
When pulpal and periodontal abscesses are separate from one another, most clinicians believe that the diagnosis is usually easier. In some instances, however, the primary diseases may have similar clinical characteristics that make the diagnosis more difficult. In other situations, no demarcation may exist between the two areas of pathosis that clinically and radiographically appear as one large and continuous lesion, with extreme pain and swelling. When this occurs, the clinician must avoid classifying these continuous lesions as true combined lesions. One must rely on all available clinical testing methods to help clarify the correct clinical diagnosis before beginning treatment.[44]

Accurately differentiating between pulpal and periodontal lesions can be challenging. If the lesion originates from a pulpal infection yet was treated by extensive periodontal therapy, it will not resolve. Conversely, performing endodontic therapy on a tooth that has an extensive periodontal defect and a vital pulp will result in persistence of the periodontal infection. Thus, identifying the primary cause of infection is a critical determinant of treatment outcome. Perhaps the most important consideration when making such a distinction is to base the diagnosis on multiple findings. These findings include the patient's symptoms, coronal integrity, shape and size of the radiographic lesions, periodontal probing, and tooth vitality. It is possible that one or more of these findings will suggest a pulpal or periodontal infection, whereas others may point to the contrary. For instance, a tooth may exhibit extensive failing restorations, recurring decay, and radiographic lesions, suggesting probable pulpal involvement. However, the tooth may test completely vital and lack any evidence of an irreversible

pulpitis on thermal testing. Under these circumstances, one would rule out primary pulpal infection and examine the patient for periodontal involvement. Thus, making the distinction between pulpal and periodontal infection requires collectively dissecting the multiple findings and synthesizing the most probable diagnosis (see Table 46.3).

Patients' Subjective Symptoms

Patients in the acute phase of pulpal infection present with symptoms that are generally absent in chronic periodontal infection. During the initial stage of pulpitis, patients may complain about sensitivity and pain exacerbated by certain stimuli, including temperature changes, pressure, and/or biting. If the symptoms result from reversible pulpitis, they will usually resolve spontaneously with time as the result of various mechanisms, such as closure of dentinal tubules, clearance of microbial irritants and toxins, and reparative dentin formation. Persistent inflammation leads to symptomatic irreversible pulpitis, which is often associated with sharp and spontaneous pain, although asymptomatic irreversible pulpitis may also occur, as described previously. Acute pain in response to thermal stimulus may subside after several days as the pulp becomes necrotic and the bacteria and their byproducts migrate down the complex canal system. As the infection extends to and then past the apical foramen or a lateral root canal, the tooth becomes particularly sensitive to bite pressure and percussion. After several days, the necrotic tooth may develop an acute apical abscess, which results in elevation of the tooth from the dentoalveolar complex. Patients frequently report that the tooth feels “high” on occlusion. However, patients with irreversible pulpitis or necrotic pulp may be asymptomatic. Thus, making the diagnosis of primary pulpal infection must be based on multiple objective findings, such as the patient's responses to percussion, palpation, biting, periodontal probing, and vitality testing, as well as a thorough evaluation of his or her subjective symptoms.

In apical and periodontal abscesses, the extent of pain may vary. Generally, an acute apical abscess causes extreme pain on pressure, bite, percussion, and, at times, palpation if the infection has

penetrated the cortical bone. Periodontal abscesses are thought to cause less pain because little or no elevation of the periosteum occurs. Edema and swelling are characteristics that may be shared by both conditions. The swelling and edema with a periodontal abscess are generally confined to the cervical portion of the tooth. An apical abscess is usually more sensitive to palpation around the tooth apex if the infection has penetrated the bony cortical plate. Redness and a smooth appearance of the marginal gingival tissues are more common with abscesses of periodontal origin, whereas redness can be detected more apically if a pulpal abscess has started to swell and elevate surrounding tissues. Objective findings in periodontal abscesses include bleeding on probing, suppuration, increased pocket depth, increased tooth mobility, and occasionally lymphadenopathy.[32] Abscesses of endodontic origin usually probe normally but may also display increased mobility, depending on the amount of bone loss. Patients may describe the tooth as feeling longer or higher than the adjacent teeth.[25]

Suppuration and drainage from periradicular and periodontal abscesses may also differ. Periodontal abscesses are associated with severe periodontal destruction. In a study investigating the incidence of anaerobes in periodontal abscesses, approximately 66% were determined to have a suppurative exudate that was evident during probing. In the same study, 100% of the patients had bleeding during probing; more than 75% had severe edema, redness, and swelling; and 78% had some degree of mobility. Only a few patients had lymphadenopathy. More than 60% of the patients had not received previous periodontal therapy, and nearly 70% of the teeth were molars. The average measured pocket depth was 7.28 mm.[32] In another study that cultured facultative anaerobic bacteria, the teeth most affected were maxillary and mandibular anterior teeth and mandibular molars. One of the typical features in this study, as in the previous one, was that most of the teeth had been previously untreated.[55] Other aspects of periodontal therapy that correlate highly with the development of acute periodontal abscesses are (1) patients undergoing current periodontal treatment,[88] (2) incomplete removal of calculus,[18] (3) a history of a previous abscess at the same site,[57] and (4) previous use of antibiotics for dental or nondental reasons.[31]

Drainage from apical abscesses usually comes from one of two sites. The most prevalent area of drainage is a sinus tract that develops when the area of swelling breaks through the mucoperiosteum and exits the mucosal tissue either near or at some distance from the site of infection. Additionally, the path of least resistance may be along the periodontal ligament, and the infection may dissect the ligament along the surface of the root and exit the tooth at the height of the epithelial attachment. This results in a periodontal defect that probes along a narrow path to the apex of the root, as previously discussed. Both the sinus tract and narrow sulcular lesions can usually be traced to the infected tooth or offending root by using a gutta-percha point.

Coronal Integrity

Periodontal infection without pulpal involvement may manifest with an intact crown structure and the absence of coronal defects. Conversely, endodontic infection is almost always associated with loss of coronal integrity such as caries, failing restorations, extensive restorations, and cracks or fractures that extend to the pulpal tissues. However, this does not mean that all periodontal infections are devoid of coronal defects or that all endodontic lesions exhibit loss of coronal integrity. When pulp tissue is severed by trauma, for example, one could expect to find necrotic pulp in the absence of coronal defects. If left untreated, such lesions originating from primary pulpal infection lead to the breakdown of the periodontium, as in asymptomatic apical periodontitis or apical abscess. Of course, primary periodontal lesions can develop in teeth with coronal defects. Furthermore, combined lesions (so-called endo-perio lesions) would manifest with a periodontal infection and extensive coronal destruction. However, careful inspection of the coronal status during either the intraoral or radiographic examination can provide supportive information in deciding whether the lesion originates from an endodontic or a periodontal infection.

Radiographic Appearance

Periapical radiographs can provide distinguishing information on

whether the lesion is of pulpal or periodontal origin. Although radiographic findings are objective data, *interpretation* of radiographs can be highly subjective, depending on who reads the radiograph. Thus, it is important to focus on specific entities on a radiograph. These should include the coronal status, crestal bone height and shape, presence of an apical or lateral radiolucency, bony trabeculation, integrity of the lamina dura, and careful evaluation of the obturation of the root canal if present. Coronal status as revealed on a radiograph can also help in the differential diagnosis, as described previously. In addition, apical lesions originating from a primary pulpal infection lead to retrograde periodontitis that migrates from the root apex in a cervical direction. On the contrary, periodontal infections lead to the loss of crestal bone from the cervical area of the tooth in an apical direction. Thus, radiographic lesions appear different in endodontically treated teeth than periodontal lesions, and the shape of the bony lesions can help distinguish between the two. For example, radiographic lesions representing severe periodontitis appear wider at the cervical end than the apical portion of the lesion. Apical or lateral radiolucencies may also result from differences in trabeculation patterns not associated with pulpal infection. For this reason, it is critical to consider the integrity of the lamina dura. A break in the lamina dura accompanied by an apical or lateral radiolucency is usually indicative of a chronic or acute pulpal infection. If the tooth had been endodontically treated, assessment of the previous obturation qualities (e.g., voids, short fills or overfills, missed canals) is also important. These radiographic features provide very useful and often distinguishing information to make the differential diagnosis between pulpal and periodontal lesions more accurate.

Vitality

Testing of tooth vitality is often one of the most important methods to differentiate between periodontal and endodontic infection. Teeth with periodontal infection usually test vital to thermal testing, unless the acute condition is a combined lesion in which both endodontic and periodontal compartments have become

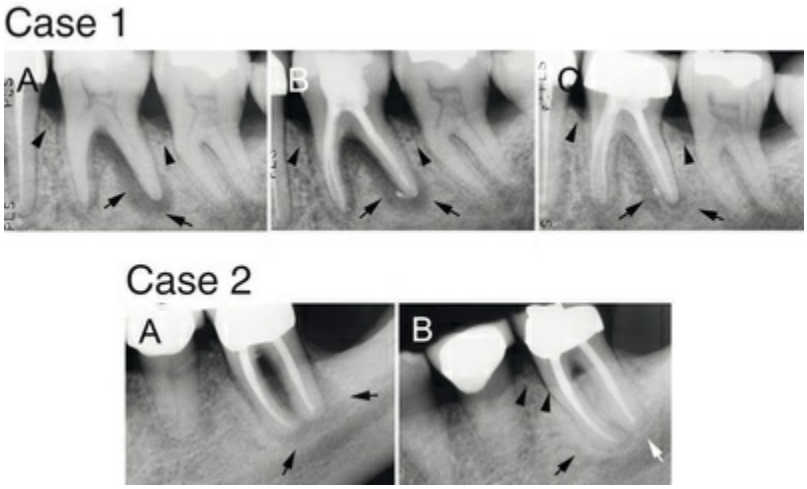
diseased. Teeth with both endodontic infection and periodontal abscess usually test nonvital. Exceptions to this are teeth with extremely calcified canals, extensively restored teeth, or multirooted teeth where canals may be partly necrotic as a result of either pulpal or periodontal disease. Other canals may still retain vital tissue that responds to thermal or electric pulp testing. Thermal testing is usually the most reliable way to determine pulpal health or disease. Patients with symptomatic irreversible pulpitis often report a lingering painful response to thermal stimulus. In later stages of pulpitis, heat exacerbates the symptom more than cold, and the application of cold may even cause short-term pain relief.[43] Although thermal testing can be informative about the status of the pulp, a patient's response to thermal stimulus may be confused with hypersensitivity resulting from exposed dentin and patent dentinal tubules in the absence of pulpitis.[2] Therefore, thermal testing must be combined with other diagnostic criteria, as discussed previously, to distinguish between lesions originating from pulpal or periodontal infection.

Treatment Considerations

In managing lesions of pulpal or periodontal origin, making an accurate diagnosis of the source of infection is a critical determinant of treatment outcome. *Primary* pulpal pathoses combined with *secondary* periodontal defects completely resolve by conventional root canal therapy alone. Fig. 46.3 shows a chronic pulpal infection associated with a necrotic pulp that led to a periodontal defect through the apical foramen. This is a classic example of primary pulpal infection causing a secondary periodontal defect. In this case, root canal therapy alone led to complete resolution of the chronic apical periodontitis involving the furcal defect. In fact, this type of lesion and healing pattern are observed in almost all secondary periodontal defects resulting from root canal infection.

Lesions originating from pulpal infections require endodontic therapy and do not resolve from periodontal treatment alone. This is exemplified in eFig. 46.1, a preoperative radiograph of an "independent" endo-perio lesion that shows an apical radiolucency spanning the entire length of the distal root of tooth #19 and

moderate bone loss at the mesial aspect. On completion of root canal therapy, the periodontal breakdown around the distal root completely resolved, whereas the mesial bony defect remained unchanged. Case 2 shows a "combined" endo-perio lesion involving extensive apical defects around the apices of tooth #19 and a periodontal defect in the bifurcation. After successful endodontic therapy alone, the apical lesions and furcation defect resolved, but incomplete healing is noted in the coronal aspect of the furcation. This finding presumes that the unhealed defect originated from a primary periodontal infection.



EFIG. 46.1 Case 1. "Independent" endo-perio lesion. (A) "Truly independent" endo-perio lesions. Vertical periodontal bone loss can be seen at the mesial surface of teeth #18 and #19. A large endodontic lesion extends around the apex and into the bifurcation. An apical and furcal defect is evident radiographically (*black arrows*). Interproximal periodontal bone loss is also evident (*black arrowheads*). (B) Final condensation film 2 weeks after initiating treatment. (C) Nearly complete healing of the endodontic lesion at 6 months and restoration of the tooth with a porcelain-fused-to-metal crown. The areas of vertical bone loss from the periodontal lesions are still present. Case 2. "Combined" endo-perio lesion. (A) Nonvital tooth with a narrow 9-mm probing defect in the bifurcation of tooth #19 and a large periapical lesion (*black arrows*). (B) At 9 months, healing demonstrates significant bone repair in the furcation

and periapical areas (*white arrow*). A small amount of bone loss in the furcation still remains (*black arrowheads*) because of a persistent periodontal defect. (Case 1, Courtesy Dr. Thomas Rauth.)

Therefore, endo-perio lesions require both endodontic and periodontal therapy for complete healing to occur. This is true whether the lesions are independent or combined. One important consideration is the sequence of therapies: Which of the two should be performed first? As discussed earlier, endodontic lesions are often associated with more pronounced symptoms than periodontal lesions. More importantly, in combined endo-perio lesions, some periodontal defects will resolve on completion of the endodontic treatment, whereas the opposite would not be the case. After resolution of the secondary periodontal defect stemming from a primary pulpal infection, the residual periodontal disease may be more accurately and predictably managed. These considerations indicate that combined endo-perio lesions are best treated by performing the necessary endodontic treatment first, followed by periodontal therapy.

When patients present with an abscess, periodontal and apical abscesses are managed differently. Previous studies suggested that treating patients with acute periodontal abscesses should be done in two stages. The first stage consists of management of the acute lesion. In the second stage, more comprehensive treatment of the original and any residual lesions is accomplished. Management of acute periodontal abscesses involves establishing drainage through the periodontal pocket and subgingival scaling and root planing.

Curettage of the epithelium lining, the pocket, and the surrounding connective tissue is then accomplished, followed by compression of the pocket wall. If the swelling is large and fluctuant, flap surgery or incision and drainage may be necessary to relieve the pressure. In cases in which the bone loss is extensive and the prognosis for the tooth is hopeless, extraction may be required.[101]

Rational use of antibiotics should be considered in acute periodontal abscesses.[37] The use of systemic antibiotics may be indicated when a patient has elevated temperature, cellulitis, or systemic disease and is immunocompromised.[101] In a study by

Jaramillo and associates,[37] some periodontal pathogens showed resistance to tetracycline, metronidazole, and amoxicillin but not azithromycin. In the management of acute apical abscesses, the abscess should be drained by incision and drainage and/or root canal debridement. Depending on the maturity of the abscess, incision and drainage may not establish draining exudate from the periapical tissues. However, it is highly recommended to initiate root canal therapy to debride the root canal and eliminate the source of infection. An incision and drainage procedure is efficient and relieves the pressure that has accumulated under the subperiosteal tissues, resulting in a fluctuant, swollen, and painful lesion. Pulpectomy removes the infected pulp tissues and microorganisms within the canal system, and calcium hydroxide is placed into each of the canals. Its use has proved to be a suitable intracanal medicament because of its stability and bactericidal effect in a limited space.[42] Substantial evidence indicates that systemic antibiotic therapy may not be beneficial for patients with acute apical abscess unless they present with systemic complications such as fever, lymphadenopathy, or cellulitis, or are immunocompromised.[54,92,104]

Penicillin V and amoxicillin are still the antibiotics of choice for the majority of bacteria isolated from acute endodontic infections. If penicillin V therapy is ineffective, the combination of penicillin V with metronidazole or amoxicillin–clavulanate potassium is recommended. Clindamycin is another excellent alternative.[45] Pain associated with acute apical periodontitis is well controlled by systemic nonsteroidal antiinflammatory drugs with or without acetaminophen (Tylenol). Narcotics are usually unnecessary unless an acute flare-up occurs.[92] The correct diagnosis of periodontal and apical abscesses is the most critical step in resolving the disease process. Failing to properly diagnose and treat these often encountered conditions results in progression of the disease, continued loss of bone and periodontal attachment apparatus, a poor prognosis, and possible loss of the tooth.

