depending on the bulk of the device and the patient's ability to close the mouth while wearing it, dry mouth (i.e., xerostomia) and hypersalivation are common initial responses to MRD wear. These conditions normally resolve over the first few weeks as the patient adapts to the device. A nonbulky MRD that permits lip seal is therefore considered superior and may encourage nasal breathing.

Initial Protrusive Position

To overcome an inherent design limitation, some MRDs have to start from approximately 50% to 70% of the patient's maximum protrusion. Ideally, the MRD should start from zero protrusion and be gradually protruded to maximize acceptance and minimize unnecessary protrusion to achieve effect.

Tongue Space Invasion

An MRD protrudes the jaw and effectively pulls the tongue away from the back of the throat. Placing a mechanism where the tongue is to be placed can be considered counterproductive.

Adjustable Protrusion: Placement of the Mechanism

MRDs can be broadly subdivided into those that place the mechanism in the buccal sulcus, incisally, or inside the tongue space. Proponents of each type vociferously defend its design logic. Recommending the suitability of one MRD over another requires a comprehensive assessment of the individual in context with proposed indications and contraindications.

Freedom of Lateral Movement

When evidence of bruxism is found during an examination, the use of an MRD that permits lateral movement and can withstand the forces imposed on it is advisable. Mechanisms that may fatigue and fracture should be considered carefully.

Durability and Ease of Cleaning

An inherently robust design and fabrication method is important because the device will be used to maintain an unconscious individual's airway. The consequences of metal fatigue should be considered. Complex mechanisms and materials that absorb saliva may present difficulty when it comes to cleaning and adversely affect the MRD's useful life.

Effect of Vertical Opening

Interincisal opening of more than 5 mm has been associated with lower patient adherence, perhaps as a result of discomfort.[38] However, a product trend based on empiric reporting suggests that an increased occlusal vertical dimension may be more comfortable in certain patients and permit the tongue to flow over the occlusal surfaces (i.e., allow the tongue to expand laterally). This may be relevant for patients with macroglossia or micrognathia.

Macroglossia and Micrognathia

Adding to an already crowded oral cavity makes wearing the MRD a challenge for the patient. Empiric evidence suggests that permitting the tongue to expand over the occlusal surface by increasing the vertical dimension (with protrusion of the mandible) in selected cases can be beneficial.

Side Effects

Maximizing the positive effects of MRD therapy while minimizing the side effects is the unstated aim of MRD design. The following sections highlight the primary side effects. Common side effects include incisor tilting, which should be discussed with the patient. Placing detected undesired tooth movement in context with OSA

treatment benefits requires a risk–benefit analysis with consideration of treatment alternatives at review appointments. Valid informed consent is advisable.

Hypersalivation or Xerostomia

Immediate short-term side effects of wearing MRDs include hypersalivation or xerostomia (i.e., dry mouth) if lip seal is impossible as a result of vertical opening or bulk, or both.

Undesired Orthodontic Effects

Tooth movement may complicate MRD therapy and "may be predictable on the basis of initial characteristics in dental occlusion and the design."[33] Some degree of retroclination of the upper incisors and proclination of the lower incisors is thought to occur with most MRDs.[9] It may manifest during long-term use as a mild reduction in overjet or overbite,[3] and it may be undetectable by the patient. Occasionally, dental changes occur that require remedial dentistry to restore the occlusion. After wearing an MRD, some patients may experience a temporary sensation of bite change. Empiric reporting has led to the creation of morning-wear devices that can lessen this effect. The morning-wear device can be designed to reverse the lateral load applied to the teeth by the MRD and the potential overbite and overjet changes.

Change in Occlusal Relationship

Obtaining valid informed consent and retaining pre-MRD therapy study casts are highly recommended because a change in the occlusal relationship may be observed in rare instances. Careful and frequent dental follow-up appointments are suggested. Communication with the patient regarding detected changes that he or she may be unaware of is recommended, and these should be discussed in the context of a risk–benefit assessment and consideration of alternative treatment modalities.

A posterior open bite may develop in some MRD users for unknown reasons. Theories include the following:

- The device frees the bite. The MRD can

eliminate interdigitation with opposing teeth and the influence of physiologic TMJ function on tooth position, either or both of which can destabilize the occlusion.
• The condylar head is moved anteriorly and off of the meniscus.
• Premature incisal contact results from inclination that appears as a posterior open bite.

Temporomandibular Joint Ache

An aggressive titration rate (i.e., increasing protrusion) or commencing MRD therapy in an excessively protruded or incorrect position (i.e., bite registration is not observed when the laboratory constructs the device) can cause TMJ ache. Frequent evaluation with gradual incremental titration from a minimal or zero protrusion starting point is advisable. TMJ ache can occur even with proper fitting and management, and the dentist should always ask the patient to communicate even seemingly minor and transient symptoms because they may indicate a developing complication.

Tooth Pain

Diffuse, low-level discomfort of the teeth may be reported.

Recording the Jaw Relationship

What

A protrusive bite registration can be considered a three-dimensional prescription to be given to the MRD manufacturer. It relates the position of the jaws, and this is the position to which the MRD is constructed. It can be merely a wax horseshoe shape into which the patient bites, or it can be a more sophisticated product with added functionality (e.g., George Gauge, IST, Airway Metrics).

Why

Every patient is unique; consequently, an approach of "*x*

millimeters of protrusion to be effective" will not work. When registering the protrusive bite, the intention is to record the relationship of the jaws in a position that is 50% to 70% of the maximum comfortable protrusion in anticipation that this will be close to the final effective position. The MRD will be constructed to this position, but therapy can ideally commence with less or no protrusion. The ideal bite registration position relates to and minimizes the vertical opening to permit lip seal and encourage nasal breathing. MRD designs vary, as does the impact of an incorrectly constructed or used protrusive bite registration.

How

Various products are available to assist the dentist with providing accurate bite registrations, including orthodontic bite forks, the George Gauge, and the IST bite fork. Alternatives include wax or putty. YouTube videos show how these products can best be used. Determining the optimal protrusion was discussed earlier in this chapter.

When or If

It is necessary to provide a protrusive bite registration for MRD construction to ensure that an even and balanced contact exists between the occlusal surfaces. Some MRDs have incisal contact only (e.g., Thornton Adjustable Positioner, MDSA), but a bite registration is still required. It is essential that deviation to the left or right on protrusion is reflected in the MRD.

Other Factors

Factors to communicate to the laboratory include the following:

- When the dental midlines do not coincide
- When the dental and facial midlines do not coincide
- When there is an acute condylar angle (commonly associated with skeletal class II)
- When there is a steep curve of Spee that leads to

posterior interference on protrusion
- Overerupted or unopposed molars that may interfere with protrusion
- Marked facial or condylar asymmetry

Some MRD manufacturers may also ask for the following information:

- A record of the maximum comfortable protrusion
- A record of the maximum opening (measured interincisally)
- Whether the device should include all of the molar teeth

It is important to ensure that the vertical space between the most posterior molar teeth is sufficient to include two devices (i.e., upper and lower) of adequate material thickness for robustness.

Fitting

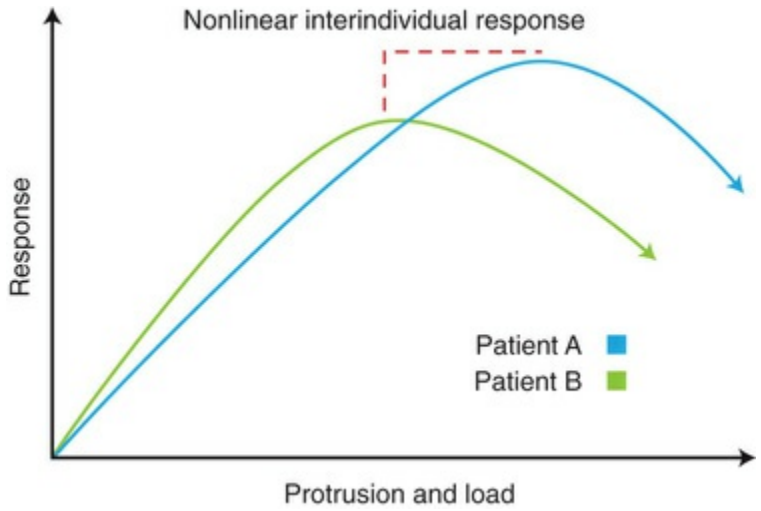
The dentist must ensure that both parts of the device are appropriately retentive and that when the MRD design incorporates posterior support, it is even and balanced. The gingiva must not blanch where it is covered. It is essential to establish that the patient can insert and remove the individual parts and subsequently the complete device. He or she must understand how the pieces of the device interrelate to achieve effect. This discussion should include the requirement for titration and regular follow-up appointments.

Determining the Optimal Protrusion

Establishing optimal jaw advancement, which is also known as *protrusion,* to deliver OSA therapy is challenging. Each patient has a unique maximum response to protrusion, which must be balanced

against increasing the load on the teeth and TMJs. This process, which is known as *titration*, has to be performed while providing sufficient time for the wearer to adapt to the device, and it must be balanced against the individual's desire and his or her bed partner's desire for rapid resolution.

Increased protrusion yields improved resolution of OSA symptoms, but subjective and objective symptom improvements are poorly correlated.[16] A nonlinear dose–response relationship exists between protrusion and response (eFig. 40.1).[23] Increased protrusion improves response until a certain patient-specific optimum has been established. Protrusion beyond this position yields no further benefit and may even diminish response.



EFIG. 40.1 Nonlinear dose–response relationship for two patients. (Courtesy Adrian Zacher, 2013, Snorer.com.)

Titration is complicated by the interindividual heterogeneous response (i.e., difference between patient A and patient B with regard to response and protrusion) and the detrimental effects of increasing the load directed toward the teeth and TMJs, which is concomitant with increased protrusion.

Several MRD titration protocols exist, and there is no consensus regarding what is optimal.[11] A multiparametric titration protocol as described by Dieltjens is suggested as ideal.[11] Subjective titration should be performed by the dental practitioner over time in response to patient and partner reporting, provided that the patient has had time to adapt to the device. The patient's maximum

tolerable protrusion is established before further titration is performed in an objective assessment environment. Protrusion can be set up to the patient's physiologic or tolerable limit.

Dental Evaluation

The dentist should provide regular follow-up appointments to monitor patients for side effects and possible complications, particularly during the early weeks and months of therapy; to promote compliance[15]; and to titrate subjective or objective improvement in the patient's symptoms. An alternate type of MRD can also be considered.

Conclusions

Around the world, the future of sleep medicine is being debated. In the United States, the American Academy of Sleep Medicine published a white paper on its website.[4] The aim of this publication was to devise "frameworks for health care delivery such as the patient-centered medical home (PCMH), patient registries, and new outcomes measures and tools for the diagnosis and treatment of sleep disorders." With the rise in awareness of how obesity, cardiology, diabetes, and OSA are interrelated, sleep laboratories may in the future evolve into metabolism centers.

In 1997, Loube and Strauss[32] concluded that "future efforts at enhancing cooperation between dentists and sleep disorders physicians in the treatment of OSA with oral appliances should be promoted as a means of standardizing treatment." Empowering appropriately trained team members to perform functions that they are well positioned to undertake seems logical and, in the face of an epidemic and a global financial crisis, necessary.

The role of dentistry in sleep medicine is developing to include increased emphasis on screening, and it may include patient evaluation (e.g., monitoring MRD compliance and objective efficacy). It may also include blood pressure and weight monitoring in an effort to recognize the best time to transition from an oral device to PAP.

The correlation of clinical indicators (e.g., incisal wear, tooth

mobility) as signs of SDB with a patient's hypertension, for example, can help the physician develop a broad-based strategy of intervention. The roles of breathing obstruction in its various forms in the amplification of periodontal damage (see Chapter 55) and masticatory system disorders (see Chapter 26) are addressed in this textbook.

Perspective is essential and can be gained through working as part of a multidisciplinary team. Tooth movement that in isolation may appear to be significant can be considered relatively unimportant when placed in the context of breathing and sleeping.

Case Scenario 40.1

Patient:
55-year-old female

Chief Complaint:
"My upper front teeth have moved, increasing the spaces between teeth and changing my bite."

Background Information:
The patient brought a photograph from 4 years before her appointment that shows the maxillary anterior teeth without increased spacing and fully coupled with the mandibular anterior teeth.

Current Findings:

Clinical evaluation reveals minimal periodontal disease or loss of attachment, including the anterior teeth. The patient does not think she snores but is not sure. She has gained weight over the past 4 years and has noticed increasing dryness of her mouth, although no new medication was taken. Deep crenations of the tongue are observed, and the mandibular posterior teeth are lingually inclined and show wear, suggesting bruxism. (A) Image of maxillary right anterior sextant shows a space that the patient reports to have developed over last several years. (B) Patient asked to make "Ahhh" sound. Because she is showing only her palate and tongue, this observation may indicate limited airway dimension. (C) Patient asked to swallow. She protrudes her tongue and shows shallow crenations of her tongue in that region, indicating less than ideal room for her tongue. (D) Models were taken 4 years ago for a bleaching tray for this patient, showing very close proximity of the cuspid and lateral incisor at that time, which is consistent with this patient's observations.

A

B

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What tentative diagnosis or explanation can you offer this patient? A. She may be experiencing separation of the teeth as a result of grinding them in her sleep and during the day. B. She may have developed an intolerance to the medications she has been taking for the past 10 years. C. Sleep-related breathing disorder can explain her symptoms, and the changes in her teeth may be a product of needing the tongue to move forward forcibly to open the	**Answer: C** **Explanation:** The patient's history and clinical presentation show multiple signs of sleep-related breathing disorder.

airway to allow adequate oxygen intake.	
2. What are your recommendations if you assume the patient's condition is a product of sleep-disorder breathing? A. You explain to her that dentists are not qualified to make the final diagnosis of sleep-disordered breathing, but there are many indications of the condition. Because there are serious medical complications related to untreated sleep-related breathing disorder, you strongly recommend that she seek evaluation by a qualified physician. B. You suggest that the patient ask her spouse to determine whether she snores while sleeping, and if not, you tell her to mention the dental problems to her physician at the next regular or annual examination. C. If the spouse confirms that the patient snores while sleeping, you suggest making a snore appliance.	**Answer: A** **Explanation:** A. Discounting the importance of a complete and accurate diagnosis of the degree of sleep-disordered breathing puts the patient at risk for serious or life-threatening medical complications. Providing snoring relief without a complete diagnosis is similarly irresponsible. Emphasizing the need to immediately seek a medical diagnosis and intervention is the only responsible action.

CHAPTER 41

Periodontal Therapy in the Female Patient

Joan Otomo-Corgel

CHAPTER OUTLINE

Puberty
Menses
Pregnancy
Oral Contraceptives
Menopause *(e-only)*
Conclusions

Throughout a woman's life, hormonal influences affect therapeutic decision making in periodontics. Historically, therapies have been gender biased. Research has provided a keener appreciation of the unique systemic influences on oral, periodontal, and implant tissues. Oral health care professionals have greater awareness of and can better deal with hormonal influences associated with the reproductive process. Periodontal and oral tissue responses can be altered, creating diagnostic and therapeutic dilemmas. The clinician

should recognize, customize, and appropriately alter periodontal therapy according to the individual woman's needs based on her stage of life.

Sex steroids exert profound biologic effects on immune function and bone metabolism.[137] Estrogen can significantly affect the periodontium, including maturation of gingival epithelium, osteoblastic differentiation of periodontal ligament cells, and bone formation.[136]

This chapter reviews phases of the female reproductive cycle from puberty through menopause. Periodontal manifestations, systemic effects, and clinical management are addressed.

Puberty

Puberty occurs, on average, between the ages of 11 to 14 in most girls. The production of sex hormones (i.e., estrogen and progesterone) increases and then remains relatively constant during the remainder of the reproductive phase. The prevalence of gingivitis increases without an increase in the amount of plaque. Gram-negative anaerobes, especially *Prevotella intermedia,* have been associated with puberty gingivitis. Kornman and Loesche[69] postulated that this anaerobic organism may use ovarian hormones as a substitute for vitamin K as a growth factor. Levels of black-pigmented *Bacteroides,* especially *P. intermedia* (formerly known as *Bacteroides intermedius*), are thought to increase with increased levels of gonadotropic hormones in puberty. *Capnocytophaga* species also increase in incidence and proportion. These organisms have been implicated in the increased bleeding tendency observed during puberty.

Studies of pubertal gingivitis indicate proportionately elevated numbers of motile rods, spirochetes, and *P. intermedia.*[47,96] Statistically significant increases in gingival inflammation and the proportions of *P. intermedia* and *Prevotella nigrescens* have been seen in pubertal gingivitis.[100] A study of 11- to 17-year-old adolescents found higher levels of *Actinobacillus actinomycetemcomitans* and *Fusobacterium nucleatum,* which were associated with bleeding indices, probing depth, and attachment loss.[83]

During puberty, periodontal tissues can have an exaggerated

response to local factors. A hyperplastic reaction of the gingiva can occur in areas where food debris, materia alba, plaque, and calculus are deposited. The inflamed tissues become erythematous, lobulated, and retractable. Bleeding may occur easily with mechanical debridement of the gingival tissues. Histologically, the appearance is consistent with inflammatory hyperplasia.

During the reproductive years, women tend to have a more vigorous immune response, including higher immunoglobulin concentrations, stronger primary and secondary responses, increased resistance to the induction of immunologic tolerance, and a greater ability to reject tumors and homografts.[135] Allergy, sensitivity, and asthma occur more often in young men, but after puberty, women become more susceptible than their male counterparts.

Key Fact

Sex steroids exert profound biologic effects on immune function and bone metabolism. Estrogen can have a significant impact on the periodontium, including maturation of gingival epithelium, osteoblastic differentiation of periodontal ligament cells, and bone formation. During puberty, periodontal tissues can have an exaggerated response to local factors. A hyperplastic reaction of the gingiva can occur. Inflamed tissues become erythematous, lobulated, retractable, and bleed easily. Histologically, the appearance is consistent with inflammatory hyperplasia.

Management

During puberty, education of the parent or caregiver is part of successful periodontal therapy. Preventive care, including a vigorous program of oral hygiene, is also vital.[5] Milder gingivitis cases respond well to scaling and root planing, with frequent oral hygiene reinforcement. Severe cases of gingivitis may require microbial culturing, antimicrobial mouthwashes and local site delivery, or antibiotic therapy. Periodontal maintenance appointments may need to be more frequent when periodontal instability is identified.

The clinician should recognize the periodontal manifestations and intraoral lesions associated with systemic diseases (e.g., diabetes).[23,106] Thorough review of the patient's medical history and medical referral should occur when deemed necessary. The clinician should be aware of the effects of chronic regurgitation of gastric contents on intraoral tissues; this age group is susceptible to eating disorders such as bulimia and anorexia nervosa.[15] *Perimolysis* (i.e., smooth erosion of enamel and dentin), typically on the lingual surfaces of maxillary anterior teeth, varies with the duration and frequency of the behavior.[17] Enlargement of the parotid glands (occasionally sublingual glands) has been estimated to occur in 10% to 50% of patients who binge and purge.[88] A diminished salivary flow rate may be identified, which can increase oral mucous membrane sensitivity, gingival erythema, and caries susceptibility.

Menses

Periodontal Manifestations

During the reproductive years, the ovarian cycle is controlled by the anterior pituitary gland. The gonadotropin follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are produced by the anterior pituitary gland. The secretion of gonadotropins also depends on the hypothalamus. Ongoing changes in the concentration of the gonadotropins and ovarian hormones occur during the monthly menstrual cycle (Fig. 41.1). Under the influence of FSH and LH, estrogen and progesterone are steroid hormones produced by the ovaries during the menstrual cycle. During the reproductive cycle, the purpose of estrogen and progesterone is to prepare the uterus for implantation of an egg.

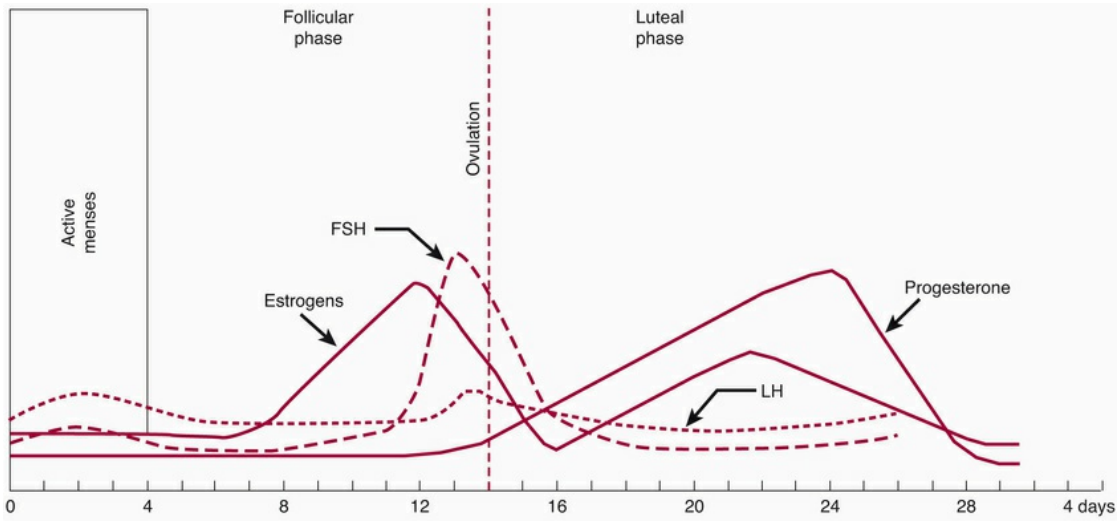

FIG. 41.1 Female menstrual cycle, showing the peak levels of progesterone and estrogen compared with follicle-stimulating hormone *(FSH)* and luteinizing hormone *(LH)*.

The monthly reproductive cycle has two phases. The first phase is referred to as the *follicular phase.* Levels of FSH are elevated, and estradiol (E2), the major form of estrogen, is synthesized by the developing follicle and peaks approximately 2 days before ovulation. Estrogen stimulates the egg to move down the fallopian tubes (i.e., ovulation) and stimulates proliferation of the stroma cells, blood vessels, and glands of the endometrium.

The second phase is called the *luteal phase*. The developing corpus luteum synthesizes estradiol and progesterone. Estrogen peaks at 0.2 ng/mL and progesterone at 10.0 ng/mL to complete the rebuilding of the endometrium for implantation of a fertilized egg. If the egg is not fertilized, the corpus luteum involutes, ovarian hormone levels drop, and menstruation ensues. It has been postulated that ovarian hormones increase inflammation in gingival tissues and exaggerate the response to local irritants. Gingival inflammation seems to be aggravated by an imbalance or increase in sex hormones.[55,56] Menstrual cycle irregularity is a risk indicator for periodontal disease before menopause.[48] Numerous in vitro and in vivo studies have demonstrated that sex hormones affect and modify the actions of cells of the immune system.

Evidence suggests that the interaction between estrogen and cells of the immune system can have nonimmune regulatory effects.[7,22] Possible mechanisms have been suggested for the increase in

hormonal gingival interaction in the menstrual cycle. Tumor necrosis factor alpha (TNF-α), which fluctuates during the menstrual cycle[13]; elevated prostaglandin E_2 (PGE_2) synthesis[93]; and angiogenetic factors, endothelial growth factors, and receptors may be modulated by progesterone and estrogen, contributing to increases in gingival inflammation during certain stages of the menstrual cycle.[65]

Progesterone has been associated with increased permeability of the microvasculature, altering the rate and pattern of collagen production in the gingiva,[84] increasing folate metabolism,[111,149] and altering the immune response. During menses, progesterone increases from the second week, peaks at approximately 10 days, and dramatically drops before menstruation (based on a 28-day cycle; individual cycles vary). Progesterone plays a role in stimulating the production of prostaglandins that mediate the body's response to inflammation. PGE_2 is one of the major secretory products of monocytes, and the level is increased in inflamed gingiva. Miyagi and colleagues[92] found that the chemotaxis of polymorphonuclear leukocytes (PMNs) was enhanced by progesterone but reduced by estradiol. Testosterone did not have a measurable effect on PMN chemotaxis. The researchers suggested that the altered PMN chemotaxis associated with gingival inflammation might be caused by the effects of sex hormones. Physiologic, experimental, and clinical data confirm differences in immune responses between the two sexes.[158]

Gingival tissues have been reported to be more edematous during menses and erythematous before the onset of menses in some women. One study reported higher gingival indices during ovulation and before menstruation despite reported increases in oral symptoms during menses.[85] An increase of gingival exudate has been observed during the menstrual period and is sometimes associated with a minor increase in tooth mobility.[43] The incidence of postextraction osteitis is also higher during initiation of menses. No significant hematologic laboratory findings accompany this, other than a slightly reduced platelet count and a slight increase in clotting time.

When the progesterone level is highest (during the luteal phase of the cycle), intraoral recurrent aphthous ulcers,[35] herpes labialis

lesions, and candidal infections occur in some women in a cyclic pattern. Because the esophageal sphincter is relaxed by progesterone, women may be more susceptible to gastroesophageal reflux disease (GERD) during this time of the cycle. Symptoms of GERD include heartburn, regurgitation, and chest pain, and when reflux is severe, some patients develop unexplained coughing, hoarseness, sore throat, gingivitis, or asthma.[127]

Management

During the peak level of progesterone (about 7 to 10 days before menstruation), premenstrual syndrome (PMS) may also occur. There appears to be no significant difference in estrogen and progesterone levels between women with PMS and those without PMS. However, women with PMS seem to have lower levels of certain neurotransmitters such as enkephalins, endorphins, γ-aminobutyric acid (GABA), and serotonin. Depression, irritability, mood swings, and difficulty with memory and concentration are symptoms of neurotransmitter reduction. Patients are more sensitive and less tolerant of procedures, have a heightened gag reflex, and can have an exaggerated response to pain.

Increased gingival bleeding and tenderness associated with the menstrual cycle require closer periodontal monitoring. Periodontal maintenance should be titrated to the individual patient's need, and if problematic, 3- to 4-month intervals should be recommended. An antimicrobial oral rinse before cyclic inflammation may be indicated. Emphasis should be placed on oral hygiene. For the patient with a history of excessive postoperative hemorrhage or menstrual flow, scheduling surgical visits after cyclic menstruation is prudent. Anemia is common, and appropriate consultation with a physician and laboratory tests, when indicated, should be maintained.

During PMS, many women exhibit physical symptoms that include fatigue, sweet and salty food cravings, abdominal bloating, swollen hands or feet, headaches, breast tenderness, nausea, and gastrointestinal upset. GERD may make it more uncomfortable for the patient to lie fully supine, especially after a meal, and she may have a more sensitive gag reflex. The clinician should be aware that

nonsteroidal antiinflammatory drugs (NSAIDs), infection, and acidic foods exacerbate GERD. Patients with GERD may take over-the-counter antacids, H_2-receptor antagonists (e.g., cimetidine, famotidine, nizatidine, ranitidine), prokinetic agents (e.g., cisapride, metoclopramide), or proton pump inhibitors (e.g., lansoprazole, omeprazole, pantoprazole, rabeprazole).[128] These medications interact with some antibiotics and antifungals, and a review of their pharmacology is necessary. Fluoride rinses and trays, frequent periodontal debridement, and avoidance of mouthwashes with high alcohol content can reduce the associated gingival and caries sequelae.

PMS is often treated with antidepressants. Selective serotonin reuptake inhibitors (SSRIs) usually are the first-line choice because they have fewer side effects than other antidepressants, do not require blood monitoring, and are safe if overdosed. Women with PMS taking the SSRI fluoxetine had a 70% response rate. Fluoxetine was ranked the fifth most dispensed prescription (i.e., new and refills) in the United States in 1998, but when the patent was lifted, sales slowed. However, overall SSRIs ranked second in total dollar sales in the 2000s. Sertraline was ranked twelfth and is the drug of choice for treatment of PMS.[166]

The clinician should be aware that patients taking fluoxetine have increased side effects with highly protein-bound drugs (e.g., aspirin), and the half-life of diazepam and other central nervous system (CNS) depressants is increased. Other common SSRIs are fluvoxamine, paroxetine, and citalopram. Other prescribed antidepressants include selective serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclics, trazodone, mirtazapine, nefazodone, and maprotiline.

Key Fact

Increased gingival bleeding and tenderness associated with the menstrual cycle require close periodontal monitoring. Periodontal maintenance should be adjusted to the individual patient's needs. If problematic, 3- to 4-month recall intervals should be recommended.

The PMS patient may be difficult to treat because of emotional and physiologic sensitivity. The dentist should treat the gingival and oral mucosal tissues gently. Gauze pads or cotton rolls should be moistened with a lubricant, chlorhexidine rinse, or water before placing them in the aphtha-prone patient. Careful retraction of the oral mucosa, cheeks, and lips is necessary in patients prone to aphthous or herpetic lesions. Because the hypoglycemic threshold is elevated, the clinician should advise the patient to have a light snack before her appointment. Of menstruating women, 70% have PMS symptoms, but only 5% meet the strict diagnostic criteria.

Pregnancy

Periodontal Manifestations

The link between pregnancy and periodontal inflammation has been known for many years. In 1778, Vermeeren discussed "toothpains" in pregnancy. In 1818, Pitcarin[118] described gingival hyperplasia in pregnancy. Despite awareness regarding pregnancy and its effect on periodontal disease, only recently has evidence indicated an inverse relationship with systemic health. Research confirms that periodontal disease alters the systemic health of the patient and adversely affects the well-being of the fetus by elevating the risk for preterm, low-birth-weight (PLBW) infants.

In 1877, Pinard[117] recorded the first case of pregnancy gingivitis. Only recently has periodontal research begun to focus on causative mechanisms. Pregnancy gingivitis is extremely common, occurring in 30% to 100% of pregnant women.[50,74,82,132] It is characterized by erythema, edema, hyperplasia, and increased bleeding. Histologically, the description is the same as for gingivitis. However, the etiologic factors are different despite clinical and histologic similarities. Cases range from mild to severe inflammation (Fig. 41.2), which can progress to severe hyperplasia, pain, and bleeding (Figs. 41.3 and 41.4).

FIG. 41.2 Moderate form of pregnancy gingivitis.

FIG. 41.3 Pyogenic granuloma of pregnancy (i.e., pregnancy tumor).

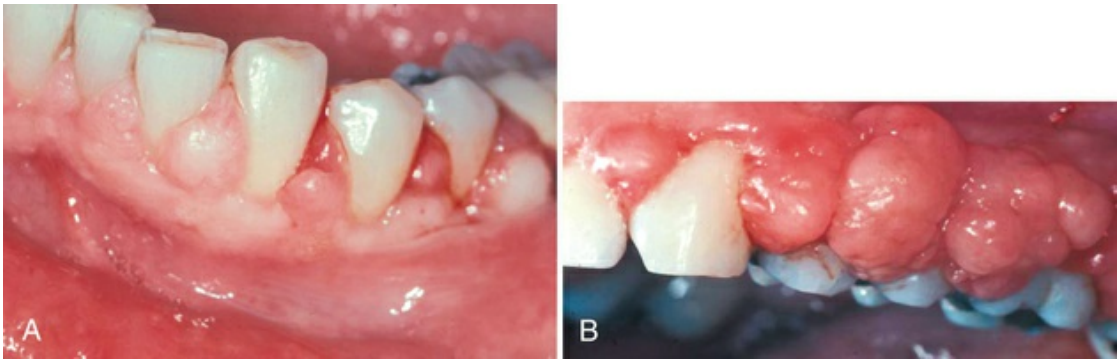

FIG. 41.4 Severe pregnancy gingivitis with hyperplasia can occur in patients with poorly controlled non–insulin-dependent diabetes mellitus. (A) Moderate gingival enlargement. (B) Severe gingival enlargement.

Other growths that resemble pregnancy granulomas must be

ruled out, such as central giant cell granulomas or underlying systemic diseases. Periodontal status before pregnancy may influence the progression or severity as the circulating hormones fluctuate. The anterior region of the mouth is affected more often, and interproximal sites tend to be most involved.[27] Increased tissue edema can lead to increased pocket depths and may be associated with transient tooth mobility.[120] Anterior site inflammation can be exacerbated by increased mouth breathing, primarily in the third trimester, from pregnancy rhinitis. The gingiva is the most common site involved (approximately 70% of cases), followed by the tongue and lips, buccal mucosa, and palate.[132] An increase in attachment loss can represent active periodontal infection accelerated by pregnancy.[75]

Pyogenic granulomas (i.e., pregnancy tumors or pregnancy epulis) occur in 0.2% to 9.6% of pregnancies. They are clinically and histologically indistinguishable from pyogenic granulomas occurring in nonpregnant women or in men. Pyogenic granulomas appear most often during the second or third month of pregnancy. Clinically, they bleed easily and become hyperplastic and nodular. When excised, the lesions usually do not leave a large defect. They may be sessile or pedunculated and ulcerated, ranging in color from purplish red to deep blue, depending on the vascularity of the lesion and degree of venous stasis.[10] The lesion classically occurs in an area of gingivitis and is associated with poor oral hygiene and calculus. Alveolar bone loss is usually not associated with pyogenic granulomas of pregnancy.

Role of Pregnancy Hormones

Subgingival Plaque Composition

Epidemiologic studies indicate a relationship between the level of home care and the severity of gingival inflammation. It appears that the association between signs of gingival inflammation and the amount of plaque is greater after parturition than during pregnancy. An alteration in the compositions of subgingival plaque occurs during pregnancy. Kornman and Loesche[70] found that during the second trimester, gingivitis and gingival bleeding increased without an increase in plaque levels. Bacterial

anaerobic/aerobic ratios increased in addition to proportions of *Bacteroides melaninogenicus* and *P. intermedia* (2.2% to 10.1%). The study authors suggested that estradiol or progesterone could substitute for menadione (vitamin K) as an essential growth factor for *P. intermedia* but not *Porphyromonas gingivalis* or *Eikenella corrodens.* There was also an increase in *P. gingivalis* during the 21st through 27th weeks of gestation, but this was not statistically significant. The relative increase in the numbers of *P. intermedia* may be a more sensitive indicator of an altered systemic hormonal situation than clinical parameters of gingivitis.[140]

One study concluded that subgingival levels of bacteria associated with periodontitis did not change. *P. gingivalis* and *Tannerella forsythia* counts were higher and associated with bleeding on probing at week 12.[2] Bacterial challenge to the gingival tissues, quantitatively (plaque scores) and qualitatively (*P. gingivalis),* appears to affect the level of gingival inflammation observed during pregnancy.[18]

Periodontal Disease and Preterm, Low-Birth-Weight Infants

Although most studies support a causal relationship regarding the hypothesis that periodontitis during pregnancy poses an increased risk of adverse pregnancy outcomes, there are conflicting results. Variations in study results may result from confounding factors, effect modifiers, populations studied, timing of intervention or evaluation, and severity of periodontal disease based on different definitions.

Several systematic reviews indicate that periodontal disease[134,153,161,162] adversely affects pregnancy outcomes. Intervention trials have shown a positive effect with periodontal therapy and reduction of adverse pregnancy outcomes,[60,80,81,105,147] but three large multicenter trials in the United States did not support these results.[90,102,141] Studies indicate that routine nonsurgical periodontal therapy after the first trimester is not associated with adverse pregnancy outcomes.[90]

Initially, Offenbacher and colleagues[104] provided evidence that untreated periodontal disease in pregnant women could be a significant risk factor for preterm (<37 weeks' gestation), low-birth-

weight (<2500 g) infants. The relationship between genitourinary tract infection and PLBW infants is well documented in human and animal studies. Periodontal researchers, suspecting periodontal disease as another source of infection, found that otherwise low-risk mothers of PLBW infants had significantly more periodontal attachment loss than control mothers having normal-weight infants at birth.

Current opinion is that the correlation of periodontal disease with PLBW birth may result from infection and is mediated indirectly, principally by the translocation of bacterial products such as endotoxin (i.e., lipopolysaccharide [LPS]) and the action of maternally produced inflammatory mediators.[38] Jared and coworkers[58] found that fetal exposure to oral pathogens in utero increased the risk of neonatal intensive care unit admission and extended length of stay. Concentrations of biologically active molecules, such as PGE_2 and TNF-α, which usually are involved in normal parturition, are raised to artificially high levels by the infection process, which can foster premature labor.[3]

Gram-negative bacteria in periodontal diseases may permit their selective overgrowth or invasion within the genitourinary tract. Han and associates[49] documented hematogenous spread of oral bacteria to the amnion, and Madianos and colleagues[86] showed that oral bacteria crossed the placental barrier and triggered an immune response by the fetus.

Gingival crevicular fluid (GCF) levels of PGE_2 were positively associated with intraamniotic PGE_2 levels ($P = 0.018$), suggesting that gram-negative periodontal infection presents a systemic challenge sufficient to initiate the onset of premature labor as a source of LPS or through stimulation of secondary inflammatory mediators such as PGE_2 and interleukin-1 beta (IL-1β).[24] Offenbacher and coworkers[103] suggested a dose–response relationship for increasing GCF PGE_2 as a marker of current periodontal disease activity and decreasing birth weight.

Four organisms associated with mature plaque and progressing periodontitis—*T. forsythia, P. gingivalis, A. actinomycetemcomitans,* and *Treponema denticola*—were detected at higher levels in PLBW mothers compared with normal-birth-weight controls. Despite

research supporting the association of periodontal disease and PLBW,[25,26] more studies with improved methodology are needed to assess the validity of the association.

Key Fact

Current opinion suggests a possible association between periodontal disease and preterm, low-birth-weight (PLBW) infants. Adverse pregnancy events can result from an infection that is mediated by one of two major pathways: (1) directly by oral microoganisms or (2) indirectly, principally by the translocation of bacterial products such as endotoxin (i.e., lipopolysaccharide) and the action of maternally produced inflammatory mediators.

Preeclampsia

A systematic review of preeclampsia and periodontitis indicated an increased risk during pregnancy. Preeclampsia is a life-threatening condition in late pregnancy that is characterized by high blood pressure and excess protein in the urine. High C-reactive protein levels also are associated with preeclampsia in this population.[130,138,152]

Maternal Immunoresponse

The maternal immune system is thought to be suppressed during pregnancy. This response may allow the fetus to survive as an allograft. Documentation of immunosuppressive factors in the sera of pregnant women shows a marked increase of monocytes (which in large numbers inhibit in vitro proliferative responses to mitogens, allogenic cells, and soluble antigen),[151] and pregnancy-specific β_1-glycoproteins contribute to diminished lymphocyte responsiveness to mitogens and antigens.[11] The ratio of peripheral helper T cells to suppressor T cells (CD4/CD8) decreases throughout pregnancy.[121]

The changes in maternal immunoresponsiveness suggest an increased susceptibility to developing gingival inflammation. In one study, the gingival index was higher, but percentages of T3

(CD3), T4 (CD4), and B cells appeared to decrease in peripheral blood and gingival tissues during pregnancy compared with a control group.[1] Other studies report decreased PMN (i.e., neutrophil) chemotaxis, depression of cell-mediated immunity, phagocytosis, and decreased T-cell response with elevated ovarian hormone levels, especially progesterone.[119] Decreased in vitro responses of peripheral blood lymphocytes to several mitogens and to a preparation of *P. intermedia* have been reported.[12,79,109] Evidence suggests a decrease in the absolute numbers of $CD4^+$ cells in peripheral blood during pregnancy compared with postpartum.[94,102]

Lapp and colleagues[73] suggested that high levels of progesterone during pregnancy affect the development of localized inflammation by downregulation of IL-6 production, rendering the gingiva less efficient at resisting the inflammatory challenges produced by bacteria. Another study indicated that live preterm birth was associated with decreased levels of immunoglobulin G (IgG) antibody to periodontal pathogens in women with periodontitis when assessed during the second trimester, but was not associated with birth outcomes.[29]

Ovarian hormone stimulates the production of prostaglandins, particularly PGE_1 and PGE_2, which are potent mediators of the inflammatory response. With the prostaglandin acting as an immunosuppressant, gingival inflammation can increase when the mediator level is high.[32,107] Kinnby and coworkers[66] found that high progesterone levels during pregnancy influenced plasminogen activator inhibitor type 2 (PAI-2) and disturbed the balance of the fibrinolytic system. Because PAI-2 is an important inhibitor of tissue proteolysis, this research implies that components of the fibrinolytic system may be involved in the development of pregnancy gingivitis.

During pregnancy, sex hormone levels rise dramatically (Box 41.1). Progesterone reaches levels of 100 ng/mL, 10 times the peak luteal phase of menses. Estradiol in the plasma may reach levels 30 times higher than during the reproductive cycle. In early pregnancy and during the normal ovarian cycle, the corpus luteum is the major source of estrogen and progesterone. During pregnancy, the placenta begins to produce estrogens and progesterone.

Box 41.1

Causes of Gingival Responses to Elevated Estrogen and Progesterone During Pregnancy

Subgingival Plaque Composition

- Increase in anaerobic/aerobic ratio
- Higher concentrations of *Prevotella intermedia* (i.e., substitutes sex hormone for vitamin K growth factor)
- Higher concentrations of *Bacteroides melaninogenicus*
- Higher concentrations of *Porphyromonas gingivalis*

Maternal Immunoresponse

- Depression of cell-mediated immunity
- Decrease in neutrophil chemotaxis
- Depression of antibody and T-cell responses
- Decrease in ratio of peripheral helper T cells to suppressor-cytotoxic T cells (i.e., CD4/CD8 ratio)
- Cytotoxicity directed against macrophages and B cells can diminish immunoresponsiveness
- Decrease in absolute numbers of $CD3^+$, $CD4^+$, and $CD19^+$ cells in peripheral blood during pregnancy versus postpartum
- Stimulation of prostaglandin production

Sex Hormone Concentration

Estrogen

- Increases cellular proliferation in blood vessels (e.g., in the endometrium)
- Decreases keratinization while increasing epithelial glycogen
- Specific receptors are found in gingival tissues

Progesterone

- Increases vascular dilation and increases permeability, resulting in edema and accumulation of inflammatory cells
- Increases proliferation of newly formed capillaries in gingival tissues (i.e., increased bleeding tendency)
- Alters rate and pattern of collagen production
- Increases metabolic breakdown of folate (i.e., folate deficiency can inhibit tissue repair)
- Specific receptors are found in gingival tissues
- Decreases plasminogen activator inhibitor type 2, increasing tissue proteolysis

Estrogen and Progesterone

- Affect ground substance of connective tissue by increasing fluidity
- Concentrations increase in saliva and fluid, with increased concentrations in serum

Estrogen regulates cellular proliferation, differentiation, and keratinization, whereas progesterone influences the permeability of the microvasculature,[76,77] alters the rate and pattern of collagen production, and increases the metabolic breakdown of folate (necessary for tissue maintenance).[164] High concentrations of sex hormones in gingival tissues, saliva, serum, and GCF also can exaggerate the response.

Regulation of most cellular processes by hormones occurs through the interaction of these products with intracellular receptors. The resulting effects depend on the concentration of unbound hormone diffused through the cell membrane. Vittek and associates[155] demonstrated specific estrogen and progesterone receptors in gingival tissues, providing direct biochemical evidence that this tissue functions as a target organ for sex hormones. Muramatsu and Takaesu[98] found increasing concentrations of sex hormones in saliva from the first month and peaking in the ninth month of gestation, along with increasing percentages of *P.*

intermedia. Probing depth, number of gingival sites with bleeding, and redness increased until 1 month after delivery. Evidence indicates sex hormone concentration in GCF, providing a growth media for periodontal pathogens.

Other Oral Manifestations of Pregnancy

Perimolysis (i.e., acid erosion of teeth) can occur if morning sickness or esophageal reflux is severe and involves repeated vomiting of the gastric contents. Severe reflux can cause scarring of the esophageal sphincter, and the patient may become more susceptible to GERD later in life.

Xerostomia is a frequent complaint among pregnant women. One study found this persistent dryness in 44% of pregnant participants.[30]

A rare finding in pregnancy is *ptyalism* (i.e., sialorrhea). Excessive secretion of saliva usually begins at 2 to 3 weeks' gestation and may abate at the end of the first trimester. The cause of ptyalism has not been identified, but it may result from the inability of a nauseated gravid woman to swallow normal amounts of saliva, rather than from a true increase in saliva production.[21]

Because pregnancy places the woman in an immunocompromised state, the clinician must be aware of her total health. Gestational diabetes, leukemia, and other medical conditions may appear during pregnancy.

Clinical Management

A thorough medical history is an imperative component of the periodontal examination, especially for the pregnant patient. Because of immunologic alterations, increased blood volume (i.e., ruling out mitral valve prolapse and heart murmurs), and fetal interactions, the clinician must diligently and consistently monitor the patient's medical and periodontal stability. Medical history discussion should include pregnancy complications, previous miscarriages, and recent history of cramping, spotting, or pernicious vomiting. The patient's obstetrician should be contacted to discuss her medical status, periodontal or dental needs, and the proposed treatment plan.

Establishing a healthy oral environment and maintaining optimal oral hygiene are primary objectives for the pregnant patient. A preventive periodontal program consisting of nutritional counseling and rigorous plaque control measures in the dental office and at home should be reinforced. Women of childbearing age, especially those trying to conceive, should be informed of the possible impact of inflammation on the unborn.

Plaque Control

The increased tendency for gingival inflammation during pregnancy should be clearly explained to the patient so that acceptable oral hygiene techniques may be taught, reinforced, and monitored throughout pregnancy. Scaling, polishing, and root planing can be performed whenever necessary during pregnancy. Some practitioners avoid the use of high-alcohol-content antimicrobial rinses for pregnant women and prefer to use non–alcohol-based oral rinses.

Prenatal Fluoride

Prescribing prenatal fluoride supplements has been an area of controversy. Although two studies have claimed beneficial results,[39,40] others suggest that the clinical efficacy of prenatal fluoride supplements is uncertain and the mechanism by which they might impart cariostasis is unclear.[139a] The American Dental Association (ADA) does not recommend the use of prenatal fluoride because its efficacy has not been demonstrated. The American Academy of Pediatric Dentistry also supports this position. The American Academy of Pediatrics has no stated position on prescribing prenatal fluorides.

Treatment

Elective Dental Treatment

Other than good plaque control, it is prudent to avoid elective dental care if possible during the first trimester and the last half of the third trimester. The first trimester is the period of organogenesis, when the fetus is highly susceptible to

environmental influences. In the last half of the third trimester, a hazard of premature delivery exists because the uterus is very sensitive to external stimuli. Prolonged chair time may need to be avoided because the woman is most uncomfortable at this time.

Supine hypotensive syndrome may occur. In a semireclining or supine position, the great vessels, particularly the inferior vena cava, are compressed by the gravid uterus. By interfering with venous return, this compression causes maternal hypotension, decreased cardiac output, and eventual loss of consciousness. Supine hypotensive syndrome can usually be reversed by turning the patient on her left side, which removes pressure on the vena cava and allows blood to return from the lower extremities and pelvic area. A preventive 6-inch soft wedge (i.e., rolled towel) should be placed on the patient's right side when she is reclined for clinical treatment.

Early in the second trimester is the safest period for providing routine dental care. The emphasis at this time is on controlling active disease and eliminating potential problems that can arise in late pregnancy. Major elective oral or periodontal surgery may be postponed until after delivery. Pregnancy tumors that are painful, interfere with mastication, or continue to bleed or suppurate after mechanical debridement may require excision and biopsy before delivery.

It is hypothesized that when the inflammatory cascade is activated during pregnancy, interventions targeting this pathway may be ineffective in reducing the rate of preterm birth. Treatment during pregnancy may be too late; it is possible that treatment before pregnancy (in nulliparous women) or in the period between pregnancies (for multiparous women, especially those with a history of preterm birth) may yield more promising results.[41]

The American Academy of Periodontology (www.perio.org) developed a position statement regarding the need to provide proper periodontal therapy for pregnant patients (Fig. 41.5). Because of research indicating a possible impact on the fetus, acute infection, abscesses, or other potential disseminating sources of sepsis may warrant prompt intervention irrespective of the stage of pregnancy.[4] A consensus report of a Joint European Workshop of Periodontology and an American Academy of Periodontology

Workshop stated that “although periodontal therapy has been shown to be safe and leads to improved periodontal conditions in pregnant women, case-related periodontal therapy, without systemic antibiotics does not reduce overall rates of preterm birth and low birth weight.”[133]

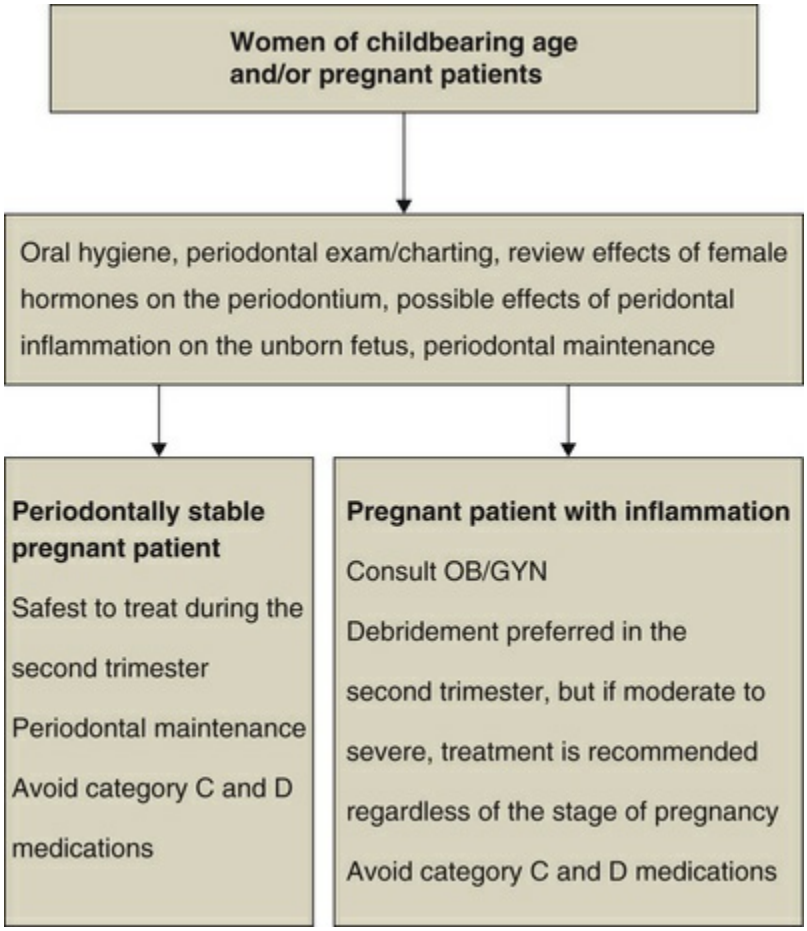

FIG. 41.5 Treatment algorithm for the pregnant patient.

Clinical Correlation

It is prudent to avoid elective dental care during the first trimester and the last half of the third trimester. The first trimester is the period of organogenesis, and the fetus is highly susceptible to environmental influences. During the last half of the third trimester, the fetus is vulnerable to premature delivery. The uterus is very sensitive to external stimuli. Early in the second trimester is

the safest period for providing routine dental care.

Dental Radiographs

The safety of dental radiography during pregnancy has been well established, provided items such as high-speed film, filtration, collimation, and lead aprons are used. However, it is most desirable not to have any irradiation during pregnancy, especially during the first trimester, because the developing fetus is particularly susceptible to radiation damage.[78] When radiographs are needed for diagnosis, the most important aid for the patient is the protective lead apron. Studies have shown that when an apron is used during contemporary dental radiography, gonadal and fetal radiation is virtually unmeasurable.[9]

Even with the obvious safety of dental radiography, x-ray films should be taken selectively during pregnancy and only when necessary and appropriate to aid in diagnosis and treatment. In most cases, only bitewing, panoramic, or selected periapical films are indicated.

Medications

Drug therapy for the pregnant patient is controversial because drugs can affect the fetus by diffusion across the placenta. Prescriptions should be used only for the duration absolutely essential for the pregnant patient's well-being and only after careful consideration of potential side effects. The classification system established by the U.S. Food and Drug Administration (FDA) in 1979 to rate fetal risk levels associated with many prescription drugs provides safety guidelines (Box 41.2). The prudent practitioner should consult references, such as Briggs and colleagues' *Drugs in Pregnancy and Lactation*[16] and Olin's *Drug Facts and Comparisons*,[108] for information on the FDA pregnancy risk factors associated with prescription drugs.

Box 41.2

FDA Drug Classification System Based on

Potential to Cause Birth Defects

A: Controlled studies enrolling women fail to demonstrate a risk to the fetus in the first trimester (there is no evidence of risk in later trimesters), and the possibility of fetal harm appears remote.

B: Animal reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women; or animal reproduction studies have shown an adverse effect (other than decreased fertility) that was not confirmed in controlled studies in women in the first trimester (there is no evidence of risk in later trimesters).

C: Studies in animals have revealed adverse effects on the fetus (i.e., teratogenic, embryocidal, or other), and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

D: There is positive evidence of human fetal risk, but the benefits of use in pregnant women may be acceptable despite the risk (e.g., the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

X: Studies in animals or humans have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of using the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Ideally, no drug should be administered during pregnancy, especially the first trimester.[78] However, it is sometimes impossible to adhere to this rule. Fortunately, most common drugs in dental practice can be given during pregnancy with relative safety, although there are a few important exceptions. Tables 41.1, 41.2, and 41.3 provide guidelines for anesthetic and analgesic, antibiotic, and sedative-hypnotic drugs, respectively.[122,150]

TABLE 41.1

Local Anesthetic and Analgesic Administration During Pregnancy

Drug	FDA Category	During Pregnancy
Local Anesthetics[a]		
Lidocaine	B	Yes
Mepivacaine	C	Use with caution; consult physician
Prilocaine	B	Yes
Bupivacaine	C	Use with caution; consult physician
Etidocaine	B	Yes
Procaine	C	Use with caution; consult physician
Articaine	B	Yes; no blocks
Analgesics		
Aspirin	C/D, third trimester	Caution; avoid in third trimester
Acetaminophen	B	Yes
Ibuprofen	B/D, third trimester	Use with caution; avoid in third trimester
Codeine[b]	C	Use with caution; consult physician
Hydrocodone[b]	B	Use with caution; consult physician
Oxycodone[b]	B	Use with caution; consult physician
Propoxyphene	C	Use with caution; consult physician

[a]Can use vasoconstrictors if necessary.

[b]Avoid prolonged use.

Sedative-Hypnotic Drug Administration During Pregnancy

Drugs	FDA Category	During Pregnancy
Benzodiazepines	D	Avoid
Barbiturates	D	Avoid
Nitrous oxide	Not assigned	Avoid in first trimester; otherwise use with caution; consult physician

FDA, U.S. Food and Drug Administration.

Antibiotics are often needed in periodontal therapy. The effect of a particular medication on the fetus depends on the type of antimicrobial, dosage, trimester, and duration of the course of therapy.[110] Research regarding subgingival irrigation and local site delivery in relation to the developing fetus is inadequate.

Breastfeeding

Usually, there is a risk that the drug can enter breast milk and be transferred to the nursing infant, on whom exposure could have adverse effects (Tables 41.4 and 41.5). Unfortunately, there is little conclusive information about drug dosage and effects through breast milk; however, retrospective clinical studies and empiric observations coupled with known pharmacologic pathways allow recommendations to be made.[78] The amount of drug excreted in breast milk is usually not more than 1% to 2% of the maternal dose; therefore it is highly unlikely that most drugs have any pharmacologic significance for the infant.[160]

TABLE 41.4

Local Anesthetic and Analgesic Administration During Breastfeeding

Drug	During Breastfeeding
Local Anesthetics	
Lidocaine	Yes
Mepivacaine	Yes
Prilocaine	Yes
Bupivacaine	Yes
Etidocaine	Yes
Procaine	Yes
Analgesics	

Aspirin	Avoid

Hydrocodone	No data
Oxycodone	Yes
Propoxyphene	Yes

TABLE 41.5

Antibiotic and Sedative-Hypnotic Administration During Breastfeeding

Drugs	During Breastfeeding
Antibiotics[a]	
Penicillins	Yes
Erythromycin	Yes
Clindamycin	Yes, with caution
Cephalosporins	Yes
Tetracycline	Avoid
Ciprofloxacin	Avoid
Metronidazole	Avoid
Gentamicin	Avoid
Vancomycin	Avoid
Sedative-Hypnotics	
Benzodiazepines	Avoid
Barbiturates	Avoid
Nitrous oxide	Yes

[a]Antibiotics carry a risk of diarrhea and sensitization in the mother and infant.

The mother should take prescribed drugs just after breastfeeding and then avoid nursing for 4 hours or more if possible[78,142] to decrease the drug concentration in breast milk.

Oral Contraceptives

Women may have responses to oral contraceptives (OCs) similar to those seen in pregnant patients. Mullally and associates found that current users of OCs had poorer periodontal health.[97] An exaggerated response to local irritants occurs in gingival tissues. Inflammation ranges from mild edema and erythema to severe inflammation with hemorrhagic or hyperplasic gingival tissues. It has been reported that more exudate is present in the inflamed gingival tissues of OC users than in those of pregnant women.[139,165]

Investigators have suggested several mechanisms for the

heightened response in gingival tissues. Kalkwarf[63] reported that the response might be caused by an altered microvasculature, increased gingival permeability, and increased synthesis of prostaglandin. Levels of PGE, a potent mediator of inflammation,[33] appear to rise significantly with increasing levels of sex hormones. Jensen and colleagues[62] found dramatic microbial changes in pregnant and OC groups compared with a nonpregnant group. A 16-fold increase in *Bacteroides* species was seen in the OC group versus the nonpregnant group, despite no statistically significant clinical differences in gingival index or GCF flow. The study authors found that the increased female sex hormones substituting for the naphthoquinone requirement of certain *Bacteroides* species was most likely responsible for this increase.

OC-associated gingival inflammation may become chronic (versus the acute inflammation of pregnancy) because of the extended periods that women are exposed to elevated levels of estrogen and progesterone.[68,113] Some have reported that the inflammation increases with prolonged use of OCs. Kalkwarf[63] did not find that duration of use made a significant difference, but the brands used resulted in different responses. Further studies are needed to elucidate the effects of dosage, duration, and type of OC on the periodontium. The concentration of female sex hormones in current OCs is significantly less than that of the 1970s, while providing the same level of contraceptive efficacy.

Salivary composition changed notably in patients taking OCs in studies from the 1970s. Decreased concentrations of protein, sialic acid, hexosamine fucose, hydrogen ions, and total electrolytes have been reported. Salivary flow rates were increased in one report[87] and decreased in 30% of subjects in another report.[31]

The dental literature reports that women taking OCs experience a twofold to threefold increase in the incidence of localized osteitis after extraction of mandibular third molars.[144] The higher incidence of osteitis among these patients may be attributed to the effects of OCs (i.e., estrogens) on clotting factors. However, several studies refute these findings.[20] Evidence is inconclusive on osteitis after third molar extraction and OC use. A spotty melanotic pigmentation of the skin may occur with OC use. This suggests a relationship between the use of OCs and the occurrence of gingival

melanosis,[52] especially in fair-skinned individuals.

Management

The medical history should include OCs along with other medications, and a discussion should include questions regarding OCs with women of childbearing age. The patient should be informed of the oral and periodontal side effects of OCs and the need for meticulous home care and compliance with periodontal maintenance. Treatment of gingival inflammation exaggerated by OCs should include establishing an oral hygiene program and eliminating local predisposing factors. Periodontal surgery may be indicated if resolution after initial therapy (i.e., scaling and root planing) is inadequate. It may be advisable to perform extraction of teeth (especially third molars) on nonestrogenic days of the OC cycle (i.e., days 23 to 28) to reduce the risk of a postoperative localized osteitis[36]; however, evidence of this association is inconclusive and warrants further investigation.

Although results from animal studies have demonstrated that antibiotic interference adversely affects contraceptive sex hormone levels, several human studies have failed to support such an interaction.[8,37,99,101] This issue is controversial, and antibiotics could render OCs ineffective in preventing pregnancy. In 1991, an ADA report stated that all women of childbearing age should be informed of possible reduced efficacy of steroid OCs during antibiotic therapy and advised women to use additional forms of contraception during short-term antibiotic therapy.[6] During long-term antibiotic therapy, women should consult their physician about using high-dose OC preparations. Although only research regarding oral manifestations attributed to OCs has been reported in the literature, the same effects presumably occur with the use of contraceptive implants. Similarly, the remote possibility of reduced efficacy of contraceptive implants with concurrent antibiotic use exists, and women can follow the same precautions as with OC use.

Menopause

Female life expectancy is 80+ years, and many women live 40% of

their lives in menopause. This cohort represents a large number of the patients who are seen in clinical practices. Dental clinicians must be aware of the effects of reduced hormones on the periodontal tissues and the systemic changes that may manifest.

Throughout a woman's lifetime, the number of oocytes steadily diminishes. Menopause is associated with symptoms of estrogen deficiency. Estradiol levels fall gradually in the years before menopause. Levels of FSH and LH begin to rise, and levels of sex hormones begin to fluctuate. This stage of perimenopause is characterized by increasing ovarian unresponsiveness and sporadic ovulation. Anovulatory cycles indicate low estradiol and progesterone levels because of absent corpus luteum function.

Oral Changes

It is important for the clinician to recognize the effects of hormonal alterations on the oral cavity as well as systemic and psychologic changes. Oral changes in menopause include thinning of the oral mucosa, oral discomfort (i.e., burning mouth), gingival recession, xerostomia, altered taste sensation, alveolar bone loss, and alveolar ridge resorption.

Fluctuations of sex hormones during menopause have been implicated in inflammatory changes in the gingiva, hypertrophy, or atrophy. Estrogen affects cellular proliferation, differentiation, and keratinization of the gingival epithelium. Hormone receptors have been identified in basal and spinous layers of the epithelium and connective tissues, implicating gingiva and other oral tissues as targets that can manifest hormone deficiencies. Sex steroids directly affect connective tissues, with estrogens increasing the intracellular fluid content. Estrogen deficiency can reduce collagen formation in connective tissues and decrease skin thickness.[159] Alterations in collagen affect tissues such as joints, hair, nails, and glands. Mohammed and associates[95] reported significantly increased recession in postmenopausal patients with low bone density. A study of postmenopausal women indicated that those who were overweight and had *T. forsythia* infections were more likely to have oral bone loss.[14]

Osteopenia and osteoporosis have been associated with

menopause. *Osteopenia* is a reduction in bone mass caused by an imbalance between bone resorption and formation, favoring resorption and resulting in demineralization and osteoporosis. *Osteoporosis* is a disease characterized by low bone mass and fragility and a consequent increase in fracture risk.[156] In most women, peak bone mass occurs between 20 and 30 years of age and then declines. Menopause accelerates declining bone mass.[154] An estimated 25 million Americans have osteoporosis, 80% of whom are female. Ongoing studies are examining the association of postmenopausal primary osteoporosis with mandibular and maxillary bone mineral density (BMD), tooth loss, alveolar ridge atrophy, and clinical periodontal attachment loss.[45,59] However, problems in extrapolation and application of data arise as a result of small sample size, study design, inadequately controlled confounding factors, and limited understanding of the relationship between the two diseases. The effects of hormone replacement therapy (HRT) and estrogen replacement therapy (ERT) on the oral bone and tooth loss also are under investigation. Evidence indicates a probable association between osteoporosis and maxillary tooth loss and alveolar bone loss.[61,112,124,125]

Studies show the greatest association of tooth loss and alveolar ridge atrophy with osteoporosis.[28,46,163] There is also less risk of tooth loss when postmenopausal women are placed on HRT.[44,145] Improved BMD with HRT has been a recognized benefit. Krall and coworkers found that the odds of being edentulous were reduced by 6% for each 1-year increase in duration of HRT use.[71] There is increased alveolar ridge resorption in edentulous patients with osteoporosis.

Current knowledge regarding the effects of osteoporosis and osteopenia on periodontal diseases and alveolar bone loss are inconclusive. However, some articles indicate stronger evidence of an association.[42,51,54,57,72,89,91,114,115,126,143,146] Articles have described an association of osteoporosis in postmenopausal women with periodontitis, attachment loss, and gingival recession.[53,148] Greater alveolar crestal height loss is seen with osteoporosis and osteopenia.[95,157] However, studies evaluating the association of clinical attachment loss and osteoporosis have had mixed results. Several studies indicate that decreased BMD is associated with

increased clinical attachment loss.[94,129,163] Others have found weak or no significant association of systemic BMD and clinical attachment loss.[34,116] Clinical trials with greater numbers, longer time intervals, and male patients that account for confounding variables need to be performed.

Most studies indicate improved periodontal status in women on HRT or ERT.[19,125,145] Increased alveolar bone mass with associated improved alveolar crestal height, reduced clinical attachment loss, and reduced periodontal inflammation have been reported for patients on hormone therapy. A review found that research supports the idea that osteoporosis independently influences alveolar bone height loss and that strategies for reducing osteoporosis can help retard alveolar bone loss.[64]

Clinical Management

It is the clinician's responsibility to review the patient's medical history and keep information up to date. Because of possible alterations in oral soft and osseous tissues during perimenopause and after menopause, appropriate questioning regarding hormonal changes should take place and be documented.

The many available therapies for HRT or ERT, from prescriptions to holistic approaches, need to be monitored. Many medications alter clotting times, prolong the effects of other medications, or interfere with the absorption or effectiveness of prescription medications. If gingival and mucosal tissue thinning occurs, soft tissue augmentation can be performed.

Brushing with an extra-soft toothbrush using the toe or heel of the brush may prevent scrubbing the thinning gingiva. Dentifrices with minimal abrasive particles should be used. Rinses should have a low alcohol content. During periodontal maintenance, root surfaces should be debrided gently, with minimal soft tissue trauma. Oral pain can result from thinning tissues, xerostomia, inadequate nutritional intake, or hormone depletion. In patients with oral symptoms who receive HRT, symptoms can be significantly reduced.

If the patient is susceptible to osteoporosis (i.e., menopausal, white or Asian, smoker, minimal physical activity, low calcium

intake, thin build or low body weight [<58 kg], systemic disease associated with predisposition, or genetic history),[59] the dentist should consult her physician about the risks and benefits of HRT or ERT and calcium plus vitamin D supplementation. Serum vitamin D_3 levels have been associated with oral bone health.[67,131] Sodium fluoride, bisphosphonates (e.g., alendronate), selective estrogen receptor modulators, and parathyroid hormone may be other therapies for osteoporotic patients.

Closely monitoring the patient's periodontal stability, performing titrated periodontal maintenance, informing the patient about potential risks of hormone depletion to the oral tissues, and consulting the treating physician are advised. The National Institutes of Health in its 1994 Conference Report on Optimal Calcium Intake recommended 1000 mg of elemental calcium/day for premenopausal women and 1500 mg/day for postmenopausal women (eBox 41.1). Vitamin D_3 recommendations are 400 IU daily for premenopausal women and 800 IU for postmenopausal women.

eBox 41.1

National Institutes of Health Consensus Conference Recommendations for Optimal Calcium Intake

- Premenopausal women (25 to 50 years old): 1000 mg/day
- Postmenopausal women (estrogen therapy): 1000 mg/day
- Postmenopausal women (no estrogen therapy): 1500 mg/day
- Men (25 to 65 years old): 1000 mg/day
- Women and men >65 years old: 1500 mg/day

No data are available regarding success or failure of periodontal regeneration procedures in osteoporotic and nonosteoporotic individuals. No scientific data are available to contraindicate the use of osseointegrated implants in osteoporotic patients, despite articles stating osteoporosis as a risk factor. Much research is needed to address the increasing number of periodontal patients

with osteoporosis and osteopenia, most of whom are undiagnosed.

Conclusions

Clinical periodontal therapy includes an understanding of the clinician's role in the total health and well-being of female patients. Dentists do not treat localized infections without affecting other systems and the fetus or the breastfed infant. The periodontal and systemic difficulties of female patients can alter conventional therapy.

The cyclic nature of the female sex hormones often is reflected in the gingival tissues as initial signs and symptoms. Medical histories and discussions should include thoughtful investigation of the individual patient's problems and needs. Questioning should reflect hormonal stability and medications associated with regulation. Patients should be educated regarding the profound effects sex hormones have on periodontal and oral tissues and the consistent need for home and office removal of local irritants.

Research regarding female issues and medical/periodontal therapy is in process. In the near future, information about the specific management and causes of sex hormone–mediated infections will enhance dentists' ability to provide quality care to their patients.

Case Scenario 41.1

Patient:

33-year-old white female

Chief Complaint:

"I have painful gums that bleed easily."

Background Information:

Patient reports brushing one or two times daily with an electric toothbrush and flossing at night. She denies tobacco use. Patient reports that she is 5 months pregnant. She started taking daytime naps due to fatigue. She does not brush her teeth before napping.

Clinical Findings:

Generalized moderate gingival erythema and edema with localized moderate gingival overgrowth occur in the anterior interproximal sites. There is generalized, severe marginal bleeding. Generalized, slight plaque is localized to distal part of the second maxillary molars.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Periodontal disease in the mother has adverse effects on the fetus, including an elevated risk for a preterm, low-birth-weight infant. A. True B. False	**Answer: A** **Explanation:** Pregnancy exacerbates periodontal disease. Research shows that periodontal disease can affect the patient's systemic health, including adverse effects on the unborn fetus.
2. What is the most likely diagnosis for this patient? A. Plaque-induced gingivitis B. Pregnancy gingivitis C. Generalized moderate chronic gingivitis D. Generalized mild chronic periodontitis	**Answer: B** **Explanation:** Pregnancy gingivitis occurs in 30% to 100% of pregnant women. Kornman and Loesche found that during the second trimester, gingivitis and bleeding increased without an increase in plaque (biofilm) levels.[70]
3. This periodontal disease can manifest with the clinical finding of A. Pregnancy tumor B. Gingival hyperplasia C. Pyogenic granuloma D. All of the above	**Answer: D** **Explanation:** All of these findings are associated with pregnancy gingivitis. Options A and C are the same.

CHAPTER 42

Periodontal Treatment for Older Adults

Sue S. Spackman, Janet G. Bauer

CHAPTER OUTLINE

The Aging Periodontium
Demographics *(e-only)*
Dental and Medical Assessments *(e-only)*
Periodontal Diseases in Older Adults
Periodontal Treatment Planning
Conclusions

Older adults are expected to comprise a larger proportion of the population than in the past. Population growth among long-lived older adults contributes to this increase worldwide. For dentistry, this means that older adults are retaining more of their natural dentition. Almost 70% of older adults in the United States have

natural teeth.[30] However, retention of teeth may result in more teeth at risk for periodontal disease, and the prevalence of periodontal disease can be associated with aging. This association was addressed by Beck[23] at the 1996 World Workshop on Periodontics: "It may be that risk factors do change as people age or at least the relative importance of risk factors change." This chapter focuses on the associations between aging and oral health, with an emphasis on periodontal health.

The Aging Periodontium

Normal aging of the periodontium is a result of cellular aging, which is the basis for the intrinsic changes seen in oral tissues over time. The aging process does not affect every tissue in the same way. For example, muscle tissue and nerve tissue undergo minimal renewal, whereas epithelial tissue, which is one of the primary components of the periodontium, always renews itself.

Intrinsic Changes

In epithelium, a progenitor population of cells (i.e., stem cells) in the basal layer provides new cells. The cells of the basal layer are the least differentiated cells of the oral epithelium. A small subpopulation of these cells produces basal cells and retains the proliferative potential of the tissue. A larger subpopulation of these cells (i.e., amplifying cells) produces cells available for subsequent maturation. This maturing population of cells continually undergoes a process of differentiation or maturation.

By definition, the differentiated cell (i.e., epithelial cell) can no longer divide. Conversely, the basal cell remains as part of the progenitor population of cells ready to return to the mitotic cycle and again produce both types of cells. There is a constant source of renewal (Fig. 42.1).

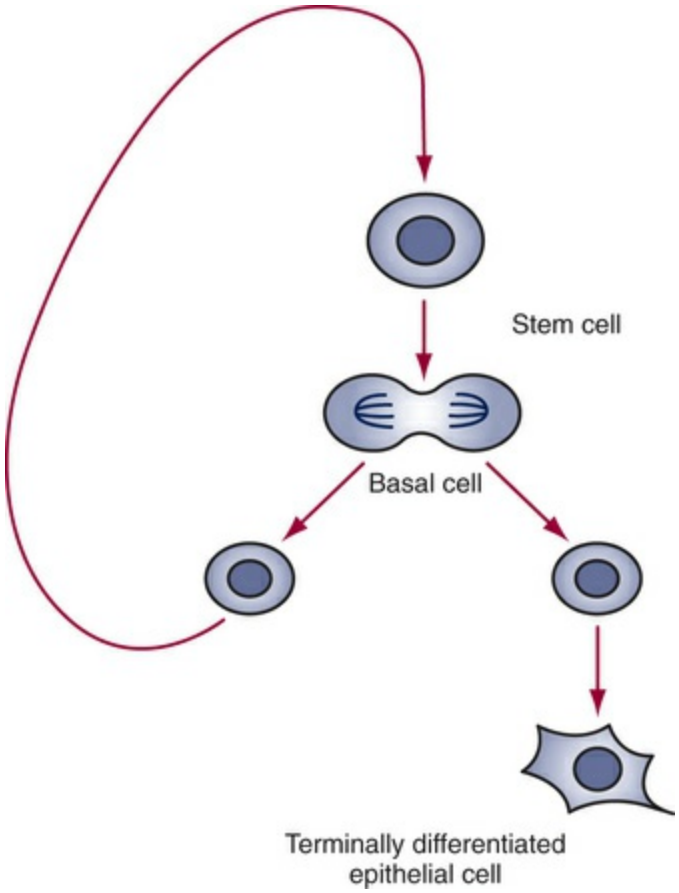

FIG. 42.1 Cell renewal cycle in which the basal cell produces an epithelial cell and returns to the progenitor cell population.

In the aging process, cell renewal takes place at a slower rate and with fewer cells. The effect is to slow down the regenerative processes. As the progenitor cells wear out and die, there are fewer and fewer of these cells to replace the dead ones. This effect is characteristic of the biologic changes that occur with aging.

Key Fact

With aging, stem cells undergo exhaustion that affects the regenerative potential of the organism. Reductions in the number of stem cells and in their response to stimuli in their local environment have been documented.

Through the action of gerontogenes or replicative senescence (i.e., Hayflick's limit and telomere shortening), the number of progenitor

cells decreases. Hayflick, an American microbiologist, observed that fetal cells (i.e., fibroblasts) displayed a consistently greater growth potential (i.e., approximately 50 cumulative population doublings) than those derived from adult tissues (i.e., 20 to 30 cumulative population doublings). The decreased cellular component has a concomitant effect of decreasing both cellular reserves and protein synthesis. This causes the oral epithelial tissue to become thin, with reduced keratinization.