Summary

Bacteria-induced inflammations of the pulpal and periodontal

tissues often occur together. Endodontic lesions are more likely to spread to surrounding periodontal tissues, with subsequent bone and tissue destruction, compared with the less frequent involvement of periodontal infections in the pulpal tissues that result in retrograde pulpitis.

Understanding the etiology and making the diagnosis of dental abscess are based on the patient's history and clinical and radiographic findings. Pulpal pathosis often results in significant pain to thermal stimulus or tissue swelling, or it may be totally asymptomatic. Radiographic evaluation may demonstrate a circumscribed periapical lesion when the tooth tests necrotic and the origin of the lesion is pulpal. Vitality testing can detect changes of sensation caused by pulpal inflammation and necrosis. If evidence indicates pulpal disease and the possibility of associated periodontal bone loss, the endodontic treatment should be completed first, and then the patient should be reevaluated. In many cases, apparent periodontal disease, including bone loss, suppuration, and pocket depth, resolves if a pulpal lesion has been successfully treated endodontically.

Residual periodontal problems can be treated after completion of successful endodontic treatment, and in many cases, successful regeneration of periodontal defects is possible in endodontically treated teeth. Knowledge of these two disciplines is necessary for successful treatment outcomes.

Video 46.1 contains a slide show that discusses the treatment of fractured teeth.

Case Scenario 46.1

Patient:

Male patient in his 50s

Chief Complaint:

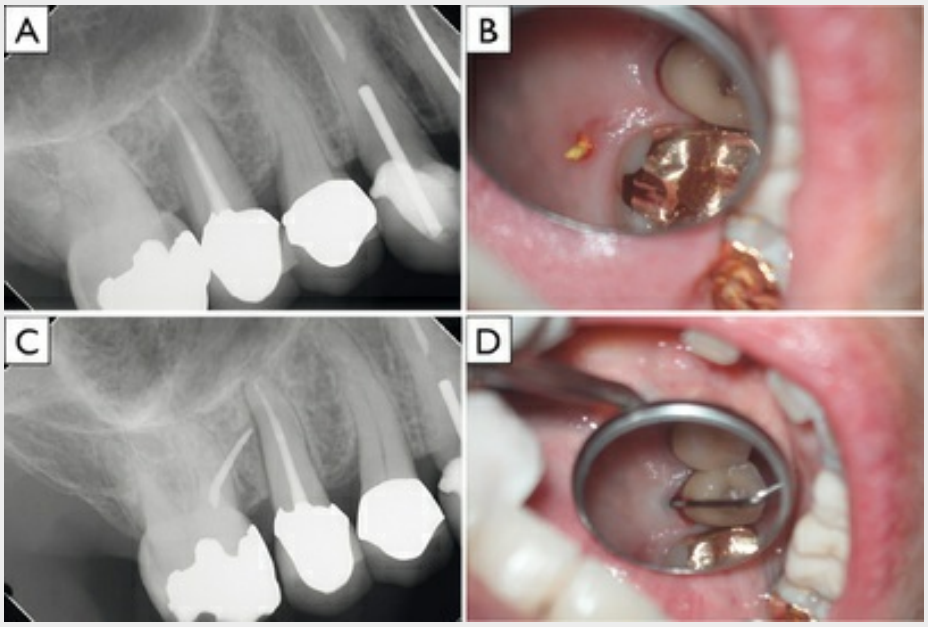
"Pain on upper right with chewing."

Background Information:

Patient is a nonsmoker, a healthy individual without systemic health concerns. Patient reports pain with chewing on upper right quadrant and points to an area between #3 and #4. Patient also notes some discomfort with gingival swelling around #3 toward the "inside."

Current Findings:

(A) Periapical radiograph is unremarkable; #3 has large coronal restoration that is intact and a highly calcified root canal space, and #4 has previous endodontic therapy with no discernible apical periodontitis. Patient does not report temperature sensitivity, whereas #3 tests vital. (B) Marginal gingiva is healthy around #3 and #4, except for a sinus tract directly palatal to the distobuccal cusp of #3. (C) Gutta-percha (GP) tracing led to the midroot area of #4. Probing depths around #3 and #4 are normal, except lingual of #4, which exhibits a 7- to 9-mm probing defect.



Case-Based Questions	Solution and Explanation
1. What is the most probable etiology of the patient's symptom?	**Answer:** The patient most likely has vertical root crack on tooth #4, as revealed by the GP tracing, which points directly to the midroot of #4. In addition, the narrow probing defect on #4 almost confirms the presence of vertical root crack. (D) Endodontic access through

	an existing porcelain-fused-to-metal crown. Thus, it is likely that vertical crack was present at the time of endodontic therapy on #4 and was not detected with access through the crown. When possible, removal of the crown is therefore recommended for examination of the integrity of the remaining tooth structure.
2. How is a vertical bony defect associated with root crack distinguished from periodontal diseases?	**Answer:** Periodontal diseases generally manifest with a broad osseous defect affecting multiple surfaces of a tooth or surfaces of multiple teeth. Conversely, vertical root crack generally leads to narrow periodontal defects surrounding the crack due to established microbial biofilm at the crack. Hence, the probing defect is a very important determinant in assessing the apical extent of vertical root crack.
3. Which of the following teeth are frequently linked to vertical root cracks? A. Mesial surface of maxillary first molars B. Distal surface of mandibular second molars C. Endodontically treated teeth D. All of the above	**Answer: D** **Explanation:** Vertical root cracks are frequently found in the mesial surface of maxillary first molars and the distal surface of mandibular second molars, whether teeth are vital, necrotic, or endodontically treated. In general, endodontically treated teeth are more susceptible to vertical root cracks than vital teeth. However, the literature indicates that dentinal brittleness is unchanged by endodontic treatment. Therefore, a higher incidence of cracks in teeth with endodontic therapy is primarily associated with loss of tooth structure, rather than substantive changes in the dentin itself. Hence, this calls for a conservative approach in cleaning and shaping of root canals during endodontic therapy.

CHAPTER OUTLINE

Rationale
Treatment Sessions
Sequence of Procedures
Results
Healing
Decision to Refer for Specialist Treatment
Conclusion

Phase I therapy or cause-related therapy[10] is the first in the chronologic sequence of procedures that constitute periodontal treatment. The objective of phase I therapy is to alter or eliminate the microbial etiology and factors that contribute to gingival and periodontal diseases to the greatest extent possible, thereby halting the progression of disease and returning the dentition to a state of health and comfort.[5] Phase I therapy is referred to by a number of

names, including *initial therapy,*[5,10] *nonsurgical periodontal therapy,*[18] and *cause-related therapy.*[10] All terms refer to the procedures performed to treat gingival and periodontal infections up to and including tissue reevaluation, which is the point at which the course of ongoing care is determined.

Rationale

Phase I therapy is defined by the evidence-based American Association of Periodontology practice guidelines[5] as the initiation of a comprehensive daily plaque or biofilm control regimen, management of periodontal-systemic interrelationships as needed, and thorough removal of supragingival and subgingival bacterial plaque or biofilm and calculus. Other problems that must be managed include the use of chemotherapeutic agents as necessary, and local factors[1–4,6] such as elimination of defective restorations and treatment of carious lesions.[7,9,15,16,20] These procedures are a required part of periodontal therapy, regardless of the extent of disease present. In many cases, only phase I therapy is required to restore periodontal health, or it constitutes the preparatory phase for surgical therapy. Figs. 47.1 and 47.2 show the results of phase I therapy in two patients with chronic periodontitis. Cause-related phase I periodontal therapy has been succinctly stated as the approach *aimed at removal of pathogenic biofilms, toxins, and calculus and the reestablishment of a biologically acceptable root surface.*[10]

FIG. 47.1 Results of phase I therapy, severe chronic periodontitis. (A) A 45-year-old patient with deep probe depths, bone loss, severe swelling, and redness of the gingival tissues. (B) Results 3 weeks after the completion of phase I therapy. Note that the gingival tissue has returned to a normal contour, with redness and swelling dramatically

reduced.

FIG. 47.2 **Results of phase I therapy, moderate chronic periodontitis. (A) A 52-year-old patient with moderate attachment loss and probe depths in the 4- to 6-mm range. Note that the gingiva appears pink because it is fibrotic. Inflammation is present in the periodontal pockets but disguised by the fibrotic tissue. Bleeding occurs on probing. (B) Lingual view of the patient with more visible inflammation and heavy calculus deposits. (C) and (D) At 18 months after phase I therapy the same areas show significant improvement in gingival health. The patient returned for regular maintenance visits at 4-month intervals.**

Phase I therapy is a critical aspect of periodontal treatment. Data from clinical research indicate that the long-term success of periodontal surgical treatment is dependent on maintaining the plaque or biofilm control results achieved with phase I therapy. In fact, patients who do not have adequate plaque or biofilm control will continue to lose attachment regardless of what surgical procedures are performed.[12] In addition, phase I therapy provides an opportunity for the dentist to evaluate tissue response and provide reinforcement about home care, both of which are crucial to the overall success of treatment.

Based on the knowledge that microbial plaque or biofilm is the major etiologic agent in gingival inflammation, one specific aim of

phase I therapy for every patient is *effective daily plaque or biofilm removal* at home. These home care procedures can be complex and time-consuming, and often require changing long-standing habits. Good oral hygiene is more easily accomplished if the tooth surfaces are free of calculus deposits and other irregularities so that they are easily accessible. Management of all contributing local factors is required in phase I therapy. The following list of elements makes up phase I therapy:

1. Patient education and oral hygiene instruction
2. Complete removal of supragingival calculus (see Chapters 50 and 51)
3. Correction or replacement of poorly fitting restorations and other prosthetic devices (see Chapter 70)
4. Restoration or temporization of carious lesions
5. Orthodontic tooth movement (see Chapter 56)
6. Treatment of food impaction areas
7. Treatment of occlusal trauma (see Chapter 55)
8. Extraction of hopeless teeth
9. Possible use of antimicrobial agents, including necessary plaque or biofilm sampling and sensitivity testing (see Chapters 8 and 52)

Treatment Sessions

After careful analysis and diagnosis of the specific periodontal condition present, the clinician must develop a treatment plan that includes all required procedures to treat the periodontal involvement and an estimate of the number of appointments necessary to complete phase I therapy. In most cases, patients require several treatment sessions for complete debridement of the tooth surfaces. All the following conditions must be considered when determining the phase I treatment plan[18]:

- General health and tolerance of treatment
- Number of teeth present
- Amount of subgingival calculus

- Probing pocket depths
- Attachment loss
- Furcation involvement
- Alignment of teeth
- Margins of restorations
- Developmental anomalies
- Physical barriers to access the dentition (i.e., limited opening or tendency to gag)
- Patient cooperation and sensitivity to therapy (requiring use of anesthesia or analgesia)

Sequence of Procedures

Step 1: Plaque or Biofilm Control Instruction

Plaque or biofilm control is an essential component of successful periodontal therapy, and instruction should begin at the first treatment appointment. Before oral hygiene instruction, the patient must understand the reason that he or she must actively participate in therapy. The explanation of the etiology of the disease must be presented to the patient. Once the patient understands the nature of periodontal disease and the etiology, it will be easier to teach the hygiene that he or she must practice. The patient must be instructed on the correct technique to remove the plaque or biofilm; this means focusing on applying the bristles at the gingival third of the clinical crowns, where the tooth meets the gingival margin. This technique is sometimes referred to as *targeted oral hygiene* (Takei H: Personal communication, 2009) and is synonymous with the Bass technique. Instructions are also initiated for interdental cleaning with dental floss and interdental brushes. The use of the multiple appointment approach to phase I therapy is favored by many clinicians because it permits the use of numerous appointments to evaluate, reinforce, and improve the patient's oral hygiene skills. (Chapter 48 details plaque and biofilm control options.)

Step 2: Removal of Supragingival and Subgingival Plaque or Biofilm and Calculus

Removal of calculus is accomplished using scalers, curettes, ultrasonic instrumentation, or combinations of these devices during one or more appointments. Evidence suggests that the treatment results for chronic periodontitis are similar for all instruments, which could be hand instrumentation or other mechanical instruments, such as ultrasonic scalers.[12,13] Most clinicians advocate the combination of hand instruments (scalers, curettes) and ultrasonic devices. In addition to calculus and plaque or biofilm removal, cementum exposed to the pocket environment should be removed. At one time it was thought that the removal of all cementum was necessary to attain a smooth, glassy, hard surface. The rationale was that cementum became necrotic from penetration of endotoxins from the microbial biofilm and would interfere with healing. Current studies have indicated that endotoxins do not penetrate into the cementum as deeply as once believed and complete removal of the cementum may not always be necessary, but removal of the plaque or biofilm and calculus is absolutely necessary. In a clinical situation, it is difficult to know whether the removal of some or all of the cementum is achieved.

Laser treatment has also been advocated for periodontal therapy by some clinicians.[8] However, some reviews suggest that further well-designed studies are needed to confirm the outcomes. In addition, gingival curettage, the systematic removal of the soft tissue lining of the pockets, has not been shown to improve the results of treatment. Thorough plaque or biofilm removal and excellent root therapy result in conversion of the soft, edematous, inflamed gingival tissue to a healthier state without removing this tissue by using intentional soft tissue curettage. Therefore curettage of the soft tissue pocket wall in phase I therapy is no longer advocated.

Photodynamic therapy has also been presented as an adjunct to scaling and root planing. This therapy uses lasers at specific wavelengths to "target microorganisms treated with a photosensitizer." Studies have not found this intervention to be useful as an alternative to scaling and root planing to improve

treatment outcomes. Further research is necessary to ascertain the efficacy of this treatment.[12]

Another interesting approach to calculus removal and debridement is full-mouth disinfection. In this technique, full-mouth treatment is performed during one session or multiple sessions within a few days. Disinfectants are used after therapy, with the intention of preventing reinfection of treated sites from untreated sites.[14,17,19,22] This treatment approach is used during phase I therapy by some clinicians, but the results have not been shown to be superior to those of any other phase I therapy.[11,12,21]

Multiple approaches are used to plan and perform nonsurgical phase I therapy. Decisions on how to proceed should be discussed and agreed on by the patient and the dentist based on the amount of disease present and the patient's tolerance to the therapy.[11] Staged therapy has the advantage of evaluating and reinforcing the oral hygiene status of the patient, but the one- or two-appointment approach can be more efficient in reducing the number of office visits the patient is required to attend.

Step 3: Recontouring Defective Restorations and Crowns

Corrections of restorative defects, which are plaque or biofilm retentive areas, may be accomplished by smoothing the rough surfaces and removing overhangs from the faulty restorations with burs or hand instruments, or complete replacement of the failing restorations may be necessary. All these steps are important to remove the risk factors that perpetuate the inflammatory process. These procedures can be completed concurrently with other phase I procedures.

Step 4: Management of Carious Lesions

Removal of the carious lesions and placement of either temporary or permanent restorations are indicated in phase I therapy because of the infectious nature of the carious process. Healing of the periodontal tissues is maximized by removing the reservoir of bacteria in these lesions so that they cannot repopulate the

microbial plaque.

Step 5: Tissue Reevaluation

After scaling, root planing, and other phase I procedures, the periodontal tissues require approximately 4 weeks to heal. This time allows the connective tissues to heal, and accurate probe depths can be measured. Patients will also have the opportunity to improve their home care skills to reduce gingival inflammation and adopt new habits that will ensure the success of treatment. At the reevaluation appointment, periodontal tissues are probed, and all related anatomic conditions are carefully evaluated to determine whether further treatment, including periodontal surgery, is indicated. Additional improvement from periodontal surgical procedures can be expected only if phase I therapy results in gingival tissues that are free of overt inflammation and the patient has adopted effective daily plaque or biofilm control procedures.

Results

Scaling and root planing therapy have been studied extensively to evaluate their effects on periodontal disease. Many studies have indicated that this treatment is both effective and reliable. Studies ranging from 1 month to 2 years in length demonstrated up to 80% reduction in bleeding on probing and mean probing depth reductions of 2 to 3 mm. Other studies demonstrated that the percentage of periodontal pockets of 4-mm or deeper was reduced by more than 50% and in many cases up to 80%.[9] Figs. 47.1 and 47.2 show examples of the effectiveness of phase I therapy.