Stochastic Changes

Stochastic changes occurring in cells also affect tissue (e.g., glycosylation and cross-linking produce morphologic and physiologic changes). Structures become stiffer, with a loss of elasticity and increased mineralization (i.e., fossilization). With a loss of regenerative power, structures become less soluble and more thermally stable. Somatic mutations lead to decreased protein synthesis and structurally altered proteins. Free radicals contribute to the accumulation of waste in the cell.

All of these changes decrease the physiologic processes of tissue. Most changes are primarily a result of aging, although some result from physiologic deterioration. For example, loss of elasticity and increased resistance of the tissue can lead to decreased permeability, decreased nutrient flow, and accumulation of waste in the cell. Vascular peripheral resistance (i.e., decreased blood supply) can decrease cellular function.

Physiologic Changes

In the periodontal ligament, a decrease in the number of collagen fibers leads to a reduction in or loss of tissue elasticity. Decreased vascularity reduces production of mucopolysaccharides.

All of these types of changes are seen in the alveolar bone. With aging, alveolar bone density decreases, bone resorption increases, and vascularity decreases. In contrast, cementum shows cemental thickening.

Functional Changes

With aging, the cells of the oral epithelium and periodontal ligament have reduced mitotic activity, and all cells experience a reduction in metabolic rate. These changes also affect the immune system and periodontium because of the reduced healing capacity and rate. Inflammation develops more rapidly and is more severe. Individuals are highly susceptible to viral and fungal infections because of abnormalities in T-cell function.

Clinical Changes

Compensatory changes that occur during aging or in response to disease manifest clinically as dental or periodontal conditions, such as gingival recession and reductions in bone height. Dental attrition, a type of tooth wear commonly seen as a normal part of aging, is a compensatory change that acts as a stabilizer between loss of bony support and excessive leveraging from occlusal forces imposed on the teeth.

A reduction in overjet of the teeth manifests as an increase in the edge-to-edge contact of the anterior teeth. Typically, this is related to the approximal wear of the posterior teeth. An increase is seen in the food table area, with loss of sluiceways, and in mesial migration.

Functional changes are associated with reduced efficiency of mastication. Although effectiveness of mastication may remain, efficiency is reduced because of missing teeth, loose teeth, poorly fitting prostheses, or noncompliance of the patient, who may refuse to wear prosthetic appliances.

Key Fact

Key Periodontal Changes With Aging

- Thinning of oral epithelium and reduced keratinization
- Reduction or loss of periodontal ligament tissue elasticity
- Gingival recession
- Attachment and bone loss

- Thickening of cementum

Demographics

Population Distribution

In 2014, adults 65 years of age or older comprised 14.5% of the U.S. population, or 46.2 million people. By 2060, this population will grow 47% to 68 million people due to aging of the baby boomer generation and immigration to the United States. The greatest growth will occur among those 85 years of age or older (29%) and those 100 years of age or older (65%). At the same time, the U.S. population is expected to increase by 40% from 319 million to 417 million.[80,85] Between 1980 and 2014, the centenarian population experienced a larger percentage increase than did the total population. There were 72,197 persons 100 years of age or older in 2014 (0.2% of the total 65+ population). This was more than double the 1980 figure of 32,194. The projected number of centenarians in the United States in 2050 is 601,000.[34]

The increase in the aging population reflects the dramatic increase in life expectancy in the 20th and 21st centuries. Average life expectancy was 78.8 years in 2013, an increase of 31.8 years since 1900. In 2014, average life expectancy (at birth) was projected to be 78.8 years. Adults who reached the age of 65 in 2013 could expect to live an average of 19.3 additional years.[32,66,80,85]

Differences in population growth between urban and rural older adults have special significance for oral health. The expected increase in the proportion of older adults will be 3% larger in rural areas. Because rural older adults use dental services less than their urban counterparts, the risk of adverse changes in oral health and self-care may be greater.[84] The worldwide population is also aging.

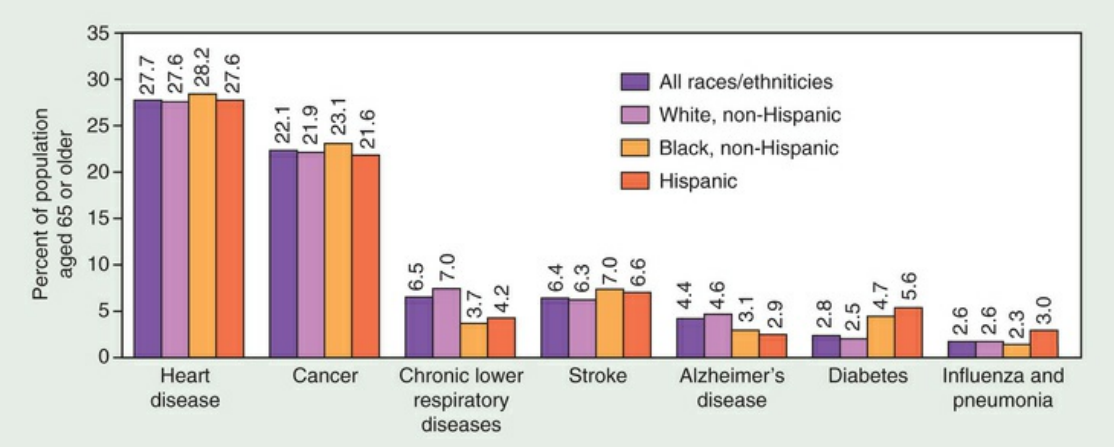
Key Fact

From 2010 to 2050, the number of people 65 years of age and older is expected to increase from 560 million, or 8% of the world's population, to 1.5 billion, which is projected to be 16% of the world's population.[82a]

Health Status

Increased life expectancy has changed the way the public and health care policy makers and providers think about aging. Instead of controlling chronic disease and reducing mortality rates, aging is seen in terms of successful aging or healthy aging. This paradigm shift is based on the study of what promotes health and longevity. Current research is examining aging in terms of the physical, mental, and social well-being of older adults, not just disease or death. The MacArthur Studies of Successful Aging asked a fundamental question: "What genetic, biomedical, behavioral, and social factors are crucial to maintaining health and functional capacities in the later years?"[55]

Despite this paradigm shift, the number of older adults with acute and chronic diseases continues to increase.[80] Visual impairments, cataracts, glaucoma, and hearing impairments increase in frequency with advancing age. Almost one-half of people 65 years of age or older have arthritis.[83] Most older adults have at least one chronic condition, and many have several chronic conditions. In 1994, the most common chronic conditions were arthritis, hypertension, heart disease, hearing impairment, cataract, orthopedic impairment, sinusitis, and diabetes (eFig. 42.1). Although heart disease remains the leading cause of death among older adults, cancer may become the leader during the 21st century. Currently, among older adults, approximately 7 in 10 deaths are caused by heart disease, cancer, or stroke.[80]



EFIG. 42.1 Demographics of major diseases that affect

people 65 years of age or older. (From Centers for Disease Control and Prevention. *The state of aging and health in America, 2013.* Atlanta: 2013, Centers for Disease Control and Prevention, US Dept of Health and Human Services.)

In the early 1900s, Dr. Ignatz Leo was the first to recognize that older adults had health needs and concerns that set them apart from younger adults.[60] Not until the latter half of the 20th century did geriatrics (i.e., medicine focused on older adults) become a discipline in health care. The geriatric patient is an older adult who is frail or dependent, or both, and who requires health and social support services to attain an optimal level of physical, psychological, and social functioning. The treatment plan must reflect professional knowledge to resolve physical and psychologic aspects of health status while being sensitive to an individual's complete social functioning, which may include aspects of race, ethnicity, culture, personal relationships, esthetics, and social and economic conditions.

The main focus of geriatrics is *frail and functionally dependent older adults.* Functionally independent older adults are included, but only to make them aware of services that they may need if they experience functional deficits that impair their daily activities (eTable 42.1).

eTABLE 42.1
Functional Categories for Older Adults

Category	Description	Issues	Limitations
Functionally independent	Those who reside in the community and receive little or no assistance	Most older adults fall into this category.	Access and use dental services similar to younger adults in the community
Frail	Those who reside in the community and maintain some degree of independence, with assistance from others	Include those who are homebound or spend most of their time in their homes and those at risk for institutionalization	Need assistance with some ADL and depend on others for most IADL[a]
Functionally dependent	Those who cannot maintain any level of independence and are totally dependent on assistance	Include those who are institutionalized or at highest risk for institutionalization	Depend on others for most or all IADL and basic ADL

[a]Bathing, dressing, and transportation problems were the three limitations that most

homebound elderly experienced.

ADL, Activities of daily living; *IADL,* instrumental ADL.

Specialists in geriatric medicine, called *geriatricians,* have additional training in health care for frail and functionally dependent older adults. Numerous assessment instruments have been developed to assist the geriatrician, and some aspects of them can help dentists in identifying risks and functional declines. Instruments include activities of daily living (ADL) assessment, Tinetti Balance and Gait assessment, geriatric depression scale (GDS), and Mini-Mental State Examination. Each assesses risk for morbidity and mortality in maintaining a patient's optimal health and functional independence.

Care for geriatric patients crosses many disciplines. An interdisciplinary team that may include a dentist is formed to care for and treat geriatric patients. Including dentistry in the interdisciplinary effort has benefits for the patient. For example, oral care has been incorporated into nursing educational programs and practice for geriatrician nurse practitioners.[62] Dieticians also have education in oral care. The point is to include oral health as part of *medical nutrition therapy* (MNT) to meet the patient's total health needs.[9]

A last frontier for the interdisciplinary team is the community. When geriatric patients require multidisciplinary strategies to improve their condition at the community level, efforts have been less than satisfactory. Problems have been encountered when coordination is needed for geriatric patients to access multiple providers across a range of health care settings. Shared decision making and patient education are needed to improve access and realize successful outcomes.[43] A detailed computer-based model on multidisciplinary and interdisciplinary decision making in the geriatric population has been described by Bauer and colleagues.[13,16,18–22]

Functional Status

In dentistry, prevention of oral diseases and improvements in healthy lifestyles have contributed to older adults keeping and maintaining their dentition. Dentistry for geriatric patients, or

geriatric dentistry, emphasizes an interdisciplinary approach to diagnosis, treatment, and prevention of dental and oral diseases.[39] Specialists in geriatric dentistry are *geriatric dentists.* Similar health and functional instruments used in geriatric medicine assist geriatric dentists in assessing risks that compromise oral health.

Functional impairments have a significant impact on oral health and self-care. Sensory impairments and arthritis make it more difficult for older adults to understand dental outcomes, communicate oral health care needs and concerns, and perform effective oral self-care. Functional testing or measuring instruments can become part of the dentist's armamentarium to assess an older adult's ability to perform oral care tasks in achieving and maintaining oral health. The Index of Activities of Daily Oral Hygiene (ADOH) is a dental assessment instrument that quantifies the functional ability of older adults, specifically frail and functionally dependent older adults, to perform oral self-care tasks.[14] The ADOH provides the dentist or dental assistant with the means to determine the functional ability of an older adult to manipulate aids used in daily oral hygiene care. From these findings, strategies can be developed to rehabilitate and then reassess improvements in functional deficits. If improvements are not forthcoming, alternative strategies and assistive devices are recommended.

Including dentists in the interdisciplinary team is increasing, including their participation in primary care. For example, edentulism and denture wearing in older adults may be related to poor quality of life and undiagnosed oral disease. They may also indicate other medical comorbidities. Medical and dental geriatricians must incorporate knowledge of comorbidities to identify risks that manifest as reciprocation of disease and poor quality of life.[86,93] In managing periodontal disease, the dental geriatrician is challenged with integrating primary care, oral health, and patient and caregiver education in nontraditional settings such as residential, institutional, and hospital practice sites.

Although geriatric medicine training programs have grown remarkably over the past 3 decades, this growth is still not producing the number of geriatricians needed to care for the growing older adult population. Comparatively, the training of

dental geriatricians is much less. In response, the geriatric dentistry community has advocated that dental geriatricians should train general dentists in the care of geriatric dental patients. Kayak and Brudvik[53] see this type of training essential to successful aging and periodontal health care in dental practice and nontraditional settings. Dental geriatricians as faculty are needed to train practitioners.[86]

In an article on periodontal dental education, Wilder and colleagues stated that "dental schools are confident about the knowledge of their students regarding oral-systemic content. However, much work is needed to educate dental students to work in a collaborative fashion with other health care providers to co-manage patients at risk for oral-systemic conditions."[94]

Nutritional Status

Diet refers to the consumption of types and varieties of food resources, and *nutrition* is the process by which food is used to provide energy and sustain, restore, and maintain tissue of living organisms. With aging, there is an increased risk of nutritional deficiencies among older adults. However, among older adults in the United States, the rate of malnutrition is low. The real risk is *unbalanced diets.*

An older adult's dietary patterns can be associated with numerous factors, including the aging process, diseases and the medications used in their treatment, and social and economic conditions. Energy needs and intake in older adults typically decline with age.

Beyond middle age, body weight and lean body mass decline with age, in part because of primary aging. Age-related changes in physiologic functioning, including metabolic, hormonal, and neural changes, have been associated with poor-quality diets in older adults.

Older adults do not compensate well by taking in more food when bodily changes alter their energy levels. A slower metabolic rate accompanied by decreased levels of physical activity explains why older adults have reduced food intake. This is also associated with altered sensations of hunger, thirst, and satiety or fullness.

Reductions are seen in fluid intake, uncompensated by increased thirst. The variety of foods eaten is reduced, or characteristic bland diets may result from lowered sensory-specific satiety. Older adults enjoy food less because of deficits in smell and possibly taste. More than one-half of people 65 to 80 years of age have a major olfactory impairment, with 75% of those 80 years or older affected. Food recognition diminishes with age.

All of these factors can place the older adult at risk for serious problems. *Anorexia,* or low food intake, increases the risk of nutrition-related illnesses. *Electrolytic imbalances* (e.g., salt and water imbalances) are associated with age-related changes in regulatory systems, such as central nervous system (CNS) receptors that detect changes in the level of sodium in blood. Dehydration, which can lead to illness and death, is a common cause of fluid and electrolyte disturbance. *Deconditioning* is an almost complete disturbance of physical functioning. These conditions may be identified when a frail older adult comes to the dental office seeking care, and they are seen more often in homebound people, hospitalized patients, and nursing home residents.

Poor nutrition and low body weight often precede and predispose older adults to secondary age changes. *Secondary aging changes* are a result of acute and chronic disease and medication use. The most common age-associated chronic diseases are hypertension, hyperlipidemia, atherosclerosis, and diabetes. Compounding effects of secondary aging can include impaired mobility, inability to feed oneself, poor oral health, and the use of dentures, all of which can affect the amount and types of food consumed. Age-associated decreases in saliva production and swallowing problems can make eating difficult. Nutrient malabsorption can be caused by altered gastric acid secretion or interaction with medications. The cumulative effect of these changes can account for taste loss in the older adult.

Economic and social factors have been linked to significant changes in eating patterns, such as loss of appetite. *Economic factors* include a lower economic status resulting from retirement, failing health, living on a fixed income, or death of a spouse. *Social factors* include isolation, loneliness, and the effects of depression or dementia. All of these factors can affect the type and quality of food

consumed. For example, socializing at meals can increase the amount of food consumed by older adults.

Impaired chewing can cause changes in food selection, such as decreasing variety in the diet, which can contribute to nutritional problems. Currently, 42% of older adults have no natural teeth. Rehabilitation with complete dentures may restore only 25% of normal chewing effectiveness.[71] Of those with teeth, 60% have tooth decay, and 90% have periodontal disease, which can contribute to impaired chewing ability or loss of appetite.

Aging-related disease states and social factors can result in inadequate consumption of nutrient-dense foods or inadequate intake of some vitamins and minerals. Minerals are important to the absorption and use of vitamins. Both are important to antibody formation and the immune system in combating infection, foreign substances, and toxins (eTable 42.2).[26]

eTABLE 42.2
Nutrient Effects on the Immune Response

Nutrient	Component in Biologic Processes	EFFECT OF INSUFFICIENT INTAKE OF NUTRIENT	
		Increased Function	Decreased Function
Protein	Energy metabolism DNA/RNA synthesis	Bacterial adhesion	Salivary antimicrobial properties Immunoglobulin production Lysozymes Lymphocyte activation Production of antibodies

Psychosocial Factors

Dental diseases have their greatest effect on behaviors and mental and social well-being. They affect psychological and social functioning and usually are preventable by behavioral and social means. On average, older adults use fewer dental services, perhaps because of conflicting economic priorities between medical and dental needs. For many older adults, dental services are a discretionary choice and not part of their primary care options. This can result from poorer health status, lack of dental insurance or coverage by government-sponsored health care programs, or decreased functional status or independence.

Older adults with a positive attitude about oral health have predictably better dental behaviors that translate into higher utilization rates of dental services. Positive attitude is highly associated with educational level.[17] The educational level of older

adults is increasing. In 1995, only 64% of noninstitutionalized older adults completed at least high school, and 13% possessed a bachelor's degree. In 2015, an estimated 76% of older adults had at least completed high school, with 20% obtaining a bachelor's degree. Those with more education were three to four times more likely to have visited a dentist in the past year, indicating that an informed and knowledgeable public creates a culture of healthy behaviors that guide older adults toward the long-term preservation of teeth and function.

Impediments to the utilization of dental services are associated with low income and an associated lack of a regular source of care. Those with higher education tend to be better off financially than those with low levels of education. Poverty is less prevalent today among older adults in all race, gender, and ethnic groups.[80,81] Older adults typically have the highest disposable income of all age groups.[90] Higher educational achievement with lower poverty level is a predictor of increased demand for oral health care among older adults.[52]

However, differences in the prevalence of periodontal disease were seen in relation to race. Among dentate non-Hispanic blacks, non-Hispanic whites, and Mexican Americans 50 years of age or older, blacks had higher levels of periodontal disease, even those in higher income groups. Borrell and colleagues[25] suggested that race and ethnicity were important factors in combating health disparities.

Reciprocally, oral disease can affect behaviors, and behavioral problems can adversely affect oral health. Adverse oral health conditions affect three aspects of daily living: systemic health, quality of life, and economic productivity.

Systemic health and quality of life are compromised when edentulism, xerostomia, soft tissue lesions, or poorly fitting dentures affect eating and food choices. Conditions such as oral clefts, missing teeth, severe malocclusion, and severe caries are associated with feelings of embarrassment, withdrawal, and anxiety. Oral and facial pain from dentures, temporomandibular joint disorders, and oral infections affect social interaction and daily behaviors.[49]

Behavioral problems can worsen oral conditions. Many older

adults grew up during Prohibition or the Great Depression, when *alcohol consumption* was much lower. Since then, alcohol consumption has increased, especially among women, along with alcohol-related health problems. Alcohol-related disorders include alcohol abuse and dependence and alcoholic liver disease, psychoses, cardiomyopathy, gastritis, and polyneuropathy.

The general consensus is that light drinking, defined as one drink per day, is not harmful as long as the older adult is reasonably healthy and not taking medications that interact with alcohol. However, alcohol can react differently in older adults compared with younger adults. Decreased body water content can produce higher peak serum ethanol levels. In particular, alcohol intake can make older adults vulnerable to changes in the capacity of the liver to metabolize drugs and to symptomatic behaviors such as confusion, depression, and dementia.

The patterns of drinking and alcohol-related problems may not be different for older and younger problem drinkers. However, numerous reports suggest that use of alcohol as the primary substance of abuse is higher among older than younger adults. Peak onset for alcohol-related problems is 65 to 74 years of age. Unfortunately, alcohol consumption directly correlates with clinical attachment loss in periodontal disease.[79]

Periodontal disease may also be exacerbated in those with depression.[6,54] *Depression* is a common public health problem among elderly people, affecting 15% of adults older than age 65 in the United States. The suicide rate for those older than 85 is about two times the national rate. Geriatric depression is treatable, and recognition of this disorder is a vital step in the prevention of disability and death.[74] However, depression is not easy to recognize. Depression can accompany a wide variety of physical conditions including fatigue, poor appetite, sleep disturbances, cardiovascular disease, and cancer. It may be the primary cause of somatic complaints, including oral discomfort. The classic signs and symptoms of depression include sadness, decreased appetite, weight loss, confusion, difficulty in decision making, dissatisfaction, and irritability. Many older adults, however, have a less dramatic level of sadness and frequently have apparent cognitive impairment, especially memory deficits, and

differentiating this from dementia is important. Recognizing the signs of depression can reduce depression by about 70% among those older than 65 years of age.

Dentate Status

In dentistry the level of illness is measured as "tooth mortality" or tooth loss. Still among the most ubiquitous of human diseases, dental disease places all segments of the population at risk. Older adults are at greatest risk, especially those older than 85 years of age.

Clinician's Corner

In elderly populations, changes in health and functional well-being (i.e., functional disabilities) potentiate the risk of oral disease, including dental caries (particularly root caries), periodontal disease, oral cancer, xerostomia (i.e., dry mouth), disorders associated with wearing dentures, and systemic diseases with oral symptoms.

Over a 30-year period, edentulism and partial tooth loss declined substantially.[30] The most current estimates of tooth loss and tooth retention in the U.S. population indicate that 75% of older adults between the ages of 65 to 69 years and more than one-half of adults 75 years of age or older are dentate (eTable 42.3).[37]

eTABLE 42.3

Prevalence of Edentulism Among Adults 65 Years of Age or Older, by Age, Gender, Race, and Hispanic Origin (2011–2012)

Characteristic	Percentage (%)	Standard Error
Total	18.6	2.2
65–74 years old	13[a]	2.5
75 years or older	25.8	2.6
Men	17.5	2.3
Women	19.4	2.3
Non-Hispanic white	16.9[b]	3.1
Non-Hispanic black	29.2	3.2
Hispanic	14.9	2.8
Non-Hispanic Asian	24.2	3.1

[a]Significantly different from age 75 or older ($P < .05$).

[b]Significantly different from non-Hispanic black adults ($P < .05$).

Data from Dye BA, Thornton-Evans G, Li X, et al: Dental caries and tooth loss in adults in the United States, 2011-2012. NCHS data brief no. 197. Hyattsville, MD: National Center for Health Statistics. May 2015. http://www.cdc.gov/nchs/products/databriefs/db197.htm.

By the year 2030, the number of teeth retained by older adults is expected to double, which is an estimated 800 million increase in tooth retention. It is expected that over the next 3 decades, the average number of retained teeth will increase from the current 20 to 25.9.[38] The risk of periodontal disease and dental caries is expected to be a major problem for older adults. Because few older adults are covered by dental insurance,[15] they will be responsible for paying for treatments. Costs and the inability to afford care will always affect health care use, particularly dentistry, which is often considered discretionary.

Periodontal Status

The classic periodontal disease model suggested that virtually all older adults would at some time in their lives become susceptible to severe periodontitis. This result was attributed to an insidious process in which gingivitis slowly progressed into periodontitis, with probable bone and tooth loss. It was asserted that susceptibility to periodontitis increased with age, resulting in tooth loss seen predominantly after 35 years of age.

The current periodontal disease model suggests that only a small proportion of adults have advanced periodontal destruction. Mild gingivitis is common, as is mild to moderate periodontitis. Most adults show some loss of probing attachment while maintaining a functional dentition. Severe periodontal disease is not a part of normal aging and is not the major cause of tooth loss. There may be exceptions to this, but when disease occurs, it is usually in those age 85 or older.

The model asserts that gingivitis does precede periodontitis, but relatively few sites with gingivitis develop periodontitis. The bacterial flora associated with gingivitis and periodontitis shows similarities but does not reciprocate causally. The current model of periodontal disease indicates the following:

- The prevalence of periodontal disease is low and possibly decreasing.
- The progress of periodontal disease is episodic and infrequent.
- Active and inactive disease sites coexist.
- Most of the reported cases of periodontal disease occur in a small, high-risk population of older adults.
- There is a continued effort to identify risk factors for periodontal disease.

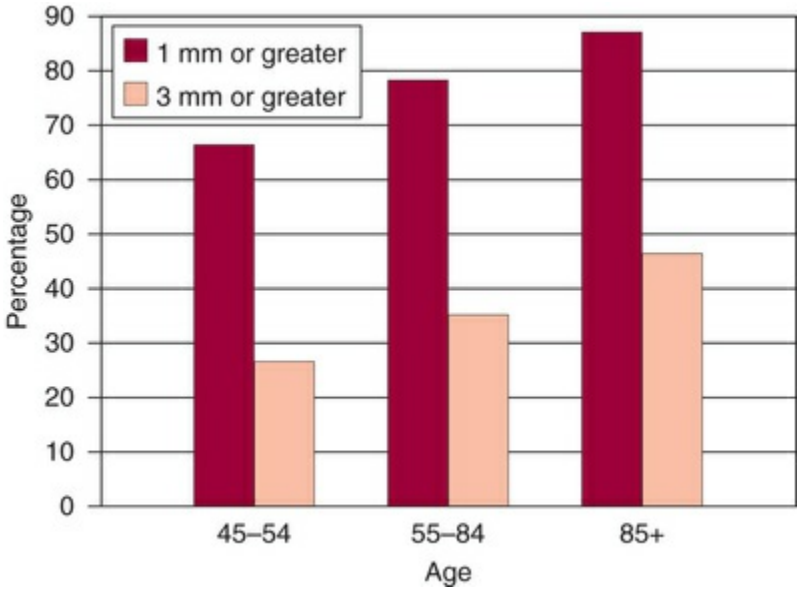
The current risk factors suggested for periodontal disease include age, smoking, diabetes mellitus, and the presence of subgingival *Porphyromonas gingivalis* and *Tannerella forsythia.*

The prevalence of periodontal disease is expected to increase with age[23] as a result of cumulative disease progression over time, not susceptibility.[7,57] In a 30-year preventive home care study, periodontal findings showed a 75% improvement in the number of healthy periodontal sites in the 51- to 65-year-old age group.[7] Data suggest that older adults who maintain optimal oral self-care are less susceptible to periodontitis.[28]

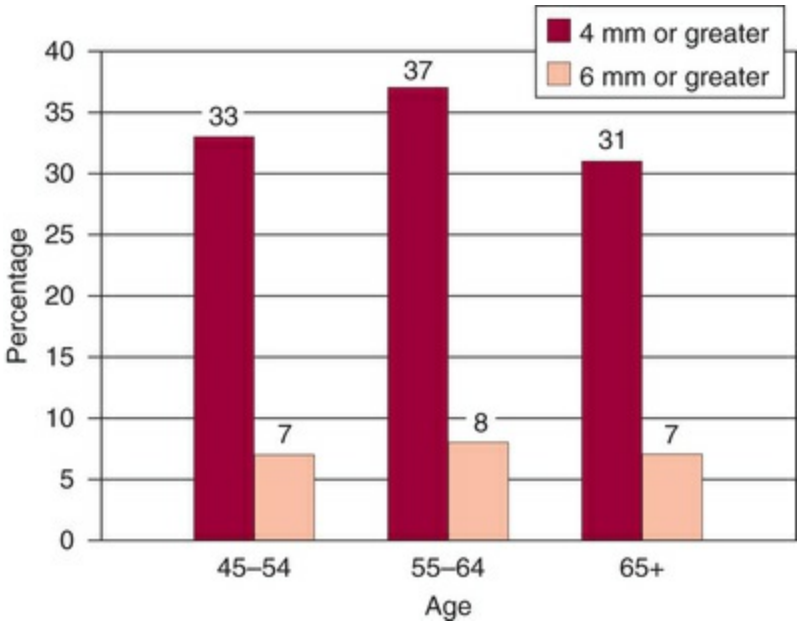
Advanced periodontal disease among older adults is not as common as once thought.[19] Moderate levels of attachment loss are seen in a high proportion of older adults, but severe loss is detected in only a small proportion of older adults (eFig. 42.2). The amount of periodontal disease associated with age does not appear to be clinically significant, and it is unclear whether the higher prevalence of periodontal disease is a function of age or time.[57] eFigs. 42.3 to 42.5 illustrate periodontal disease data from phase I of the Third National Health and Nutrition Examination Survey (NHANES III) conducted in the United States from 1988 to 1991.[18] Gingival recession increased with advancing age, with 35% of people 55 to 84 years of age and 46% of those 85 years of age or older having 3 mm or more of gingival recession (see eFig. 42.3). Pocket depth of 6 mm or greater was detected in 7% of people 45 to 54 years of age, 8% of people 55 to 64 years of age, and 7% of those

65 years of age or older (see eFig. 42.4). Attachment loss increases with age, although less than half of persons age 65 and older had loss of attachment measuring 5 mm or greater (see eFig. 42.5).

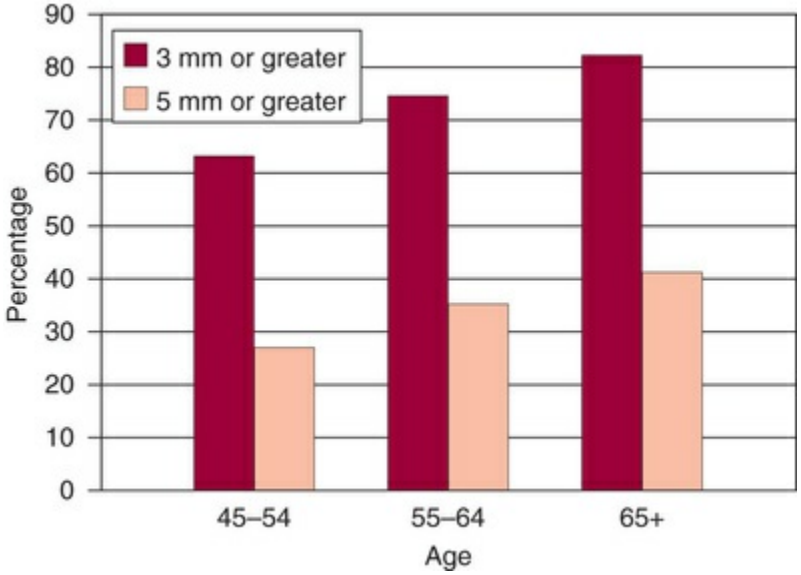
EFIG. 42.2 Severe periodontal disease with potential danger of tooth aspiration.



EFIG. 42.3 Percentage of older persons with gingival recession, 1988 to 1991. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988-1991; prevalence, extent, and demographic variation. *J Dent Res* 75:672, 1996.)



EFIG. 42.4 Percentage of older persons with pocket depths of ≥4 mm or ≥6 mm by age, 1988 to 1991. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988-1991; prevalence, extent, and demographic variation. *J Dent Res* 75:672, 1996.)



EFIG. 42.5 Percentage of older persons with loss of attachment of ≥3 mm or ≥5 mm by age, 1988 to 1991. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988–1991; prevalence, extent, and demographic variation. *J Dent Res* 75:672, 1996.)

Periodontal regenerative therapy for aging periodontal tissue is

being investigated by Benatti and others.[24] Deciphering the biologic properties of periodontal ligament cell (PDLC) regeneration with the use of aging periodontal ligament cells in the laboratory will likely change the way periodontal disease is treated.[24]

Caries Status

Root caries is a disease that has a particular predilection for older adults. Exposed root surfaces in combination with compromised health status and use of multiple medications put older adults at high risk for root caries. Examinations from phase I of NHANES III indicate that root caries prevalence increases greatly with age. Decayed or filled root surfaces were detected in 47% of people between the ages of 65 and 74 and in 55.9% of those 75 years of age or older.[97]

Most older adults are at low risk for root caries, but mediating factors increase this risk, including immune system dysfunction and ineffective oral self-care. With the prospect of older adults retaining more of their teeth through improved access, prevention programs, and personal oral hygiene, it is likely that sound root surfaces will remain caries free. However, one-surface and multiple-surface lesions progress aggressively to infect adjoining tooth surfaces rather than cavitating the infected surface. This natural occurrence in older adults is caused by dentinal sclerosis; caries progression spreads without cavitation. In older adults, the active four-surface lesion produces a characteristic apple coring or collar of caries extending circumferentially along the cementoenamel junction, below the clinical enamel crown of the tooth. The four-surface lesion becomes chronic, with morphologic loss depending on the balance of forces during demineralization and remineralization. Loss of the root structure may be so significant that it undermines the support of the clinical crown. When tooth structure is compromised, the tooth is at high risk for fracture, and oral or tooth function is impaired (eFig. 42.6). The tooth may then be lost because of clinical outcomes that do not allow rehabilitation.

EFIG. 42.6 Root tips remain after coronal portion of the tooth is lost as a result of root caries, leaving a pathway for infection.

Dental Visits

Fundamentally, dental visits by older adults correlate with having teeth, not with age.[96] Data from the 1995 Behavioral Risk Factor Surveillance System (BRFSS), which is a continuous state-based, random-digit-dialed telephone survey of the U.S. noninstitutionalized population age 18 years or older, indicate that older adults are frequent users of dental services.[29]

Although their total consumption of dental services approximates that of younger adults, older adults make fewer dental visits: 21% to 53% of dentate adults visited the dentist in the past 12 months. Approximately 40% of these older adults use the visits for episodic care, indicating a lack of sustained and consistent care. Those least likely to visit a dentist were older adults who were homebound or institutionalized.

When dentate and edentulous adults express positive attitudes regarding the efficacy of dental care, their care-seeking behaviors translate into use, continuous use, and recent use of dental services. However, the belief among dentate and edentulous older adults that their dental problems are a result of aging prevails. Despite clinically evident disease or problems, beliefs and values of older adults regarding the usefulness of dental care to resolve oral problems are limited. They have difficulty incorporating their perceived need into care-seeking behaviors. Nursing home residents often refuse dental care, even when cost is not a barrier,

and think that prevention or treatment would not be efficacious in solving their oral problems.

Studies report dramatic increases in dentate older adults accessing dental care, with older adults now using dental services to the same extent as dentate adults between the ages of 35 and 44. Among adults 65 years of age or older, 62% of respondents reported having a dental visit during the previous year, and 75% of those with natural teeth reported a dental visit in the past year.[29]

As the trend for tooth retention in older adults continues, older adults will account for a greater proportion of dental practice income and visits. Even the oldest persons in the elderly population have reversed earlier, negative attitudes and demonstrated increased awareness and concern for oral health.[54,56,92] Dental expenditure data indicate that older adults have a higher cost per visit than younger persons and are willing to make a significant investment in dental care.[90] Despite these trends, older adults in nursing homes seldom access dental services.

Xerostomia

Saliva plays an essential role in maintaining oral health. Besides the loss of acinar cells occurring with aging, many older adults take medications for chronic medical conditions and disorders. When challenged with medications that cause dry mouth, older adults are more adversely affected than younger adults, which supports the secretory reserve hypothesis of salivary function.[28,46]

More than 500 prescription and over-the-counter (OTC) medications are associated with decreased saliva, dry mouth, and xerostomia. The medications most often associated with xerostomia and decreased saliva are tricyclic antidepressants, antihistamines, antihypertensives, and diuretics. Medication use is frequently associated with dry mouth, but certain medical diseases, disorders, and conditions are also associated with dry mouth, such as radiation treatment for oral, head, neck, and thyroid cancers; Sjögren syndrome; poorly controlled diabetes; bone marrow transplantation; thyroid disorders; and depression (eFig. 42.7).

EFIG. 42.7 Severe xerostomia after radiation therapy during which the parotid glands were not spared.

Symptomatic and corrective therapies, such as parotid-sparing radiation therapy, have been suggested. This treatment has been shown to reduce the effects of xerostomia in each of four domains of quality of life: eating, communication, pain, and emotion. Xerostomia and quality-of-life scores improved significantly over time during the first year after therapy. These results suggest that the efforts to reduce xerostomia using parotid-sparing radiation therapy can improve broad aspects of quality of life.[56] Medications that induce xerostomia can be associated with compromised chewing, speaking, tasting, or swallowing and increased risk of caries, periodontal disease, and candidiasis.

Future research directions include (1) gene therapy approaches to direct salivary growth and differentiation or modify remaining tissues to promote secretion, (2) creation of a biocompatible artificial salivary gland, and (3) salivary gland transplantation. With improved secretagogues, the effects of conditions that result in reduced salivary function and increased caries can be ameliorated.[44]

Candidiasis

Candidiasis is caused by an overproliferation of *Candida albicans.* A pathogenic infection occurs when *C. albicans* infiltrates the oral mucosal layers. Candidiasis can be local or systemic.[47] Treating candidiasis is challenging because *C. albicans* is found in the oral cavity in 40% of people. Candidiasis can affect soft tissues throughout the oral cavity, including gingival tissue.[72]

Any condition compromising a patient's immune system can be considered a risk factor for candidiasis. Oral candidiasis can occur

with long-term use of antibiotics, steroid therapy, or chemotherapy. Diabetes mellitus, head and neck radiation therapy, and human immunodeficiency virus (HIV) infection are risk factors for acute pseudomembranous candidal infection. *Pseudomembranous candidiasis* manifests as white lesions that can be wiped away with gauze, leaving an erythematous area.[47]

Chronic atrophic candidiasis typically manifests as an erythematous area under a maxillary denture and is associated with poor oral hygiene. In patients without a prosthesis, chronic atrophic candidiasis can manifest as a generalized redness or even generalized burning of the mouth.[47] When a person wears dentures or partial dentures continuously, has xerostomia, or is immunocompromised, an ideal environment is created for *Candida* overgrowth. Many methods to overcome oral candidiasis infection have focused on dentures or removable partial dentures, with inclusions such as nystatin, chlorhexidine, metallic oxide powders, natural and herbal oils, photocatalysts, or silver nanoparticles in the liner to promote prolonged delivery of the antimicrobial. Many antimicrobials are useful for controlling overgrowth of *C. albicans* in vitro, but more in vivo research is needed to develop the best protocols.[51]

Barriers to Care

As a person ages, life can become more complicated from a health, functional, nutritional, and psychosocial standpoint. As a result, dental care may not be readily accessible in the traditional care setting for reasons of transportation, finances, or medical complexity, which makes assistance necessary. This challenges the dental profession as a whole and periodontal care specifically. Although these challenges are surmountable with technology and understanding, large gaps are seen in care patterns for older people who cannot access traditional care. This leads to more difficult dental procedures, higher cost of care (due to lack of prevention), and increased morbidity and mortality rates due to lack of care.[3]

Schools such as the University of Rochester in New York and the University of Minnesota in Minneapolis are training dentists in geriatric dentistry to meet the needs of older populations. Training

of the general dentist can be improved to include the preventive strategies needed to enable older people to maintain oral and systemic health throughout the entire lifespan.[48,64] Matt Salo, executive director of the National Association of Medicaid Direction, suggested that "the primary barrier to accessing dental care for older adults appears to be a complete lack of attention—a lack of any kind of benefit from the Medicare program. Not all seniors are eligible for Medicaid and obviously Medicaid benefits vary, but this wouldn't be an issue if Medicare provided basic [dental] benefits for the population it serves."[3a,5]

Iain Pretty from the University of Manchester said, "The growing number of older people has implications for oral health care delivery and will require the development of care pathways that are centered around need, evidence-based, responsive to setting, and take into account current social care models, payment systems and local priorities and circumstances."[68] This is true globally and locally.

Dental and Medical Assessments

Review of Dental History

Initially, the patient interview helps the patient to disclose needs, desires, preferences, and values with regard to dental treatment. The dental history includes dates of the last dental examination and visit, radiographs taken, and frequency of tooth prophylaxis. It also includes a review of past restorations, endodontic therapies, extractions, oral surgeries, prosthetic appliances (including single and multiple, removable and fixed units), periodontal therapies, and gnathologic treatments. Other useful information can include daily oral self-care regimen, fluoride status of the drinking water (i.e., bottled, well, or community sources), and type of toothpaste used (i.e., fluoride or nonfluoride).

Review of Medical History

The medical history of the older adult should be detailed and include a careful review of past and current medical and mental

conditions, including emergency and hospital visits and serious illnesses (eBox 42.1). The review should focus on a careful evaluation of systemic diseases and disorders, particularly those that influence dental treatment, such as bleeding disorders and use of anticoagulants,[36] diabetes, heart valve problems,[1,58] certain cardiovascular conditions, stroke, artificial joints,[7] and use of corticosteroids. A consultation with the patient's physician is advisable, especially for older adults with medical problems or if complicated or invasive procedures are planned. The medical history review should also include medications taken regularly and allergies to medications, metals, and environmental allergens.

eBox 42.1

Dental Interview for Older Adults

Medical (Physical) History

Assess for endocrine and nutritional disorders.
Assess for systemic disease.

Behavior History

Assess overdependence: Is the patient demanding, repetitious, or expressing urgency in his or her demands?
Assess pseudocooperativeness: Is the patient noncompliant in maintaining daily self-care?
Assess perfectionism: Is the patient unrealistic in his or her expectations but noncompliant in maintaining an oral self-care regimen?

Social History

Assess the presence or lack of a support system for the frail and dependent older adult.

The social history is reviewed to determine the patient's age,

tobacco use (i.e., type and pack-years estimate), alcohol use, and caregiver status. Caregiver status indicates the functional level of the patient as functionally independent, frail, or functionally dependent.

Obtaining a complete medical history may take longer for severely compromised older adults. However, the time spent to disclose conditions will determine whether use of the interdisciplinary team is indicated. Coordinating and managing oral health care in this manner can increase the success of dental outcomes.[76]

Review of Medication Use

Older adults are high users of prescription and OTC medications. eTable 42.4 lists the top 20 drugs prescribed in the United States in 2003. Many medications used by older adults can have a negative impact on oral health. To obtain a complete list of prescription and OTC medications, dentists should ask patients to bring each medication bottle or package to the dental office. This helps to obtain a complete medication list and provides additional information such as dosages and number of physicians prescribing medications.

eTABLE 42.4

Twenty Most Frequently Mentioned Drugs by Therapeutic Drug Category at Office Visits in the United States, 2010

Therapeutic Drug Category[a]	Number of Occurrences in Thousands (Standard Error in Thousands)		Percentage of Drug Mentions (Standard Error of Percentage)[b]	
Analgesics[c]	278,720	(18,134)	10.9	(0.2)
Antihyperlipidemic agents	147,191	(11,036)	5.7	(0.2)
Antidepressants	108,760	(7,799)	4.2	(0.2)
Immunostimulants	101,579	(9,883)	4.0	(0.4)
Antidiabetic agents	99,741	(9,710)	3.9	(0.3)
Anxiolytics, sedatives, and hypnotics	92,522	(6,794)	3.6	(0.2)
Antiplatelet agents	92,246	(7,247)	3.6	(0.2)
Beta-adrenergic blocking agents	87,322	(6,046)	3.4	(0.1)
Bronchodilators	85,327	(6,853)	3.3	(0.2)

Anticonvulsants	74,246	(5,644)	2.9	(0.1)
Dermatologic agents	74,004	(5,146)	2.9	(0.2)
Angiotensin converting enzyme inhibitors	73,280	(4,999)	2.9	(0.1)
Proton pump inhibitors	71,701	(5,730)	2.8	(0.1)
Diuretics	65,361	(5,383)	2.6	(0.1)
Antihistamines	58,293	(5,342)	2.3	(0.1)
Vitamins	55,470	(4,992)	2.2	(0.1)
Vitamin and mineral combinations	51,886	(4,484)	2.0	(0.1)
Thyroid hormones	48,688	(4,352)	1.9	(0.1)
Minerals and electrolytes	47,482	(4,020)	1.9	(0.1)
Adrenal cortical steroids	46,638	(3,978)	1.8	(0.1)

[a]Based on the Multum Medisource Lexicon second-level therapeutic drug category (ww.multum.com/lexicon.htm).

[b]Based on an estimated 2,562,072,000 drug mentions at office visits in 2010.

[c]Includes narcotic and nonnarcotic analgesics and nonsteroidal antiinflammatory drugs.

From National Center for Health Statistics, Centers for Disease Control and Prevention: National Ambulatory Medical Care Survey (NAMCS), 2012. https://ftp.cdc.gov/pub/Health_Statistics/NCHS/Dataset_Documentation/NAMCS/doc2

It is important to beware of medications that are not physiologically sound for use in older adults. Beer's Criteria[10] were updated to reflect changes in polypharmacy related to aging, bringing in new findings to reduce complications when prescribing medications for older adults. It is also recommended to use the team approach to prescribing to ensure that the dental and pharmacy practitioners have the most current and complete information about the medications, to reduce drug–drug interactions and health changes with reduced renal and liver function.[89]

Extraoral and Intraoral Examinations

The extraoral examination provides an assessment of the head and neck. The head and neck examination determines whether the skull is normal in shape, with no traumatic injuries. The temporomandibular joint, skin, lymph nodes, and cranial nerves involved in oral function also are assessed. Findings can include

changes in normal tissue, apparent lesions, and dysfunction.

The intraoral examination assesses soft and hard tissues of the oral cavity (eBox 42.2). Assessments help to determine the state of the teeth, including past restorations, caries, occlusal dysfunction, and missing teeth. The periodontal examination includes gingival bleeding points and pocket depths. The remaining intraoral examination assesses the lips, cheeks, tongue, gingiva, floor of the mouth, palate, retromolar region, and oropharyngeal area for tissue abnormalities, red or white patches, ulcerations, and swellings. A major focus of these examinations is the assessment for oral and pharyngeal cancer.

eBox 42.2

Dental Examination of Older Adults

Oral Epithelium

Assess for a decrease in intracellular water content, amount of subcutaneous fat, elasticity and vascularity of tissue, muscle tone, and vertical dimension.
Assess for a thin, waxy appearance of the tissue.
Assess for hyperkeratosis of keratin areas.

Tongue

Assess for defoliation of papillae, fissures (dorsum side), and varicosities (ventral side).
Assess for alterations in taste.
Assess clinical complaints of the following:

- Smooth, glossy, and painful tongue (may indicate vitamin B_{12} deficiency)
- Geographic tongue (erythema migrans)
- Oral infections such as candidiasis

Saliva

Assess for xerostomia (i.e., altered salivary flow) that produces a decrease in the following:

- Antibacterial activity
- Buffering capacity
- Transport of taste sensors
- Lubrication of the oral cavity
- Digestive function

Look for signs of xerostomia, including the following:

- Intraoral dryness
- Burning sensation
- Altered tongue surface
- Dysphagia
- Cheilosis
- Alterations in taste
- Difficulty with speech
- Root caries

Immune System

Assess for pronounced inflammatory responses of the gingiva to infection.

It can be difficult to differentiate a benign lesion from a precancerous or early cancerous lesion. A product called OralCDx has been developed; this computer-assisted brush biopsy test can aid in screening for cancer.[33,73]

Oral cancer can appear as an ulceration, a swelling, or a red or white sore that does not heal in 1 to 2 weeks. Other signs of oral cancer include swollen lymph nodes and difficulty swallowing and speaking.[41] Particularly alarming, oral and pharyngeal cancer lesions may not be painful. Unfortunately, the 5-year survival rate of patients with oral cancer has not improved.[8]

Xerostomia screening can be done by sialometry or by oral examination. With *sialometry,* depending on the type of gland, the precise collection of saliva may require 5 to 15 minutes (eTable 42.5). Specific screening tools may be required for different gland types. For example, modified Carlson–Crittenden collectors are used to suction saliva from the parotid gland through the Stensen

duct, and specialized equipment is used for the submandibular gland (through Wharton ducts) and the minor salivary glands.

eTABLE 42.5

Sialometry for Xerostomia Screening: Salivary Flow Rates

Category	Normal Flow Rate	Abnormal Flow Rate
Whole saliva	0.5–1.2 mL/min	0.0–0.2 mL/min
Whole saliva, stimulated	1.0–2.0 mL/min	0.01–0.4 mL/min

A less quantitative measure of saliva for determination of xerostomia is an oral examination using a tongue blade (eFig. 42.8). The saliva collected from the floor of the mouth or the buccal vestibules is absorbed onto the tongue blade (see eFig. 42.8A and B). If only the tip of the tongue blade demonstrates wetness rather than a greater portion of the end of the blade, an abnormal finding is recorded (see eFig. 42.8C).

EFIG. 42.8 A tongue blade is used to measure saliva to screen for xerostomia. (A) Screening begins by placing the tongue blade in the sublingual area at the mandibular anterior quadrant. (B) The tongue blade is left in place for about 5 seconds to collect saliva from the floor of the mouth or the buccal vestibules. (C) Only the tip of the tongue blade demonstrates wetness, an indication of xerostomia.

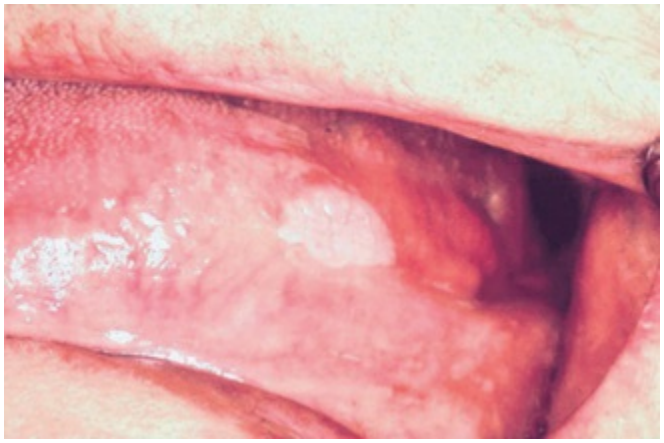
Assessment of Risk

Assessment of risk is determined after completion of the patient interview and the extraoral and intraoral examinations. Oral and medical problems can influence the risk of disease, pain, oral

dysfunction, and nutritional disorders related to the quality and quantity of foods.[70] Risk assessment also can serve as a predictor for successful treatment outcomes, maintenance protocols, and patient compliance. For example, the risk factors that influence periodontal therapy are smoking, genetic susceptibility, compliance, and diabetes.[95]

Assessment tests use genetic markers to demonstrate susceptibility to periodontal disease. Specific genetic markers associated with increased levels of interleukin-1 (IL-1) production indicate a strong susceptibility to severe periodontitis in older adults. When the genotype for the polymorphic IL-1 gene cluster was identified, it correlated with an odds ratio of 18.9, indicating severe periodontitis in nonsmoking adults.

Risk factors for oral and pharyngeal cancer are age, tobacco use, frequent use of alcohol, and exposure to sunlight (i.e., lip cancer). Oral cancer is treatable if discovered and treated early. Most dentists can easily identify an early carcinoma in situ (eFig. 42.9). At this stage, however, the lesion may have already spread to the lymph nodes. Oral and pharyngeal cancer detected at later stages can cause disfigurement, loss of function, decreased quality of life, and death. The Surveillance, Epidemiology, and End Results (SEER) Program data indicated that more than 50% of tongue and floor of the mouth cancers had metastasized to a distant site at the time of diagnosis.[75]



EFIG. 42.9 Early carcinoma in situ.

Another predisposing risk factor for oral cancer is human

papilloma virus (HPV) infection contracted earlier in life. There is a rise in oropharyngeal squamous cell carcinoma (OPSCC) incidence in aging populations coincident with HPV DNA found in patients with OPSCC. This is occurring as the incidence of tobacco-related cancers of the head and neck has abated.[100]

Quality of Life

The conditions predisposing the older patient to disease or changes in oral health status can result from physical or psychological problems, or both. Problems may be the result of the older person's social conditions. Whatever the cause, the underlying problems must be addressed so that dental outcomes will be positive. This may require the dentist to first address the patient's fears and expectations about treatment outcomes. For example, older adults who are experiencing the loss of teeth and adjusting to removable appliances or dentures can have tremendous difficulty accepting a reduced level of oral functioning. Their coping mechanism may also be stressed because of other socially important factors, such as aesthetics and social esteem. The patient's presenting conditions can affect implementation of the treatment plan.

Many conditions limit an older person's ability to withstand or cope with dental treatment. For example, some older adults with physically or psychologically based behavior problems may require premedication for the dentist to deliver treatment. Other conditions can limit the dentist's ability to render treatment. For example, an older patient may not tolerate a reclining chair position for restorative procedures because of a chronic heart ailment or arthritis.

With treatment, there is a concomitant risk for causing problems, referred to as *iatrogenic effects.* Iatrogenic problems arise from the side effects of treatment or from treatment procedures and range from drug interactions to medical emergencies.

Under certain conditions, the most appropriate care is to do nothing. In some severely compromised patients, treatment is rendered only if the potential for sepsis is suspected. Otherwise, treatment is withheld. In less serious situations, a dentist may decide not to treat a cracked tooth but to dome it and leave its root

intact in tissue. This maintains the bone in the area and allows a prosthetic appliance to be placed. The dentist determines the risks and benefits of treatment to a patient when deciding whether to provide treatment.

The dentist may not have the special skills, equipment, or training to meet the needs of poorly functioning or nonfunctioning older adults. The dentist may need to obtain the additional training and equipment to treat this population, especially in a rural community where access to services is extremely limited. Alternatively, the dentist may need to become familiar with referral resources to contact clinicians who can treat these patients. A major referral source is a trained hospital dentist who can treat patients impaired by dementia or physical problems or diseases.

Periodontal Diseases in Older Adults

Etiology

Periodontal disease in older adults is usually referred to as *chronic periodontitis.*[47,78] Because periodontitis is a chronic disease, much of the ravage of the disease detected in older adults accumulated over time. The advanced stages of periodontitis are less prevalent than the moderate stages in the older adult population.[27] One theory is that many sites of advanced periodontal disease have resulted in tooth loss earlier in life, suggesting that older age is not a risk factor for periodontal disease.[47,78]

Evidence is limited on whether the risk factors for periodontal disease fluctuate with age.[23] General health status, immune status, diabetes, nutrition, smoking, genetics, medications, mental health status, salivary flow, functional deficits, and finances can modify the relationship between periodontal disease and age.[23,95]

Some frequently prescribed medications for older adults can alter the gingival tissues. *Steroid-induced gingivitis* has been associated with postmenopausal women receiving steroid therapy. *Gingival overgrowth* can be induced by medications such as cyclosporine, calcium channel blockers, and anticonvulsants (e.g., nifedipine, phenytoin) in the setting of poor oral hygiene. Gingival overgrowth further decreases a person's ability to maintain good oral hygiene.[47]

Relation to Systemic Disease

Padilha and colleagues,[67] using data from the Baltimore Longitudinal Study of Aging, reached the conclusion that "the number of teeth is a significant risk indicator for mortality … and that improving oral health and preventing tooth decay may substantially improve the oral status of the population and increase longevity."

A review of the literature by Loesche and Lopatin[59] indicates that poor oral health has been associated with medical conditions such as aspiration pneumonia and cardiovascular disease. In particular, periodontal disease can be associated with coronary heart disease and cerebrovascular accident (CVA). The Surgeon General's Report on Oral Health emphasizes that animal- and population-based studies demonstrate an association between periodontal disease and diabetes, cardiovascular disease, and stroke.[82]

Investigations confirm these associations. For example, a periodontal examination can assist in cardiovascular risk assessment in hypertensive patients. Angeli and coworkers[11] reported an association between periodontal disease and left ventricular mass in untreated patients with essential hypertension. In another investigation, diabetes mellitus type 2 HbA1c levels declined with periodontal therapy in a large study by the U.S. Department of Veterans Affairs in South Carolina.[61]

Pneumonia is a common cause of morbidity and mortality in the older adult. Improvements in oral care have greatly reduced the incidence of pneumonia in elderly nursing home patients. Although the mechanism is under investigation, it is thought that the cough reflex can be improved by reducing the numbers of oropharyngeal microbial pathogens.[87] Expanding on these findings, studies have been conducted on the prevention of ventilator-associated pneumonia. Providing oral therapy for intensive care patients to reduce bacterial colonization in the mouth and teeth can reduce mortality and morbidity rates by 42%.[45]

The presence and extent of periodontal disease may be related to an increased risk of weight loss in older, well-functioning adults. This association is independent of smoking and diabetes mellitus. Changes in nutrient intake may be related to periodontal disease and a higher systemic burden of inflammation.[92]

Periodontal Treatment Planning

Periodontal disease in older adults usually is not a rapidly progressive disease but often manifests as long-standing chronic disease. Because periodontal disease has periods of exacerbation and remission, understanding and documenting periods of active disease compared with quiescent periods is essential to the formulation of the treatment plan and prognosis.[78]

Periodontal disease must be diagnosed regardless of age. The goal of periodontal treatment for young and old patients is to preserve function and eliminate or prevent the progression of inflammatory disease.[91]

The goal of clinically managing periodontal disease in older adults is based on specific, individualized care. The major consideration is improving or maintaining function, with an emphasis on quality-of-life issues. Emphasizing care over cure is the cornerstone of any proposed treatment plan. Prevention, comfort, function, aesthetics, and ease of maintenance are the criteria for successful care of an older adult, particularly a frail or functionally dependent older patient.

Several factors must be considered during treatment planning for older individuals.[78] It is important first to remember that periodontal healing and recurrence of disease are *not* influenced by age.[23] Factors to consider in the older patient are medical and mental health status, medications, functional status, and lifestyle behaviors that influence periodontal treatment, outcome, or progression of disease.[91] Periodontal disease severity, ability to perform oral hygiene procedures, and ability to tolerate treatment should be evaluated during treatment planning. The risks and benefits of surgical and nonsurgical therapy should be considered.[59] The amount of remaining periodontal support or past periodontal destruction, tooth type, number of occlusal contacts, and individual patient preferences are also important.[91]

Dental implants are reliable replacements for missing teeth in older adults[96]; age alone is not a contraindication for implant placement. Risk factors for the success of implants have been investigated. Although aging is a factor in decision making, most failures are associated with smoking, diabetes, head and neck

irradiation, and postmenopausal estrogen therapy.[65]

For older adults, a nonsurgical approach is often the first treatment choice. Depending on the nature and extent of periodontal disease, surgical therapy may be indicated. Surgical technique should minimize the amount of additional root exposure. Individuals who respond best to surgical therapy are those who are able to maintain the surgical result. Age alone is not a contraindication to surgery. For individuals who are unable to comply with treatment, have poor oral hygiene, or are medically or mentally compromised or functionally impaired, palliative supportive periodontal care instead of surgical periodontal treatment is often the optimal approach.[59,76]

The U.S. Food and Drug Administration (FDA) approved silver diamine fluoride to reduce sensitivity, and its off-label use can arrest root caries and reduce bacteria on roots, where combined caries and periodontal infections is an issue and traditional dental treatment is not optimal or possible.[50]

A common goal for all older adults is to decrease bacteria through oral hygiene and mechanical debridement. Clinical trials enrolling older adults showed that the development or progression of periodontal disease could be prevented or arrested by controlling plaque. For certain patients, topical antibiotic therapy may complement repeated subgingival instrumentation during supportive care. Oral hygiene maintenance should also focus on root surfaces susceptible to caries.[91] Decision making for frail and functionally dependent older adults may be challenging for the general dentist. For this reason, dentists, other health care professionals, and other scientists are creating high-quality office-based methods to access evidence-based decision-making programs and accommodating websites to help with complicated oral health care issues.[4,77]

Disease Prevention and Maintenance of Periodontal Health in Older Adults

For younger and older people, the most important factors determining a successful outcome of periodontal treatment are plaque control and frequency of professional care. Advanced age

does not decrease plaque control,[12] but older adults may have difficulty performing adequate oral hygiene because of compromised health, altered mental status, medications, or altered mobility and dexterity.[91] Older adults may change toothbrushing habits because of disabilities such as hemiplegia due to CVA, visual difficulties, dementia, or arthritis. The newer, lightweight electric-powered toothbrush may be more beneficial than a manual toothbrush for older adults with physical and sensory limitations.

The proportion of people who floss their teeth decreases after 40 years of age.[90] This may be partly caused by impairment of fine motor skills due to disease or injury. Interproximal brushes, shaped wooden toothpicks, and mechanical flossing devices often can be used in place of traditional flossing with satisfactory outcomes.

Multidisciplinary strategies are increasingly becoming part of periodontal health care promotion. Assessments of overall health, functional status, and patient education are fundamental to promoting and maintaining optimal periodontal health. Older adults, their families, and caregivers need to be informed and trained by dentists on the appropriate devices, chemotherapeutic agents, and techniques to provide oral self-care and maintain a healthy lifestyle.[40]

The outcomes are instrumental in achieving overall health, oral and periodontal health, self-esteem, nutrition, and quality of life. Barriers to achieving these benefits are access and cost. For older adults who are homebound or institutionalized, these barriers inhibit their achieving and maintaining optimal oral and periodontal health.

Chemotherapeutic Agents

Antiplaque Agents

Patients who are unable to remove plaque adequately due to disease or disability may benefit from antiplaque agents such as chlorhexidine, sub-antimicrobial tetracycline, or Listerine or its generic counterparts.[63,78,91]

Chlorhexidine is a cationic bisbiguanide that has been used as a broad-spectrum antiseptic in medicine since the 1950s. In Europe, a 0.2% concentration of chlorhexidine has been used for years as a

preventive and therapeutic agent.[59,90] Chlorhexidine is bacteriostatic or bactericidal, depending on the dose. Adverse effects of chlorhexidine include an increase in calculus formation, dysgeusia (i.e., altered taste), and permanent staining of teeth.[8] Chlorhexidine is a prescription rinse for short-term use (<6 months); long-term use (>6 months) has not been extensively studied.[90]

The American Dental Association (ADA) Council on Dental Therapeutics[6] has approved chlorhexidine to help prevent and reduce supragingival plaque and gingivitis. Although chlorhexidine has not been studied in older adults, outcomes in younger persons, including those with disabilities, suggest that it is also effective in older adults. Chlorhexidine may be particularly useful for older adults who have difficulty with plaque removal and those who take phenytoin, calcium channel blockers, or cyclosporine and who are at risk for gingival hyperplasia.[78,90]

Sub-antimicrobial tetracycline (Periostat) is useful in treating moderate to severe chronic periodontitis. The active ingredient in Periostat is doxycycline hyclate. In concert with scaling and root planing, Mohammad and colleagues[63] showed this treatment to be effective in institutionalized older adults. Periostat is contraindicated for patients with an allergy to tetracycline.

Listerine antiseptic and its generic counterparts are approved by the ADA Council on Dental Therapeutics[8] to help prevent and reduce supragingival plaque and gingivitis. The active ingredients in Listerine are methyl salicylate and three essential oils (i.e., eucalyptol, thymol, and menthol). Listerine was effective in reducing plaque and gingivitis compared with placebo rinses in young healthy adults. Listerine may exacerbate xerostomia because of its high alcohol content, ranging from 21.6% to 26.9%. Listerine is generally contraindicated in patients under treatment for alcoholism who take disulfiram (Antabuse). Listerine may benefit patients who do not tolerate the taste or staining of chlorhexidine or who prefer OTC medicaments that are less expensive and easier to obtain.[78,90]

Antimicrobial photodynamic therapy (aPDT) is being investigated for the treatment of periodontitis. Using low-powered lasers and cells treated with a drug to make them susceptible to the light, it is possible to kill microorganisms specific to periodontal

disease.[35]

Fluoride

Fluoride, nature's cavity fighter, is an effective caries-preventive agent (see Periodontal Treatment Planning). Fluoride's effects are as follows[78,90]:

1. Reduces enamel solubility
2. Promotes remineralization of early carious lesions
3. Is bactericidal for bacterial plaque

Topical fluorides are recommended for the prevention and treatment of dental caries. OTC fluorides include fluoride dentifrices, rinses, and gels that contain concentrations of 230 to 1500 parts per million (ppm) of fluoride ions. Prescription 1.1% neutral sodium fluoride gels are available with a fluoride concentration of 5000 ppm of fluoride ions. Professionally applied fluoride gel, foam, or varnish products have between 9050 and 22,600 ppm of fluoride ions.[8]

Saliva Substitutes

Saliva substitutes, which are intended to match the chemical and physical traits of saliva, are available to relieve the symptoms of dry mouth. Their composition varies, but they usually contain salt ions, a flavoring agent, paraben (a preservative), cellulose derivative or animal mucins, and fluoride. The ADA's seal of approval has been granted for some artificial saliva products (e.g., Saliva Substitute, Salivart).[8] Most saliva substitutes can be used as desired by patients and are dispensed in a spray bottle, rinse or swish bottle, or oral swab stick.[8,90] Products such as dry-mouth toothpastes and moisturizing gels are also available. Biotene products such as Oral Balance are marketed to relieve the symptoms of xerostomia.

Patients with dry mouth can benefit from stimulating saliva flow with sugarless candies and sugarless gum. Xylitol chewing gum has been shown to have anticariogenic properties in children. Medicated chewing gum with xylitol and chlorhexidine or xylitol alone has the added benefit of reducing oral plaque and gingivitis

in elderly people who live in residential facilities.[9]

Salivary substitutes and stimulants are only effective in the short term. Under investigation is acupuncture-like transcutaneous nerve stimulation (Codetron), a method to treat radiation-induced xerostomia. Unlike traditional acupuncture therapy, Codetron does not use invasive needles to achieve stimulation. This method helps patients produce their own saliva and reduces symptoms of xerostomia for several months. Acupuncture therapy has demonstrated improvements lasting up to 3 years.[98]

Risk Reduction

Cessation of tobacco use has been primarily an issue of patient compliance. Most smokers (90%) quit cold turkey. However, nicotine replacement therapy may help strongly addicted patients. The transdermal nicotine patch or nicotine polacrilex (gum) can reduce the symptoms of nicotine withdrawal. For behavioral modification, the four steps to tobacco cessation are as follows:

1. Ask the patient about tobacco use.
2. Advise the patient to stop using tobacco.
3. Assist the patient in stopping by selecting a quitting date (usually within the next 4 weeks).
4. Arrange patient follow-up services.

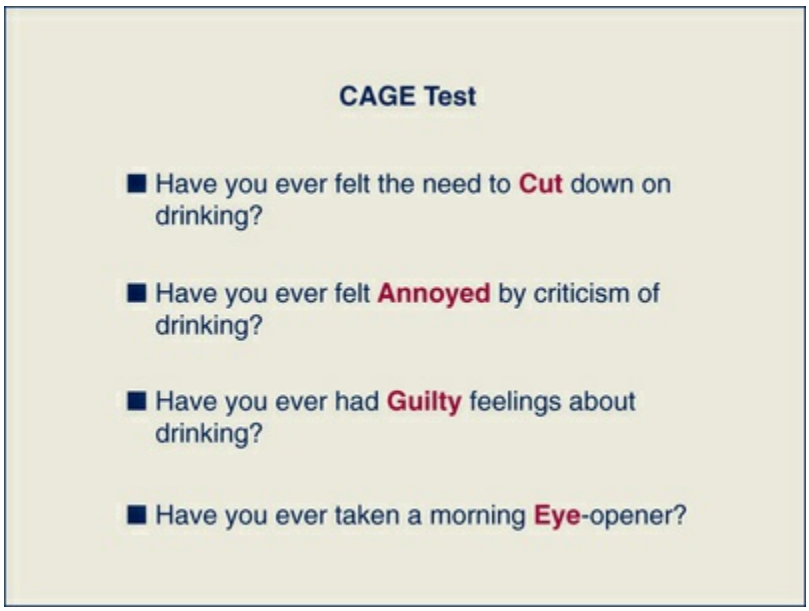
Clinical studies show that all four components, used routinely, result in much higher patient cessation rates than if only two or three are used. Both forms of nicotine replacement have been shown to increase cessation rates when used in combination with behavioral interventions.

Nicotine replacement therapy is intended to be used for 6 to 12 weeks so that patients can learn psychological and social coping skills without going through nicotine withdrawal at the same time. It is not recommended for use for more than 6 months. Nicotine replacement therapy should probably not be considered for the following people:

- Individuals who have not previously tried to

quit
- Individuals who use only small amounts of tobacco or who are occasional users
- Individuals who have tried to quit and have not had significant physical symptoms of nicotine withdrawal
- Individuals who do not receive behavioral support from clinic staff

Alcoholism and alcohol abuse are diagnosed using the *Diagnostic and Statistical Manual of Mental Disorders,* third edition, revised (DSM-IIIR), and fourth edition (DSM-IV). The tests suggested to screen for alcohol abuse are the self-administered questionnaire, the Michigan Alcoholism Screening Test (MAST), and the CAGE (from a series of questions about drinking: *c*ut down, *a*nnoyed, *g*uilty, and *e*ye-opener) questionnaire, which is a four-item screening tool (eFig. 42.10). A score of 2 (i.e., an affirmative answer to two questions) by the elderly patient provides clinical evidence or suspicion of alcohol abuse, with a sensitivity of about 50% and a specificity of more than 90%. The MAST, with a cutoff score of 5, produces sensitivity ranging from 50% to 70% and a specificity above 90%.



EFIG. 42.10 Method of determining alcohol abuse

using the modified CAGE test. The acronym CAGE is derived from a series of four questions about drinking: *c*ut down, *a*nnoyed, *g*uilty, and *e*ye-opener. (From Mallin R: Smoking cessation: integration of behavioral and drug therapies. *Am Fam Physician* 65:1107-1114, 2002.)

The most common treatment for alcoholism is referral to a substance abuse facility. For older adults, the most effective treatment is a program that emphasizes groups specific to that population that use nonconfrontational therapy and encourage reminiscence along with discussion of current problems. Discussion of current problems is relevant because of the role that stress plays in recent widowhood, recent retirement, or disruption or removal from one's residence.

Conclusions

Future oral health care trends will include increased numbers of older adults seeking periodontal therapy. Dental practitioners of the 21st century should be comfortable providing comprehensive periodontal care for this segment of the population. Aging dental patients have particular oral and general health conditions that dentists should be familiar with detecting, consulting on, and treating. Medical diseases and conditions that occur more often with age may require modification of periodontal preventive tools and the planning and treatment phases of periodontal care.

Case Scenario 42.1

Patient:
75-year-old male

Chief Complaint:
"My gums in the lower front hurt and bleed when I brush."

Background Information:
Patient is a nonsmoker and has controlled hypertension. He did not report any other systemic conditions. Patient is taking lisinopril

for hypertension and reports going to medical examinations annually. He reports brushing once per day but not flossing. He also reports that he used to brush his teeth aggressively in the past and that he underwent his last professional dental cleaning 2 years ago.

Current Findings:

Probing depths were in the range of 2 to 7 mm. Degree of bleeding on probing was 47%. Patient has poor oral hygiene.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Is the patient's age a risk factor for gingival recession? A. Yes B. No	**Answer: B** **Explanation:** Age by itself is not a true risk factor for gingival recession. The cumulative effect of trauma and periodontitis leads to gingival recession.
2. This patient requires nonsurgical periodontal therapy to eliminate local factors before addressing his concerns (i.e., high frenal pull). Can age significantly influence the outcome of therapy? A. Yes B. No	**Answer: B** **Explanation:** Aging by itself has no or minimal effect on periodontal therapy outcomes.
3. Which of the following is important when planning periodontal surgery in elderly patients? A. Acquiring a thorough medical history B. Evaluating cognitive skills C. Evaluating motor skills D. All of the above	**Answer: D** **Explanation:** The medical conditions of the elderly can contraindicate a periodontal procedure. Cognitive and motor skills should also should be assessed before planning surgery in an elderly patient.

CHAPTER 43

Treatment of Aggressive and Atypical Forms of Periodontitis

Perry R. Klokkevold

CHAPTER OUTLINE

Aggressive Periodontitis
Periodontitis Refractory to Treatment *(e-only)*
Necrotizing Ulcerative Periodontitis
Conclusions

The majority of patients with common forms of periodontal disease respond predictably well to conventional therapy, including oral hygiene instruction, nonsurgical debridement, surgery, and supportive periodontal maintenance. However, patients diagnosed

with aggressive periodontitis and some atypical forms of periodontal disease often do not respond as predictably or as favorably to conventional therapy. Fortunately, only a small percentage of patients with periodontal disease are diagnosed with aggressive periodontitis. Patients who are diagnosed with periodontal disease of any type that is *refractory* to treatment present in small numbers as well. Even fewer patients are diagnosed with necrotizing ulcerative periodontitis. Each of these atypical disease entities poses significant challenges for the clinician, not only because they are infrequently encountered but also because they may not respond favorably to conventional periodontal therapy.[24,40] Furthermore, the severe loss of periodontal support associated with these cases leaves the clinician faced with uncertainty about treatment outcomes and difficulty in making decisions about whether to save affected teeth or extract them.

Aggressive Periodontitis

Aggressive periodontitis, by definition, causes rapid destruction of the periodontal attachment apparatus and the supporting alveolar bone (see Chapter 28). The responsiveness of aggressive periodontitis to conventional periodontal treatment is unpredictable, and the overall prognosis for these patients is poorer than for patients with chronic periodontitis. Because these patients do not respond typically to conventional methods and their disease progresses unusually fast, the logical question is whether there are problems associated with an impaired host immune response that may contribute to such a *different* disease and result in a *limited* response to the usual therapeutic measures. There have been reports of defects in the function of polymorphonuclear leukocytes (i.e., neutrophils) in some patients with aggressive periodontitis.[30,31] Also, in a small number of cases, a systemic disease such as neutropenia can be identified that appears to explain the unusual severity of the periodontal disease for that individual.[12,13] In most patients with aggressive periodontitis, however, these factors cannot be identified,[1] and in fact, these patients are typically quite healthy. Numerous attempts to examine immunologic profiles of patients with aggressive periodontitis have failed to identify any

specific etiologic factors common to all patients.

The prognosis for patients with aggressive periodontitis depends on (1) whether the disease is generalized or localized, (2) the degree of destruction present at the time of diagnosis, and (3) the ability to control future progression. *Generalized* aggressive periodontitis rarely undergoes spontaneous remission, whereas *localized* forms of the disease have been known to arrest spontaneously.[29] This unexplained curtailment of disease progression has sometimes been referred to as a "burnout" of the disease. It appears that cases of localized aggressive periodontitis often have a limited period of rapid loss of periodontal attachment and alveolar bone, followed by a slower, more chronic phase of disease progression. Overall, patients with generalized aggressive periodontitis tend to have a poorer prognosis because they typically have more teeth affected by the disease and the disease is less likely to go into remission spontaneously compared with localized forms of aggressive periodontitis.

Therapeutic Modalities

Early detection is critically important in the treatment of aggressive periodontitis (generalized or localized) because prevention of further destruction is often more predictable than regeneration of lost supporting tissues. Therefore, at the initial diagnosis, it is helpful to obtain any previously taken radiographs to assess the rate of progression of the disease. Together with future radiographs, this documentation also facilitates the clinician's assessment of treatment success and control of the disease.

Treatment of aggressive periodontitis must be pursued with a logical and regimented approach. Several aspects of treatment must be considered. One of the most important aspects of treatment success is educating the patient about the disease, including the causes and risk factors, and stressing the importance of the patient's role in the success of treatment.[50] Essential therapeutic considerations for the clinician are controlling the infection, arresting disease progression, correcting anatomic defects, replacing missing teeth, and ultimately helping the patient maintain periodontal health with frequent periodontal maintenance care.