In addition, deeper probing depths present the dentist with greatly increased instrumentation challenges due to the complexity of root anatomy and difficulty accessing the root surfaces. Badersten and colleagues[7] reported in the 1980s that residual calculus remained on 44% of the surfaces in deeper pockets. Other studies have confirmed these findings, including studies comparing the use of hand instruments with that of powered scaling instruments.[12]

Additional individual treatments, such as caries control and

correction of poorly fitting restorations, clearly help the healing gained by good plaque or biofilm control and debridement by making tooth surfaces accessible to hygiene procedures. Fig. 47.3 demonstrates the effects of an overhanging amalgam restoration on gingival inflammation in an otherwise healthy periodontium. Maximal healing from phase I treatment is not possible when local conditions retain biofilm and provide reservoirs for repopulation of periodontal pathogens.

FIG. 47.3 Effects of overhanging amalgam margin on interproximal gingiva of maxillary first molar in otherwise healthy mouth. (A) Clinical appearance of rough, irregular, and overcontoured amalgam. (B) Gentle probing of interproximal pocket. (C) Extensive bleeding elicited by gentle probing indicating severe inflammation in the area.

Healing

Healing of the gingival epithelium consists of the formation of a long junctional epithelium rather than new connective tissue

attachment to the root surfaces. This long junctional epithelium occurs about 1 week after therapy. Gradual reductions in inflammatory cell population, crevicular fluid flow, and repair of connective tissue result in decreased clinical signs of inflammation, including less redness and swelling. One or two millimeters of recession is often apparent as the result of tissue shrinkage.[9] Connective tissue fibers are disrupted and lysed by the disease process and also by the inflammatory reaction to treatment. These tissues require 4 or more weeks to reorganize and heal, and many cases may require several weeks for complete healing.

Transient root sensitivity frequently accompanies the healing process. Although evidence suggests that relatively few teeth in a few patients become highly sensitive, this problem can be disconcerting to patients. The extent of the sensitivity can be diminished with good plaque or biofilm removal, but this may take several weeks to months.[23] Patients should also be warned and educated before the therapy is undertaken regarding the potential outcomes of several changes, such as the teeth appearing longer due to shrinkage of the periodontal tissues and root sensitivity. Knowledge of these changes before therapy will prevent the possibility of the patient complaining if they should occur. Unexpected and possible uncomfortable consequences of treatment may result in the patient's distrust and loss of motivation to continue therapy.

Decision to Refer for Specialist Treatment

It is fortunate that many periodontally involved cases do not require any further therapy beyond phase I therapy. Therefore, these patients can be seen by general dentists for routine maintenance therapy. However, advanced or complicated cases benefit from specialist care. Heitz-Mayfield and Lang[12] demonstrated that surgical treatment in deep pockets, those >6 mm, gained 0.6 mm more probing depth reduction and 0.2 mm more clinical attachment gain than did deep pockets treated with scaling and root planing alone. This study also confirmed that in pockets of

4 to 6 mm probing depth, scaling and root planing resulted in 0.4 mm more attachment gain than surgical procedures, and shallow pockets of 1 to 3 mm had 0.5 mm less attachment loss compared with surgical results.[12] It is critical to be skilled in determining which patients would benefit from specialist care and deciding when a patient should be referred.

The concept of the *critical probing depth* of 5.4 mm has been advanced to assist in making the determination to proceed to surgical intervention. This is the measurement above which therapy will result in clinical attachment gain and below which it will result in clinical attachment loss. This determination was made based on statistical analysis of surgical outcomes data.[12] A similar *5-mm standard* has been commonly used as a guideline for identifying candidates for surgical referral based on the understanding that the typical root length is about 13 mm and the crest of the alveolar bone is at a level approximately 2 mm apical to the bottom of the pocket. When there is 5 mm of clinical attachment loss, the crest of bone is about 7 mm apical to the cementoenamel junction, and therefore only about half of the bony support for the tooth remains. Periodontal surgery can help improve support for teeth in these cases through pocket reduction, bone augmentation, and regeneration procedures. Fig. 47.4 depicts the relationship of clinical attachment loss to tooth support.

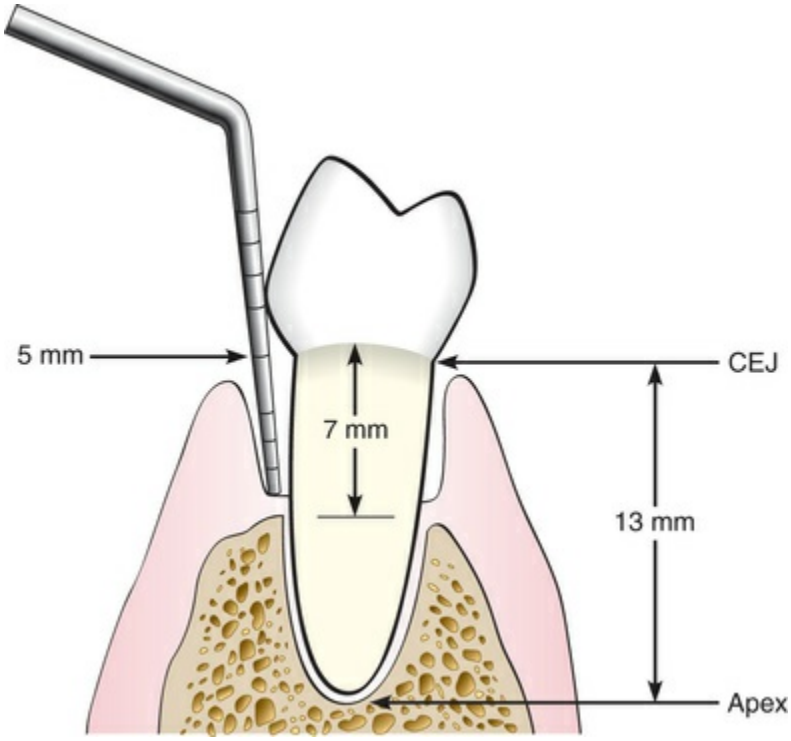

FIG. 47.4 The 5-mm standard for referral to a periodontist is based on root length, probing depth, and clinical attachment loss. The standard serves as a reasonable guideline to analyze the case for referral for specialist care. *CEJ,* Cementoenamel junction.
(Redrawn with permission from Armitage G, editor: *Periodontal maintenance therapy*, Berkeley, CA, 1974, Praxis.)

In addition to the 5-mm probing depth criterion, other factors must be considered in the decision to refer to a periodontal specialist:

1. *Extent of the disease and generalized or localized periodontal involvement.* The amount of bone loss, even in localized areas, suggests the need for specialized surgical techniques.
2. *Root length.* Short-rooted teeth are jeopardized to a greater extent by the 5-mm clinical attachment loss criterion than teeth with long roots.
3. *Hypermobility.* Excessive tooth mobility suggests that contributing factors may be responsible for the mobility. The extent of mobility could mean that the prognosis for the tooth may be guarded to poor.
4. *Difficulty of scaling and root planing.* The presence of deep pockets and furcations makes instrumentation difficult, but

the results can often be improved with surgical access.

5. *Restorability and importance of particular teeth for reconstruction.* Long-term prognosis of each tooth is important when considering extensive restorative work.
6. *Age of the patient.* Younger patients with extensive attachment loss are more likely to have aggressive forms of disease that require advanced therapy.
7. *Lack of resolution of inflammation after thorough plaque or biofilm removal and excellent scaling and root planing.* If inflammation and progressive deepening of the pocket continue, further therapy will be necessary. Such cases require an understanding of the etiology to determine the best course of treatment.

Every patient is unique, and the decision process for each patient is complex and difficult. The considerations presented in this chapter should provide guidance for understanding the significance of phase I therapy and making referral decisions.

Conclusion

The major goal of phase I therapy is to control the factors responsible for periodontal inflammation; this involves educating the patient in the removal of bacterial plaque or biofilm. Phase I therapy also includes scaling, root planing, and other therapies such as caries control, replacement of defective restorations, occlusal therapy, orthodontic tooth movement, and cessation of confounding habits such as tobacco use. Comprehensive reevaluation after phase I therapy is essential to determine treatment options and establish a prognosis. Many patients can attain periodontal disease control with phase I therapy alone and do not require further surgical intervention. For patients who require surgical intervention, phase I therapy is an advantageous element of treatment in that it permits tissue healing, thus improving the surgical management and healing response of the tissues.

Periodontal surgical intervention should be considered for patients with deep pocket depths and those with 5 mm or more of

attachment loss after phase I therapy. Periodontal specialists can best provide treatment to preserve the teeth for patients with advanced disease. Moreover, patients who do not demonstrate the ability to control plaque or biofilm on a daily basis effectively are poor candidates for surgery and should be closely monitored on a recall maintenance program unless conditions change.

Conclusion

Microbial plaque biofilm control, also referred to as periodontal self-care,[32] is an effective way of treating and preventing gingivitis and is an essential part of all procedures involved in the treatment and prevention of periodontal diseases.[50] It is a critical element in the long-term success of all periodontal and dental treatment.[3] In 1965, Löe and colleagues[89] conducted the classic study demonstrating the relationship between microbial plaque biofilm accumulation and the development of experimental gingivitis in humans. Subjects in the study stopped brushing and other plaque biofilm control procedures, thus resulting in the development of gingivitis in every person within 7 to 21 days. The composition of the biofilm bacteria also shifted so that more virulent gram-negative organisms predominated, and these changes were shown to be reversible within 7 days. Good supragingival biofilm control has also been shown to affect the growth and composition of subgingival plaque biofilm so that it favors a healthier microflora and reduces calculus formation.[121] Carefully performed daily home plaque biofilm control, combined with frequent professionally delivered plaque biofilm and calculus removal, reduces the amount of supragingival biofilm, decreases the total number of microorganisms in moderately deep pockets, including furcation areas, and greatly reduces the quantity of periodontal pathogens.[29,61] Reviews of home care procedures in 2011 and 2013 confirmed the positive effects of daily plaque biofilm removal but cautioned that these gains appear to be small, and best results also require professional maintenance care.[32,107]

Microbial biofilm growth occurs within hours, and it must be completely removed at least once every 48 hours in the experimental setting with periodontally healthy subjects to prevent inflammation.[120] The American Dental Association (ADA) recommends that individuals should brush twice per day and use floss or other interdental cleaners once per day to effectively remove microbial plaque biofilms and prevent gingivitis.[3] The ADA recommends twice-daily brushing because most individuals do not

adequately remove microbial biofilms at one brushing, and doing it a second time improves the results.

Periodontal lesions are predominantly found in interdental locations, so toothbrushing alone is not sufficient to control gingival and periodontal diseases.[75] It has been demonstrated in healthy subjects that plaque biofilm formation begins on the interproximal surfaces, where the toothbrush does not reach. Masses of biofilm first develop in the molar and premolar areas, followed by the proximal surfaces of the anterior teeth and the facial surfaces of the molars and premolars. Lingual surfaces accumulate the least amount of biofilm. Patients consistently leave more plaque biofilm on the posterior teeth than the anterior teeth, with interproximal surfaces retaining the highest amounts of biofilm. It is in these interproximal areas where periodontal infections and carious lesions begin.[120] In addition, periodontal patients tend to have increased susceptibility to disease[123] due to complex defects in gingival architecture and long exposed root surfaces to clean, which compounds the difficulty of practicing thorough hygiene.

Clinical Correlation

Daily plaque biofilm control practices result in improved periodontal and gingival health. Cessation of plaque control practices for 7 to 21 days results in:

- Accumulation of thick plaque on tooth surfaces
- Reddened gingiva that bleeds easily
- Shift to more virulent gram-negative flora
- Changes that are completely reversed in about 7 days when plaque control practices are resumed

Chemical inhibitors of plaque biofilm and calculus that are incorporated in mouthwashes or dentifrices also play an important role in controlling microbial biofilms.[32] Fluoride delivered through toothpastes and mouthrinses are essential for caries control.[38] Many products are available as adjunctive agents to mechanical techniques. These medicaments, as with any drug, should be

recommended and prescribed according to the needs of the individual patient. Also note that the interest in supplementing oral hygiene procedures with natural products has increased in our society. However, the evidence base supporting the use of these products is currently lacking valid studies to determine their efficacy.[22]

Daily plaque biofilm control permits patients to assume responsibility for their own oral health every day. Without it, optimal oral health through periodontal treatment cannot be attained or preserved. Elements of biofilm control include mechanical cleaning and chemical adjuncts.

The Toothbrush

Toothbrushes vary in size and design, as well as in length, hardness, and arrangement of the bristles[115] (Fig. 48.1). Some toothbrush manufacturers claim superiority of design for such factors as minor modifications of bristle placement, length, and stiffness. These claims are primarily based on plaque biofilm removal shown to be significantly superior to other toothbrushes in short-term clinical studies. However, research does not indicate significant differences in gingivitis scores or bleeding indices, which are the more important measures of improved gingival health. In fact, at least one study compared four commercially available toothbrushes for total plaque biofilm removal at a single brushing. All four toothbrushes removed biofilm equally, and the investigators concluded that no one design was superior to the others.[25] In addition, systematic review of multiple studies did not identify a superior design.[32]

FIG. 48.1 **Manual toothbrushes. (A) Toothbrushes from the 19th and 20th centuries, one with an ivory handle from about 1890 *(left),* one with a composition handle from the 1950s *(center),* and one with a sterling silver handle from the early 20th century *(right).* The ivory-handled brush belonged to a dental student who used the handle to practice cutting preparations and filling the "preps" with amalgam or gold foil. (B) Various types of toothbrushes are available; note the variations in brush head and handle design. (C) Brush heads, showing various bristle configurations.** (Antique brushes courtesy Dean John D.B. Featherstone, University of California, San Francisco School of Dentistry Historical Collection, San Francisco.)

« Flash Back

Early toothbrushes were mostly made of hog bristles and were very stiff and hard. Hard-bristled toothbrushes have been shown

to abrade tooth surfaces and scratch the gingiva. Few remain on the market, but in general, hard-bristled toothbrushes should be avoided.

When recommending a particular toothbrush, ease of use by the patient and the perception that the brush is effective are the important considerations. The effectiveness of and potential injury from different types of brushes depend to a great degree on how the brushes are used. Data from in vitro studies of abrasion by different manual toothbrushes suggest that brush designs that permit the bristles to carry a greater amount of toothpaste while brushing contribute to abrasion more than the bristles themselves.[33] However, it has been shown that several factors contribute to the problem of abrasion: (1) the use of hard toothbrushes, (2) vigorous horizontal brushing, and (3) the use of extremely abrasive dentifrices; all these factors may contribute to and lead to cervical abrasions of teeth and recession of the gingiva.[74]

Toothbrush Design

Toothbrush bristles are grouped in tufts that are usually arranged in three or four rows. Rounded bristle ends cause fewer scratches on the gingiva than flat-cut bristles with sharp ends[28,115] (see Fig. 48.1). Two types of bristle material are used in toothbrushes: natural bristles from hogs and artificial filaments made of nylon. Both remove microbial plaque biofilm, but nylon bristle brushes predominate in the market. Bristle hardness is proportional to the square of the diameter and inversely proportional to the square of the bristle length.[56] Diameters of common bristles range from 0.007 inch (0.2 mm) for soft brushes to 0.012 inch (0.3 mm) for medium brushes and 0.014 inch (0.4 mm) for hard brushes.[63] Soft-bristle brushes of the type described by Bass[11] have gained wide acceptance (Fig. 48.2). Handle design characteristics are entirely a matter of personal preference.

FIG. 48.2 (A) Toothbrushes of different bristle design and configuration. (B) The brush on the *far left* in (A) is the most appropriate of the four brushes displayed for biofilm removal.

Softer bristles are more flexible, clean slightly below the gingival margin when used with a sulcular brushing technique,[12] and reach farther apically to the proximal surfaces[45] (see Fig. 48.2). As indicated earlier, the use of hard-bristled toothbrushes is associated with greater gingival recession.[74] However, the manner in which a brush is used and the abrasiveness of the dentifrice affect abrasion to a greater degree than the bristle hardness itself.[93] Bristle hardness does not significantly affect wear on enamel surfaces.[108]

The amount of force used to brush is not critical for effective plaque biofilm removal.[125] Vigorous brushing is not necessary and

can lead to gingival recession, wedge-shaped defects in the cervical area of root surfaces,[109] and painful ulceration of the gingiva.[101]

Toothbrushes must also be replaced periodically, although the amount of visible bristle wear does not appear to affect plaque biofilm removal for up to 9 weeks.[27] Most clinicians recommend that toothbrushes be replaced every 3 to 4 months.