Educating family members is another important factor because aggressive periodontitis is known to have familial aggregation. Family members, especially younger siblings of the patient diagnosed with aggressive periodontitis, should be examined for signs of disease, educated about preventive measures, and monitored closely. It cannot be stressed enough that early diagnosis, intervention, and, if possible, prevention of disease is more desirable than attempting to reverse the destruction that results from aggressive periodontitis.

Conventional Periodontal Therapy

Because aggressive periodontitis is primarily a bacterial infection, initial treatment is comparable to treatment rendered for chronic periodontitis. Conventional periodontal therapy for aggressive periodontitis consists of patient education, oral hygiene improvement, scaling and root planing, and regular (frequent) recall maintenance. It may or may not include periodontal flap surgery.[3] However, the response of aggressive periodontitis to conventional therapy alone may be limited and less predictable. Patients who are diagnosed with aggressive periodontitis at an early stage and are able to enter therapy may have a better outcome than those who are diagnosed at an advanced stage of destruction. In general, the earlier the disease is diagnosed, the more conservative the therapy and the more predictable the outcome.

Teeth with moderate to advanced periodontal attachment loss and bone loss often have a poor prognosis and pose the most difficult challenge. Depending on the condition of the remaining dentition, treatment of these teeth may offer a limited prospect of improvement and may even diminish the overall treatment success. Clearly, some of these teeth should be extracted; however, other teeth may be pivotal to the stability of the dentition, making it desirable to attempt treatment to maintain them. Treatment options for teeth with deep periodontal pockets and bone loss may be nonsurgical or surgical. Surgery may be purely resective, regenerative, or a combination of these approaches.

Key Fact

Patients who are diagnosed with aggressive periodontitis at an early stage and who are able to enter therapy may have a better outcome than those who are diagnosed at an advanced stage of destruction. In general, the earlier the disease is diagnosed, the more conservative the therapy and the more predictable the outcome. Teeth with advanced periodontal attachment loss and bone destruction often have a poor prognosis and pose the biggest challenge for treatment.

Surgical Resective Therapy

Resective periodontal surgery can be effective in reducing or eliminating pocket depth in patients with aggressive periodontitis, but it may be difficult to accomplish if adjacent teeth are unaffected. If a significant height discrepancy exists between the periodontal support of the affected tooth and the adjacent unaffected tooth, the gingival transition (soft tissue following the bone) often results in deep probing pocket depth around the affected tooth that cannot be eliminated. A less-than-ideal outcome must be considered before deciding to treat increased pocket depth surgically.

It is important to realize the limitations of surgical therapy and to appreciate the possible risk that surgical therapy may further compromise teeth that are mobile due to extensive loss of periodontal support. For example, in a patient with severe horizontal bone loss, surgical resective therapy may result in increased tooth mobility that is difficult to manage, and a nonsurgical approach may be preferable. Careful evaluation of the risks versus the benefits of surgery must be performed on a case-by-case basis.

Regenerative Therapy

The concept and application of periodontal regeneration have been established in patients with chronic forms of periodontal disease (see Chapter 63). Regenerative materials, including bone grafts, barrier membranes, and wound-healing agents, are often employed, and their use is well documented. Intrabony defects, particularly vertical defects with multiple osseous walls, are often

amenable to regeneration with these techniques. Most of the success and predictability of periodontal regeneration have been achieved in patients with chronic periodontitis; much less evidence is available regarding the use of periodontal regeneration for patients with aggressive periodontitis.

Periodontal regenerative procedures have been successfully demonstrated in patients with localized aggressive periodontitis in some clinical case reports. Dodson and colleagues[14] demonstrated the regenerative potential of a severe, localized osseous defect around a mandibular incisor in a healthy 19-year-old black man diagnosed with localized aggressive periodontitis. The patient presented with severe localized bone loss around one of the mandibular incisors. Using open flap surgical debridement, root surface conditioning (tetracycline solution), and an allogenic bone graft reconstituted with sterile saline and tetracycline powder, the surgeons reduced the probing pocket depth from 9–12 mm to 1–3 mm (3 mm of recession was noted); significant bone fill of the defect (about 80%) was reported (Fig. 43.1). This case illustrates the potential for healing of severe defects in patients with localized aggressive periodontitis, especially when local factors are controlled and sound surgical principles are followed. The authors cited several factors that likely contributed to the success of this case, including a probable transition of disease activity from aggressive to chronic, tooth stabilization before surgery, sound surgical management of hard and soft tissues, and good postoperative care.[14]

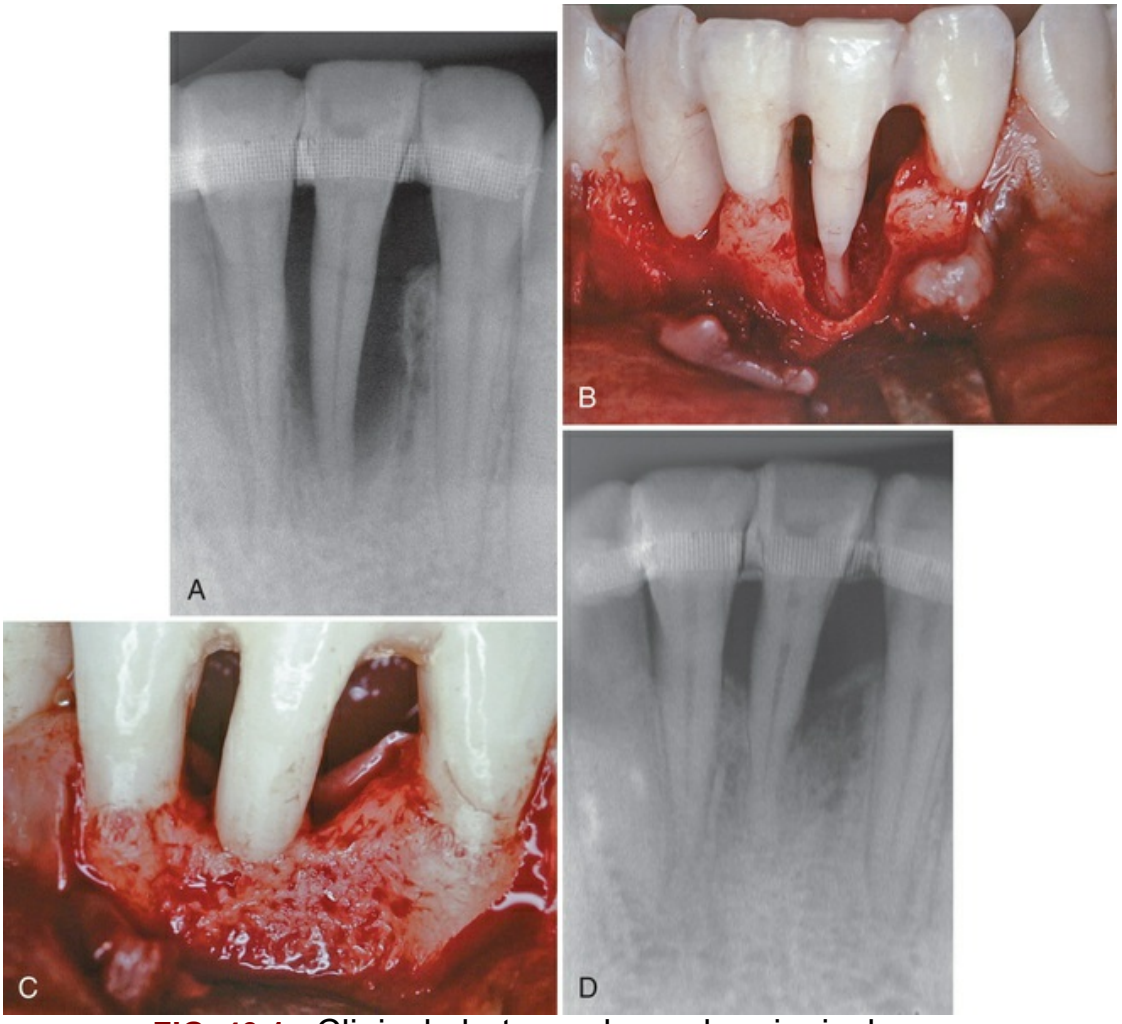

FIG. 43.1 Clinical photographs and periapical radiographs demonstrating regenerative success in a patient with localized aggressive periodontitis. (A) Periapical radiograph of the right lateral incisor at the initial diagnosis. Notice the severe vertical bone loss associated with the right lateral incisor. The tooth has been splinted to adjacent teeth for stability. (B) Facial view of the circumferential osseous defect around the lower right lateral incisor during open flap surgery. There is complete loss of buccal, lingual, mesial, and distal bone around the lateral incisor, with minimal bone support limited to the apical few millimeters. (C) Facial view of reentered surgical site 1 year after treatment. Bone fill around all surfaces demonstrates remarkable potential for regeneration of a large osseous defect in a young patient with localized aggressive periodontitis. (D) Periapical radiograph taken 1 year after regenerative therapy. Notice the increased radiopacity and bone fill. (From Dodson SA, Takei HH, Carranza FA Jr: Clinical success in regeneration: report of a case. *Int J Periodont*

Restor Dent 16:455, 1996.)

Although the potential for regeneration in patients with aggressive periodontitis appears to be good, expectations are limited for patients with severe bone loss. This is especially true if the bone loss is horizontal or has progressed to involve furcations.

Key Fact

Periodontal regeneration has been successfully demonstrated in patients with localized aggressive periodontitis, illustrating the potential for healing severe defects in these patients. As with periodontal regeneration in nonaggressive forms of periodontitis, it is important to control local factors and follow sound surgical principles.

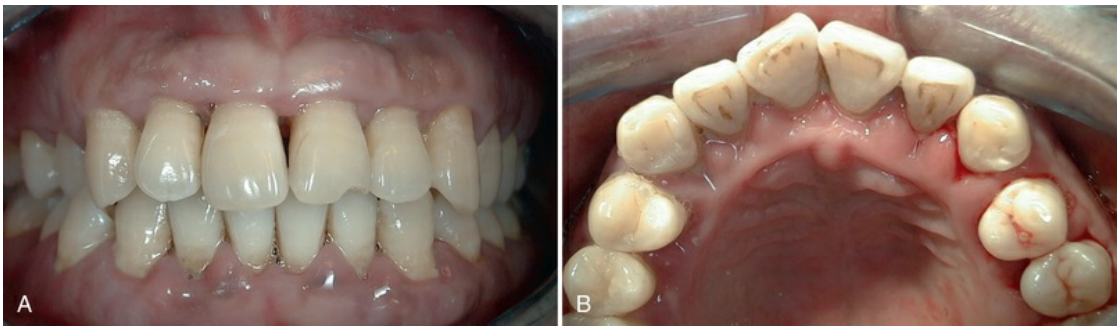
Antimicrobial Therapy

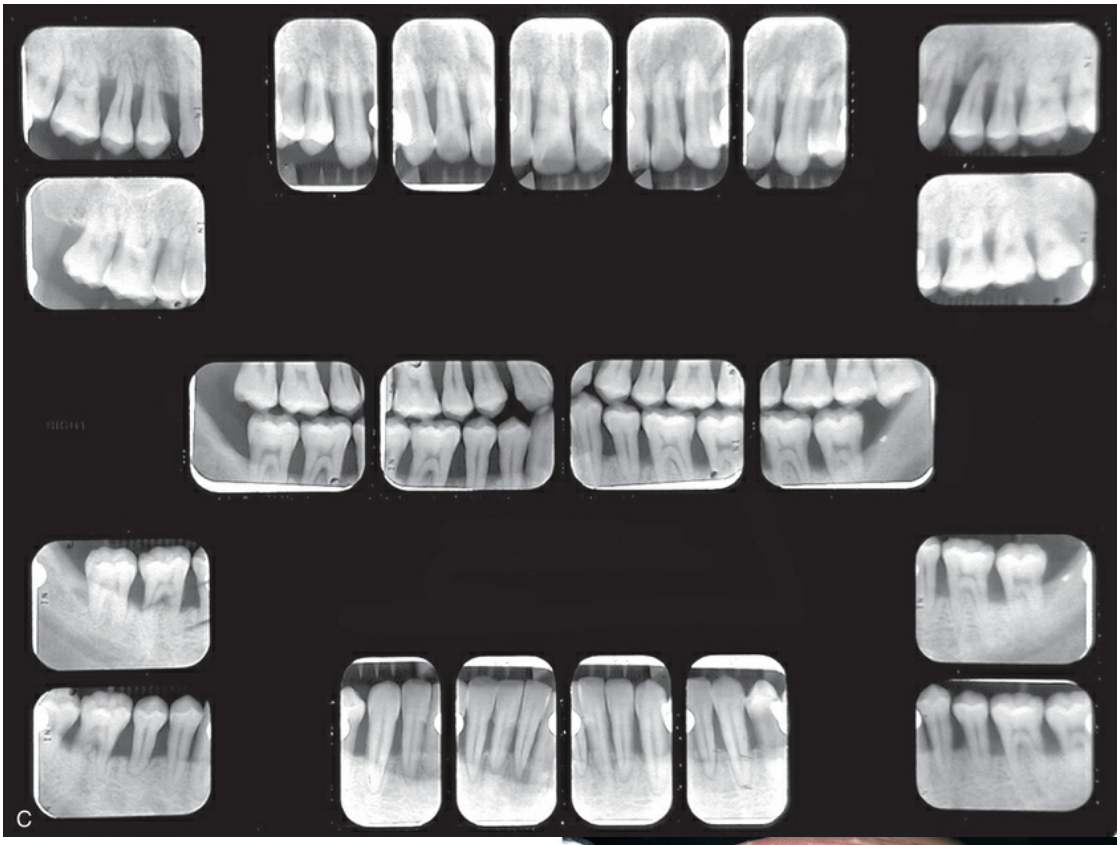
Aggressive periodontitis is a disease with a bacterial etiology. The presence of periodontal pathogens, specifically *Aggregatibacter actinomycetemcomitans,* has been implicated as the reason that aggressive periodontitis does not respond to conventional therapy alone. These pathogens are known to remain in the tissues after therapy and to reinfect the pocket.[9,58] In the late 1970s and early 1980s, the identification of *A. actinomycetemcomitans* as a major culprit and the discovery that this organism penetrates the tissues offered another perspective on the pathogenesis of aggressive periodontitis and new hope for therapeutic success—namely, antibiotics.[9] The use of systemic antibiotics was thought to be necessary to eliminate pathogenic bacteria (especially *A. actinomycetemcomitans*) from the tissues. Indeed, several authors have reported success in the treatment of aggressive periodontitis using antibiotics as adjuncts to standard therapy.[33–35,71]

There is compelling evidence that adjunctive antibiotic treatment frequently results in a more favorable clinical response than mechanical therapy alone.[66] In a systematic review, Herrera and colleagues[23] found that systemic antimicrobials in conjunction with scaling and root planing offered benefits greater than scaling and

planing alone in terms of clinical attachment level, probing pocket depth, and reduced risk of additional attachment loss. Patients with deeper, progressive pockets seemed to benefit the most from systemic administration of adjunctive antibiotics. Many different antibiotic types and regimens were reviewed, but because of limitations in comparing data from different studies, definitive recommendations were not possible. In a meta-analysis of the literature (including six randomized clinical trials), Sgolastra and associates[60] found that the systemic use of combined amoxicillin and metronidazole as an adjunct to scaling and root planing for the treatment of generalized aggressive periodontitis resulted in significant clinical attachment gain (P <0.05) and pocket reduction (P <0.05) compared with scaling and root planing alone.

Fig. 43.2 shows the results of treatment in a case of aggressive periodontitis treated nonsurgically with scaling and root planing and adjunctive antibiotic therapy. The patient, a 34-year-old Asian man, presented with a complaint of loose teeth and bleeding gums. He requested treatment to save his teeth. Treatment consisted of patient education, including oral hygiene instructions, and nonsurgical therapy with adjunctive antibiotics. All teeth were thoroughly scaled and root planed under local anesthesia over two treatment appointments, and the patient was treated with systemic amoxicillin (500 mg, three times daily for 2 weeks) during the period of treatment. All areas responded favorably, with probing pocket depths decreasing from 3–13 mm to 2–5 mm. Bleeding on probing diminished from generalized to very few isolated areas. The patient continued on periodontal maintenance with good results for more than 5 years.





C

D

E

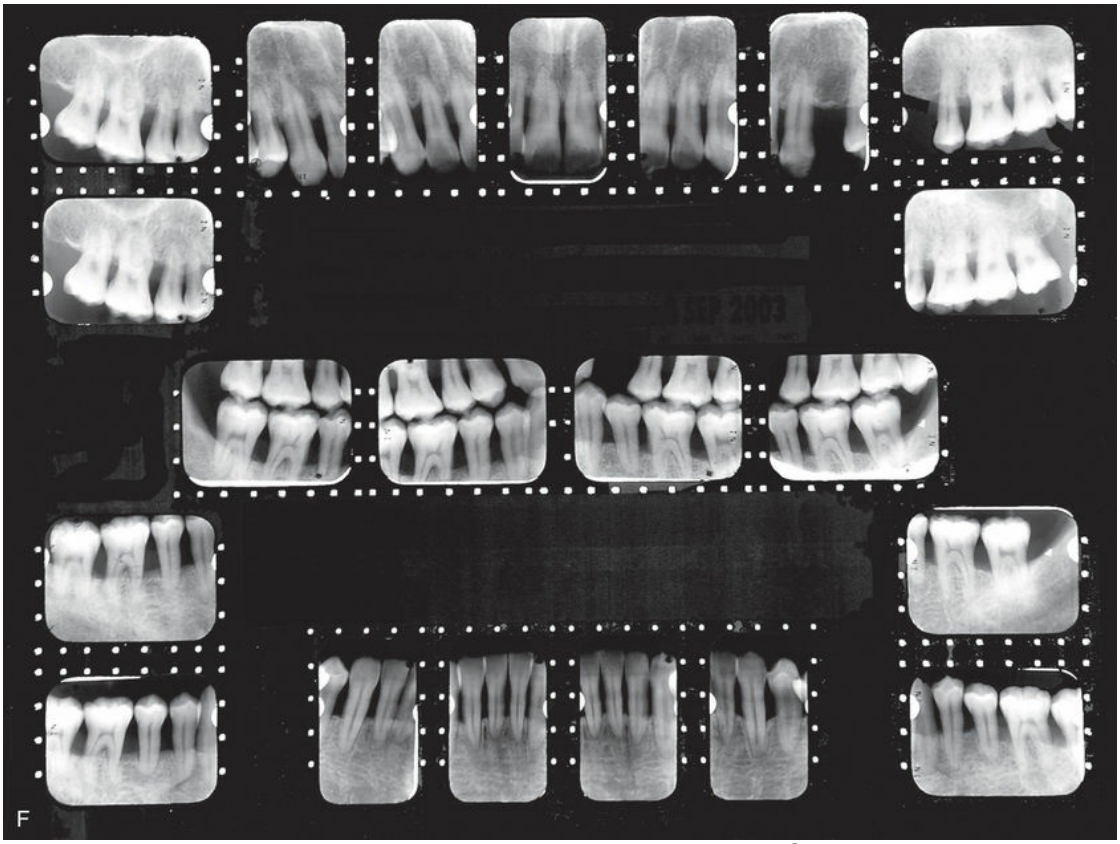


FIG. 43.2 Intraoral clinical photographs and full-mouth radiographs taken before and after treatment of aggressive periodontitis in a 34-year-old Asian man. (A and B) Intraoral clinical photographs of pretreatment periodontal condition. Notice the gingival edema, inflammation, and bleeding. Probing pocket depths ranged from 3 to 13 mm, with generalized bleeding on probing and purulent exudate. (C) Pretreatment full-mouth radiographs demonstrate generalized severe horizontal bone loss. Notice the periapical radiolucency at the apex of the upper left premolar, indicating pulpal disease. (D and E) Intraoral clinical photographs of posttreatment results after 5 years. Treatment included nonsurgical scaling and root planing along with adjunctive systemic antibiotics (amoxicillin). Patient improved his oral hygiene and continued to be seen for professional maintenance every 3 months. Probing pocket depths have been maintained in the range of 2 to 5 mm, with only a few localized areas of bleeding on probing. (F) Full-mouth radiographs after 5 years demonstrate no additional bone loss. The endodontically involved maxillary premolar was extracted and replaced with a removable partial denture.

Genco and coworkers[18] treated localized aggressive periodontitis with scaling and root planing plus systemic administration of tetracycline (250 mg, four times daily for 14 days every 8 weeks). Measurements of vertical defects were made at intervals of up to 18 months after the initiation of therapy. Bone loss stopped, and one-third of the defects demonstrated an increase in bone level, whereas in the control group, bone loss continued.

Liljenberg and Lindhe[33] treated localized aggressive periodontitis with systemic administration of tetracycline (250 mg, four times daily for 2 weeks), modified Widman flaps, and periodic recall visits (one visit every month for 6 months, then one visit every 3 months). The lesions healed more rapidly and more completely than similar lesions in control patients. These investigators reevaluated their results after 5 years and found that the treatment group continued to demonstrate resolution of gingival inflammation, gain of clinical attachment, and refill of bone in angular defects.[34] Figs. 43.3 and 43.4 show radiographs of a case with similar treatment and results.[4]

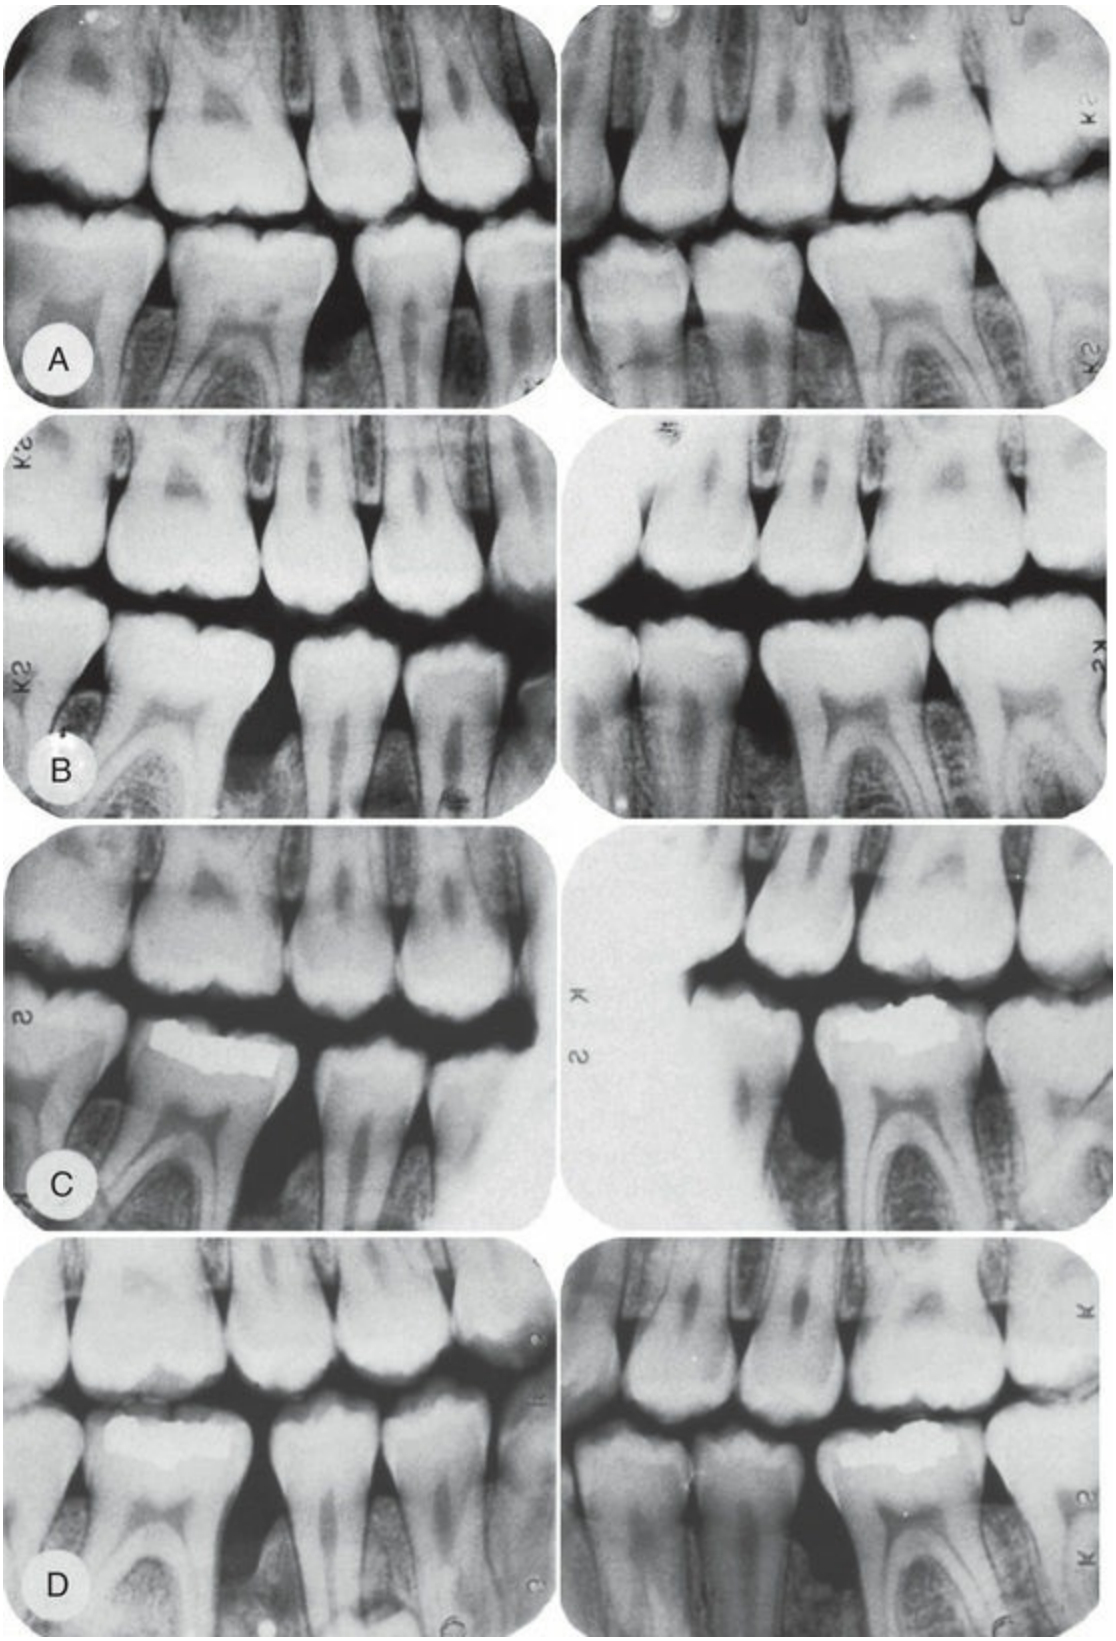

FIG. 43.3 Radiographs depicting progression of an osseous lesion in a patient with localized aggressive periodontitis (formerly “localized juvenile periodontitis”). (A) January 29, 1979; (B) August 16, 1979; (C) February 22, 1980; (D) May 15, 1981. Notice the

progressive deterioration of the osseous level. (From Barnett ML, Baker RL: The formation and healing of osseous lesions in a patient with localized juvenile periodontitis, case report. *J Periodontol* 54:148, 1983.)

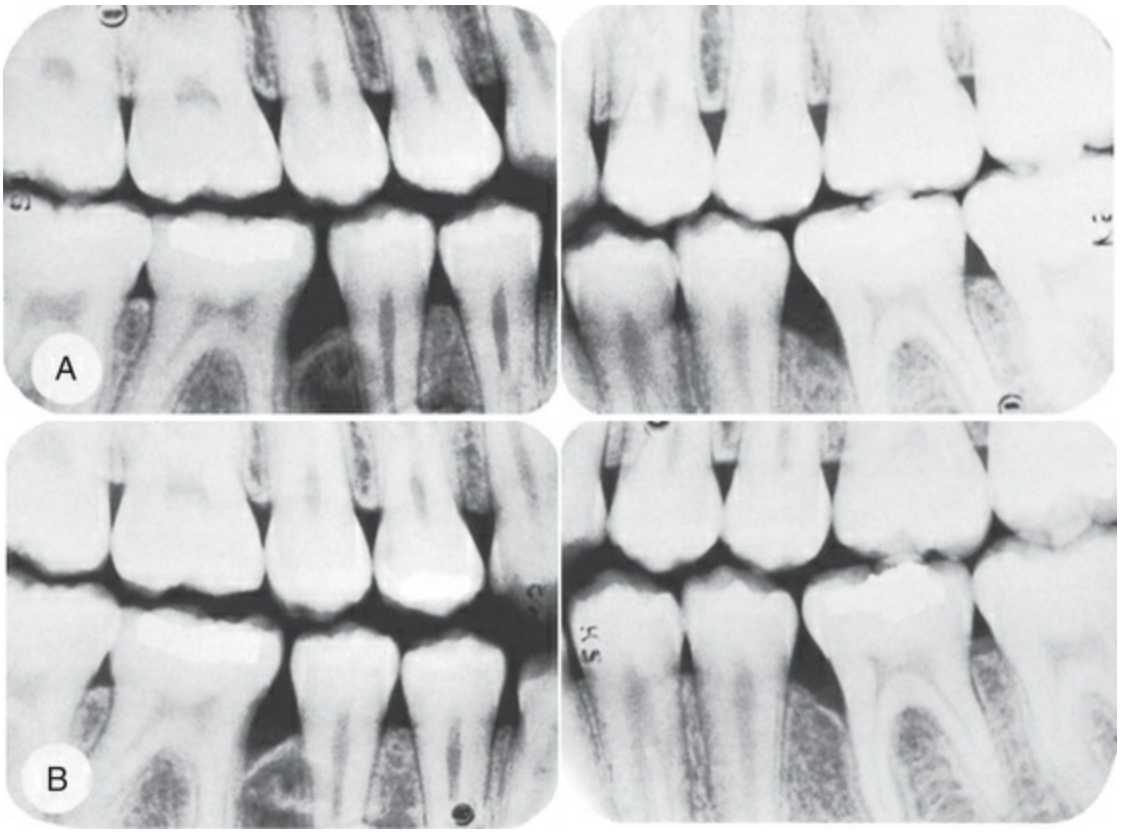

FIG. 43.4 Postoperative radiographs of the patient in Fig. 43.3. (A) November 6, 1981; (B) March 3, 1982. Treatment consisted of oral hygiene instruction, scaling and root planing concurrent with 1 g of tetracycline per day for 2 weeks, and modified Widman flaps. (From Barnett ML, Baker RL: The formation and healing of osseous lesions in a patient with localized juvenile periodontitis, case report. *J Periodontol* 54:148, 1983.)

Numerous studies support the use of adjunctive tetracycline along with mechanical debridement for the treatment of *A. actinomycetemcomitans*–associated aggressive periodontitis (Box 43.1). Given the possible emergence of tetracycline-resistant *A. actinomycetemcomitans,* there is concern that tetracycline may not be effective. In these cases, the combination of metronidazole and amoxicillin may be advantageous. The use of these two antibiotics along with conventional periodontal therapy[21,22] provides better

disease control and better clinical improvement in attachment levels in difficult-to-manage periodontitis than similar periodontal therapy without antibiotics. Similar effects have been seen for a variety of antibiotic types. However, a lack of sufficient sample sizes among studies makes it difficult to offer specific recommendations on which antibiotics are most effective.[23]

Box 43.1

Systemic Tetracycline in the Treatment of Aggressive Periodontitis

Systemic tetracycline (250 mg of tetracycline hydrochloride four times daily for at least 1 week) should be given in conjunction with local mechanical therapy. If surgery is indicated, systemic tetracycline should be prescribed and the patient should be instructed to begin taking it approximately 1 hour before surgery. Doxycycline 100 mg/day may be used instead of tetracycline. Chlorhexidine rinses should be prescribed and continued for several weeks to enhance plaque control and facilitate healing.

The criteria for selecting antibiotics are not clear. Good clinical and microbiologic responses have been reported with several individual antibiotics and antibiotic combinations (Table 43.1). The optimal antibiotic or combination for any particular infection probably depends on the case. Choices must be made based on patient-related and disease-related factors.

TABLE 43.1

Antibiotic Therapy for Aggressive Periodontitis

Associated Microflora	Antibiotic of Choice
Gram-positive organisms	Amoxicillin–clavulanate potassium (Augmentin)[10,68]
Gram-negative organisms	Clindamycin[19,20,64,68]
Nonoral gram-negative facultative rods	Ciprofloxacin[36]
Pseudomonads, staphylococci	
Black-pigmented bacteria and spirochetes	Metronidazole[19,61]
Prevotella intermedia, Porphyromonas gingivalis	Tetracycline[51]
Aggregatibacter actinomycetemcomitans	Metronidazole-amoxicillin[19,61]

	Metronidazole-ciprofloxacin
	Tetracycline[48]
P. gingivalis	Azithromycin[49]

Clinical Correlation

The use of amoxicillin and metronidazole as an adjunctive therapy to scaling and root planing for the treatment of aggressive periodontitis has been shown to significantly improve clinical attachment gain and pocket depth reduction when compared with scaling and root planing alone. Aggressive periodontitis is a disease with a bacterial etiology.

Microbial Testing

Some investigators and clinicians advocate microbial testing to identify the specific periodontal pathogens responsible for disease and selecting an appropriate antibiotic based on sensitivity and resistance. There may be specific cases in which bacterial identification and antibiotic-sensitivity testing is valuable. For example, in some cases of localized aggressive periodontitis, tetracycline-resistant *Actinobacillus* species have been suspected. If an antibiotic susceptibility test determines that tetracycline-resistant species exist in the lesion, the clinician may be advised to consider another antibiotic or an antibiotic combination, such as amoxicillin and metronidazole.[15,51,62]

In practice, antibiotics are often used empirically without microbial testing. One study evaluated and compared the results of microbial testing offered by two independent laboratories.[41,59] Two microbiologic cultures, sampled simultaneously from the same sites in 20 patients, were submitted separately to each of the two laboratories for bacterial identification and antibiotic-sensitivity testing. The reported presence of bacterial species varied between the two laboratories, as did their antimicrobial recommendations. The combination of amoxicillin and metronidazole yielded the highest level of agreement (80%), likely because of the effectiveness of this combination and a clinical predisposition to favor a known regimen. These findings suggested that the usefulness of microbial testing may be limited and led the authors to conclude that the

empiric use of antibiotics, such as a combination of amoxicillin and metronidazole, may be more clinically sound and cost-effective than bacterial identification and antibiotic-sensitivity testing.[41,59]

Nonetheless, microbial testing should be considered whenever a case of aggressive periodontitis is not responding or if the destruction continues despite good therapeutic efforts.

Local Delivery

Local delivery for administration of antibiotics is a novel approach to the management of localized periodontal infections. The primary advantage of local therapy is that smaller total dosages of topical agents can be delivered inside the pocket, avoiding the side effects of systemic antibacterial agents while increasing the exposure of the target microorganisms to higher concentrations and therefore more therapeutic levels of the medication. Local delivery agents are available in many different forms, including solutions, gels, fibers, and chips[16,17,27] (see Chapter 53).

Full-Mouth Disinfection

Another approach to antimicrobial therapy in the control of infection associated with periodontitis is full-mouth disinfection. The concept, described by Quirynen and coworkers,[52] consists of full-mouth debridement (removal of all plaque and calculus) completed in two appointments within a 24-hour period. In addition to scaling and root planing, the tongue is brushed with chlorhexidine gel (1%) for 1 minute, the mouth is rinsed with chlorhexidine solution (0.2%) for 2 minutes, and periodontal pockets are irrigated with chlorhexidine solution (1%).

In a clinical and microbiologic study,[52] 10 patients with advanced chronic periodontitis were randomly assigned to a test or control group. Test patients were treated as just described, whereas control patients received scaling and root planing by quadrant at 2-week intervals along with oral hygiene instructions. At 1 and 2 months after treatment, the test group showed significantly higher reduction in probing pocket depth, especially for deeper pockets (7–8 mm). Patients in the test group also had significantly lower concentrations of pathogenic microorganisms after treatment compared with controls. Several follow-up studies by the same

center demonstrated similar results for up to 6 months after therapy.[5,6,63] In another study, the same researchers included a test group who did *not* use chlorhexidine as part of the one-stage, full-mouth disinfection.[53] The results for both test groups (i.e., with and without chlorhexidine) were similar and were significantly better than for controls. The authors concluded that the beneficial effects of one-stage, full-mouth disinfection probably result from the full-mouth debridement within 24 hours rather than the adjunctive chlorhexidine treatment.

A few reports have included patients with aggressive (early-onset) periodontitis in their evaluation of the one-stage, full-mouth disinfection protocol.[11,45,54] As in patients with advanced chronic periodontitis, De Soete and colleagues[11] found a significant reduction in probing pocket depth and gain in clinical attachment in patients with aggressive periodontitis compared with controls up to 8 months after treatment (scaling and root planing by quadrant at 2-week intervals). They also found significant reductions in periodontal pathogens up to 8 months after therapy. *Porphyromonas gingivalis* and *Tannerella forsythia* were reduced to levels below detection.

Host Modulation

A novel approach in the treatment of aggressive periodontitis and difficult-to-control forms of periodontal disease is the administration of agents that modulate the host response. Several agents have been used or evaluated to modify the host response to disease (see Chapter 54).

Treatment Planning and Restorative Considerations

Successful management of aggressive periodontitis must include tooth replacement as part of the treatment plan. In some advanced cases, the overall treatment success for the patient may be enhanced if severely compromised teeth are extracted. The outcome of treatment for these teeth is limited, and, more important, the retention of severely diseased teeth over time may result in additional bone loss and teeth that are further compromised. The

risk of further bone loss is an even greater concern now, with the current success and predictability of dental implants and the desire to preserve bone for implant placement. Any additional alveolar bone loss in an area that has already undergone severe bone loss may further compromise residual anatomy and impair the opportunity for tooth replacement with a dental implant. This is especially true for certain areas with poor bone quality or limited bone volume, such as the posterior maxilla. Fortunately, healing of extraction sites is typically uneventful in patients with aggressive periodontitis, and bone augmentation of defect sites is predictable.

In the patient with aggressive periodontitis, the approach to restorative treatment should be chosen based on a single premise: Extract severely compromised teeth early, and plan treatment to accommodate future tooth loss. The teeth with the best prognosis should be identified and considered when planning the restorative treatment. The lower cuspids and first premolars are typically more resistant to loss, probably because of the favorable anatomy (i.e., single roots, no furcations) and easier access for patient oral hygiene. As a rule, an extensive fixed prosthesis should be avoided, and removable partial dentures should be planned in such a way as to allow for the addition of teeth.

When hopeless teeth are extracted, they need to be replaced. The desire to replace missing teeth in a permanent manner without preparation of adjacent teeth for a fixed partial denture has motivated clinicians to attempt transplantation of teeth from one site to another. Transplantation of developing third molars to the sockets of hopeless first molars has been attempted with limited success.[7,32,39] Now, however, the success and predictability of dental implants have obviated the need to transplant teeth to edentulous sites.

Use of Dental Implants

Initially, the use of dental implants was suggested for and implemented in patients with aggressive periodontitis with much caution, because of an unfounded fear of bone and implant loss. However, evidence appears to support the use of dental implants in these patients.[37,43,44,46,70] Therefore, it is possible to consider the use of dental implants in the overall treatment plan for patients with

aggressive periodontitis.

There is scant evidence to support the use of bone augmentation procedures in preparation for or in combination with implant placement in patients being treated for aggressive periodontitis. One case report with short-term follow-up suggested that it was successful.[25] A prospective study of 10 patients treated for generalized aggressive periodontitis who underwent guided bone regeneration followed by implant placement found that the implant survival rate was 100% after 3 years.[42] However, slightly greater attachment loss (0.65 mm) and bone loss (1.78 mm) were observed in the aggressive periodontitis group compared with 10 periodontally healthy controls who received implants without bone augmentation.

Clinical Correlation

Special consideration must be given to the risk of occlusal overload of implants placed in a periodontally compromised dentition. This is especially true when only one or a few implants are used to replace a limited number of teeth with an implant-supported fixed crown or bridge in a patient with a moderately mobile remaining dentition. The immobility of implants in a dentition that does not have a stable vertical occlusal stop may lead to implant overload.

Periodontal Maintenance

When patients with aggressive periodontitis are transferred to maintenance care, their periodontal condition must be stable (i.e., no clinical signs of disease and no periodontal pathogens). Each maintenance visit should consist of a medical history review, an inquiry about any recent periodontal problems, an assessment of risk factors, a comprehensive periodontal and oral examination, thorough root debridement, and prophylaxis, followed by a review of oral hygiene instructions. If oral hygiene is not good, patients may benefit most from a review of oral hygiene instructions and visualization of plaque in their own mouth before debridement and prophylaxis.

Frequent maintenance visits appear to be one of the most

important factors in the control of disease and the success of treatment in patients with aggressive periodontitis.[31,64] In a study of 25 individuals with aggressive (early-onset) periodontitis followed with maintenance every 3 to 6 months for 5 years, it was concluded that these patients can be effectively maintained with clinical and microbiologic improvements after active periodontal therapy.[26] High bacterial counts (particularly *P. gingivalis* and *Treponema denticola*), number of acute episodes, number of teeth lost, smoking, and stress appeared to be significant factors in the small percentage of sites that showed progressive bone loss. In a 5-year follow-up study of 13 patients with aggressive periodontitis treated with comprehensive mechanical, surgical, and antimicrobial therapy and supportive periodontal maintenance every 3 to 4 months, periodontal disease progression was arrested in 95% of the initially affected lesions. Only 2% to 5% experienced discrete episodes of loss of periodontal support.[8]

A supportive periodontal maintenance program aimed at early detection and treatment of sites that begin to lose attachment should be established. The interval between these recall visits is short during the first period after the patient's completion of therapy, usually no longer than 3 months. Acute episodes of gingival inflammation can be detected and managed earlier when the patient is on a frequent monitoring cycle. Monitoring as frequently as every 3 to 4 weeks may be necessary when the disease is thought to be active. If signs of disease activity and progression persist despite therapeutic efforts, frequent visits, and good patient compliance, microbial testing may be indicated. The rate of disease progression may be faster in younger individuals, and therefore the clinician should monitor such patients more frequently. Over time, the recall maintenance interval can be adjusted (more or less often) to suit the patient's level of oral hygiene and control of disease, as determined by each examination.

Close collaboration among members of the treatment team, including the periodontist, general dentist, dental hygienist, and patient's physician, is required for continuity of care and for patient motivation and encouragement. It is important to monitor and observe the patient's overall physical status as well, because weight loss, depression, and malaise have been reported in patients with

generalized aggressive periodontitis. Finally, there is a constant need to reinforce patient education about disease etiology and preventive practices (i.e., oral hygiene and control of risk factors).

Periodontitis Refractory to Treatment

Although refractory periodontitis is not currently considered a separate disease entity (see Chapter 5), patients who fail to respond to conventional therapy are considered to have periodontitis that is refractory to treatment. It is possible to characterize any form of periodontal disease (e.g., chronic periodontitis, aggressive periodontitis) as refractory to treatment.

These cases are difficult to manage because the etiology behind their lack of response to therapy is unknown. Initially, because contributing factors may have been overlooked, it is important to evaluate the adequacy of treatment attempts thoroughly and to consider other possible etiologies before concluding that a case truly is refractory. A patient with periodontitis that is refractory to treatment often does not have any distinguishing clinical characteristics on initial examination compared with patients who have periodontitis that responds normally. Therefore the initial treatment would follow conventional therapeutic modalities for periodontitis. After treatment, if the response is not as expected, the clinician should rule out the following conditions:

1. *Inadequately treated periodontitis.* Most forms of periodontitis can be treated effectively with currently available modalities if they are performed properly. After treatment, if it is determined that the patient has not responded, the clinician must evaluate whether the therapy was adequately performed. Undetected or inaccessible subgingival calculus may be present in one or more areas. Retreatment may be the best way to ensure that therapy was adequately performed. All root surfaces must be meticulously inspected.
2. *Poor plaque control.* Plaque control is essential to the success of periodontal therapy.[47,56,57] Patients must understand the role of bacterial plaque in their disease process, and they

must comply with daily oral hygiene instructions. Patient compliance and the adequacy of daily plaque control should be assessed before concluding that a case of periodontitis is refractory to treatment.

3. *Endodontic infection.* The presence of nonperiodontal infections in the area can perpetuate periodontal disease activity and prevent a normal healing response to conventional periodontal therapy. Endodontic infection of teeth in the area should be suspected and ruled out before concluding that a case is refractory to treatment. The clinician should suspect an endodontic etiology especially in those patients with localized recurrent disease.

A case may be considered *refractory* to treatment only when loss of periodontal attachment and bone continues after well-executed treatment in a patient with good oral hygiene and no other infections or etiologic factors.

Clinicians are in a quandary when presented with a patient who is not responding to periodontal therapy. Therapeutic means must be broad in scope and thorough to ensure that all aspects of the host response are addressed. At a minimum, a frequent and intensive recall maintenance and home care program is necessary. Mechanical debridement with scaling and root planing can reduce total supragingival and subgingival bacterial masses, but major periodontal pathogens may persist. Surgical treatment may aid in providing access for debridement and in elimination of bacterial pathogens.[58] In addition, the morphology of the gingival tissues should be modified to facilitate daily plaque removal by the patient.

Systemic antibiotic therapy is administered to reinforce mechanical periodontal treatment and support the host defense system in overcoming the infection by killing subgingival pathogens that remain after conventional mechanical periodontal therapy. Many antibiotics have been used according to the target microflora, with varying degrees of success[20] (see Table 43.1). For patients with refractory disease that fails to respond to initial antibiotic therapy, subsequent treatment should include microbial testing, with bacterial identification and antimicrobial susceptibility.

Antibiotic resistance is a potential problem. Patients with periodontitis that is refractory to treatment often present with a history of previous tetracycline therapy and may have a microflora that is resistant to that drug.[28,38,66,67] Tetracycline-resistant bacteria have been isolated from patients with periodontitis refractory to treatment.[48] However, some patients with refractory disease may still benefit from the use of tetracycline or one of its derivatives.

Cases of refractory periodontitis in which the associated microflora consisted primarily of gram-positive microorganisms have been successfully treated with *amoxicillin–clavulanate potassium.* Many efforts have been made to establish the most appropriate regimen of antibiotic therapy for these patients. A regimen consisting of 250 mg of amoxicillin and 125 mg of clavulanate potassium administered three times daily for 14 days, together with scaling and root planing, produced a reduction in attachment loss for at least 12 months. A regimen of one capsule containing the same amount of drug every 6 hours for 2 weeks, with intrasulcular full-mouth lavage using a 10% povidone-iodine solution and chlorhexidine oral rinses twice daily, resulted in a reduction in attachment loss that persisted at approximately 34 months.[10] A regimen of 500 mg of metronidazole three times daily for 7 days was shown to be effective in treating refractory periodontitis in patients who were culture positive for *T. forsythia* in the absence of *A. actinomycetemcomitans.*[69]

Clindamycin is a potent antibiotic that penetrates well into gingival fluid, although it is not usually effective against *A. actinomycetemcomitans* or *Eikenella corrodens.*[66] Clindamycin has been effective in controlling the extent and rate of disease progression in refractory cases in patients who have a microflora susceptible to this antibiotic.[20,36,65] A regimen of clindamycin hydrochloride 150 mg four times daily for 7 days, combined with scaling and root planing, produced a decrease in the incidence of disease activity from an annual rate of 8% to 0.5% of sites per patient.[19] Clindamycin should be prescribed with caution because of the potential for pseudomembranous colitis due to superinfection with *Clostridium difficile.* Patients should be warned and advised to discontinue the antibiotic if symptoms of diarrhea develop.

Azithromycin may be effective in periodontitis that is refractory to

treatment, especially in patients infected with *P. gingivalis.*[49]

Combinations of antibiotic therapy may offer greater promise as adjunctive treatment for the management of refractory periodontitis.[2,10,15,38] The rationale is based on the diversity of putative pathogens[18,62] and the fact that no single antibiotic is bactericidal for all known pathogens. Combination antibiotic therapy may help broaden the antimicrobial range of the therapeutic regimen beyond that attained by any single antibiotic. Other advantages include lowering the dose of individual antibiotics by exploiting the possible synergy between two drugs against targeted organisms. In addition, combination therapy may prevent or forestall the emergence of bacterial resistance. Many combinations of antibiotics have demonstrated significant improvement in the clinical aspects of the disease.[38] Examples of combinations include amoxicillin-clavulanate[15] or metronidazole-amoxicillin for the treatment of *A. actinomycetemcomitans*–associated periodontitis; metronidazole-doxycycline for the prevention of recurrent periodontitis; metronidazole-ciprofloxacin[55] for the treatment of recurrent cases that involve a microflora associated with enteric rods and pseudomonads; and amoxicillin-doxycycline[38] in the treatment of periodontitis associated with *A. actinomycetemcomitans* and *P. gingivalis.*

Some cases of periodontitis that are refractory to treatment may not respond to a given antibiotic regimen. When this occurs, the clinician should consider a different antimicrobial therapy based on microbial susceptibility analysis. At this point in the therapy, strong consideration should be given to consulting with the patient's physician for evaluation of a possible host immune system deficiency or a metabolic problem such as diabetes.

Necrotizing Ulcerative Periodontitis

Necrotizing ulcerative periodontitis (NUP) is a rare disease, especially in developed countries. Often, NUP is diagnosed in individuals with a compromised host immune response. The incidence of NUP in specific populations, such as patients who are positive for human immunodeficiency virus (HIV) infection or have acquired immunodeficiency syndrome (AIDS), has been reported to

be between 0% and 6%. Most patients diagnosed with NUP have diseases or conditions that impair their host immune response. These patients often have an underlying predisposing systemic factor that renders them susceptible to NUP disease. For this reason, patients presenting with NUP should be treated in consultation with their physician.

A comprehensive medical evaluation and diagnosis of any condition that may be contributing to an altered host immune response should be completed. It is also important to rule out any hematologic disease (e.g., leukemia) before initiating treatment of any case that has a similar presentation to NUP (see Figs. 14.13 and 14.15 in Chapter 14).

Treatment can be initiated only after a thorough medical history and examination to identify the existence of any systemic diseases. Treatment for NUP includes local debridement of lesions with scaling and root planing, lavage, and instructions for good oral hygiene. It may be necessary to use local anesthesia during the debridement because lesions are frequently painful. The use of ultrasonic instrumentation with profuse irrigation may enhance debridement and flushing of deep lesions. Achieving good oral hygiene may also be challenging until the lesions and associated pain resolve.

Antimicrobial adjuncts, such as chlorhexidine, added to the oral hygiene regimen may contribute to the daily reduction of bacterial loads. Patients frequently complain of pain. Locally applied topical antimicrobials and systemic antibiotics, as well as systemic analgesics, should be used as indicated by signs and symptoms.

Patients with NUP often harbor bacteria, fungi, viruses, and other nonoral microorganisms, complicating the selection of antimicrobial therapy. Superinfection or overgrowth of fungi and viruses may be propagated by antibiotic therapy. Antifungal and/or antiviral agents may be considered against these infections prophylactically or after they are diagnosed. Because oral hygiene for these patients is complicated by the painful lesions, alternative methods should be encouraged. Irrigation with diluted cleansing and antibacterial agents can be of some benefit.

Ultimately, the successful treatment of NUP may depend on the resolution or treatment of the systemic condition (e.g., immune

compromise) that predisposed the individual to the disease. Evaluation and treatment of patients with known systemic conditions, such as HIV infection, should be coordinated with the patient's physician.

Conclusions

Treatment of aggressive and atypical forms of periodontal disease is challenging for clinicians because these forms are infrequently encountered, can manifest with more severe bone loss, and do not respond as predictably or as favorably to conventional therapy. Fortunately, only a small percentage of patients are diagnosed with these forms of periodontitis. This chapter discussed therapies and rationales for management of these challenging cases.

Case Scenario 43.1

Patient:
21-year-old Asian female

Chief Complaint:
"My dentist said I have bone loss."

Background Information:

- No systemic medical conditions
- Medications: oral contraceptives
- No use of tobacco, recreational drugs, or alcohol
- Infrequent dental care throughout life

Clinical Findings:
Localized erythema and edema between the mandibular right lateral and canine (#26–27) with light plaque and calculus. Probing depths are generalized 2–3 mm with localized 6 mm at the mesial surface of the canine, #27, and 9 mm at the distal surface of the lateral incisor, #26, with bleeding on probing. Radiographs reveal a localized vertical defect on the distal aspect of the lateral incisor.

Otherwise, there are normal bone levels.

A. Buccal view B. Lingual view

Case-Based Question	Solution and Explanation
1. Which of the following is the most appropriate treatment choice? A. Extract #26 and #27 because response to treatment is unpredictable. B. Provide oral hygiene instructions (OHI) and place patient on a 3-month recall to monitor disease progression. C. Provide OHI, prescribe antibiotics, and place patient on a 3-month recall. D. Provide OHI, prescribe antibiotics in conjunction with scaling and root planing, and reevaluate in 4–6 weeks.	**Answer: D** **Explanation:** Aggressive periodontitis may respond unpredictably, but it can and should be treated. Systemic antibiotics have been shown to improve results in atypical and refractory cases of periodontitis, but only when used in conjunction with mechanical debridement.
2. Which microbe has been implicated in aggressive periodontitis that may reduce the response to conventional therapy? A. *Porphyromonas gingivalis* B. *Aggregatibacter actinomycetemcomitans* C. *Prevotella intermedia* D. *Fusobacterium nucleatum*	**Answer: B** **Explanation:** Studies have shown that *A. actinomycetemcomitans* has the ability to penetrate into the tissues, preventing its removal with conventional therapy and allowing it to continually reinfect the pocket environment.

3. Implants are *not* an appropriate option to replace a missing tooth for a patient with a history diagnosis of aggressive periodontitis. A. True B. False	**Answer: B** **Explanation:** Although any form of active periodontal disease is a contraindication to implant therapy, implants have been shown to be successful in patients with treated/resolved aggressive periodontitis.

CHAPTER 44

Treatment of Acute Gingival Disease

Perry R. Klokkevold, Fermin A. Carranza

CHAPTER OUTLINE

Necrotizing Ulcerative Gingivitis
Primary Herpetic Gingivostomatitis
Pericoronitis
Conclusion

The treatment of acute gingival disease entails alleviation of the acute symptoms and elimination of all etiologic factors, including periodontal disease, both chronic and acute, throughout the oral cavity. Treatment is not complete if periodontal pathologic changes or predisposing factors capable of causing them remain. Systemic risk factors that increase susceptibility to these acute gingival diseases also need to be assessed and eliminated or modified if possible.

Necrotizing Ulcerative Gingivitis

Necrotizing ulcerative gingivitis (NUG) results from an impaired host response to a potentially pathogenic microflora. Depending on the degree of host compromise or immunosuppression, NUG may occur in a mouth essentially free of other gingival involvement or may be superimposed on underlying chronic gingival or periodontal disease. Treatment should include alleviation of the acute symptoms and correction of the underlying chronic gingival or periodontal disease. The former is the simpler part of the treatment; the latter often requires more comprehensive procedures, follow-up, and patient education.

The treatment of NUG consists of (1) alleviation of the acute inflammation by reduction of the microbial load and removal of necrotic tissue, (2) treatment of chronic disease either underlying the acute involvement or elsewhere in the oral cavity, (3) alleviation of generalized symptoms such as fever and malaise, and (4) correction of systemic conditions or factors that contribute to the initiation or progression of gingival changes. Chapter 30 provides further information on the management and treatment of NUG necrotizing ulcerative periodontitis (NUP) in patients with acquired immunodeficiency syndrome (AIDS).

Treatment of NUG should follow an orderly sequence, according to specific steps, at three clinical visits.

First Visit

At the first visit, the clinician should conduct a comprehensive evaluation of the patient, including a thorough medical history, with special attention to recent illness, living conditions, dietary background, cigarette smoking, type of employment, hours of rest, risk factors for human immunodeficiency virus (HIV) infection, and psychosocial parameters (e.g., stress, depression). The patient is questioned regarding the history of the acute disease, including its onset and duration, as follows:

- Is the disease recurrent?
- Are the recurrences associated with specific

factors such as menstruation, particular foods, exhaustion, or mental stress?
- Has there been any previous treatment? When and for how long?

The clinician should also inquire as to the type of treatment received and the patient's impression regarding the effectiveness of previous treatment.

The initial physical examination should include an assessment of general appearance, presence of halitosis, presence of skin lesions, vital signs including temperature, and palpation for the presence of enlarged lymph nodes, especially submaxillary and submental nodes.

The oral cavity is examined for the characteristic NUG lesions (see Chapter 20), distribution, and the possible involvement of the oropharyngeal region. Oral hygiene is evaluated, with special attention to the presence of pericoronal flaps, periodontal pockets, and local risk factors (e.g., poorly contoured and ill-fitting restorations, presence and distribution of calculus). Periodontal probing of NUG lesions is likely to be very painful, will not aid in the primary diagnosis, and may need to be deferred until after the acute lesions are resolved.

Key Fact

The goals of initial therapy for NUG are reduction of the microbial load and removal of necrotic tissue to facilitate the healing process of repair and regeneration so that normal tissue barriers can be reestablished.

The goals of initial therapy are reduction of the microbial load and removal of necrotic tissue to the degree that repair and regeneration of normal tissue barriers can be reestablished. Treatment during the initial visit is confined to the acutely involved areas, which are isolated with cotton rolls and dried. A topical anesthetic is applied, and after 2 or 3 minutes the areas are gently

swabbed with a moistened cotton pellet to remove the pseudomembrane and nonattached surface debris. Bleeding may be profuse. Each cotton pellet is used in a small area, then discarded; sweeping motions over large areas with a single pellet are not recommended. After the area is cleansed with warm water, the superficial calculus is removed. Ultrasonic scalers are very useful for this purpose, because they do not elicit pain and the water jet and cavitation aid in lavage of the area.

Subgingival scaling and curettage are contraindicated at this time, because these procedures may extend the infection into the deeper tissues and may also cause bacteremia. *Unless an emergency exists, procedures such as extractions or periodontal surgery are postponed until the patient has been symptom free for 4 weeks, to minimize the likelihood of exacerbating the acute symptoms.*

Antibiotics are effective in the treatment of patients with NUG.[5] Patients with moderate or severe NUG and local lymphadenopathy or other systemic signs or symptoms are placed on an antibiotic regimen of amoxicillin 500 mg orally every 6 hours for 10 days. For amoxicillin-sensitive patients, other antibiotics are prescribed, such as erythromycin (500 mg every 6 hours) or metronidazole (500 mg twice daily for 7 days). Systemic complications should subside in 1 to 3 days. *Antibiotics are not recommended in NUG patients who do not have systemic complications.*

Instructions to the Patient

The patient is discharged with the following instructions:

1. Avoid tobacco, alcohol, and condiments.
2. Rinse with a glassful of an equal mixture of 3% hydrogen peroxide and warm water every 2 hours and/or 0.12% chlorhexidine solution twice daily.
3. Get adequate rest. Pursue usual activities, but avoid excessive physical exertion or prolonged exposure to the sun, as in golfing, playing tennis, swimming, or sunbathing.
4. Confine toothbrushing to removal of surface debris with either a bland dentifrice or just water and an ultrasoft brush; overzealous brushing and the use of dental floss or interdental cleaners will be painful. Chlorhexidine mouth

rinses are also helpful in controlling biofilm throughout the mouth.

5. An analgesic, such as a nonsteroidal antiinflammatory drug (NSAID; e.g., ibuprofen), is appropriate for pain relief.
6. Patients who have systemic complications such as high fever, malaise, anorexia, or general debility are given antibiotics and instructed to get plenty of bed rest and drink lots of fluids.

Patients are asked to report back to the clinician in 1 to 2 days. They should be advised about the extent of total treatment required to resolve the condition and warned that treatment is not complete when pain stops. They should be informed of the presence of chronic gingival or periodontal disease, which must be eliminated to reduce the likelihood of recurrence of the acute symptoms.

A large variety of drugs have been used in the treatment of NUG.[3] Topical drug therapy, however, is only an adjunctive measure; no drug, when used alone, can be considered complete therapy. Systemic antibiotics, when used, also reduce the oral bacterial flora and alleviate the oral symptoms,[12,13] but they are only an adjunct to the complete local treatment that the disease requires. If patients are treated by drugs or systemic antibiotics alone, the acute painful symptoms often reoccur after treatment is discontinued.

Second Visit

At the second visit, 1 or 2 days after the first visit, the patient is evaluated for amelioration of signs and symptoms. The patient's condition is usually improved; the pain is diminished or is no longer present. The gingival margins of the involved areas are erythematous but without a superficial pseudomembrane.

Scaling is performed if it is necessary and sensitivity permits. Shrinkage of the gingiva may expose previously covered calculus, which is gently removed. Instructions to the patient are the same as those given previously.

Third Visit

At the next visit, approximately 5 days after the second visit, the patient is evaluated for resolution of symptoms, and a comprehensive plan for management of the patient's periodontal condition is formulated. The patient should be essentially symptom-free at this time. Some erythema may still be present in the involved areas, and the gingiva may be slightly painful on tactile stimulation (Fig. 44.1A and B). The patient is instructed in biofilm control procedures (see Chapter 48), which are essential for the success of the treatment and the maintenance of periodontal health. The patient is further counseled on nutrition, smoking cessation, and other conditions or habits associated with potential recurrence. The hydrogen peroxide rinses are discontinued, but chlorhexidine rinses may be maintained for an additional 2 or 3 weeks. Scaling and root planing is repeated if necessary. Unfortunately, patients often discontinue treatment because the acute condition has subsided; however, this is when comprehensive treatment of the chronic periodontal problem should begin. Patients need to be educated about the importance of comprehensive periodontal treatment and encouraged to complete it.

FIG. 44.1 (A) Initial view of the anterior gingival tissues in a 22-year-old white female smoker with acute necrotizing ulcerative gingivitis. (B) Palatal view of the

same patient. (C) Facial view of the same patient, 2 days after initial scaling and cessation of smoking. (D) Palatal view of the same patient, 2 days after initial scaling and cessation of smoking. (From Rose LF, Mealey BL, Genco RJ, Cohen DW: *Periodontics: medicine, surgery, and implants*, Mosby, St. Louis, 2005.)

Appointments should be scheduled for treatment of chronic gingivitis, periodontal pockets, and pericoronal flaps, as well as for elimination of all forms of local risk factors (see Chapter 13). The patient should be reevaluated approximately 4 to 6 weeks after treatment to determine compliance with oral hygiene, health habits, psychosocial factors, the potential need for reconstructive or esthetic surgery, and the interval of subsequent recall visits.

Gingival Changes With Healing

The characteristic lesion of NUG undergoes the following changes during the course of healing in response to treatment:

1. Removal of the surface pseudomembrane exposes underlying red, hemorrhagic, craterlike depressions in the gingiva, indicating inflammation caused by necrosis and microbial infiltration of tissue that has lost the normal barrier function of the epithelium.
2. In the next stage, the bulk and redness of the crater margins are reduced, indicating a reduction in inflammation and reepithelialization, but the surface remains shiny (see Fig. 44.1C and D).
3. This is followed by the early signs of restoration of normal gingival contour and color, indicating reestablishment of the normal barrier function of the epithelium, including keratinization, and further reduction of inflammation.
4. In the final stage, the normal gingival color, consistency, surface texture, and contour may be restored. Portions of the root exposed by the acute disease may be covered by healthy gingiva (Fig. 44.2).

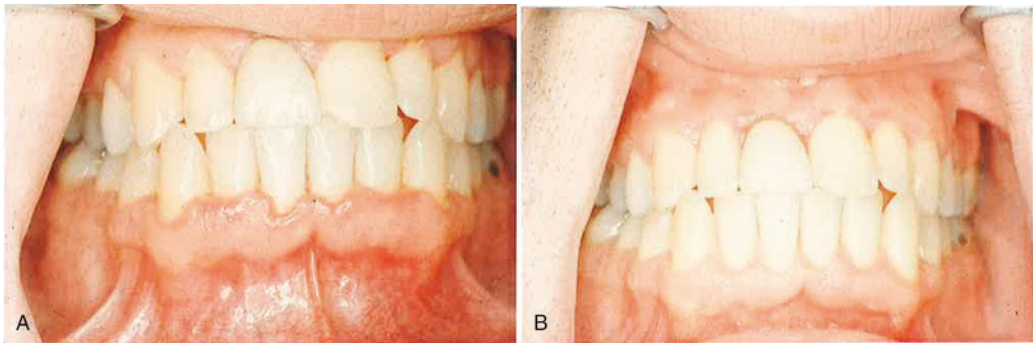

FIG. 44.2 Treatment of acute necrotizing ulcerative gingivitis. (A) Before treatment. Notice the characteristic interdental lesions. (B) After treatment, showing restoration of healthy gingival contour.

Additional Treatment Considerations

Contouring of Gingiva as an Adjunctive Procedure

Even in cases of severe gingival necrosis, healing often leads to restoration of the normal gingival contour, although normal architecture of the gingiva may be achieved only after several weeks or months. However, if there has been loss of interdental bone, if the teeth are irregularly aligned, or if the entire papilla is lost, healing sometimes results in the formation of a shelf-like gingival margin, which favors retention of biofilm and recurrence of gingival inflammation and is an esthetic problem. This can be corrected by an attempt to restore lost tissue through periodontal plastic procedures or by reshaping the gingiva surgically (Fig. 44.3). Effective biofilm control by the patient is particularly important to establish and maintain the normal gingival contour in areas of tooth irregularity.

FIG. 44.3 Reshaping the gingiva in the treatment of acute necrotizing ulcerative gingivitis. (A) Before

treatment. Bulbous gingiva and interdental necrosis are present in the mandibular anterior area. (B) After treatment. Gingival contours are still undesirable. (C) Final result. Physiologic contours are obtained by reshaping the gingiva.

Role of Drugs

A large variety of drugs have been used for topical treatment of NUG. Topical drug therapy is only an adjunctive measure. *No drug, when used alone, can be considered complete treatment*.

Escharotic drugs, such as phenol, silver nitrate, chromic acid, or potassium bichromate, should not be used. They are necrotizing agents that alleviate pain by destroying the nerve endings of the ulcerated gingiva but also destroy young cells that are needed for repair and delay healing. Repeated use of these agents results in loss of gingival tissue that is not restored when the disease subsides.[4]

Key Fact

No drug, when used alone, can be considered complete treatment for the resolution of acute gingival disease (e.g., NUG). Local therapy and elimination of risk factors are essential for complete resolution.

Persistent or Recurrent Cases

Adequate local therapy with optimal home care will resolve most cases of NUG. If a case of NUG persists despite therapy or if it recurs, the patient should be reevaluated, with a focus on the following factors:

1. *Reassessment of differential diagnosis to rule out diseases that resemble NUG.* Several diseases and conditions (e.g., desquamative gingivitis) may initially manifest with an appearance similar to that of NUG. A renewed search for skin lesions and other signs or symptoms should be

undertaken, with a biopsy if warranted (see Chapter 22).

2. *Underlying systemic disease causing immunosuppression.* In particular, HIV infection may frequently manifest with symptoms of NUG or necrotizing ulcerative periodontitis (NUP). The patient should be reassessed for risk factors and may need counseling about testing for HIV or other suspected underlying systemic diseases (e.g., lymphoproliferative disease). The patient will likely need referral to his or her physician for further evaluation.
3. *Inadequate local therapy.* Too often, treatment is discontinued when the symptoms have subsided, without elimination of the chronic gingival disease and periodontal pockets that remain after the superficial acute condition is relieved. Remaining calculus and other local factors that predispose to gingival inflammation may contribute to recurrence. Recurrent acute involvement in the mandibular anterior area can be associated with persistent pericoronal inflammation arising from partial eruption and pericoronal inflammation of third molars.[9] Anterior involvement is less likely to recur after the third molar situation is corrected.
4. *Inadequate compliance.* Poor biofilm control, heavy use of tobacco, ineffective stress management, and continued malnutrition can also contribute to persistence or recurrence of NUG. The clinician should evaluate the quality and consistency of biofilm control. Further assessment and counseling on tobacco use will also determine the role of tobacco. If the clinician perceives that unresolved psychosocial factors are complicating health, the patient should be referred to an appropriate professional. A reassessment of the patient's nutritional state, with dietary analysis or nutritional testing, may be required.[6,8]

Clinical Correlation

Acute gingival disease may be a sign of a more serious systemic condition such as acquired immunodeficiency disease (AIDS) or another condition that renders the host immunocompromised.

Primary Herpetic Gingivostomatitis

Primary infection with herpes simplex virus in the oral cavity results in a condition known as acute herpetic gingivostomatitis, which is an oral infection that is often accompanied by systemic signs and symptoms (see Chapter 20). This infection typically occurs in children but can occur in adults as well. It runs a 7- to 10-day course and usually heals without scarring. A recurrent herpetic episode may be precipitated by dental treatment,[14] respiratory infection, sunlight exposure, fever, trauma, exposure to chemicals, or emotional stress in individuals with a history of herpesvirus infection.

Treatment consists of early diagnosis and immediate initiation of antiviral therapy. Historically, therapy for primary herpetic gingivostomatitis consisted of palliative care alone. However, since the development of antiviral therapy, the standard of care now includes the use of antiviral medications. In a randomized, double-blind, placebo-controlled study, Amir and colleagues[1] demonstrated that antiviral therapy with 15 mg/kg of an acyclovir suspension given five times daily for 7 days substantially changed the course of the disease without significant side effects. Acyclovir reduced the duration of symptoms, including fever, from 3 days to 1 day, decreased new extraoral lesions from 5.5 to 0 days, and reduced difficulty with eating from 7 to 4 days. Furthermore, viral shedding stopped at 1 day for the acyclovir group but persisted up to 5 days for the control group. Overall, oral lesions were present for only 4 days in the acyclovir group but persisted for 10 days in the control group. Although no clear clinical evidence indicates that this regimen will reduce recurrences, research data suggest that a greater number of latent virus copies incorporated into ganglia will increase the severity of recurrences.[1]

« Flash Back

As part of the primary infection, the herpes simplex virus (HSV) ascends through the sensory and autonomic nerves, where it persists as latent HSV in neuronal ganglia that innervate the site.

In summary, if primary herpetic gingivostomatitis is diagnosed within 3 days of onset, acyclovir suspension should be prescribed: 15 mg/kg 5 times daily for 7 days. If diagnosis occurs more than 3 days after onset in an immunocompetent patient, acyclovir therapy may have limited value. All patients, including those who present more than 3 days after disease onset, may receive palliative care, including removal of biofilm and food debris. An NSAID (e.g., ibuprofen) can be given systemically to reduce fever and pain. Patients may either take nutritional supplements or use topical anesthetics (e.g., viscous lidocaine) before eating to aid in proper nutrition during the early phases of acute herpetic gingivostomatitis. Periodontal therapy should be postponed until the acute symptoms subside to avoid the possibility of exacerbation (Fig. 44.4).

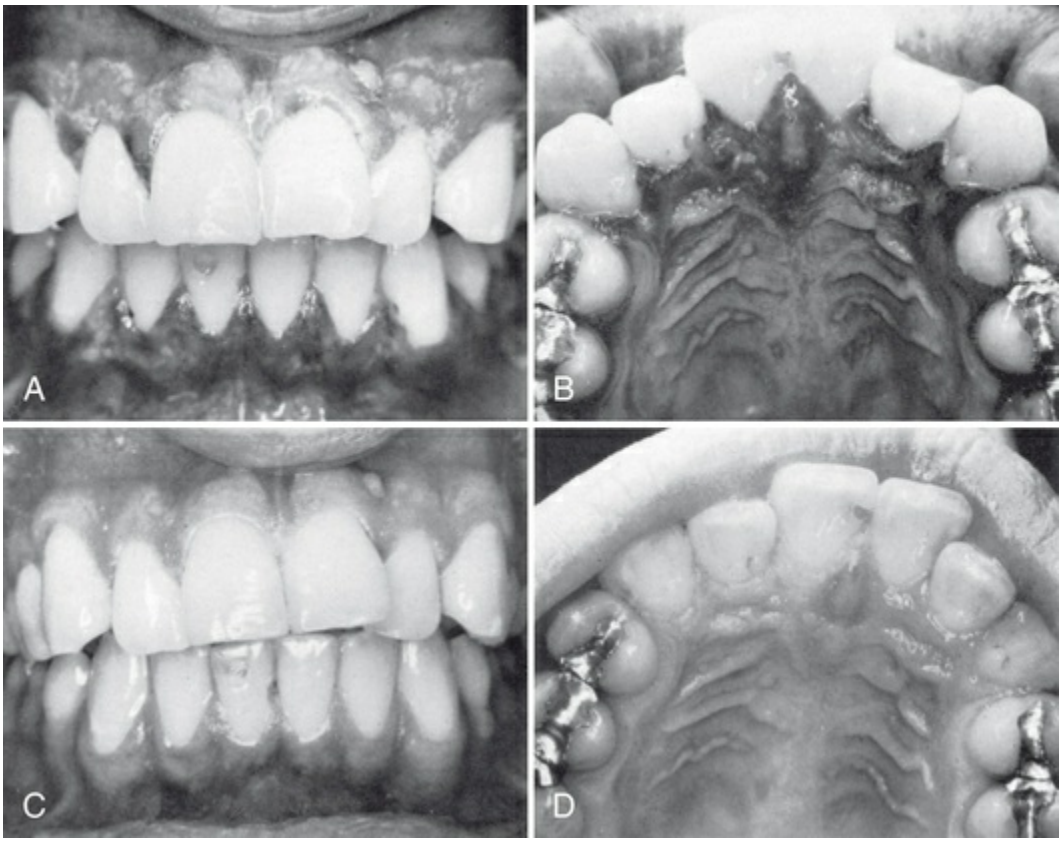

FIG. 44.4 Treatment of acute herpetic gingivostomatitis. (A) Before treatment. Note diffuse erythema and surface vesicles. (B) Before treatment, palatal view, showing gingival edema and ruptured vesicle on palate. (C) One month after treatment,

showing restoration of normal gingival contour and stippling. (D) One month after treatment, palatal view.

Local or systemic application of antibiotics is sometimes advised to prevent opportunistic bacterial or fungal infection of ulcerations, especially in the immunocompromised patient. If the condition does not resolve within 2 weeks, the patient should be referred to a physician for medical consultation.[7] The patient should be informed that herpetic gingivostomatitis is contagious at certain stages, such as when vesicles are present (highest viral titer). All individuals exposed to an infected patient should take precautions. Herpetic infection of a clinician's finger, referred to as *herpetic whitlow,* can occur if a seronegative clinician is exposed and becomes infected with herpesvirus from a patient's herpetic lesions.[10,11]

Pericoronitis

As described in Chapter 20, pericoronitis refers to inflammation of the excess flap of soft tissue that overlies the crown of an incompletely erupted tooth. It is most frequently associated with mandibular third molars (see Fig. 20.10 in Chapter 20). The treatment of pericoronitis depends on several factors, including position and quality of the surrounding tissues, severity of the inflammation, presence and/or risk of systemic complications, and advisability of retaining the involved tooth. All pericoronal flaps, even in the absence of symptoms, should be viewed with suspicion. Strong consideration should be given to removal of any pericoronal flaps that persist as a preventive measure against subsequent acute involvement.