Key Facts

When recommending toothbrushes, keep these general recommendations in mind:

- Soft nylon bristle toothbrushes clean effectively when used properly and tend not to traumatize the gingiva or root surfaces.
- Toothbrushes become worn due to wear and should be replaced about every 3 to 4 months.
- If patients perceive a benefit from a particular design of toothbrush, they should use it as long as it is not too stiff and hard.

Powered Toothbrushes

Electrically powered toothbrushes designed to mimic back-and-forth brushing techniques were invented in 1939. Subsequent models featured circular or elliptical motions, and some had combinations of motions. Currently, powered toothbrushes have oscillating and rotating motions (Fig. 48.3), and some brushes use low-frequency acoustic energy to enhance cleaning ability. Powered toothbrushes rely primarily on mechanical contact between the bristles and the teeth to remove plaque biofilm. The addition of low-frequency acoustic energy generates dynamic fluid movement and provides cleaning slightly away from the bristle tips.[43] The vibrations have also been shown to interfere with bacterial adherence to oral surfaces. Neither the sonic vibration nor the mechanical motion of powered toothbrushes has been shown to affect bacterial cell viability.[91] Hydrodynamic shear forces created

by these brushes disrupt biofilm a short distance from the bristle tips, thus explaining the additional interproximal biofilm removal.[67]

FIG. 48.3 Powered toothbrush designs offer options in head shape and size.

Typically, comparison studies of powered toothbrushes, manual toothbrushes, and other powered devices demonstrate slightly improved plaque biofilm removal for the device of interest in short-term clinical trials.[95,106] A Cochrane review reported that mechanical brushes with oscillating and rotating motions reduced microbial plaque biofilm 11% better and demonstrated 6% greater reduction in gingival bleeding than manual brushing. These improvements were maintained over 3 months. Although long-term benefits have not been established, this particular style of mechanical brush resulted in better microbial plaque biofilm and gingivitis reduction in a number of well-controlled studies.[32,58]

Patients' acceptance of powered toothbrushes is favorable. One study reported that 88.9% of patients introduced to a powered toothbrush would continue to use it.[127] However, patients have been reported to discontinue the use of the powered toothbrushes after 5 or 6 months, presumably when the novelty has worn off. Powered toothbrushes have been shown to improve oral health for the following: (1) children and adolescents; (2) people with physical

or mental disabilities; (3) hospitalized patients, including older adults who require the assistance of caregivers for hygiene; and (4) patients with fixed orthodontic appliances. Powered brushes have not been shown to provide benefits routinely for patients with rheumatoid arthritis, children who are motivated, or patients with chronic periodontitis.[60]

Key Facts

When recommending powered toothbrushes, keep in mind that:

- Powered toothbrushes with oscillating and rotating motions remove plaque biofilm and reduce gingival bleeding slightly better than manual toothbrushes.
- Patients who want to use powered toothbrushes should be encouraged to do so.
- Patients need to be instructed in the proper use of powered devices.
- Patients who are not dextrous, children, and caregivers may particularly benefit from using powered toothbrushes.

Dentifrices

Dentifrices aid in cleaning and polishing tooth surfaces. They are used mostly in the form of pastes, although powders and gels are also available. The contents of dentifrices are abrasives (e.g., silicon oxides, aluminum oxides, and granular polyvinyl chlorides), water, humectants, soap or detergent, flavoring and sweetening agents, therapeutic agents (e.g., fluoride, pyrophosphates), coloring agents, and preservatives.[57,119] Abrasives are insoluble inorganic salts that enhance the abrasive action of toothbrushing as much as 40 times and make up 20% to 40% of dentifrices.[93] Tooth powders are much more abrasive than pastes and contain about 95% abrasive materials. The abrasive quality of dentifrices affects enamel slightly and is a much greater concern for patients with exposed root surfaces. Dentin is abraded 25 times faster and cementum even faster, 35 times the rate of enamel. Therefore root surfaces with

exposed dentin and cementum are easily abraded, leading to notching and tooth sensitivity.[119] It can be concluded that oral hygiene procedures that use abrasive toothpaste are the main cause of hard tissue damage, and it is possible that gingival lesions can also be produced[101,108] (Fig. 48.4). Dentifrices are very useful for delivering therapeutic agents to the teeth and gingiva. The successful caries-preventive effect of *fluoride* incorporated in dentifrices has been proven without question.[118] Fluoride ion must be available in the amount of 1000 to 1100 parts per million (ppm) to achieve caries-reduction effects. Toothpaste products that have been tested by the ADA and have fluoride ion available in the appropriate amount carry the ADA seal of approval to provide for caries control.[5]

FIG. 48.4 Vigorous toothbrushing with an abrasive dentifrice can result in trauma to the gingiva and wearing away of the tooth surfaces, especially root surfaces, and can contribute to gingival recession.

"Calculus control" toothpastes, also referred to as "tartar control" toothpastes, contain *pyrophosphates* and have been shown to reduce the deposition of new calculus on teeth as it forms. These ingredients interfere with crystal formation in calculus but do not affect the fluoride ion in the paste or increase tooth sensitivity.

Dentifrice with pyrophosphates has been shown to reduce the formation of new supragingival calculus by 30% or more.[70,92,131] Pyrophosphate-containing toothpastes do not affect subgingival calculus formation or gingival inflammation. The inhibitory effect reduces the deposition of new supragingival calculus but does not affect existing calculus deposits. To achieve the greatest effect from calculus control toothpaste, the teeth must be cleaned and completely free of supragingival calculus when adding these products to the daily home care regimen.

Key Facts

Considering dentifrices, keep in mind that:

- Dentifrices increase the effectiveness of brushing.
- Products containing fluoride and antimicrobial agents provide additional benefits for controlling caries and gingivitis.
- Patients who form significant amounts of supragingival calculus benefit from the use of a calculus control dentifrice, but remember that calculus formation is directly related to plaque biofilm accumulation.

Toothbrushing Methods

Many methods for brushing the teeth have been described and promoted as being efficient and effective. These methods can be categorized primarily according to the pattern of motion when brushing and are primarily of historic interest, as follows[68]:

Roll: Roll[2] or modified Stillman technique[64]
Vibratory: Stillman,[117] Charters,[21] and Bass[12] techniques
Circular: Fones technique[42]
Vertical: Leonard technique[82]
Horizontal: Scrub technique[103]

Patients with periodontal disease are most frequently taught a sulcular brushing technique using a vibratory motion to improve

access to the gingival margin areas. It is important for patients to understand that plaque biofilm removal at the dentogingival junction is necessary to prevent caries as well as periodontal disease. This emphasis to clean the area of the dentogingival junction is referred to as *target hygiene* (Takei H: Personal communication, 2009). The method most often recommended is the *Bass technique* because it emphasizes the placement of the bristles at this most important area. Sulcular placement of the bristles and adapting the bristle tips to the gingival margin to reach the supragingival plaque biofilm and accessing some of the subgingival biofilm may be the most important aspects of target hygiene. A controlled vibrating motion is used to dislodge microbial plaque biofilm and avoid trauma. The brush is systematically placed on all the teeth in both arches. Figs. 48.5 and 48.6 illustrate this brushing technique. Almost everybody brushes their teeth, but some individuals may have both carious and periodontal problems. Patients must understand why, where, and how to practice meaningful plaque biofilm removal properly at the target area to prevent oral diseases.

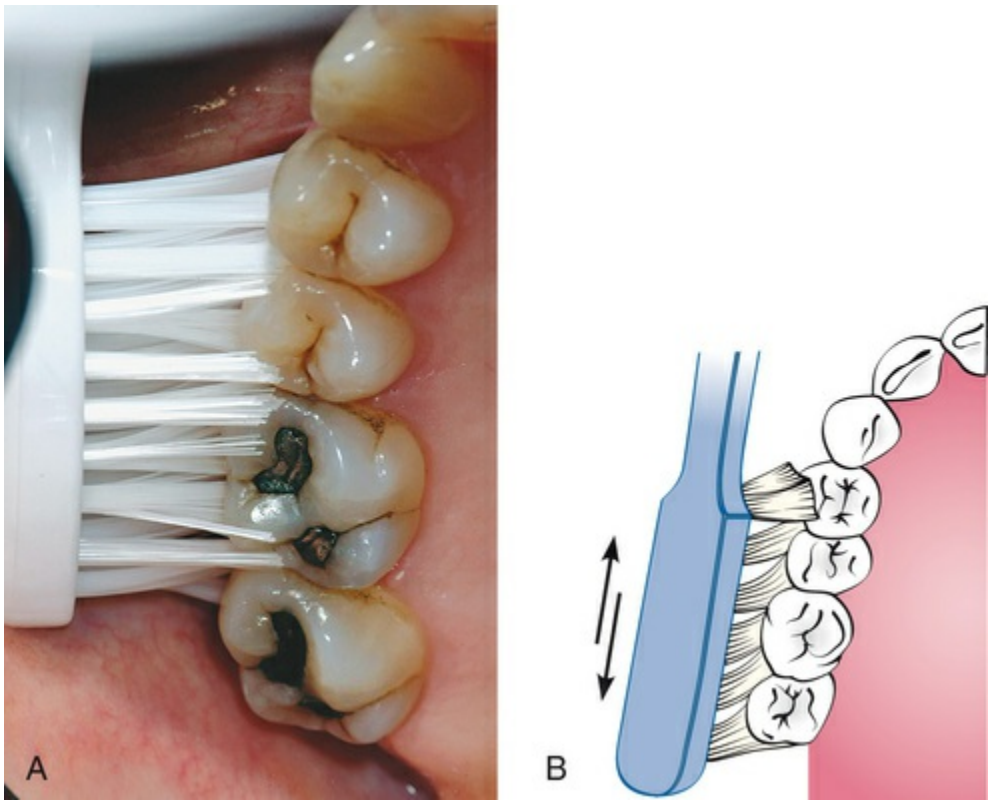

FIG. 48.5 **Bass method. (A) Place the toothbrush so that the bristles**

are angled approximately 45 degrees from the tooth surfaces. (B) Start at the most distal tooth in the arch, and use a vibrating back-and-forth motion to brush.

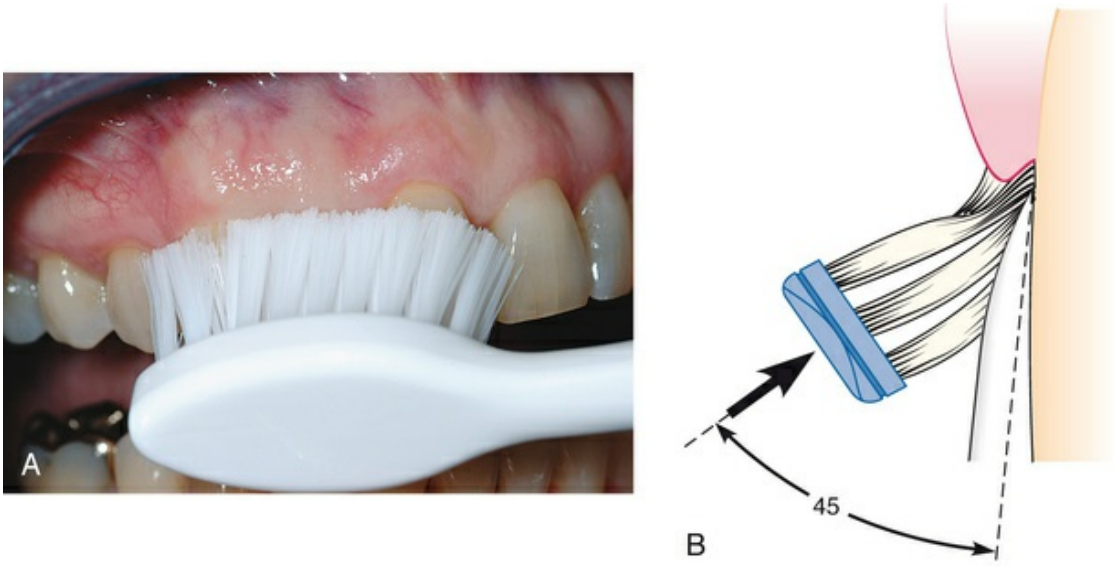

FIG. 48.6 **Bass method. (A) Proper positioning of the brush in the mouth aims the bristle tips toward the gingival margin. (B) Diagram shows the ideal placement, which permits slight subgingival penetration of the bristle tips.**

Bass Technique

1. Place the head of a soft brush parallel to the occlusal plane, with the brush head covering three to four teeth. This hygiene procedure begins at the most distal tooth in the arch and systematically proceeds mesially.[11]
2. Place the bristles at the gingival margin, pointing at a 45-degree angle to the long axis of the teeth.
3. Exert gentle vibratory pressure using short, back-and-forth motions without dislodging the tips of the bristles. This motion forces the bristle ends into the gingival sulcus area (see Fig. 48.5), as well as partly into the interproximal embrasures. The pressure should be firm enough to blanch the gingiva

Brushing With Powered Toothbrushes

The various mechanical motions built into powered toothbrushes means they do not require special techniques. The patient should place the brush head next to the teeth at the gingival margin, similar to the position with the manual brush. This is the target hygiene area, and it proceeds systematically around the arch.[124] As indicated earlier, it is the routine brushing method described for manual brushing, except it is with the powered toothbrush (Fig. 48.7).

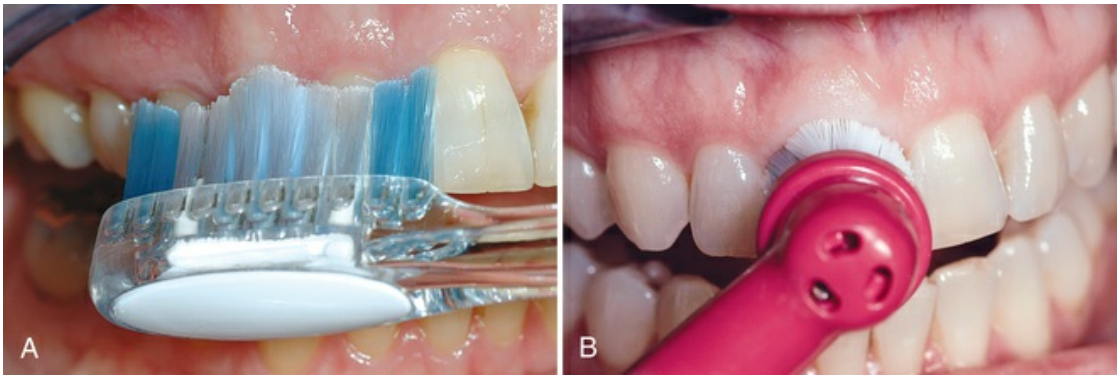

FIG. 48.7 Positioning the powered toothbrush head and bristle tips so that they reach the gingival margin is critical to achieving the most effective cleaning results. (A) Straight-head placement. (B) Round-head placement.

Key Facts

When recommending toothbrushing techniques, remember what research has taught us:

- Targeted hygiene[121] focuses brushing efforts on the critical cervical and interproximal areas of teeth.
- Brushing with either a manual or powered toothbrush requires a systematic routine to be effective.[95]
- Patients will modify any technique to their needs, so emphasize brushing all the surfaces of the teeth effectively.

Interdental Cleaning Aids

Any toothbrush, regardless of the brushing method used, does not completely remove interdental plaque biofilms. This is true for all patients, even for periodontal patients with wide-open embrasures.[47,111] Daily interdental plaque biofilm removal is crucial to augment the effects of toothbrushing because most dental and periodontal diseases originate in interproximal areas.[1]

Tissue destruction associated with periodontal disease often leaves large, open spaces between teeth and exposed root surfaces with anatomic concavities and furcations. These defects also occur after resective periodontal surgery. The best example of an anatomic root concavity is the mesial root surface of the maxillary first bicuspid. With attachment loss, the concavity located on this mesial surface is exposed where plaque biofilm will accumulate. These areas shelter plaque biofilm and are difficult for patients to clean with the toothbrush alone.[75] In addition, dental floss does not reach these concave surfaces (see Fig. 48.16). Patients should understand that the purpose of interdental cleaning is to remove microbial plaque biofilm, not just food that has wedged between two approximating teeth. Many instruments are available for interproximal cleaning, and they should be recommended based on the size of the interdental spaces, the presence of furcations, root surface concavities, tooth alignment, and the presence of orthodontic appliances or other fixed prostheses. Moreover, ease of use and patient cooperation are important considerations. Common aids for interdental hygiene are dental floss, interdental brushes, rubber tips, and wooden or plastic tips.