The initial treatment of acute pericoronitis consists of (1) gently flushing the area with warm water to remove debris and exudate and (2) swabbing with antiseptic after the pericoronal flap has been lifted gently away from the tooth with an instrument. The underlying debris is removed, and the area is flushed with warm water. The occlusion is evaluated to determine whether an opposing tooth is contacting the pericoronal flap. It may be necessary to reduce soft tissue surgically and/or adjust the opposing tooth as a palliative measure to alleviate pain. Antibiotics

can be prescribed in severe cases and for patients who have clinical evidence of diffuse microbial infiltration of the tissue. If the pericoronal flap is swollen and fluctuant, an incision and drainage procedure may be indicated to establish drainage and relieve pressure.

Once the acute symptoms have subsided, the prognosis of the tooth can be evaluated. The decision is governed by the likelihood that the tooth will continue erupting into a functional position or that impaction and the factors predisposing to pericoronitis will persist. Bone loss on the distal surface of the second molar is a concern when third molars are impacted along the distal surface (see Chapter 60).[2] The problem is significantly greater if the third molars are extracted after the roots are formed or when the patient is older (i.e., mid-twenties or later). To reduce the risk of bone loss around second molars, partially or completely impacted third molars should be extracted early in their development.

The quality of the soft tissues and the amount of space and vestibular depth are important factors to assess when deciding whether to retain or extract the tooth. If the decision is made to retain the tooth, the pericoronal flap is surgically reduced. It is necessary to reduce and reposition the tissue distal to the coronal aspect of the tooth, as well as remove the pericoronal flap on the occlusal surface. See Chapter 60 for a detailed description of distal surgical procedures and the proper management of tissues posterior to mandibular molars. Simply excising the occlusal portion of the pericoronal flap without managing the distal tissue leaves a deep periodontal pocket on the distal surface, which invites recurrence of acute pericoronal involvement. It is critical to leave the patient with a site that is cleansable and maintainable. As always, patient education and appropriate instruction in long-term maintenance of periodontal health is an essential part of successful therapy.

Conclusion

The treatment of acute gingival disease requires an accurate assessment and diagnosis of the problem that includes identification of risk factors. The objective of initial therapy is the

alleviation of acute symptoms and elimination of all local and systemic contributing factors. Treatment is not complete if predisposing factors remain. Systemic risk factors that increase susceptibility to acute gingival disease should be eliminated or reduced.

Case Scenario 44.1

Patient:
24-year-old male

Chief Complaint:
"It hurts to bite, and my gums are swollen in the back."

Background Information:
Patient is a nonsmoker. Patient is overweight but denies serious illness. He brushes almost every day. He does not floss. He has never been to the dentist.

Current Findings:
Examination reveals a flap of tissue overlying the distal aspect of both mandibular third molars. There is no keratinized attached tissue and very little vestibular depth. There is generalized inflammation of the gingival margins. Probing depths are in the range of 2–4 mm with localized areas of 5–7 mm. Bleeding on probing is 84%. Oral hygiene is poor.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Does this patient appear to be suffering from pericoronitis? A. Yes B. No	**Answer: A** **Explanation:** Pericoronitis refers to inflammation of the excess flap of soft tissue overlying the crown of an incompletely erupted tooth, most often a mandibular third molar.
2. Initial treatment of acute pericoronitis is excision of the excess flap of soft tissue. A. True B. False	**Answer: B** **Explanation:** Simply excising the occlusal portion of the pericoronal flap without managing the distal tissue leaves a deep periodontal pocket on the distal surface, which invites recurrence of acute pericoronal involvement.
3. Treatment of pericoronitis depends on which of the following factors? A. Severity of inflammation B. Quality of surrounding tissues C. Risk of systemic complications D. Consideration of whether to extract tooth E. All of the above	**Answer: E** **Explanation:** Several factors must be considered when deciding on treatment for pericoronitis, including all of those listed and the advisability of retaining or removing the partially erupted tooth.

CHAPTER 45

Treatment of Periodontal Abscess

Philip R. Melnick, Henry H. Takei

CHAPTER OUTLINE

Classification of Abscesses
Specific Treatment Approaches

Classification of Abscesses

The periodontal abscess is a localized purulent inflammation of the periodontal tissues.[6,15,18,19] It has been classified into three diagnostic groups: gingival abscess, periodontal abscess, and pericoronal abscess. The *gingival abscess* involves the marginal gingival and interdental tissues. The *periodontal abscess* is an infection located contiguous to the periodontal pocket and may result in destruction of the periodontal ligament and alveolar bone. The *pericoronal abscess* is associated with the crown of a partially erupted tooth.[15,18,25]

Learning Box 45.1

Periodontal abscess has been classified into three categories: gingival abscess, periodontal abscess, and pericoronal abscess. Each category is classified according to the location and the tissue surrounding this localized lesion.

Periodontal Abscess

Periodontal abscesses are typically found in patients with untreated periodontitis and in association with moderate to deep periodontal pockets.[5,15,18,19,28] Periodontal abscesses often arise as acute exacerbations of preexisting pockets[6,15,18,19] (Fig. 45.1). Primarily related to incomplete calculus removal, periodontal abscesses have been linked to several clinical situations.[8,15–19,27] They have been identified in patients after periodontal surgery,[12] after preventive maintenance (Fig. 45.2),[7,10,20,24] after systemic antibiotic therapy,[29] and as the result of recurrent disease.[15–17] Conditions in which periodontal abscesses are not related to inflammatory periodontal disease include tooth perforation or fracture[1,27] (Fig. 45.3) and foreign body impaction.[2,26] Poorly controlled diabetes mellitus has been considered a predisposing factor for periodontal abscess formation[18,25] (Fig. 45.4). Formation of periodontal abscess has been reported as a major cause of tooth loss[12–14,16,17,20–24]; however, with proper treatment followed by consistent preventive periodontal maintenance, teeth with significant bone loss may be retained for many years[7] (see Fig. 45.10).

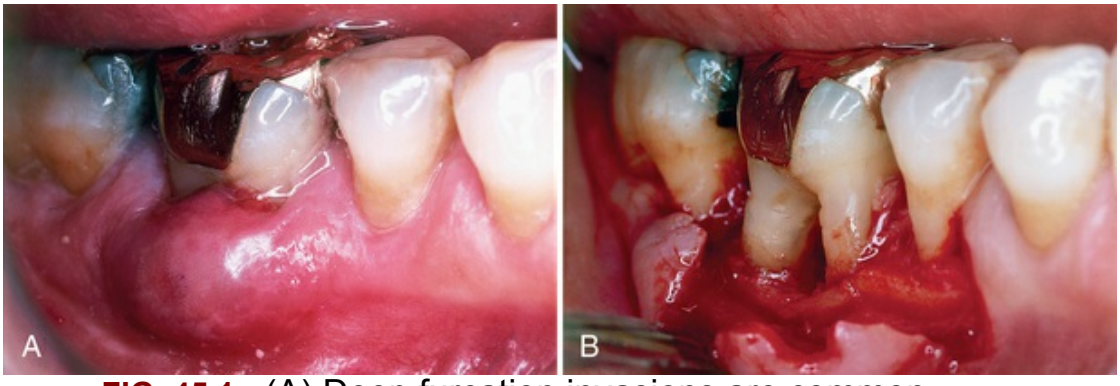

FIG. 45.1 (A) Deep furcation invasions are common

locations for the periodontal abscess. (B) Furcation anatomy often prevents the definitive removal of calculus and microbial plaque.

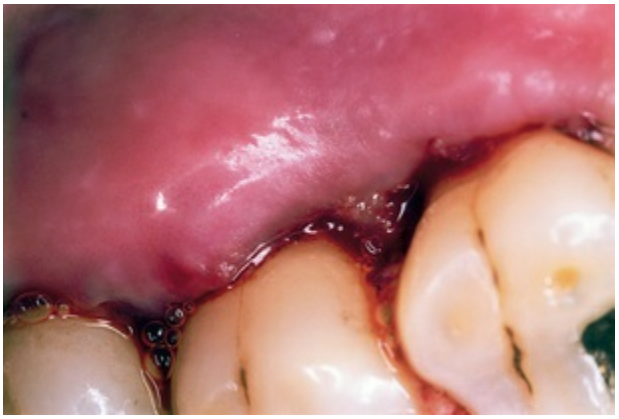

FIG. 45.2 **Postprophylaxis periodontal abscess resulting from partial healing of a periodontal pocket over residual calculus.**

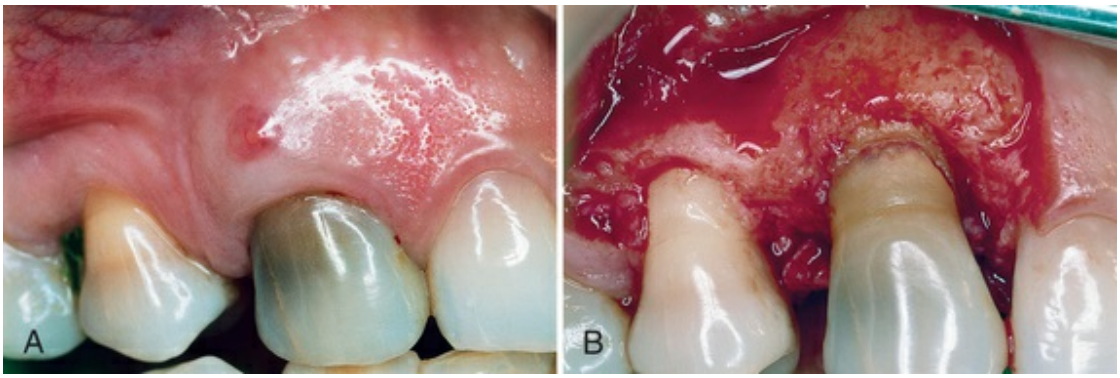

FIG. 45.3 (A) Fistula is observed in attached gingiva of a maxillary right canine. (B) Elevated flap shows the cause to be a root fracture.

FIG. 45.4 **Localized periodontal abscess of a mandibular right canine in a male adult with poorly controlled type 2 diabetes mellitus. For some patients, periodontal abscess formation may be the first sign of the disease.**

Learning Box 45.2

Most periodontal abscesses are due to the incomplete removal of subgingival calculus in a periodontal pocket.

Gingival Abscess

The gingival abscess is a localized acute inflammatory lesion that may arise from a variety of sources, including microbial plaque infection, trauma, and foreign body impaction.[18,25] Clinical features include a red, smooth, sometimes painful, often fluctuant swelling (Fig. 45.5).[15]

FIG. 45.5 **Plaque-associated gingival abscess of a mandibular right canine.**

Pericoronal Abscess

The pericoronal abscess results from inflammation of the soft tissue operculum, which covers a partially erupted tooth. This situation is most often observed around the mandibular third molars. As with the gingival abscess, the inflammatory lesion may be caused by the retention of microbial plaque biofilm, food impaction, or trauma.

Acute Versus Chronic Abscess

Abscesses are categorized as acute or chronic. The *acute abscess* is often an exacerbation of a chronic inflammatory periodontal lesion. Influencing factors include increased number and virulence of bacteria combined with lowered tissue resistance and lack of spontaneous drainage.[11,15,28] The drainage may have been prevented by deep, tortuous pocket morphology, debris, or closely adapted pocket epithelium blocking the pocket orifice. Acute abscesses are characterized by painful, red, edematous, smooth, and ovoid swelling of the gingival tissues.[16,17,28] Exudate may be expressed with gentle pressure; the tooth may be percussion sensitive and feel elevated in the socket (Fig. 45.6). Fever and regional lymphadenopathy are occasional findings.[25]

FIG. 45.6 **Patient presenting with acute abscess complained of dull**

pain and a sensation of tooth elevation in the socket. Signs of tissue distention and exudation are evident.

The *chronic abscess* forms after the spreading infection has been controlled by spontaneous drainage, host response, or therapy. Once homeostasis between the host and infection has been reached, the patient may have few or no symptoms.[9] However, dull pain may be associated with the clinical findings of a periodontal pocket, inflammation, and a fistulous tract.[25]

Box 45.1 compares the signs and symptoms of acute and chronic abscesses.

Box 45.1

Signs and Symptoms of Periodontal Abscess

Acute Abscess

Mild to severe discomfort
Localized red, ovoid swelling
Periodontal pocket
Mobility
Tooth elevation in socket
Tenderness to percussion or biting
Exudation
Elevated temperature[a]
Regional lymphadenopathy[a]

Chronic Abscess

No pain or dull pain
Localized inflammatory lesion
Slight tooth elevation
Intermittent exudation
Fistulous tract often associated with a deep pocket
Usually without systemic involvement

[a]May indicate the need for systemic antibiotics.

Data from Dahlen G: Microbiology and treatment of dental abscesses and periodontal-endodontic lesions. *Periodontol 2000* 28:206, 2002; Meng HX: Periodontal abscess. *Ann Periodontol* 4:79, 1999; and Sanz M, Herrera D, van Winkelhoff AJ: The periodontal abscess. In Lindhe J, editor: *Clinical periodontology*, Copenhagen, 2000, Munksgaard.

Periodontal Versus Pulpal Abscess

To determine the cause of an abscess and thus establish a proper treatment plan, it is often necessary to perform a differential diagnosis between periodontal abscess and pulpal abscess[4] (Box 45.2 and Figs. 45.7 and 45.8). Box 45.2 lists the differential diagnosis comparing the signs and symptoms of the two lesions. The correct diagnosis for these two lesions may overlap in some cases, but careful examination and patient questioning are important for an accurate diagnosis because the therapy for these two lesions is completely different.

Box 45.2

Differential Diagnosis of Periodontal and Pulpal Abscess

Periodontal Abscess

Associated with a preexisting periodontal pocket.
Radiographs show periodontal angular bone loss and furcation radiolucency.
Tests show vital pulp.
Swelling usually includes gingival tissue, with an occasional fistula.
Pain is usually dull and localized.
Sensitivity to percussion may or may not be present.

Pulpal Abscess

The offending tooth may have large restoration.
The tooth may have no periodontal pocket or, if present, it

probes as a narrow defect.
Tests show nonvital pulp.
Swelling is often localized to the apex, with a fistulous tract.
Pain is often severe and difficult to localize.
Sensitivity to percussion is noted.

Modified from Corbet EF: Diagnosis of acute periodontal lesions. *Periodontol 2000* 34:204, 2004.

FIG. 45.7 (A) Maxillary right first molar with fistula on the attached gingiva. (B) With local anesthesia, periodontal probe is introduced through the fistula and angled toward the root end. (C) Surgical flap elevation demonstrates failed endodontic therapy and tooth fracture as causing the fistula.

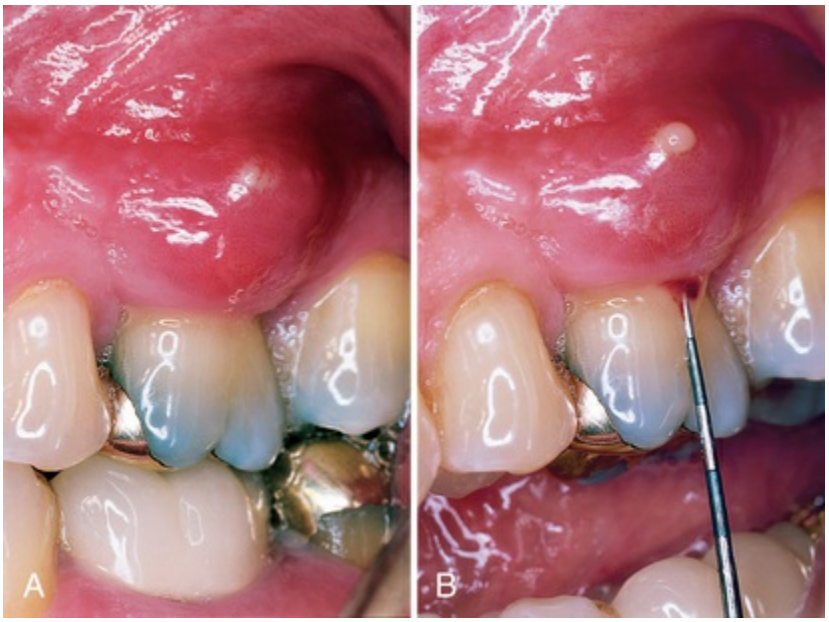

FIG. 45.8 (A) Periodontal abscess of maxillary left first molar. (B) Periodontal probe is used to retract the

pocket wall gently.

Specific Treatment Approaches

Treatment of the periodontal abscess includes two phases: resolving the acute lesion, then managing the resulting chronic condition[15,18,27] (Box 45.3).

Box 45.3

Treatment Options for Periodontal Abscess

1. Drainage through pocket retraction or incision
2. Scaling and root planing
3. Periodontal surgery
4. Systemic antibiotics
5. Tooth removal

Modified from Sanz M, Herrera D, van Winkelhoff AJ: The periodontal abscess. In Lindhe J, editor: *Clinical periodontology,* Copenhagen, 2000, Munksgaard.

Acute Abscess

The acute abscess is treated to alleviate symptoms, control the spread of infection, and establish drainage.[15,22] Before treatment, the patient's medical history, dental history, and systemic condition are reviewed and evaluated to assist in the diagnosis and determine the need for systemic antibiotics[3] (Boxes 45.4 and 45.5).

Box 45.4

Indications for Antibiotic Therapy in Patients With Acute Abscess

1. Cellulitis (nonlocalized, spreading infection)

2. Deep, inaccessible pocket
3. Fever
4. Regional lymphadenopathy
5. Immunocompromised status

Box 45.5

Antibiotic Options for Periodontal Infections

Antibiotic of Choice

Amoxicillin, 500 mg

- 1.0-g loading dose, then 500 mg three times a day for 3 days
- Reevaluation after 3 days to determine need for continued or adjusted antibiotic therapy

Penicillin Allergy

Clindamycin

- 600-mg loading dose, then 300 mg four times a day for 3 days

Azithromycin (or Clarithromycin)[a]

- 1.0-g loading dose, then 500 mg four times a day for 3 days

[a]To be used with caution in patients with high baseline cardiovascular risk.

Data from American Academy of Periodontology: Position paper: systemic antibiotics in periodontics. *J Periodontol* 67:1553, 2004.

Drainage Through the Periodontal Pocket

The peripheral area around the abscess is anesthetized with sufficient topical and local anesthetic agents to ensure comfort. The pocket wall is gently retracted with a periodontal probe or curette

in an attempt to initiate drainage through the pocket entrance (see Fig. 45.8). Gentle digital pressure and irrigation may be used to express the exudate and drain the pocket (Fig. 45.9). If the lesion is minimal and access is uncomplicated, debridement in the form of scaling and root planing may be undertaken at this appointment.

FIG. 45.9 **Gentle digital pressure may be sufficient to express purulent discharge.**

If the lesion is large and drainage cannot be established, root debridement by scaling and root planing or surgical access should be delayed until the major clinical signs have abated.[19,21] In these patients, use of adjunctive systemic antibiotics[13,14,16,17,19] with a short-term high-dose regimen is recommended[23] (see Box 45.5). Antibiotic therapy alone without subsequent drainage and subgingival scaling is contraindicated.[14]

Drainage Through an External Incision

To drain the abscess, the lesion is dried and isolated with gauze sponges. A topical anesthetic agent is applied, followed by a local anesthetic agent injected peripheral to the lesion. A vertical incision through the most fluctuant center of the abscess is made with a no. 15 surgical blade. The tissue lateral to the incision can be separated with a curette or periosteal elevator. The fluctuant matter is expressed, and the wound edges are approximated under light

digital pressure with a moist gauze pad.

In abscesses manifesting with severe swelling and inflammation, aggressive mechanical instrumentation should be delayed in favor of antibiotic therapy to avoid damage to healthy contiguous periodontal tissues.[27]

Once bleeding and suppuration have ceased, the patient may be dismissed. For patients who do not need systemic antibiotics, posttreatment instructions include frequent rinsing with warm salt water (1 tbsp/8-oz glass) and periodic application of chlorhexidine gluconate 0.12% oral rinse either by rinsing or applied locally with a cotton-tipped applicator. Reduced physical exertion and increased fluid intake are often recommended for patients showing systemic involvement. Analgesics may be prescribed for comfort. By the following day, the signs and symptoms have usually subsided. If the problem continues and the patient is still uncomfortable, the previously recommended regimen is repeated for an additional 24 hours. This often results in satisfactory healing, and the lesion can be treated as a chronic abscess.[28]

Chronic Abscess

As with a periodontal pocket, the chronic abscess is usually treated with scaling and root planing and, if indicated, surgical therapy. Surgical treatment is suggested when deep vertical pocket or furcation defects are encountered that are beyond the therapeutic capabilities of nonsurgical instrumentation (Fig. 45.10). Access to subgingival calculus must be achieved in areas of deep pockets. The patient should be advised of the possible postoperative sequelae usually associated with periodontal nonsurgical and surgical procedures. As with the acute abscess, antibiotic therapy may be indicated.[15,19,28]

FIG. 45.10 (A) Chronic periodontal abscess of a maxillary right canine. (B) With local anesthesia, periodontal probe is inserted to determine severity of the lesion. (C) With mesial and distal vertical incisions, a full-thickness flap is elevated, exposing severe bone dehiscence, a subgingival restoration, and root calculus. (D) Root surface has been planed free of calculus, and the restoration has been smoothed. (E) Full-thickness flap has been replaced to its original position and sutured with absorbable sutures. (F) At 3 months, gingival tissues are pink, firm, and well adapted to the tooth, with minimal periodontal probing depth.

Learning Box 45.3

Periodontal abscess due to a deep periodontal pocket often requires a surgical flap to access the subgingival calculus. This also allows the clinician to reduce the pocket at the same surgical appointment.

Gingival Abscess

Treatment of the gingival abscess is aimed at reversal of the acute phase and, when applicable, immediate removal of the cause. To ensure comfort, topical or local anesthesia by infiltration is administered. When possible, scaling and root planing are completed to establish drainage and remove microbial deposits. In more acute situations, the fluctuant area is incised with a no. 15 scalpel blade, and exudate may be expressed by gentle digital pressure. Any foreign material (e.g., dental floss, impression material) is removed. The area is irrigated with warm water and covered with moist gauze under light pressure.

Once bleeding has stopped, the patient is dismissed with instructions to rinse with warm salt water every 2 hours for the remainder of the day. After 24 hours, the area is reassessed, and if resolution is sufficient, scaling not previously completed is undertaken. If the residual lesion is large or poorly accessible, surgical access may be required.

Pericoronal Abscess

As with other abscesses of the periodontium, treatment of the pericoronal abscess is aimed at management of the acute phase, followed by resolution of the chronic condition. The acute pericoronal abscess is properly anesthetized for comfort, and drainage is established by gently lifting the soft tissue operculum with a curette. If the underlying debris is easily accessible, it may be removed, followed by gentle irrigation with sterile saline. If the patient has regional swelling, lymphadenopathy, or systemic signs, systemic antibiotics may be prescribed.

The patient is dismissed with instructions to rinse with warm salt water every 2 hours, and the area is reassessed after 24 hours. If

discomfort was one of the original complaints, appropriate analgesics should be used. Once the acute phase has been controlled, the partially erupted tooth may be definitively treated with either surgical excision of the overlying tissue or removal of the offending tooth.

Case Scenario 45.1

Patient:

35-year-old male

Background Information

A medically healthy patient presents with a diagnosis of advanced, generalized, chronic periodontitis with periodontal pockets measuring 5 to 7 mm throughout his dentition. All of his teeth are present except for his third molars. The remaining molar dentition manifests class II furcation involvement. Heavy subgingival calculus is present throughout, and the gingival tissues are fibroedematous, partially due to his heavy smoking. The clinician recommends full mouth scaling at this first appointment and attempts the nonsurgical therapy. The next day the patient returns with a fluctuant periodontal abscess around the buccal class II furcation area of the mandibular first molar.

Case-Based Question

This periodontal abscess is probably due to the following:

1. There was incomplete subgingival scaling, and residual calculus deep in the pockets was not removed. The coronal portion of the deep pocket was easily scaled, but the subgingival portion could not be reached due to the depth and the fibroedematous nature of the gingival tissue, which is partially due to his smoking.
2. The gingival margin of this deep pocket was accessed and easily scaled, which caused the gingival margin tissue to shrink and tighten around the tooth. The exudate from the infection that remains in the subgingival area due to the

calculus that could not be removed can no longer drain due to the closure of the coronally located gingival margin.
3. The class II furcation area presents a unique access problem for both the patient's ability to remove biofilm and the clinician's ability to scale and root plane. Therefore, periodontal abscess occurs often in these furcation areas.
4. Attempting to scale and root plane the entire mouth on the patient's first visit is not possible, and the therapy will be incomplete. The result of incomplete therapy will often create an environment for periodontal abscesses.
5. Smoking is a risk factor for periodontal abscesses.
6. All of the above.

CHAPTER 46

Endodontic-Periodontic Lesions

Pathogenesis, Diagnosis, and Treatment Considerations

Mo K. Kang, Kenneth C. Trabert, Shebli Mehrazarin

CHAPTER OUTLINE

Factors Initiating Pulpal and Apical Diseases
Classification of Pulpal and Apical Diseases
Biologic Effects of Pulpal Infection on Periodontal Tissues
Biologic Effects of Periodontal Infection on the Dental Pulp
Effect of Endodontic Pathosis on Development of Retrograde Peri-Implantitis *(e-only)*
Interactions Between Extraradicular Infection and the Periodontium *(e-only)*
Differential Diagnosis of Pulpal and Periodontal Infection *(e-only)*

Treatment Considerations *(e-only)*
Summary

Periodontium and pulpal spaces represent the two primary sites of dental infection from oral bacteria. These two spaces are separated by hard shell of dentin, but they may communicate through various portals, such as root canal foramina, dentinal tubules, and even crack lines, through which bacteria and microbial irritants may trigger inflammatory responses in surrounding tissues. At the clinical level, compound dentoalveolar infections involving both periodontium and pulpal spaces are common and present challenges for diagnosis and treatment. Conversations occur daily among periodontists, endodontists, and general practitioners to try to ascertain whether a lesion surrounding one or more teeth is of periodontal or endodontic origin or is possibly a true combined lesion that affects both compartments and will require endodontic as well as subsequent periodontal treatment. In this chapter, we discuss the proper diagnosis of these various conditions and offer treatment modalities to ensure the retention of teeth that could otherwise be extracted.

Persistent infection in the pulp tissue leads to secondary infection and breakdown of tissues in the periodontium. Conversely, severe periodontal disease may initiate or exacerbate inflammatory changes in the pulp tissue. This mutuality of infection between pulp and periodontium is mediated through anatomic routes, allowing for communication between the two spaces. The main and obvious routes of communication are the apical foramina. Advanced pulpitis leads to pulp necrosis, which often is accompanied by inflammatory bone resorption at the root apex, as found in cases of apical periodontitis or an apical abscess (Fig. 46.1). This is also known as *retrograde periodontitis* because it represents periodontal tissue breakdown from an apical to a cervical direction and is the opposite of *orthograde periodontitis,* which results from a sulcular infection. This condition is typically identified as a periapical radiolucency (Fig. 46.2). Retrograde periodontitis is the most common example of pulpal diseases leading to secondary

periodontal breakdown. The presence of patent apical foramina may also lead to inflammatory changes in the pulp secondary to severe periodontitis in cases where the periodontal defect reaches the apical foramina.

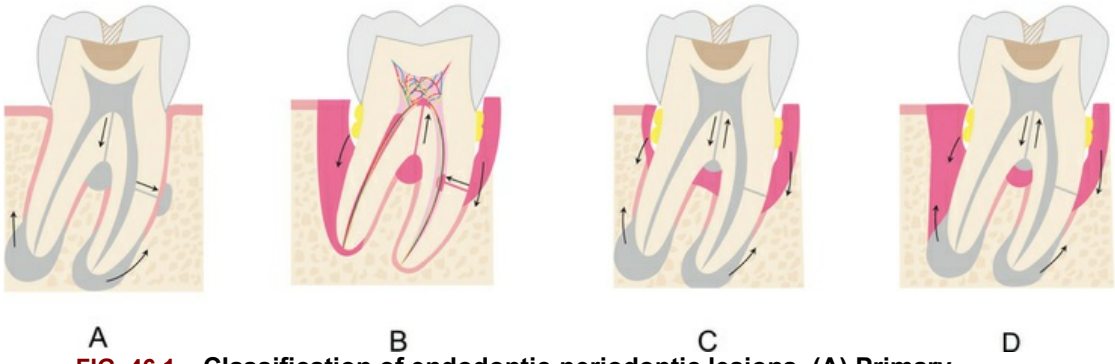

FIG. 46.1 Classification of endodontic-periodontic lesions. (A) Primary pulpal infection can lead to chronic periradicular periodontitis by which a periapical radiolucency can develop and migrate cervically. Mandibular molars can also have accessory canals in lateral orientation or in the furcation area. These accessory canals can allow migration of the primary pulpal infection and cause secondary breakdown of the periodontium at their respective loci. (B) Primary periodontal infection can lead to extensive breakdown of alveolar crest bone that migrates from the cervical area to the apex. In these lesions, one would find generalized bone loss around a single tooth or that often could involve multiple adjacent teeth. Because of the pulpal-periodontal continuum through main root canal foramina or through accessory canals, extensive periodontal infection can cause irritation in the pulp tissues. (C) Both primary pulpal infection and primary periodontal infection can occur simultaneously in an "independent" endo-perio lesion, exhibiting the characteristics of both. (D) Primary pulpal and primary periodontal infections can occur extensively in this "combined" endo-perio lesion.

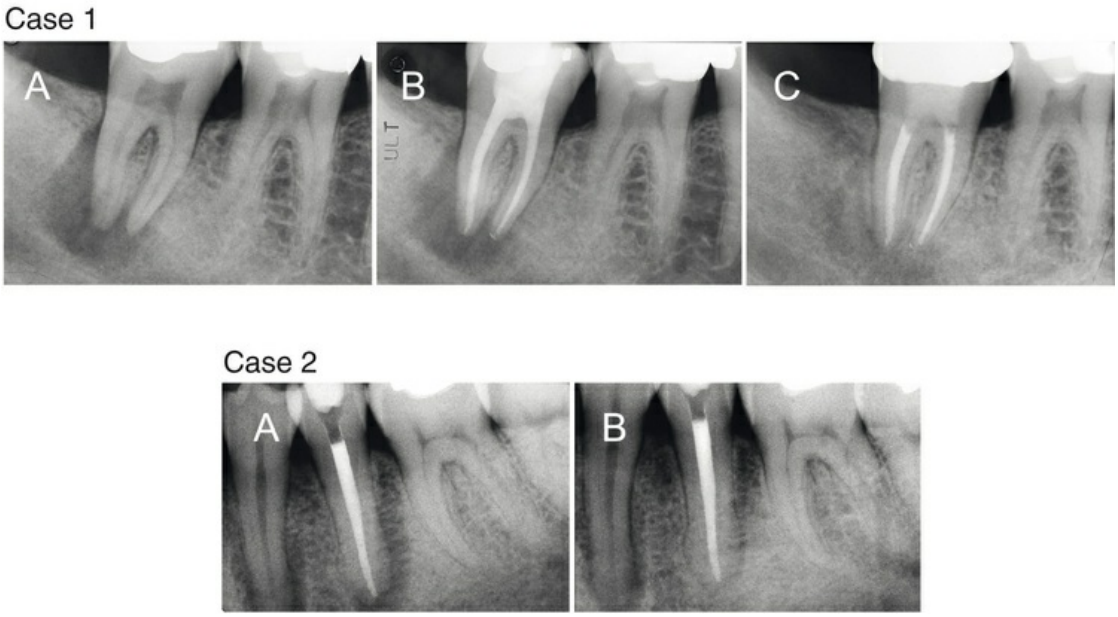

FIG. 46.2 **Retrograde periodontitis. Case 1. (A) Large periapical lesion extending around the periapex of tooth #31. No visible fractures were detected on the mesial or distal marginal ridges. The tooth tested nonvital. A sinus tract was visible on the buccal gingiva. (B) Endodontic therapy was completed in two visits, and the canals were obturated. (C) Healing of the periradicular bone is evident at 6 months, and a crown providing complete coverage has been placed. Case 2. (A) Tooth #20 had a broad periradicular lesion extending from the apex to the distal root surface that resembled a J-shaped lesion. Conventional root canal therapy was completed. (B) Healing of periradicular bone lesion after 6-month recall.** (Case 1, Courtesy Dr. Thomas Rauth.)

Alternatively, lateral or accessory canals may comprise the route of periodontal and pulpal communication. The prevalence of accessory root canals in various human teeth and their contribution to the complexity of the root canal system have been well established. Accessory canals are found along the length of the root canals, albeit at varying frequencies depending on their location. By using the "clearing technique" for transparent root canal visualization, prior studies showed that 59.5% of maxillary second premolars possess lateral canals; 78.2% of those canals are located in the apical regions of the root canals.[105] Notably, accessory canals were also found in both midroot and cervical regions, albeit at reduced frequencies, at 16.2% and 4.0%, respectively. A subsequent study showed that 28.4% of permanent molars exhibit patent accessory canals in furcation regions,[27] a finding suggesting that these accessory canals allow a pulpal and periodontal communication to exist. Root canal therapies frequently fail in maxillary molars because of unidentified second mesiobuccal

canals. These canals are found in a surprisingly high percentage (80.8%) of teeth.[40] Clearly, accessory canals can lead to asymptomatic apical periodontitis resulting from chronic pulpal diseases. This condition can be readily detected in periapical radiographs (Fig. 46.3), and the periodontal lesions usually heal after successful completion of endodontic therapy. Questions also arise about whether pulpitis develops from periodontal infections through accessory root canals. Kirkham[48] in 1975 reported that only 2% of teeth possessed accessory canals within the periodontal pockets among those teeth extracted for severe periodontal disease. Thus, the likelihood that primary periodontal infections will reach the dental pulp through accessory canals is highly remote.

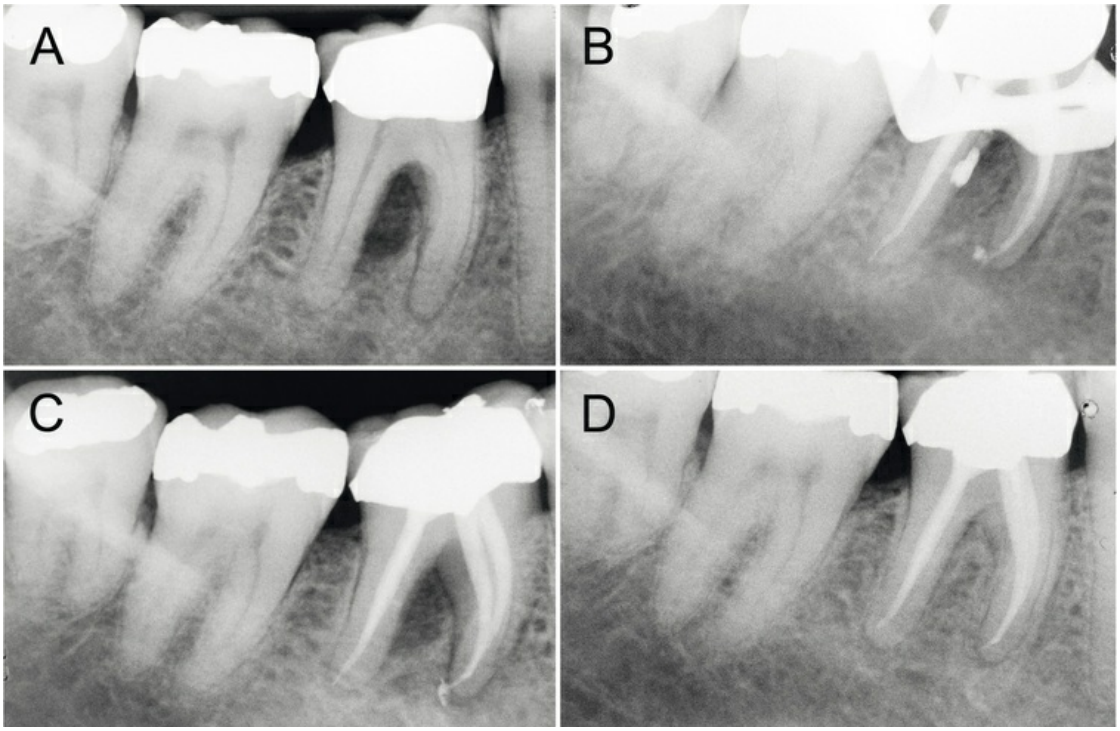

FIG. 46.3 Lateral canal-led periodontal defect from a primary endodontic infection. (A) Bone loss is present in the furcation with sinus tract present on the buccal mucosa. Tooth #30 tested nonvital. (B) During condensation, a large amount of sealer was expressed through a large lateral canal in the distal root. (C) Sealer was removed after obturation by curettage of the furcation and irrigation with anesthetic solution through the sinus tract. (D) Healing at 12 months demonstrates complete repair of periradicular bone. (Courtesy Dr. Thomas Rauth.)

The third route of communication between the periodontium and the pulp is through the dentinal tubules. Dentinal tubules maintain

a tapered structure along the length from the pulpodentinal complex to the dentinoenamel junction with a diameter of 2.5 μm at the pulpodentinal complex and 0.9 μm at the dentinoenamel junction.[97] It is therefore conceivable that dentinal permeability changes at different locations along the root surface according to the size and density of the dentinal tubules. Bacterial colonization in the tubules from infected root canals has been well documented.[83] In addition, bacterial invasion into dentinal tubules from the periodontal pocket has been demonstrated,[23] suggesting that dentinal tubules may allow pulpal irritation from chronic periodontal infections. Periodontal pathogens penetrating into the dentinal tubules also may be the source of persistent periodontal infection.[23]

Dentin permeability through dentinal tubules is a clinically important issue. The permeability may be measured through hydraulic conductance, as described earlier.[71] Subsequently, investigators studied the effects of various agents and stresses on dentin permeability. Root planing as part of routine periodontal therapy, for example, is shown to decrease dentin permeability and result in the formation of a smear layer that is acid labile.[22] However, dentin permeability may increase on removal of the smear layer, thus resulting in tubular penetration of oral pathogens and subsequent pulpal irritation. Further study is necessary to delineate the role of dentinal tubules in causing secondary infection in pulpal or periodontal tissues. Clinicians need to be aware that patent dentinal tubules can provide effective irritant conduits between these two otherwise distinct tissues.

In addition to the foregoing routes of anatomic communication between pulpal and periodontal tissues, in some instances communication is established between the pulp and periodontium by iatrogenic defects such as vertical root fractures and tooth perforations. Both of these situations represent nonanatomic communication between the pulp and periodontium and result in the spread of infection from one compartment to the other.

Factors Initiating Pulpal and Apical Diseases

Pulpal and apical diseases are initiated by numerous external factors that may include microorganisms, trauma, excessive heat, restorative procedures, restorative agents, and malocclusion. These insults lead to inflammatory changes in the pulp, starting from reversible or irreversible pulpitis and ultimately progressing to pulpal necrosis and subsequent breakdown of the periodontium. Dental caries is a prominent cause of pulpal disease, and bacterial infection is the primary form of microbial insult to the pulp. A systematic review of literature from 1966 to 2000 showed causative effects of mutans streptococci and the lactobacilli for human dental caries, whereas other bacteria such as *Streptococcus sanguinis, Streptococcus salivarius*, and enterococci could not be associated with the disease.[94] More recent understanding of the caries process has emphasized the importance of homeostatic balance in biofilm, which describes the microbial ecosystem on tooth surfaces rather than the virulence of individual bacterial species.[93] Regardless, pulpal infection is polymicrobial and often starts from incipient caries causing localized pulpal inflammation or pulpitis.

Local invasion of the cariogenic bacteria or a shift in the bacterial content of biofilm can lead to inflammatory changes in the dental pulp. This frequently happens in the absence of caries extension into the pulp chamber. Bacterial byproducts relevant to pulpitis include lactic acid, ammonia, urea, lipopolysaccharide, and lipoteichoic acid. It is notable that the dental pulp is capable of managing numerous microbial insults because of its extensive intrapulpal lymphatic system. However, an overwhelming pulpal inflammatory response may be induced through various mechanisms and numerous microbial challenges. Lipopolysaccharide and lipoteichoic acid bind Toll-like receptors. These are present on the surface of some immune cells in the pulp and induce the release of inflammatory mediators such as prostaglandins, cytokines, and chemokines.[38] In particular, tumor necrosis factor alpha, interleukin-1 (IL-1), IL-8, IL-12, and chemokines CCL2 and CXCL2 are well described for their role in pulpitis.[28] IL-1 is known to be released from macrophages after stimulation with lipopolysaccharide and is responsible for bone resorption leading to apical periodontitis.[34] During acute pulpitis, the inflammatory mediators trigger vasodilation, a transient

increase of pulpal blood flow, inflammatory cell infiltration, increased intrapulpal pressure, and finally ischemic necrosis of the pulp (Fig. 46.4).

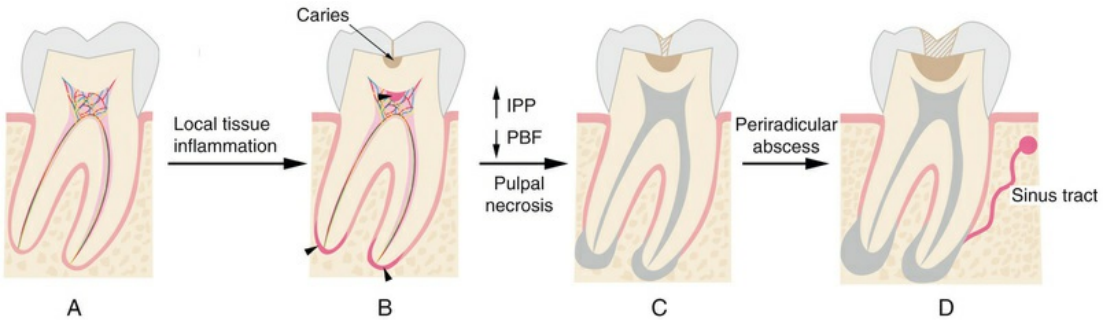

FIG. 46.4 Progression of the pulpal and periradicular pathosis. (A) Normal tooth without any pulpal pathosis is richly vascularized and innervated. (B) With microbial challenges such as caries, local tissue inflammation can occur in the pulp adjacent to the site of carious lesions, as well as in the apical regions *(arrowheads).* (C) Pulpal inflammation can lead to reduction in pulpal blood flow *(PBF)* caused by an increase in intrapulpal pressure *(IPP),* causing pulpal necrosis (shown in *gray*). (D) Pulpal necrosis, if left untreated, can cause chronic inflammation of periradicular tissues and abscess formation, leading to a draining sinus tract.

In acute apical abscess, anaerobic bacteria are predominant over aerobic strains and anaerobes, and microaerophiles were predominant in 82% of the cases studied.[45] The most prevalent isolated bacteria are *Fusobacterium nucleatum, Parvimonas micra,* and *Porphyromonas endodontalis.*[86] Depending on the virulence of the organisms and host resistance, a lesion that has been chronic may exacerbate and become an acute apical abscess. The presence of spirochetes is also well documented in apical and periodontal abscesses and has been studied by various identification techniques.[16] Spirochetes most often isolated in root canal infections are *Treponema denticola* and *Treponema maltophilium.*[39,74] When comparing chronic and acute apical abscesses, Baumgartner and colleagues[6] found a significantly higher incidence of spirochetes in acute abscesses and cellulitis than in asymptomatic infected root canals. *Treponema socranskii* was the most frequently encountered species.[6]

Thermomechanical irritants can induce altered pulpal circulation and pulp tissue damage. Earlier studies demonstrated that thermal changes caused by dental procedures such as tooth preparation led

to a marked diminution of pulpal blood flow and plasma extravasation, resulting in an inflammatory response.[47,70] Extreme heat caused by dry tooth preparation triggers vascular stasis and hemorrhage in the subodontoblastic vascular plexus.[60] Investigators noted that even a small increase in pulpal temperature (5° to 6° C) is capable of inducing necrotic changes in the pulp.[108] Pulpal necrosis eventually leads to apical periodontitis. Similarly, chemical irritants impose measurable changes in the pulp status. One study showed the cytotoxicity of dental resin material (2-hydroxyethyl methacrylate [HEMA]) on pulp stromal cells through induction of apoptotic cell death.[66] Etching the dentin surface with high phosphoric acid content causes deleterious effects on dental pulp.[79] In addition, bonding resins used as pulp capping materials led to acute pulpitis and varying degrees of necrosis in human teeth.[1] Root canal overfills with gutta-percha and sealers invariably cause severe inflammatory reactions in the apical tissues, even though patients may be completely asymptomatic.[72] Thus, dental materials often contain chemical irritants that affect both the pulpal and periodontal tissues, and one must be aware of the potential iatrogenic endodontic pathosis associated with their misuse.

Classification of Pulpal and Apical Diseases

The diagnosis of endodontic lesions that may often have a periodontal component can be confusing. The diagnostic terminology used in various dental schools and textbooks further compounds the confusion for students and practitioners alike. In an attempt to simplify and unify a standardized diagnostic terminology, the American Association of Endodontists established new endodontic diagnosis terminology in 2009. The reader is referred to this revised terminology, published in the *Journal of Endodontics,* for a more complete discussion of this subject.[24] Throughout this chapter we refer to this new terminology, which is also summarized in Tables 46.1 and 46.2.

TABLE 46.1

Classification of Pulpal Diseases[a]

Pulpal State	Symptom	Vitality	Response to Cold
Normal pulp	Asymptomatic	Vital	Within normal limits
Reversible pulpitis	Sensitive to pressure or temperature[b]	Vital	Hypersensitive to cold
Symptomatic irreversible pulpitis[c]	Spontaneous throbbing pain	Vital	Hypersensitive to cold and lingering response
Asymptomatic irreversible pulpitis[d]	None	Vital	Within normal limits
Pulp necrosis[e]	Asymptomatic[e]	Nonvital	No response
Previously treated	Variable	Nonvital	No response
Previously initiated therapy	Variable	Variable	Variable

[a]Different pulpal conditions cannot be discerned by periapical radiographs. Symptoms and responses to cold explained herein are the general findings, but there can be exceptions.

[b]Patients' response to pressure may be due to hyperocclusion in reversible pulpitis cases. In the absence of such factors, patients' complaints mainly revolve around thermal sensitivity.

[c]Symptomatic irreversible pulpitis may be symptomatic and painful as described or may be asymptomatic and nonpainful.

[d]Asymptomatic irreversible pulpitis is based on the presence of pulpal inflammation (e.g., extensive caries, hyperemia, or traumatic injury) in the absence of patients' subjective symptoms.

[e]Necrotic pulp may cause acute exacerbation of symptoms, including spontaneous throbbing pain. However, such sensitivity results from periradicular inflammation.

TABLE 46.2

Classification of Periradicular Diseases[a]

Periradicular State	Symptom	Pulpal Status	Percussion Response	Palpation Response	Periapical Radiolucency	Sinus Tract
Normal periapex	None	Varies[b]	None	None	Not present	Not present
Symptomatic apical periodontitis[c]	Painful	Inflamed	Painful	Varies[d]	Not present	Not present
Asymptomatic apical periodontitis	None	Nonvital	None	None	Present	Not present
Acute apical abscess[c]	Painful	Inflamed	Painful	Painful	Varies[e]	Not present
Chronic apical	None	Nonvital	None	None	Present	Present

abscess						
Condensing osteitis	None/pain	Inflamed	None	None	Radiopaque	Not present

[a]Symptom and other descriptions of the individual periradicular pathosis are the general findings, which can deviate.

[b]Normal periapex can be associated with normal, inflamed, or necrotic pulp.

[c]The difference between acute periradicular periodontitis and acute periradicular abscess is that the former is confined to the involved tooth and the latter is more generalized and frequently manifests with gross swelling of the affected periradicular tissues.

[d]Palpation in acute periradicular periodontitis may elicit tenderness after progression of the disease through the cortical plate.

[e]Periapical radiolucency may be present in advanced acute periradicular abscess.

Diagnostic terminology based on the recommendations of the American Association of Endodontists consensus conference, as shown in Glickman GN: AAE consensus conference on diagnostic terminology: background and perspectives. *J Endod* 35:1634, 2009.

To make a proper endodontic diagnosis, the clinician must evaluate the symptoms of the patient, the radiographic and clinical findings, and the presence or absence and location of any swelling or drainage. Given all these variables, it is easy to understand why a lack of clarity exists and mistakes are made about whether the lesion is primarily endodontic or periodontal, or a true combined lesion.

The classification of diseases of the dental pulp depends on the extent of pulpal injury and its ability to repair. Many factors influence whether a tooth will be classified as normal, or whether it will develop reversible pulpitis or irreversible pulpitis, or will become necrotic.

Previous studies have found little correlation between the histologic features of pulpal disease and the symptoms that the patient experienced before treatment.[51,102] A review of the diagnosis of pulpal pain by Bender[7] in 2000 found that 80% of patients who gave a previous history of odontogenic pain manifested histopathologic evidence of pulpitis and partial necrosis in the dental pulp. Bender also concluded that a clinician can determine the degree of pulp histopathosis by asking the patient about his or her previous pain history and symptoms related to the involved tooth.[7] Controversy still remains, however, regarding the degree of correlation between pulpal symptoms and the histopathologic

features of the pulpal tissues, and additional studies are needed to confirm the correlation between the two.

Apical pathoses of endodontic origin are inflammatory processes occurring in periradicular tissues surrounding root apices. They result from various microbial agents that originate from root canal infection and create a series of inflammatory and immunologic responses. These agents exit through the apical foramen, lateral canals, or dentinal tubules.[48,68] It is an infectious process caused by a large number of microbial species, unlike classic infectious diseases occurring elsewhere in the body that may be caused by only one or two specific organisms. These species reside in ecologically balanced communities discussed previously and constitute the *biofilm*.[65] The different characteristics of pulpal and periodontal lesions are summarized in Table 46.3.

TABLE 46.3

Different Characteristics of Pulpal and Periodontal Lesions[a]

	Primary Pulpal	Primary Periodontal	Independent Endodontic-Periodontic	Combined Endodontic-Periodontic
Patient symptom	Varies[b]	Mild discomfort	Varies[b]	Varies[b]
Coronal integrity	Compromised	Intact	Compromised	Compromised
Radiographic lesions	Periapical radiolucency	Crestal bone loss	Separate periapical radiolucency and crestal lesions	Continuous bony lesions from alveolar crest to apex
Vitality	Nonvital	Vital	Nonvital	Nonvital
Periodontal probing	Narrow probing to apex[c]	Generalized bone loss	Generalized bone loss	Generalized bone loss with narrow probing to apex

[a]These are generalized summaries, and there can be deviations.

[b]Patients' symptoms of pulpal lesions may vary, depending on the type of pathosis. Chronic lesions can be completely asymptomatic, whereas acute pain symptoms can be triggered without any radiographic lesions.

[c]Primary pulpal lesions may not manifest with any periodontal defect. Narrow probing in pulpal lesions may indicate a sinus tract through the sulcus.

Biologic Effects of Pulpal Infection on

Periodontal Tissues

The effects of pulpal disease on the surrounding periodontal tissues are widely accepted by clinicians and researchers, and these effects have been studied since the 1960s. Early inflammatory changes in the pulp exert very little effect on the periodontium. Even a pulp that is significantly inflamed may have little or no effect on the surrounding periodontal tissues. Investigators believe that this initial pulpal inflammatory response is an attempt to prevent the spread of infection to the apical tissues.

When the pulp becomes necrotic, however, it produces a significant inflammatory response involving extremely complex inflammatory and immune reactions. This response can traverse the apical foramen, the furcation, lateral canals, dentinal tubules, and areas of trapped necrotic tissue along the surface of the root that extend past the periodontal ligament and into the surrounding apical tissues.[82] This initial inflammatory response of the pulp and subsequent necrosis that permeates the numerous spaces of the canal system include various bacterial strains, spirochetes, fungi, yeasts, and viruses.[61] The nature and extent of the periodontal destruction that follows depend on the virulence of the pathogens in the root canal system, the chronicity of the disease, and the defense mechanism of the host.[13]

In a classic study by Kakehashi and colleagues,[41] the infected pulp of germ-free rats remained vital, whereas the infected pulp of normal rats that were left open to the oral environment developed pulpal necrosis with subsequent inflammation and formation of periapical lesions. This was the first experimental evidence to demonstrate microbial infection as the etiology of pulpal and periapical pathoses. Similarly, bacterial infection plays a pivotal role in endodontic-periodontic lesions in the form of bacterial biofilm, which is composed of a 15% cellular component and a matrix material that comprises the remaining 85%. The formation of biofilm communities is under the control of complex chemical signals that both regulate and guide the formation of the slime-enclosed colonies and water channels.[14] Proteolytic bacteria predominate in early root canal infections and then change over time to a flora that contains a greater number of anerobes.[21,90]

Several nonliving irritants have also been implicated in the inflammatory process. These include foreign bodies, epithelial rests, cholesterol crystals, Russell bodies, Rushton hyaline bodies, and Charcot-Leyden crystals. In addition, these irritants may also be responsible for the lack of healing of apical lesions in teeth that have received appropriate endodontic treatment.[75] If the growth of epithelial cells is stimulated by any of these living or nonliving pathogens, the integrity of the periodontal tissues also may be affected.

As the degree of pulpal inflammation becomes more extensive, a greater amount of destruction of the periodontal tissues ensues. Extension of the infection through the periodontal ligament space, tooth socket, and surrounding bone occurs, and the patient begins to experience a localized or diffuse swelling that may result in cellulitis that invades the various facial spaces. Most often, however, the infection erupts through the labial, buccal, or lingual mucosa and results in a draining sinus tract. In cases where the path of least resistance for the infectious process is along the attached gingiva, the infection may dissect the periodontal ligament space, resulting in the formation of a deep but narrow periodontal pocket. This pocket usually extends to the main site of the infection (e.g., root apex) when probed or traced with a gutta-percha point. Confusion often results among both general dentists and specialists about whether the probing defect is the result of an endodontic or periodontal problem or the result of vertical root crack. Generally, a narrow probing defect combined with a nonvital pulpal response indicates that the problem is usually of endodontic rather than periodontal origin. In addition, a probing defect associated with vertical root crack generally extends to the level of the crack, as opposed to the root apex. Vertical root crack is generally detected during access into the pulp chamber under high-power magnification or by using transillumination. If vertical root crack is not detected, it should be ruled out as a potential cause of the narrow probing defect.

In a few situations, adjacent teeth, their root surfaces, or furcation areas may also probe deeply. Care must be taken to test all maxillary and mandibular teeth thoroughly to assess correctly whether the problem is endodontic or periodontal. Once the correct

diagnosis is made, only then should the treatment plan be formulated and discussed with the patient. When endodontic therapy is the main cause of the swelling or breakdown of the periodontium, successful endodontic treatment usually results in healing of both the periapical and periodontal tissues. At times, however, trauma to the tooth, severe loss of adjacent periodontal tissues, continued tooth mobility, and occlusal trauma do not provide an environment that allows for apical healing to occur. In these cases, splinting is sometimes necessary to help stabilize the tooth and allow for potential repair of the apical tissues (Fig. 46.5).

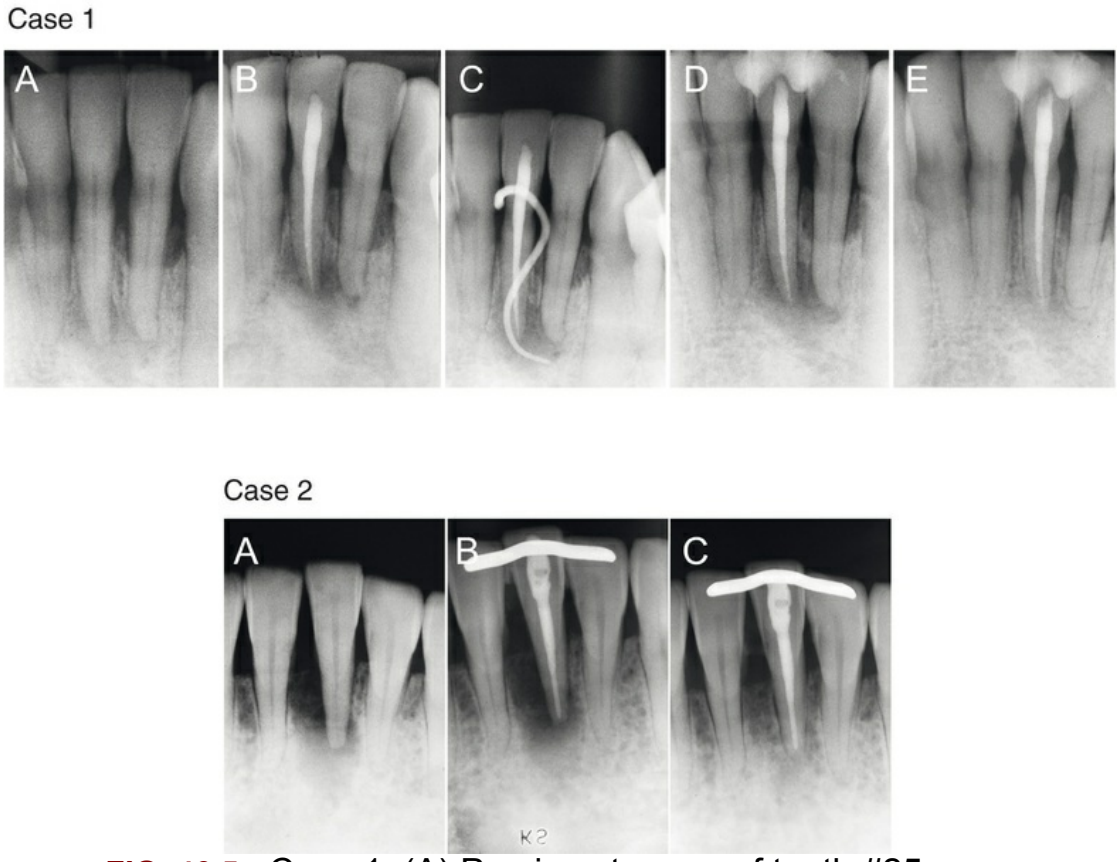

FIG. 46.5 Case 1. (A) Previous trauma of tooth #25 with complaints of pain on biting and chewing. The tooth tested nonvital, and tooth #26 probed 6 mm on the lingual surface. (B) Postoperative radiograph after obturation of the canal. Treatment was completed in two appointments with the interappointment placement of calcium hydroxide. (C) After 4 months, the tooth was mobile and a sinus tract was present. (D) The occlusion was adjusted, and composite resin was

bonded to the mesial and distal surfaces to stabilize both teeth #25 and #26. (E) Healing of the periradicular lesion is apparent after 13 months, and tooth #26 probed only 4 mm. Case 2. (A) Previously traumatized tooth #25. The tooth was class III mobile and tested nonvital to both carbon dioxide and electric pulp testing. (B) After obturation of the tooth with gutta-percha, a cast gold splint was bonded to the lingual surface to stabilize it. (C) At 13-month recall, radiograph demonstrates repair of the periradicular bone and no mobility as a result of splint placement and stabilization. (Case 1, Courtesy Dr. Thomas Rauth.)

If an endodontic infection is left untreated, the progression of periodontal disease continues. Untreated and unresolved infections of endodontic origin can sustain the growth of various endodontic pathogens that may lead to increased pocket formation, bone loss, calculus deposition, osteoclastic activity, and subsequent bone and tooth resorption. They may additionally impair wound healing and aggravate the development and progression of the periodontal disease state.[20]

The ability of the periodontium to regenerate and heal the lost attachment apparatus has been controversial. This is especially true when the teeth have been endodontically treated and the cement layer is no longer present.[44] A study by Sanders and associates[78] demonstrated a 60% osseous regeneration rate in teeth that had not undergone endodontic treatment compared with a regeneration rate of only 33% in teeth that had completed endodontic treatment. One study compared the loss of attached gingiva and found a 0.2-mm greater loss of attached tissue in the presence of teeth with root canal infection and periapical radiolucency.[36] These same investigators, in a later study, found a three times greater loss of marginal proximal bone when using radiographic measurements in teeth with endodontic infections compared with teeth without endodontic infections or subsiding endodontic involvement.[35] Other investigators, however, have reported that all periodontal tissues have the ability to regenerate, regardless of whether the tooth is vital, partially treated and medicated, or partially filled, or whether endodontic treatment has been successfully completed.[19] Additional studies need to be done to understand more clearly the relationship

between the presence of endodontic infection and the increased loss of marginal bone and attached tissue in patients prone to periodontal disease.

It is evident that endodontium and periodontium are closely related from the structural, functional, and pathogenic perspective and that microorganisms and nonliving irritants play important roles in the disease progression of both structures. Proper diagnosis of endodontic-periodontic lesions therefore is critically important and will dictate the appropriate course of treatment.

Biologic Effects of Periodontal Infection on the Dental Pulp

Effects of periodontal disease on the dental pulp appear to be more controversial compared with the effects of pulpal disease on the periodontium.[8,81] Not all studies agree about the effects of periodontal disease on the pulp. Even though inflammation and localized pulpal necrosis have been observed next to lateral canals exposed by periodontal diseases,[76,81,82] other studies have not confirmed a correlation between periodontal disease and changes within the pulp.[15,56,96] Langeland and colleagues[51] indicated that when pathologic changes do occur in the pulp as a result of advanced periodontal disease, the pulp does not usually undergo degenerative changes as long as the main canal has not been involved. If the vasculature of the pulp remains vital, no inflammatory reaction occurs and no symptoms of pulpal pathosis develop. An animal study conducted by Bergenholtz and Lindhe[9] found that 70% of animal specimens showed no pathologic changes even when 30% to 40% of the periodontal attachment was lost. The remainder showed only minor inflammatory changes, formation of reparative dentin, or resorptive defects where the root had been exposed.

Researchers and clinicians, however, have observed the spread of advanced periodontal lesions that extend to the apical foramen and result in pulpal necrosis. This retrograde infection may proliferate through large accessory canals on the lateral surfaces of the tooth, canals positioned closer to the apical foramen, and the area where

the main canal exits the tooth apex.[76] Kobayashi and associates[49] compared the microflora from root canals and periodontal pockets of caries-free teeth that were necrotic and tested nonvital with an electric pulp tester. The aerobic-to-anaerobic ratio in the periodontal pocket was 0.23 compared with 0.0022 in the root canal. Although far fewer bacteria were present in the root canal, both areas demonstrated similar bacterial strains. The similarity of strains in both areas suggested that the periodontal pocket may be the source of bacteria found in infections within the root canal system.

Protection and preservation of the cementum and dentin surrounding the tooth are also important in preserving the health of the pulp and preventing the ingress of periodontal pathogens. The presence of an intact layer of cementum is important in protecting the pulp from dental plaque and other periodontal pathogens that migrate along the root surface during the development of advanced periodontal disease. Excessive root planing and curettage that remove the cementum and dentin from the root surface encourage narrowing of the pulp canals. This process is thought to be reparative rather than inflammatory.[8,52] Several studies have also suggested that periodontal disease is degenerative to pulpal tissues and results in continued calcification, fibrosis, collagen resorption, and inflammation.[51,53]

Dentin thickness also contributes to the protection of the pulp. Stanley[89] stated that if a 2-mm thickness of dentin remains between the pulp and an irritating stimulus, little chance of pulpal damage exists. Weine[106] summarized the precautions that can be taken during the course of periodontal therapy: (1) avoid using irritating chemicals on the root surface, (2) minimize the use of ultrasonic scalers when less than 2 mm of dentin remains, and (3) allow minor pulpal irritations to subside before completing additional procedures. When these precautions are not followed and the microvasculature of the pulp is damaged during periodontal procedures that involve deep curettage or periodontal surgical efforts to save the tooth, necrosis may result.[107]

The healing success and failure rates after endodontic microsurgery were studied in teeth that had lesions of only endodontic origin compared with teeth that had lesions of

combined endodontic-periodontal origin. Lesions of only endodontic origin had a success outcome of 95.2%, whereas teeth with combined lesions had a success outcome of only 77.5%. This finding suggests that bone healing and tissue healing are negatively affected after endodontic surgery for lesions of combined origin.[46]

It appears, therefore, that the pulp and periodontal compartments influence each other. Periodontal disease, however, seems to have less of an influence on the pulpal tissues compared with the influence of pulpal disease on the periodontium. Clearly, advanced periodontal disease has some biologic effects on the pulpal state (Fig. 46.6). Unless the microvasculature of the pulp is compromised during aggressive periodontal procedures or excessively deep curettage severs the apical vessels, most periodontal interventions result in only a localized pulpal response and dentin hypersensitivity.[103]

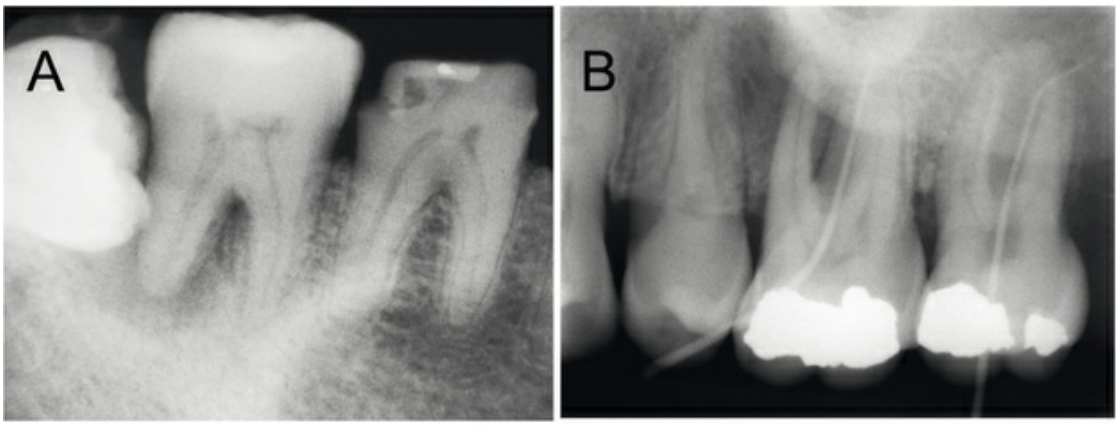

FIG. 46.6 **Primary periodontal defects causing periradicular bony lesions and pulpal irritation. (A) Primary periodontal lesion is evident on the distal surface of tooth #31. The defect was probed to a depth of 7 mm, and the tooth tested vital to both thermal and electrical pulp testing. The defect was most likely the result of the impacted third molar and formation of a chronic periodontal abscess. (B) Primary periodontal lesions both probing 12 mm into the furcation. Teeth #14 and #15 tested vital to thermal and electrical testing. The patient's chief complaint was discomfort to cold, thus exemplifying pulpitis secondary to the primary periodontal infection.** (B, Courtesy Dr. Gregory Kolber.)

Effects of Endodontic Pathosis on Development of Retrograde Peri-

implantitis

The management and resolution of adjacent endodontic and periapical infection are important considerations when planning the placement of a dental implant. Persistence of endodontic bacteria and inflammatory cells commonly facilitates the development of retrograde peri-implantitis or a radiographically evident periapical lesion at the apex of an osseointegrated implant, accompanied by swelling, pain, tenderness, and sinus tract formation.[4,17] Although retrograde peri-implantitis can occur as a result of overloading or premature loading on the implant or contamination of the external surface of the implant upon placement, the presence of preexisting periapical inflammation, endodontic bacteria, or inflammatory cells at, near, or adjacent to the site of implant placement has also been shown to play an important role in the development of this condition.[59,69] Understanding the role that persistent periapical infection plays in the development of retrograde peri-implantitis and the treatment options in cases of refractory periapical periodontitis is critical to long-term periodontal and implant success.

Two scenarios exist in which the interaction between the implant and the adjacent tooth may lead to retrograde peri-implantitis. Under circumstances where complications arise during implant placement, such as overheating of bone during preparation of the implant osteotomy, placement of the implant too close to the adjacent tooth, or altering of the blood supply of the adjacent tooth during implant surgery, the implant placement itself may result in devitalization of the adjacent tooth and subsequent development of peri-implantitis.[91] More common, however, is the presence of existing or recurrent periapical disease from an endodontically treated tooth resulting in contamination of the adjacently placed implant, which may also lead to peri-implantitis.[91,110]

Root canal therapy is critical for resolution of intraradicular or periapical infection. Although radiographic evidence of periapical lesion healing may be noted on endodontic treatment, periapical inflammation may persist and be detectable only histologically.[11,26,80] Brisman and colleagues[10] demonstrated several cases in which implants placed adjacent to asymptomatic, endodontically treated

teeth exhibiting no clinical or radiographic signs of periapical disease resulted in peri-implantitis, which resolved with surgical intervention. The presence of persistent or refractory periapical inflammation adjacent to the implant may increase the risk of developing retrograde peri-implantitis.

Certain treatment considerations should be taken into account when planning implant placement adjacent to an endodontically involved tooth. First and foremost, conventional root canal therapy should be performed to resolve underlying symptomatic or radiographic endodontic and periapical disease, and endodontic retreatment should be performed to address failure of endodontic therapy.[58,95] Delaying the placement of an implant after completion of endodontic treatment on an adjacent tooth or increasing the distance between the implant and the adjacent endodontically treated tooth may reduce the likelihood of peri-implantitis.[110] The use of nonmachined surfaced implants may also decrease the chances of implant failure because machined-surfaced implants placed adjacent to or at the site of previous endodontic infection are more likely to result in the development of retrograde peri-implantitis.[69]

Under circumstances where endodontic infection results in peri-implantitis, surgical debridement and disinfection of the implant surface and resolution of the endodontic pathosis are critical to continued success of the implant.[12] Implant stability is also an important consideration when planning for treatment of retrograde peri-implantitis. Affected implants exhibiting poor stability require removal of the implant, debridement of granulation tissue within the implant osteotomy site, and either placement of bone graft and subsequent implant or immediate placement of a longer or wide implant.[12,67,100] Stable implants exhibiting radiographic evidence of periapical pathosis may be surgically debrided and the implant surface disinfected using chlorhexidine or tetracycline while ensuring that it is not damaged and that systemic antibiotics are administered upon successful debridement.[3,4] Brisman and associates[10] demonstrated a case in which an implant placed at the site of the mandibular incisor succumbed to retrograde peri-implantitis and fistula that, on removal of the implant, was found to lead to the adjacent mandibular canine, which had been

endodontically treated several years earlier. Subsequent apicoectomy of the adjacent tooth and placement of a new implant prevented further implant apical inflammation and failure.[10] Thus, management of both endodontic and implant periapical disease is critical to the resolution of retrograde peri-implantitis and the long-term prognosis of the implant.

Interactions Between Extraradicular Infection and the Periodontium

Although failure of endodontic therapy and persistence of periapical pathology are typically the result of persistent or secondary infection arising from incomplete obturation or abnormal root canal anatomy, in some instances extraradicular infection is to blame. This bacterial infection occurs periapically along the external surface of the root apex and can lead to or exacerbate acute periapical abscess development.[63,84,99] Extraradicular infection can occur either as a result of or independent of intraradicular infection,[85] and unhealed periapical lesions resulting from extraradicular lesions have been found to harbor bacteria of *Actinomyces, Propionibacterium, Treponema, Porphyromonas, Prevotella,* and *Fusobacterium* species.[62,63]

Among the causes of extraradicular infection, the formation of acute apical abscesses secondary to intraradicular infection is the most common and can be resolved nonsurgically with endodontic therapy. Unlike periapical abscess formation, extraradicular infection can less commonly occur as a result of periapical actinomycosis or the asymptomatic development of a granulomatous infection facilitated by gram-positive bacteria of *Actinomyces* and *Propionibacterium* species.[62,85] Among these, *Actinomyces israelii* and *Propionibacterium propionicum* have been predominantly found in actinomycosis lesions.[29,33,85] Whereas periapical abscesses are resolved by conventional root canal therapy, periapical actinomycosis does not respond to endodontic therapy and requires apical surgery.[85] Periapical actinomycosis may develop when infected intraradicular tissue or debris is moved past the apex during instrumentation, when intraradicular bacteria are

moved into the periapical lesion, or when an apical abscess persists, resulting in extraradicular infection that requires surgical intervention.[33,85]

Although intraradicular infection is the predominant source of extraradicular infection, far less common external factors also propagate extraradicular pathosis. One such source is the accumulation of calculus on the external surface of the root apex, which is associated with failed periapical lesion healing, persistent sinus tract formation, and refractory apical periodontitis. Several case reports have identified the presence of calculus along the root apex upon removal by apicoectomy and found that persistent sinus tract and periapical disease resolved on calculus removal.[30,73,77] The formation of calculus around the root apex is thought to be the result of accumulation and calcification of plaque from the external oral environment and periodontium by means of the open persistent sinus tract present in these cases.[73]

In addition to calculus, bacterial biofilms held together by extracellular polysaccharides have also been found along the external surface of the root tip.[98] *Actinomyces naeslundii*, *Actinomyces meyeri*, *P. propionicum*, *Clostridium botulinum*, *P. micra*, *Bacteroides ureolyticus*, *Tannellera forsythensis, F. nucleatum,* and *Porphyromonas gingivalis* have been identified within bacterial biofilms found around the root apex that led to extraradicular infection and refractory apical periodontitis.[64,84] Although the origin of these biofilms is unclear, it is possible that they originate from leaking exudate from junctional epithelium due to periodontal inflammation.[98] Extraradicular bacteria have proven difficult to eliminate by means of systemic antibiotic administration, and in cases where bacterial biofilms are found, this may be due to the presence of bacteria within the extracellular polysaccharide, which facilitates their survival and proliferation.[5,98,109] Although extraradicular infection is not common,[87] its implications in endodontic failure and management of refractory periapical periodontitis are evident. Whereas conventional root canal therapy successfully treats intraradicular infection, the presence of microorganisms beyond the apical foramen often makes extraradicular periapical infections difficult to resolve without surgical intervention.[73,85]

Differential Diagnosis of Pulpal and Periodontal Infection

Acute infections of the periodontium and the pulp must be differentiated from each other for clinicians to be able to establish a correct diagnosis with reasonable certainty and initiate appropriate therapy. A thorough understanding of both disease processes and the correct interpretation of clinical and radiographic findings will aid the dentist in establishing a diagnosis that results in the rapid relief of acute and painful condition.