Dental Floss

Dental floss is the most widely recommended tool for removing biofilm from proximal tooth surfaces.[46] Floss is made from nylon filaments or plastic monofilaments, and it comes in waxed, unwaxed, thick, thin, and flavored varieties. Some prefer monofilament floss made of nonstick material because they are slick and do not fray. Clinical research has demonstrated no significant differences in the ability of the various types of floss to remove

dental plaque biofilm; they all work equally well.[40,62,72,73] Waxed dental floss was thought to leave a waxy film on proximal surfaces, thus contributing to biofilm accumulation and gingivitis. It has been shown, however, that wax is not deposited on tooth surfaces,[102] and improvement in gingival health is unrelated to the type of floss used.[40] Factors influencing the choice of dental floss include the tightness of tooth contacts, the roughness of proximal surfaces, and the patient's manual dexterity, not the superiority of any one product. Therefore, recommendations about type of floss should be based on ease of use and personal preference. As indicated previously, the limitations of dental floss must also be explained to the patient, and alternative methods must be demonstrated.

« Flash Back

Recommended by Bass in the 1930s, and popularized in the 1960s, unwaxed floss is still recommended as being superior to waxed versions. The rationale is that it does not leave a waxy film that would cause more plaque deposition on the interproximal surfaces of the teeth. No evidence supports this. Given that waxed floss is easier for most people to use, patients should floss with whatever type they like. The important thing is that they adopt the flossing habit!

Technique for the Use of Dental Floss

The floss must contact the proximal surface from line angle to line angle to clean effectively. It must also clean the entire proximal surface, including accessible subgingival areas. Flossing technique requires the following:

1. Start with a piece of floss long enough to grasp securely; 12 to 18 inches is usually sufficient. It may be wrapped around the fingers, or the ends may be tied together in a loop.
2. Stretch the floss tightly between the thumb and forefinger (Fig. 48.8) or between both forefingers, and pass it gently through each contact area with a firm back-and-forth

motion. Do not snap the floss past the contact area, because this may injure the interdental gingiva. In fact, zealous snapping of floss through contact areas creates proximal grooves in the gingiva.

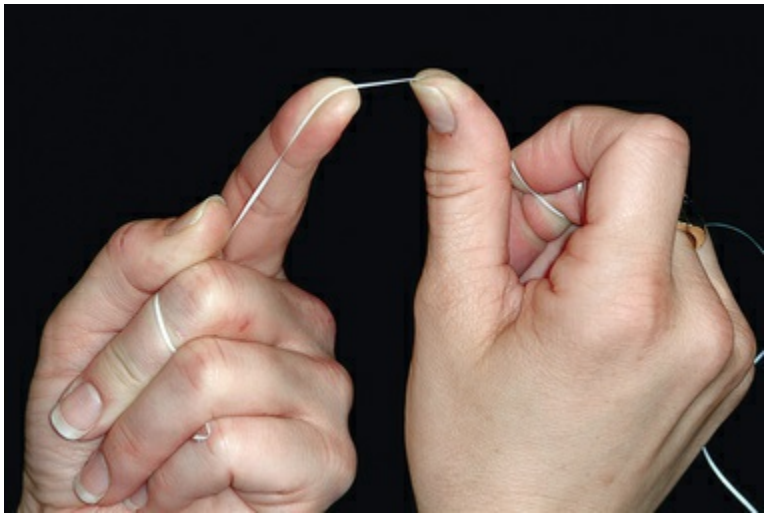

FIG. 48.8 Dental floss should be held securely in the fingers or tied in a loop.

3. Once the floss is apical to the contact area between the teeth, wrap the floss around the proximal surface of one tooth and slip it under the marginal gingiva. Move the floss firmly along the tooth up to the contact area and gently down into the sulcus again, repeating this up-and-down stroke two or three times (Fig. 48.9). Then move the floss across the interdental gingiva, and repeat the procedure on the proximal surface of the adjacent tooth.

FIG. 48.9 **Dental floss technique. The floss is slipped between the contact areas of the teeth (in this case, teeth #7 and #8) and wrapped around the proximal surface, and removes plaque by using several up-and-down strokes. The process must be repeated for the distal surface of tooth #8.**

4. Continue through the whole dentition, including the distal surface of the last tooth in each quadrant. When the working portion of the floss shreds or becomes contaminated, move the floss to a fresh portion.

Flossing can be facilitated by using a *floss holder* (Fig. 48.10A). Floss holders are helpful for patients lacking manual dexterity and for caregivers assisting patients in cleaning their teeth. A floss holder should be rigid enough to keep the floss taut when penetrating tight contact areas, and it should be simple to string the floss onto the holder. The disadvantage of these floss holders is that using them tends to be time-consuming because they must be rethreaded frequently when the floss shreds.

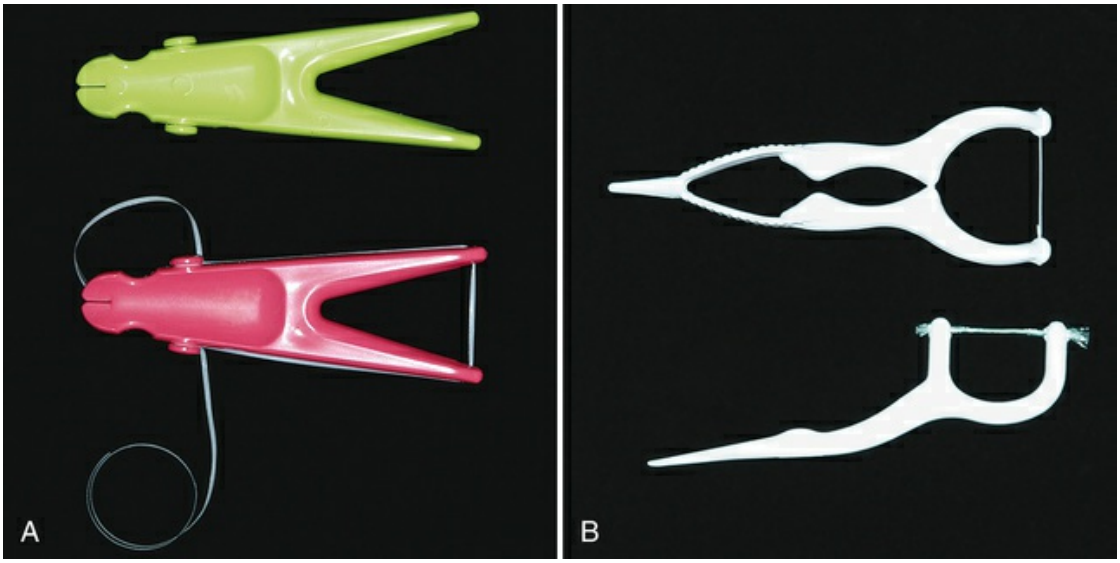

FIG. 48.10 Floss holders can simplify the manipulation of dental floss. (A) Reusable floss tools require stringing the floss around a series of knobs and grooves to secure it. (B) Disposable floss tools have prestrung floss and are easy to use, but the floss may shred and break, requiring several tools to complete flossing the teeth.

Disposable single-use floss holders with prethreaded floss are

also available. Short-term clinical studies suggested that plaque biofilm reduction and improvement in gingivitis scores are similar for patients using disposable floss devices and patients who hold the floss with their fingers[19,116] (Fig. 48.10B).

Powered flossing devices are also available (Fig. 48.11). These devices have been shown to be safe and effective, but they are no better at plaque biofilm removal than holding the floss with the fingers.[26,51]

FIG. 48.11 Powered flossing devices can be easier for some patients to use than handheld floss. The tip is inserted into the proximal space, and a bristle or wand comes out of the tip and moves in a circular motion when the device is turned on *(left)*. Alternately, the device moves the prestrung floss in short motions to provide interproximal cleaning *(right)*.

Establishing a lifelong habit of flossing the teeth is difficult to

achieve for both patients and dentists, regardless of whether one uses a tool or flosses with fingers. In fact, it is thought that the daily use of dental floss by patients is inconsistent. Investigators reported that only about 8% of young teenagers in Great Britain flossed daily,[90] with similar percentages reported for other countries.[75] It has been suggested that motivational interviewing and instructional techniques are helpful in encouraging this habit.[44] No information is available regarding long-term flossing habits comparing the various instruments used to floss with flossing with one's fingers. However, these instruments may be useful to help individuals begin flossing or to make flossing possible for patients who have limited dexterity.

Key Facts

The benefits to gingival health of interproximal cleaning are undisputed.

- Dental floss is a simple and readily available tool to clean where the toothbrush cannot reach. The thorough removal of plaque biofilm from the interdental tooth surfaces is the most important hygiene step in the treatment of periodontal disease.
- Flossing tools work as well as flossing using one's fingers.
- The flossing habit is difficult to establish and requires positive reinforcement during dental visits.

Interdental Brushes

Probably the most effective plaque biofilm removal method for interdental areas, where the papilla does not completely fill the space, is the use of interdental brushes. As indicated earlier, the concave root surfaces, such as the mesial aspect of the maxillary first bicuspid and furcation areas, are usually not cleaned efficiently with dental floss. A comparison study of dental floss and interdental brushes used by patients with moderate to severe periodontal disease indicated that the interproximal brushes removed a greater amount of interproximal plaque biofilm and that

the subjects found it easier to use these brushes than dental floss. However, no difference was found when probe depth reductions or bleeding indices were compared.[23] Therefore, interproximal cleaning aids such as dental floss and interdental brushes are excellent for proximal cleaning of teeth when interdental spaces permit their access.[75]

Embrasure spaces vary greatly in size and shape. Fig. 48.12 provides a representation of the size and anatomy of three types of embrasures and the interdental cleaning instrument most often recommended for each. As a general rule, the larger the spaces, the larger the instruments needed to clean them properly.

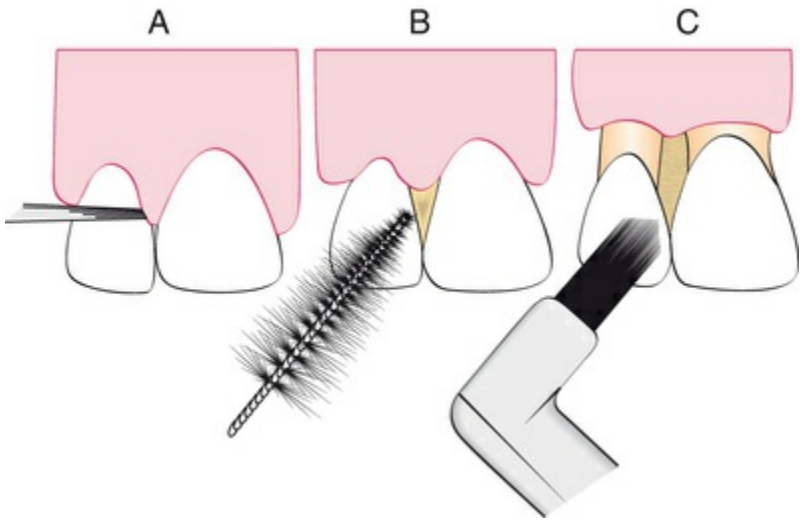

FIG. 48.12 Interproximal embrasure spaces vary greatly in patients with periodontal disease. (A) In general, embrasures with no gingival recession are adequately cleaned using dental floss. (B) Larger spaces with exposed root surfaces require the use of an interproximal brush. (C) Single-tufted brushes clean efficiently in interproximal spaces with no papillae.

Technique

An interdental brush of any style is inserted through the interproximal spaces and moved back and forth between the teeth with short strokes. The diameter of the brush should be slightly larger than the gingival embrasures to be cleaned. This size permits the bristles to exert pressure on both proximal tooth surfaces by

working their way into concavities on the roots. The brush bristles must also reach the interdental gingival margin.

Single-tufted brushes provide access to furcation areas, or isolated areas of deep recession, and are effective on the lingual surfaces of mandibular molars and premolars. These areas are often missed when using a toothbrush and floss.

Other Interdental Cleaning Devices: Rubber Tips, Wooden Toothpicks, and Tufted Brushes

Other interdental cleaning devices are available for removing microbial plaque biofilm from between the teeth (Fig. 48.13). Rubber tips with angled shanks, tapered wooden toothpicks that are round or triangular in cross-section, and single-tufted brushes are all helpful in attaining interdental hygiene. Many interdental devices have handles and contoured shanks for convenient manipulation around the teeth and in posterior areas. Clinical research has indicated that these devices are all effective for both lingual and facial tooth surfaces, as well as for proximal surfaces.[75,111]

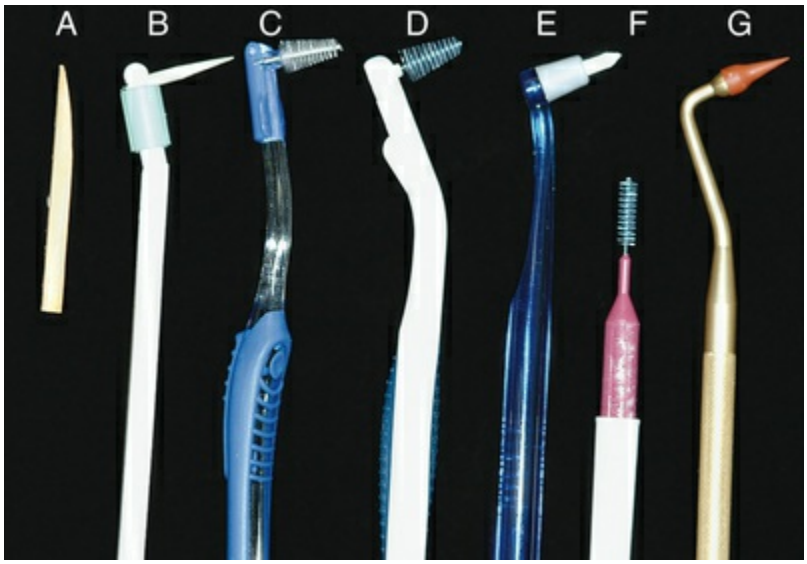

FIG. 48.13 (A) and (B) Interproximal cleaning devices include wooden tips, (C to F) interproximal brushes, and (G) rubber-tip stimulators.

Wooden toothpicks are used either with or without a handle (see Fig. 48.13A and B). Access is easier from the buccal surfaces for tips without handles but is limited primarily to the anterior and bicuspid areas. Wooden toothpicks on handles improve access to all areas and have been shown to be as effective as dental floss in reducing plaque biofilm and bleeding scores in subjects with gingivitis.[84] Triangular wooden tips are also available; this design is most useful in the anterior areas when used from the buccal surfaces of the teeth.

Rubber tips are conical and are mounted on handles or the ends of toothbrushes. They are reusable and can be easily adapted to all proximal surfaces in the mouth. The rubber tips that are mounted on handles with a curved shank, as in curettes, are excellent not only for cleaning the interdental spaces but also for demonstrating to the patient the location of the plaque biofilm during oral hygiene instruction. For hygiene purposes, the rubber tip should be placed into the embrasure space, resting on the gingiva, and used in a circular motion. It can be applied to interproximal spaces and other defects throughout the mouth and is easily adaptable to lingual surfaces. Plastic tips that resemble wooden or rubber tips are also available and are used in the same way.

Technique

Toothpicks are common devices and readily available in most homes. They can be used around all surfaces of the teeth when attached to commercially available handles (see Fig. 48.13B). Once mounted on the handle, the toothpick is broken off so that it is only 5 or 6 mm long. The tip of the toothpick is used to trace along the gingival margin and into the proximal areas from both the facial and lingual surface of each tooth (Fig. 48.14). Toothpicks mounted on handles are efficient for cleaning along the gingival margin,[46] can penetrate periodontal pockets and furcations, and permit patients to target their hygiene efforts at the gingival margin (Takei H: Personal communication, 2009).

FIG. 48.14 **Wooden toothpick. (A) The tip is a common wooden toothpick held in a handle and broken off. It is used to clean subgingivally and reach into periodontal pockets. (B) The tip can also be used to clean along the gingival margins of the teeth and reach under the gingiva.**

Soft triangular wooden picks or plastic picks are placed in the interdental space with the base of the triangle resting on the gingiva and the sides in contact with the proximal tooth surfaces (Fig. 48.15). The pick is then moved in and out of the embrasure several times to remove the biofilm. The disadvantage of triangular wooden or plastic tips is that they do not reach into the posterior areas or on the lingual surfaces.

FIG. 48.15 Triangular wooden tips are also popular with patients. The tip is inserted between the teeth, with the triangular portion resting on the gingival papilla. The tip is moved in and out to remove plaque; however, it is very difficult to use on posterior teeth and from the lingual aspect of all teeth.

Key Facts

Periodontal patients often have to clean large interdental spaces, so it is extremely important to find an interdental device that is easy to manipulate and that the patient will use regularly.

- Patients may need to try several of the many devices available before finding one that satisfies their needs.
- In general, the largest brush or device that fits into a space will clean most efficiently (Fig. 48.16).

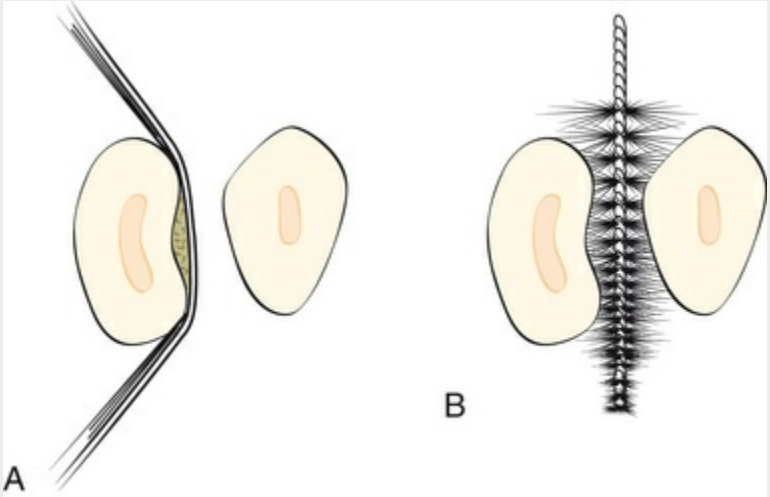

FIG. 48.16 Cleaning of concave or irregular proximal tooth surfaces. (A) Dental floss may be less effective than (B) an interdental brush on long root surfaces with concavities.

Gingival Massage

Massaging the gingiva with a toothbrush or an interdental cleaning device produces epithelial thickening, increased keratinization, and increased mitotic activity in the epithelium and connective tissue.[17,20,49] The increased keratinization occurs only on the gingiva facing the oral cavity (oral epithelium), but not on the areas more vulnerable to microbial attack, which are the sulcular epithelium and the interdental areas where the gingival col is present. Epithelial thickening, increased keratinization, and blood

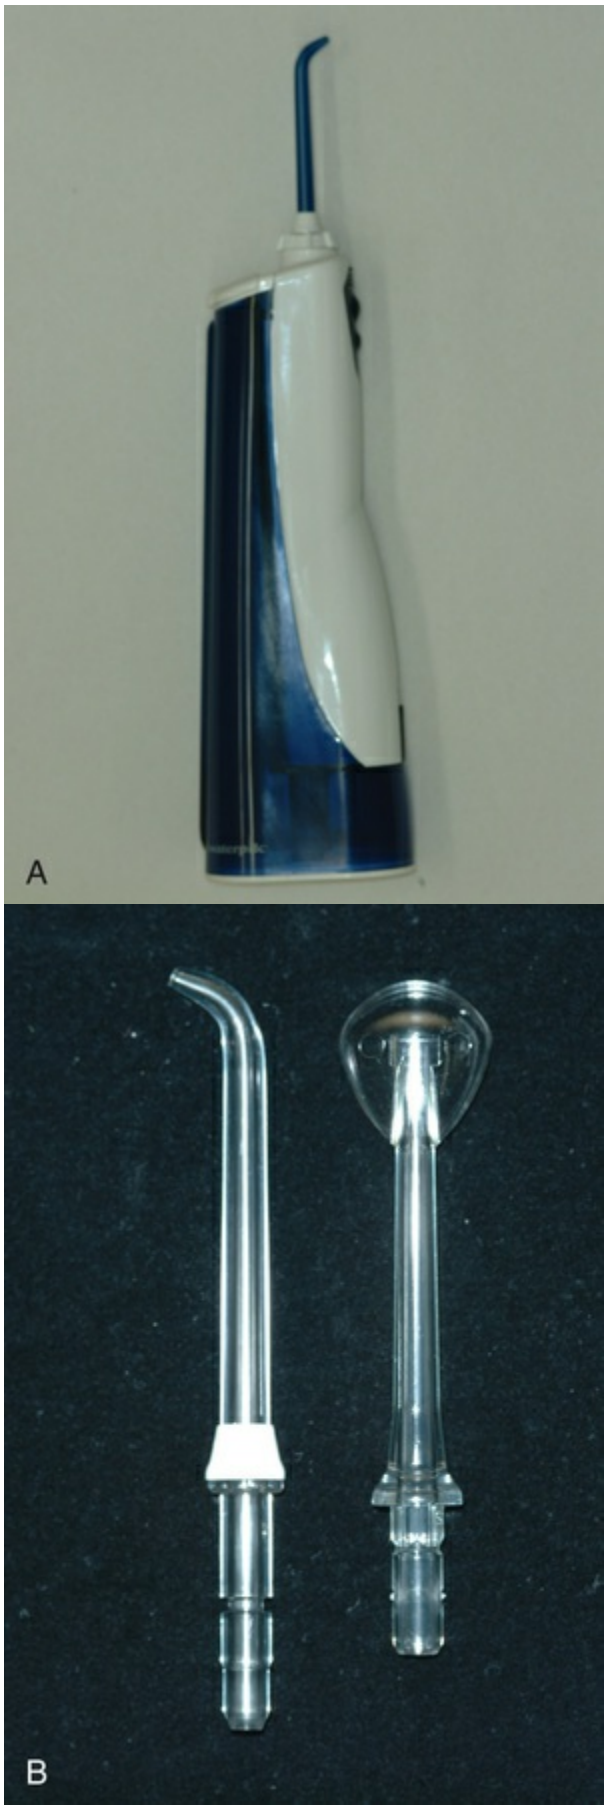
circulation have not been shown to be beneficial for restoring gingival health.[48] Improved gingival health associated with interdental stimulation is the result of inadvertent microbial plaque biofilm removal rather than the effects of gingival massage. No clinical evidence indicates that massaging the gingiva is essential or necessary to attain gingival health.

Oral Irrigation

See also Chapter 51.

Supragingival Irrigation

Oral irrigators for daily home use function by directing a pulsating stream of water through a nozzle to the tooth surfaces. Most often, a device with a built-in pump generates the pressure (eFig. 48.1A). Oral irrigators remove nonadherent bacteria and debris from the oral cavity more effectively than toothbrushes and mouthrinses. They are particularly helpful for removing debris from inaccessible areas around orthodontic appliances and fixed prostheses. When used as adjuncts to toothbrushing and interdental cleaning, these devices can have a beneficial effect on periodontal health by reducing the accumulation of microbial plaque biofilm,[87,105] as well as by decreasing inflammation and pocket depth.[18,32,105]



A
B

EFIG. 48.1 **Oral irrigation. (A) The most common oral irrigators have a built-in pump and reservoir. (B) Conventional plastic tips are used for daily supragingival irrigation at home by the patient. *Left,* Tip for gingival irrigation. *Right,* Tip for cleaning dorsal surface of the tongue. (C) Soft rubber tip is used for daily subgingival irrigation.**

Oral irrigation has been shown to disrupt and detoxify subgingival plaque biofilm and can be useful in delivering antimicrobial agents to periodontal pockets.[4] Daily supragingival irrigation with dilute chlorhexidine for 6 months resulted in significant reductions in bleeding and gingivitis compared with water irrigation and chlorhexidine rinse controls. Irrigation with water alone also reduced gingivitis significantly, but the positive effect was greater when diluted chlorhexidine was used.[41]

Technique

1. The common home-use irrigator tip is a plastic nozzle with a 90-degree bend at the tip (see eFig. 48.1B) attached to a pump providing pulsating beads of water at speeds regulated by a dial. Patients should be instructed to aim the

pulsating jet across the proximal papilla, hold it there for 10 to 15 seconds, trace along the gingival margin to the next proximal space, and repeat the procedure.

2. The irrigator should be used for both the buccal and lingual surface.
3. Patients with gingival inflammation should start at low pressure, and they can increase the pressure comfortably to about medium as tissue health improves. Some individuals like to use the device on the highest pressure setting, with no reported harm. Patient comfort should be the guide for pressure setting.

Subgingival Irrigation

Subgingival irrigation can be performed both in the dental office and at home by the patient. Home irrigation is performed by aiming or placing the irrigation tip or a blunt syringe tip at least 3 mm into the periodontal pocket.[31] A soft rubber irrigator tip is shown in eFig. 48.1C. Irrigation performed in the dental office, also called *lavage* or *flushing of the periodontal pocket,* as a one-time treatment after scaling and root planing has not been shown to improve clinical healing, and data do not support its use in improving therapeutic results.[4,54,112]

Subgingival irrigation with an oral irrigator using chlorhexidine diluted to one-third strength performed regularly at home and after scaling, root planing, and in-office irrigation therapy produced significant gingival improvement compared with control subjects.[54,69,112] Subgingival irrigation has been shown to disrupt more than half the subgingival plaque biofilm[65] and reach about half the depth of pockets, up to 7 mm, which is much farther apically than a toothbrush or floss can reach.[34] These data suggest that patients can benefit from daily subgingival irrigation, whether using an oral irrigator or a blunt syringe technique. This is especially true in difficult sites such as furcations and residual pockets that may remain after both phase I and II therapy. A detailed discussion of irrigation is presented in Chapter 51.

Technique

The soft rubber irrigator tip reduces the pressure and flow of the pulsating jet of water (see eFig. 48.1C) when it is inserted subgingivally, and it permits penetration of irrigant to up to 70% of pocket depth in laboratory simulations.[24,65] The subgingival irrigation tip should be gently inserted into pockets or furcation areas, 3 mm if possible, and each pocket should be flushed for a few seconds.

One caution must be considered. Transient bacteremia has been reported after water irrigation in patients with periodontitis[39] and patients receiving periodontal maintenance therapy.[126] However, bacteremia has also been found after toothbrushing,[99] and it is known to occur in a significant number of patients after scaling of the teeth by the clinician.[126] Subgingival irrigation at home is not the recommended oral hygiene procedure for patients requiring antibiotic prophylaxis before dental treatment, especially if extensive inflammation is present.[31] For these patients, supragingival irrigation in combination with toothbrushing and other interdental cleaning aids is recommended.

Key Facts

Gingival irrigation can be a useful adjunct for periodontal patients who have residual pockets and complex dental architecture to clean every day.

- Supragingival irrigation reduces gingival inflammation and is easy to perform with water irrigation devices.
- Subgingival irrigation with specialized tips or blunt syringes for deep pockets and furcation areas is effective for maintaining residual pockets and furcation areas when it is used as part of the daily home care routine.

Caries Control

Dental caries, particularly root caries, is a problem for periodontal patients because of attachment loss and exposed root surfaces associated with the disease process and periodontal therapy

procedures.[15] *Root caries* develops through a process similar to coronal caries, involving an alternating cycle of demineralization and remineralization of the surfaces and other risk factors associated with diet and salivary flow. The demineralization process requires the fermentation of carbohydrates in the plaque biofilm by oral bacteria, with resulting loss of mineral from the root surface. *Lactobacillus* and *Streptococcus* species are involved in the root caries process, as with coronal caries. The major difference is that the amount of organic material in the root surfaces is greater than in enamel, so once demineralization has occurred, the organic matrix, mostly collagen, is exposed. Organic material is then further broken down by bacterial enzymes, thus resulting in rapid destruction of the root surface.[36,128]

Fluoride is effective primarily by topical effects to prevent and reverse the caries process, whether in enamel, cementum, or dentin. Low concentrations of topical fluoride inhibit demineralization, enhance remineralization, and inhibit the enzyme activity in bacteria by acidifying the cells.[37,38] Adult patients benefit from the prevention and reversal of root caries provided by low-concentration topical fluoride delivered by toothpaste or other topical applications.[37] It also has been demonstrated that fluoride dentifrice containing 5000 ppm of fluoride was more effective in reversing active root caries lesions than the fluoride level of 1100 ppm found in conventional toothpastes.[13]

Key Facts

Periodontal patients should be aware of caries, and the use of fluoride products minimizes the risk for caries.

- All periodontal patients should be encouraged to use a fluoride-containing toothpaste daily.
- Patients at high risk for caries should use higher-concentration fluoride toothpaste or gel until the caries risk is controlled. A lower concentration can be used during maintenance therapy.
- A periodic chlorhexidine rinsing regimen to control cariogenic bacteria in the oral cavity is part of the caries risk management

program for high-risk individuals.[38]

- Other considerations in caries control, such as diet and reduced salivary flow, should be evaluated, and modifications should be made where possible.

Chemical Plaque Biofilm Control With Oral Rinses

Improved understanding of the infectious nature of dental diseases has dramatically increased interest in chemical methods of plaque biofilm control and holds great promise for advances in disease control and prevention. The ADA Council on Scientific Affairs has adopted a program for accepting chemical plaque biofilm control agents. The agents must be evaluated in placebo-controlled clinical trials of 6 months or longer that demonstrate significantly improved gingival health compared with control subjects. To date, the ADA has accepted two agents for treatment of gingivitis: prescription solutions of chlorhexidine digluconate oral rinse and nonprescription essential oil mouthrinse.

Prescription Chlorhexidine Rinse

The agent that has shown the most positive antibacterial results to date is chlorhexidine, a diguanidohexane with pronounced antiseptic properties. Several clinical investigations confirmed an initial finding that two daily rinses with 10 mL of a 0.2% aqueous solution of chlorhexidine digluconate almost completely inhibited the development of microbial plaque biofilm, calculus, and gingivitis in the human model for experimental gingivitis.[55] Clinical studies of several months' duration reported plaque biofilm reductions of 45% to 61% and, more importantly, gingivitis reductions of 27% to 67%.[55,79] The 0.12% chlorhexidine digluconate preparation available in the United States for reducing plaque biofilm and gingivitis has been shown to be equally effective as the higher-concentration product.[71,77]

Localized, reversible side effects of chlorhexidine use occur, primarily brown staining of the teeth, tongue, and silicate and resin

restorations[79] and transient impairment of taste perception.[88] Chlorhexidine has very low systemic toxic activity in humans, has not produced any appreciable resistance of oral microorganisms, and has not been associated with teratogenic alterations.[77] The preparation contains 12% alcohol, which may be of interest to clinicians and patients with regard to concerns that alcohol increases the risk of oropharyngeal cancer.[35] However, an extensive review of the available epidemiologic evidence associating alcohol-containing oral rinse preparations with cancer concluded that existing data do not support this association.[114] A nonalcoholic form of chlorhexidine mouthrinse is also available. It has been shown to be equally effective for microbial plaque biofilm control,[10,85] and it may be preferred by patients.

Nonprescription Essential Oil Rinse

Essential oil mouthrinses contain thymol, eucalyptol, menthol, and methyl salicylate. These preparations have been evaluated in long-term clinical studies and have demonstrated plaque biofilm reductions of 20% to 35% and gingivitis reductions of 25% to 35%.[30,52,76] This type of oral rinse has had a long history of daily use and safety since the 19th century, and many patients have used these products for decades. These products also contain alcohol (up to 24% depending on the preparation), which must be a consideration for some patients not to use these products.

Other Products

A preparation containing *triclosan* has shown some effectiveness in reducing plaque biofilm and gingivitis. It is available in toothpaste form, and the active ingredient is more effective in combination with zinc citrate or a copolymer of methoxyethylene.[8] Other oral rinse products on the market have shown some evidence of plaque biofilm reduction, although long-term improvement in gingival health has not been substantiated. These include stannous fluoride, cetylpyridinium chloride (quaternary ammonium compounds), and sanguinarine. Evidence suggests that these and other available mouthrinse products do not possess the antimicrobial potential of either chlorhexidine products or essential oil preparations.[94,100]

One type of agent has been marketed as a prebrushing oral rinse to improve the effectiveness of toothbrushing. The active ingredient is sodium benzoate. Research to support its effectiveness is contradictory, but the preponderance of evidence suggests that using a prebrushing rinse is no more effective than brushing alone.[14,16]

It has been reported that chemical plaque biofilm control has been effective for both plaque biofilm reduction and improved wound healing after periodontal surgery.[110] Both chlorhexidine[6] and essential oil[130] mouthrinses have significant positive effects when prescribed for use after periodontal surgery for 1 to 4 weeks.

Key Facts

The use of chemical agents helps mechanical plaque biofilm control procedures and reduces gingivitis and caries.

- Chlorhexidine rinses can be used to improve plaque biofilm control during phase I therapy, for patients with recurrent disease, after periodontal or oral surgery, and for caries management.
- Essential oil rinses are effective as irrigants, have fewer side effects, and are available without a prescription.
- The use of cosmetic oral rinses and prebrushing rinses should not replace proven mechanical and chemical means of plaque biofilm removal, but these rinses can be useful if patients perceive benefits from them.

Disclosing Agents

Disclosing agents are solutions or wafers that stain bacterial biofilm on the surfaces of the teeth, tongue, and gingiva. Wafers are crushed and rinsed in the mouth for a few seconds before they are expectorated. They can be used as educational and motivational tools to improve the efficiency of plaque biofilm control procedures[7] (eFig. 48.2). Solutions are applied to the teeth as concentrates on cotton swabs or diluted as rinses. They usually

produce staining of plaque biofilm, gingiva, tongue, lips, and fingers. Either form, rinses or wafers, can be used for plaque biofilm control instruction in the office and dispensed for home use to help periodontal patients evaluate the effectiveness of their oral hygiene routine.

EFIG. 48.2 **Effect of a disclosing agent. (A) Unstained, the teeth look clean, but close inspection shows subtle signs of gingivitis. (B) Plaque shows as dark-red particulate matter when stained with a disclosing dye. It is useful to demonstrate toothbrushing in the patient's mouth with the teeth disclosed and plaque visible.**

Frequency of Plaque Biofilm Removal

In the controlled and supervised environment of clinical research,

where well-trained individuals remove all visible plaque biofilm, gingival health can be maintained by one thorough cleaning with brush, floss, and toothpicks every 24 to 48 hours.[29,68,75,78] However, this is not true with most patients. The average daily home care routine lasts less than 2 minutes and removes only 40% of plaque biofilm.[31] It has been reported that improved plaque biofilm removal and therefore improved periodontal health are associated with increasing the frequency of brushing to twice per day.[68,96] Cleaning three or more times per day does not appear to improve periodontal conditions further. Clinical experience has also indicated that more important than the number of times the patient practices oral hygiene during a given day is effective target hygiene, meaning thorough plaque biofilm removal at the proper location. One could be cleaning several times a day, but if the target areas are missed, plaque biofilm will persist in these critical areas.

Patient Motivation and Education

In periodontal therapy, plaque biofilm control has two important purposes: to minimize gingival inflammation and to prevent the recurrence or progression of periodontal diseases and caries. Daily mechanical removal of plaque biofilm by the patient, including the use of appropriate antimicrobial agents, is the only practical means for improving oral health on a long-term basis. The process requires interest and compliance on the part of the patient and education and instruction from the dentist, followed by encouragement and reinforcement. Keeping records of patients' performance facilitates this process. eFig. 48.3 provides an example of a plaque biofilm control record that permits comparison over time.

EFIG. 48.3 The plaque control record can be an effective motivator for patients. This form permits easy comparison of scores over time. (Courtesy Dean John D.B.

Motivation for Effective Plaque Biofilm Control

Motivating patients to perform effective plaque biofilm control is one of the most critical and difficult elements of long-term success in periodontal therapy. It requires commitment by the patient to change poor daily habits and return for regular visits for maintenance therapy. The scope of this compliance problem is immense. It has been shown that patients will stop using interproximal cleaning aids after a very short time. Heasman and associates[59] followed 100 patients treated for moderate to severe periodontal disease who were taught to use one or more interdental cleaning aids. These investigators found that only 20% of the patients used the aids after 6 months. Of the patients who had started using three devices, one-third had stopped all interdental cleaning at 6 months; the others used one or two of the aids.[66] The situation is not any better when patients' willingness to return for maintenance visits is reviewed. In a study of 1280 patients, most of whom had periodontal surgery in multiple sites after intensive scaling, root planing, and home care instruction, 25% never returned for a follow-up visit and only 40% returned regularly.[97] Wilson and colleagues[129] reported that 67% of periodontal patients were noncompliant with return visits in a 20-year retrospective study in a private periodontal practice.

Adopting new habits and returning for maintenance visits are not impossible tasks. To be successful requires the following: (1) the patient must understand the etiology of the disease and its importance in treatment and maintenance; the patient must also be compliant and receptive and must understand the concepts of pathogenesis, treatment, and prevention of periodontal disease; (2) the patient must be willing to alter harmful habits such as smoking; (3) the patient must be able to adjust personal beliefs and values to eliminate risk factors; motivational interviewing and instruction techniques can assist in achieving these goals[44]; and (4) manual

skills must be developed to establish an effective plaque biofilm control regimen. In addition, the patient must understand the dentist's critical role in treating and maintaining periodontal health.[104] If none of these factors can be managed, the long-term success of treatment is not likely.

Education and Scoring Systems

Many patients prefer to believe that treatment is a passive process, so it is incumbent on the dentist to educate and reinforce to each patient his or her personal role in the long-term success of therapy. Today's health-conscious society presents a great advantage with regard to patient education. Most patients are aware of what periodontal disease is. They have been exposed to it through television, newspapers, magazines, and the Internet. They must be willing to spend time and money on the many new products that are available. Examples are better-designed toothbrushes and mouthrinses such as chlorhexidine.

Patients must also be informed of the importance of maintenance therapy and periodic assessment in the dental office to prevent recurrence of periodontal diseases and identify problems that may arise. These procedures work best when combined with an individualized oral hygiene regimen practiced daily at home. Therefore, patient education and motivating patients about microbial plaque biofilm control procedures are central to care. Many patients believe that “cleanings” every few months are sufficient for calculus and biofilm removal and disease control. Only the combination of regular maintenance visits and conscientious home care has been shown to reduce gingivitis and loss of supporting periodontal tissues over the long term.[86,123]

Periodontal patients should be shown how periodontal disease has manifested in their mouths through demonstrations of plaque biofilm, the bleeding of inflamed gingiva, and where possible, the example of the periodontal probe inserted into the pockets. In addition, it is of educational value for patients to have their oral cleanliness and periodontal condition recorded periodically.[9] The positive improvements in performance can be used for reinforcement. The plaque biofilm control record and the bleeding

points index are simple indices that are useful for patient education and motivation.

Plaque Biofilm Control Record (O'Leary Index)

Have the patient use a disclosing solution or tablet and examine each tooth surface (except occlusal surfaces) for the presence or absence of stained biofilm at the dentogingival junction. Plaque biofilm is recorded on the appropriate box in a diagram for four surfaces on each tooth.[98] After all teeth have been scored, the index number is calculated for the percentage of surfaces with biofilm by dividing the number of surfaces with microbial plaque biofilm by the total number of surfaces scored and then multiplying by 100. A reasonable goal is 10% or fewer surfaces with plaque biofilm. If biofilm is always present in the same areas, provide instructions to improve cleaning procedures in those areas. It is extremely difficult to achieve a perfect score of 0, so patients should be rewarded if that is achieved.

Several frequently used plaque biofilm indices do not require staining of the teeth; one of these is the Plaque Index of Silness and Löe.[113] They are convenient to use and often acceptable to patients, even though they are not as dramatic for patient education.

Bleeding Points Index

The bleeding points index provides an evaluation of gingival inflammation around each tooth.[81] Retract the cheek and place the periodontal probe 1 mm into the sulcus or pocket at the distal aspect of the most posterior tooth in the quadrant on the buccal surface. Carry the probe lightly across the length of the sulcus to the mesial interproximal area on the facial aspect. Continue along all the teeth in the quadrant from the facial aspect. Wait 30 seconds, and record the presence of bleeding on the distal, facial, and mesial surfaces on the chart. Repeat on the lingual-palatal aspect, and record bleeding only for the direct lingual surface, not for the mesial or distal surfaces. This results in four separate scores for each tooth and does not score the mesial and distal surfaces twice. Repeat the steps for each quadrant. The percentage of the number of bleeding surfaces is calculated by dividing the number of surfaces that bled by the total number of tooth surfaces (four per

tooth) and multiplying by 100 to obtain a percentage. This index is designed to demonstrate gingival inflammation characterized by bleeding rather than the presence of microbial plaque biofilm. Again, a goal of 10% or fewer bleeding points is good, but 0 is ideal. If a few bleeding points repeatedly occur in the same areas, cleaning procedures for those areas should be reinforced or modified because usually a residual piece of subgingival calculus that was not noted during therapy is the cause of the localized gingival bleeding.

Significance of Plaque Biofilm Scores and Bleeding Scores

Plaque biofilm scores are helpful as indicators of patients' compliance and success with daily home care procedures. However, biofilm levels themselves do not necessarily reflect gingival health or risk of disease progression, even though the location of the plaque biofilm is highly correlated with the presence of gingivitis.[89] Bleeding is a much better predictor of success in controlling inflammation and reducing the chance of disease progression. Although bleeding on probing is not the most specific or sensitive measure of health, it has a strong negative correlation with disease progression. If bleeding is absent at any given site in the mouth, reflecting good plaque biofilm control and disease management, it is unlikely that periodontal disease will progress.[80]

Instruction and Demonstration

Patients can reduce the incidence of plaque biofilm and gingivitis with repeated instruction and encouragement much more effectively than with self-acquired oral hygiene habits.[53,111] However, instruction in how to clean teeth must be more than a cursory chairside demonstration on the use of a toothbrush. It is a painstaking procedure that requires the patient's participation, careful supervision with correction of mistakes, and reinforcement during return visits until the patient achieves the necessary proficiency.[83] Any strategy for introducing plaque biofilm control to the periodontal patient includes several elements. Before receiving hygiene instructions, the patient must understand the nature and

etiology of the disease. This aspect is important so the patient can understand why plaque biofilm removal on a daily basis is critical. Patients are aware that they have "brushed their teeth" all their lives, but they still have periodontal disease. Instruction on the technique of hygiene should follow an understanding of the disease. At the first instruction visit, the patient should be given a toothbrush and rubber tip along with a hand mirror to observe the procedure in his or her own mouth. The plaque biofilm can be disclosed to allow the patient to see it in the location where it is found (see eFig. 48.1). Many patients do not wish to use the disclosing agent, because it stains many areas in the mouth where staining is not desired. Polished dental restorations do not take up the stain, but the oral mucosa and lips may retain the stain for several hours. Applying petroleum jelly will keep the disclosing agent off the patient's lips. For these patients, the location and true color of the plaque biofilm can be demonstrated with the rubber tip. Once the plaque biofilm is demonstrated, the clinician can proceed with the hygiene instruction in the patient's mouth.

The rubber tip is used to demonstrate the plaque biofilm located at the gingival margin, which is the target area. The nondisclosed plaque biofilm is almost the same color as the teeth, which impresses and educates the patient about the reason for not recognizing biofilm in the past. Toothbrushing should also be demonstrated in the patient's mouth while he or she observes with a hand mirror. The patient then repeats the procedure with the clinician giving assistance, correction, and positive reinforcement. Repeat the demonstration and instruction with dental floss and other interdental cleaning aids according to the patient's needs. Depending on the patient's skill and understanding of the technique, instruction on interdental hygiene may be postponed until the patient is able to manipulate the toothbrush properly. The rubber tip is an excellent instrument to demonstrate plaque biofilm, but it is also used to clean the interdental area. The rubber tip is placed interdentally, and the plaque biofilm is removed with a scooping motion.

Encourage patients to clean the teeth thoroughly at least once a day. Be sure to inform them that home care procedures for a full dentition may take 5 to 10 minutes. For complex periodontal cases,

home care procedures may take longer, depending on the dexterity of the patient. The patient should set aside a convenient time and place in the daily schedule to perform the hygiene procedures every day. Subsequent visits should be used to reinforce or modify previous instructions and periodically record the state of gingival health and amount of plaque biofilm.

To introduce an oral hygiene program effectively, the clinician must choose a strategy that will be convincing to the patient while understanding that some strategies do not work. Waiting until the end of the appointment when the patient is sore, exhausted, and possibly anesthetized will not be conducive to learning. Failing to provide positive reinforcement, introducing the patient to unfamiliar instruments, and relying only on pamphlets and printed material to provide education are likely to result in an ineffective educational experience.

Key Facts

Strategies that will assist you in educating and motivating your patients include:

- Provide encouragement and positive reinforcement.[122] Threats are not effective.
- Demonstrate how devices work, and allow practice time.
- Provide samples so that patients do not have to stop and buy products on the way home because they will not do it.
- Show and reinforce improvements at subsequent appointments, even if changes are modest.

Conclusion

- After thorough patient education regarding the disease and the etiology, the hygiene technique is initiated by demonstrating the procedure in the patient's own mouth. The rubber tip is an excellent

instrument to demonstrate plaque biofilm. All patients require regular use of a toothbrush, either manual or electric, at least once per day. The brushing method should emphasize access to the gingival margins (dentogingival junction) of all accessible tooth surfaces. Emphasize the importance of *targeted hygiene* and extending as far onto the proximal surfaces as possible.

- Dental floss should be used in all interdental spaces that are filled with gingiva.
- Interdental aids such as interproximal brushes, rubber tips, wooden tips, or toothpicks should be used in all areas where the toothbrush and floss techniques cannot adequately remove the plaque biofilm. This includes large embrasure spaces and furcation areas, as well as the mesial surface of the maxillary first bicuspid, which presents a concavity on the root surface near the cementoenamel junction.
- Daily at-home subgingival irrigation and lavage are useful for reduction of inflammation and maintenance for patients with residual deep pockets and those who struggle with mechanical interproximal cleaning devices. The effectiveness of irrigation and lavage is enhanced by the addition of a chlorhexidine or essential oil rinse as an irrigant.
- Caries control requires the daily use of a dentifrice with low-concentration fluoride. Topical oral rinses and gels with higher concentrations of

fluoride should be used for patients with a high risk for caries.

- Chemical antimicrobial agents, such as chlorhexidine and essential oils, can be used to disinfect the patient's mouth and control infection. These oral rinses may be continued indefinitely. Staining of teeth and taste alteration are side effects that may limit the patient's acceptance of these products.
- Reinforcement of daily plaque biofilm control practices and routine visits to the dental office for maintenance care are essential for successful microbial plaque biofilm control and the long-term success of therapy.

Successful prevention, treatment, and maintenance in periodontal therapy are based on scientific knowledge of the etiology, risk factors, and host resistance involved in periodontal disease. The importance of the patient's understanding of the etiology and active participation in partnership with the therapist to prevent and treat periodontal disease is well understood in the current understanding of periodontal therapy.

Case Scenario 48.1

Patient:
A 49-year-old female patient presented for periodontal evaluation before orthodontic treatment.

Health History:
Patient stated she is healthy. Last physical exam was 6 months ago. No medications. No known drug allergies.

Dental History:

Patient did not go to the dentist for about 10 years because of a previous “bad dental experience,” until her teeth shifted.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Based on the clinical photo of the right side, the best interdental cleaning aid is A. Dental floss B. Interdental brush C. Rubber tip D. Toothbrush E. Antimicrobial mouthrinse	**Answer: B** Interdental cleaning with an interdental brush is the most effective method for interproximal biofilm removal when interdental spaces are present and the interdental brush fits into these spaces. Interdental brushes are associated with higher levels of biofilm removal when compared with flossing and the use of wood sticks because of the presence of root surface concavities. However, when no interproximal attachment loss has occurred and the interdental spaces are occluded with soft tissue, the use of interdental brushes may lead to loss of interdental papillae and formation of black triangles. In these instances, dental floss should be considered.

CHAPTER 49

Breath Malodor

Marc Quirynen, Isabelle Laleman, Sophie De Geest, Charlotte De Hous, Christel Dekeyser, Wim Teughels

CHAPTER OUTLINE

Semantics and Classification
Epidemiology *(e-only)*
Etiology
Fundamentals of Malodor Detection *(e-only)*
Diagnosis of Malodor
Treatment of Oral Malodor
Conclusion

Semantics and Classification

Breath odor can be defined as the subjective perception after smelling someone's breath. It can be pleasant, unpleasant, or even disturbing, if not repulsive. If unpleasant, the terms *breath malodor, halitosis, bad breath,* or *fetor ex ore* can be applied. Breath malodor is a common complaint in the general population. One in four persons has bad breath at a given time in his/her life. It has a significant socioeconomic impact but unfortunately has been neglected until

recently by scientists and clinicians, and it is still hardly covered in the medical curricula. Halitosis can lead to personal discomfort and social embarrassment, and it remains one of the biggest taboos of society.

The three main categories of halitosis are genuine halitosis, pseudo-halitosis, and halitophobia. *Genuine halitosis* is the term that is used when the breath malodor really exists and can be diagnosed organoleptically or by measurement of the responsible compounds. A distinction should be made between physiologic and pathologic halitosis (Fig. 49.1).

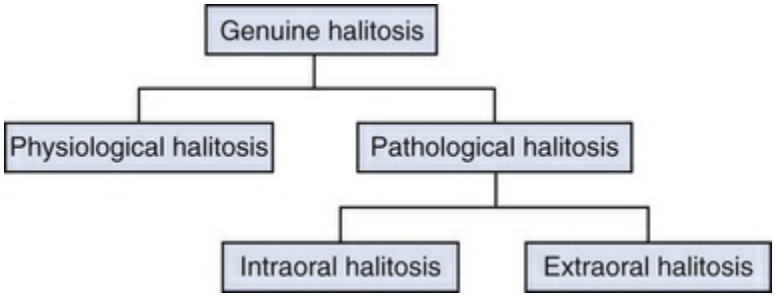

FIG. 49.1 Genuine halitosis: classification.

Transient disturbing odors caused by food intake (e.g., garlic, onions, and certain spices), smoking, or medications (e.g., metronidazole) do not reveal a health problem and are common examples of physiologic halitosis. The same is true for "morning" bad breath, as habitually experienced on awakening. This malodor is caused by decreased salivary flow and increased putrefaction during the night, and it spontaneously disappears after breakfast or after oral hygiene measures. A persistent breath malodor, by definition, does reflect some pathology (pathologic halitosis). The causes of this condition are discussed later in the chapter. When the origin of pathologic halitosis can be found in the oral cavity, one speaks of *oral malodor.* When an obvious breath malodor cannot be perceived but the patient is convinced that he or she suffers from it, this is called *pseudo-halitosis.* If the patient still believes that bad breath is present after treatment of genuine halitosis or diagnosis of pseudo-halitosis, one considers halitophobia, which is a recognized psychiatric condition.[167]

Important Terms for the Diagnosis of Bad Breath

Genuine halitosis	Malodor that can be verified objectively
Physiologic halitosis	Malodor that is transient and caused by physiologic factors, such as food intake or smoking
Oral malodor or intraoral halitosis	Obvious malodor originating from the oral cavity
Extraoral halitosis	Bad breath originating from pathologic conditions outside the oral cavity
Pseudo-halitosis	Malodor that cannot be perceived objectively even though the patient complains of its existence. This condition can be improved by oral hygiene instruction and counseling.
Halitophobia	No malodor that can be perceived objectively after treatment of halitosis or pseudo-halitosis even though the patient persists in believing that halitosis exists

Epidemiology

Only few studies have documented the prevalence of oral malodor. Moreover, these studies used different methodologies, ranging from self-reported breath malodor to more objective assessments such as measurement of volatile sulfur compounds (VSCs). Because self-reported halitosis correlates weakly with objective measurements and tends to overestimate the problem, data should be interpreted carefully. These studies have been performed in different parts of the world.* Despite the different approaches of these studies, the results point out that about one in four to one in three subjects has persistent bad breath. If a VSC level of 75 ppb (limit for social acceptance)[169] is used as a threshold for halitosis, the prevalence reported in the different populations can be calculated as 23% (late-morning group) and 20% for the Japanese and Chinese studies, respectively. In line with this, a prevalence of 27.5% and 29.8% for the Chinese and Israeli groups, respectively, can be calculated when an organoleptic score of at least 2 is considered as being representative for halitosis. With the same criterion, the calculated prevalence varied between 11.0% and 29.7% for different age groups in the Polish population.

From large-scale inventories in multidisciplinary outpatient clinics for breath odor,[26,27,107] no sex predominance seems to exist for bad breath, although other studies indicate a higher prevalence in women.[80,123] It has also been observed that women seek treatment more often than men.[78] Age can range from 2 years to more than 80 years. No association was found between increased age and oral malodor.[26,27] Most of the patients had been complaining about breath malodor for several years before seeking proper advice.[107]

Etiology

In most patients, breath malodor originates from the oral cavity. Tongue coating is the predominant cause of oral malodor. Furthermore, periodontal diseases (gingivitis and periodontitis) are the second most important causative factors.[27,97,98,107,168,169]

A large-scale study including 2000 patients with halitosis complaints showed that for those patients whose bad breath could be objectively detected, the cause was mostly found within the oral cavity (90%). Tongue coating (51%), gingivitis or periodontitis (13%), or a combination (22%) accounted for the majority of the cases.[107] Because a large part of the population has tongue coating or gingivitis/periodontitis, the risk always exists that an intraoral condition is too easily considered as the cause, whereas more important pathologic conditions are overlooked. Indeed, for a minority of patients (4% in the same study), extraoral causes could be identified, including ear, nose, and throat (ENT) disorders, systemic diseases (e.g., diabetes), metabolic or hormonal changes, hepatic or renal insufficiency, bronchial and pulmonary diseases, or gastroenterologic disorders.[27,86,102,107,152]

Intraoral Causes

Tongue coating, poor oral hygiene, gingivitis, and periodontitis are the predominant causative factors.[107,130] In these cases the term *oral malodor* applies. It is the result of the degradation of organic substrates by anaerobic bacteria. During the process of bacterial putrefaction, peptides and proteins present in saliva, food debris, gingival crevicular fluid, interdental plaque, shed epithelial cells,

postnasal drip, and blood are hydrolyzed to sulfide-containing and non–sulfide-containing amino acids, which can be further metabolized. The proteolytic degradation of sulfur-containing amino acids (cysteine, cystine and methionine) by gram-negative bacteria produces sulfur-containing gases such as hydrogen sulfide (H_2S) and methylmercaptan (CH_3SH).[162]

The most commonly involved bacteria are *Porphyromonas gingivalis, Prevotella intermedia, Prevotella nigrescens, Aggregatibacter actinomycetemcomitans, Campylobacter rectus, Fusobacterium nucleatum, Peptostreptococcus micros, Tannerella forsythia, Eubacterium* spp., and spirochetes. A study by Niles and Gaffar[88] made clear that these gram-negative species in particular cause an unpleasant smell by the production of sulfur compounds. However, because of the large microbial diversity found in patients with halitosis, it is suggested that breath malodor is the result of complex interactions among several bacterial species. One study indicated that some gram-positive microorganisms, such as *Streptococcus salivarius,* also contribute to oral malodor production by deglycosylating salivary glycoproteins, thus exposing their protein core to further degradation by gram-negative microorganisms.[139] More recently, the presence of *Solobacterium moorei,* a gram-positive bacterium, has also been linked to oral malodor.[49,50,58]

Thus, for oral malodor, the unpleasant smell of the breath mainly originates from volatile sulfur compounds (VSCs), especially hydrogen sulfide, methylmercaptan, and (less significantly) dimethyl sulfide ($(CH_3)_2S$), as first discovered by Tonzetich.[149] Other compounds, such as the diamines indole and skatole, the polyamines putrescine and cadaverine, and the carboxylic acids acetic, butyric, and propionic acid, are also formed by proteolytic degradation of non–sulfur-containing amino acids by oral microorganisms.[42]

Tongue and Tongue Coating

The dorsal tongue mucosa, with an area of 25 cm^3, has a very irregular surface topography.[19,129] The innumerable depressions in the tongue surface are ideal niches for bacterial adhesion and growth, sheltered from cleaning actions.[25,168] Moreover, desquamated cells and food remnants also remain trapped in these

retention sites and consequently can be putrefied by the bacteria.[8] A fissured tongue (deep fissures on the dorsum, also called *scrotal tongue* or *lingua plicata*) and a hairy tongue (*lingua villosa*) have an even rougher surface (Fig. 49.2).

FIG. 49.2 (A) to (C) Clinical pictures of heavily coated tongues.

Accumulated food remnants intermingled with exfoliated cells and bacteria form a coating on the tongue dorsum. The latter cannot be easily removed because of retention by the irregular surface of the tongue dorsum (see Fig. 49.2). As such, the two factors essential for putrefaction (bacteria and their nutrients) are united. Several investigators have identified the dorsal posterior surface of the tongue as the primary source of oral malodor.[8,18,25,118] Indeed, high correlations have been reported between tongue coating and odor formation.[8,21,78,168]

In both healthy individuals and patients with periodontitis with or without complaints of oral halitosis, a significant positive correlation was found between the presence or amount of tongue coating and levels of VSCs[78,108] and/or organoleptic scores of the mouth odor.[25] In a group of 2000 patients visiting a multidisciplinary halitosis clinic,[107,159] significant correlations were found between organoleptic scores and tongue coating ($R = 0.52$; $P < 0.001$). In another study,[92] it was also observed that the amount of tongue coating was significantly greater in the halitosis-positive group compared with the halitosis-negative group. Morita and Wang[80] found that the volume of tongue coating and the percentage of sites with bleeding on probing were significantly associated with oral malodor.[80] In 1992, Yaegaki and Sanada[168,169] demonstrated that

even in patients with periodontal disease, 60% of the VSCs were produced from the tongue surface.[168,169]

Research has showed that the strongest determinant of the presence of tongue coating is suboptimal oral hygiene. Other influencing factors were periodontal status, presence of a denture, smoking, and dietary habits.[158]

Periodontal Infections

A relationship between periodontitis and oral malodor has been shown. However, periodontally healthy patients can suffer from halitosis, not all patients with gingivitis and/or periodontitis complain about bad breath, and some disagreement exists in the literature over to what extent oral malodor and periodontal disease are related.[8,119,136] Bacteria associated with gingivitis and periodontitis are indeed able to produce VSCs.[61,84,88,97,98,149]

Several studies have shown that VSC levels in the mouth correlate positively with the depth of periodontal pockets (the deeper the pocket, the more bacteria, particularly anaerobic species) and that the amount of VSCs in the breath increases with the number, depth, and bleeding tendency of the periodontal pockets.[18,96,107,169] VSCs aggravate the periodontitis process by increasing the permeability of the pocket and mucosal epithelium, therefore exposing the underlying connective tissues of the periodontium to bacterial metabolites. Methylmercaptan enhances interstitial collagenase production, interleukin-1 production by mononuclear cells, and cathepsin B production, thus further mediating connective tissue breakdown.[70,112] It was shown that human gingival fibroblasts developed an affected cytoskeleton when exposed to methylmercaptan.[10,112] Furthermore, the reaction of hydrogen sulfide with collagen can alter the protein structure, thereby rendering the periodontal ligament and bone collagen more susceptible to destruction by proteases.[87] Investigators have shown, in cases of gingivitis and periodontitis, a decrease in the content of acid-soluble and total collagen in the affected tissues.[128] These findings suggest that increased production of VSCs may accelerate the progression of periodontal disease. Toxic VSCs are able to damage the periodontal tissues and create even more loss of attachment. A mutual reinforcement of the loss of periodontal

attachment and production of VSCs occurs, resulting in a vicious cycle.

Some studies, however, have shown that when the presence of tongue coating is taken into account, the correlation between periodontitis and oral malodor is much lower, thus indicating that tongue coating remains a key factor for halitosis. The prevalence of tongue coating is six times higher in patients with periodontitis, and the same bacterial species associated with periodontal disease can also be found in large numbers on the dorsum of the tongue, particularly when tongue coating is present.[168] The reported association between periodontitis and oral malodor may thus primarily be due to the effects of periodontal disease on tongue coating. It may also explain why other articles did not find a correlation.[8,136]

Other relevant malodorous pathologic manifestations of the periodontium are pericoronitis (the soft tissue "cap" being retentive for microorganisms and debris), major recurrent oral ulcerations, herpetic gingivitis, and necrotizing gingivitis/periodontitis. Microbiologic observations indicate that ulcers infected with gram-negative anaerobes (i.e., *Prevotella* and *Porphyromonas* species) are significantly more malodorous than noninfected ulcers.[9]

Clinician's Corner

What is the influence of bad breath in patients with periodontitis?

The increased production of volatile sulfur compounds in people with bad breath may accelerate the progression of periodontal disease. For example, it is known that methylmercaptan and hydrogen sulfide can adversely affect collagen structure and gingival fibroblasts.

Dental Disorders

Possible causes within the dentition are deep carious lesions with food impaction and putrefaction, extraction wounds filled with blood clots, and purulent discharge leading to important putrefaction. Other causes include interdental food impaction in large interdental areas and crowding of teeth favoring food

entrapment and accumulation of debris. Acrylic dentures, especially when kept continuously in the mouth at night or not regularly cleaned, can lead to infections (e.g. candidiasis), which produce a typical smell. The denture surface facing the gingiva is porous and retentive for bacteria, yeasts, and debris, which are compounds needed for putrefaction.

Dry Mouth

Saliva has an important cleaning function in the oral cavity. Patients with xerostomia often present with large amounts of plaque on teeth and extensive tongue coating. The increased microbial load and the escape of VSCs when salivary flow is reduced explain the strong breath malodor.[61] Several studies link stress with VSC levels, but it is not clear whether this can simply be explained by a reduction of salivary flow.[67,104] Other causes of xerostomia are medication,[79] alcohol abuse,[36] Sjögren syndrome (a common autoimmune rheumatic disease),[74] and diabetes.[160]

Extraoral Causes

For a minority of patients, extraoral causes can be identified, including ENT disorders, systemic disease (e.g., diabetes or kidney disease), metabolic or hormonal changes, hepatic or renal insufficiency, bronchial and pulmonary diseases, or gastroenterologic disorders.[4,5] Moreover, multiple causes may be present at the same time, and over the course of time the etiology may shift.

Extraoral halitosis can be subdivided into two types: non–blood-borne halitosis and blood-borne halitosis.[147] Non–blood-borne halitosis is uncommon, and most information about it comes from case reports. Non–blood-borne halitosis encompasses, for example, throat infections, nasal infections, infections of the respiratory system, lung diseases, and stomach disorders.

Blood-borne halitosis is the result of bad-smelling metabolites that can be formed or absorbed at any place in the body (e.g., the liver, the gut) and transported by the bloodstream to the lungs. Exhalation of these volatiles in the alveolar air then causes halitosis, at least when the concentrations of the bad-smelling metabolites are

sufficiently high. The crevicular fluid reflects the circulating molecules in the blood and can thus also play a relevant role, but due to the small amount, probably not a very dominant one.

The extraoral causes are much more difficult to detect, although they can sometimes be recognized by a typical odor. Uncontrolled diabetes mellitus can be associated with a sweet odor of ketones, liver disease can be revealed by a sulfur odor, and kidney failure can be characterized by a fishy odor because of the presence of dimethylamine and trimethylamine.[102]

Clinician's Corner

What is the most important cause of halitosis?

Tongue coating is the most important cause of halitosis. The innumerable depressions in the tongue surface are ideal niches for bacterial adhesion and growth; additionally, desquamated cells and food remnants also remain trapped in these retention sites. The degradation of organic substrates by anaerobic bacteria results in the production of a range of unpleasant-smelling volatile compounds.

Ear, Nose, and Throat

During chronic or purulent tonsillitis, the deep crypts of the tonsils accumulate debris and bacteria, especially periopathogens, resulting in putrefaction. In the crypts, even calculus (e.g., subgingivally) can be formed (tonsilloliths or tonsil stones). Other examples include acute pharyngitis (viral or bacterial) and postnasal drip. The latter is a rather common condition, which is perceived by patients as a liquid flow in the throat originating from the nasal cavity.[118] It is often associated with chronic sinusitis or regurgitation esophagitis, in which the acidic contents of the stomach reach the nasopharynx and cause mucositis. Ozena (caused by *Klebsiella ozaenae*) is a rare atrophic condition of the nasal mucosa, with the appearance of crusts that cause a very strong breath malodor. Finally, a foreign body in a nasal or sinus cavity can cause local irritation, ulceration, and subsequent putrefaction (e.g., children and mentally handicapped persons tend to put

objects such as peas or wet paper in the nose).

Bronchi and Lungs

Pulmonary causes include chronic bronchitis, bronchiectasis (infection of standing mucus secretion in cystic dilations through walls of bronchioles), pneumonia, pulmonary abscess, bronchial carcinoma, and carcinoma of the lung.[73,75] The relevance of an early diagnosis is evident.

Gastrointestinal Tract

Contrary to common public opinion, even among medical physicians, gastrointestinal disorders are rarely responsible for bad breath.[91,148] The following may be responsible for less than 1% of malodor cases:

- A Zenker diverticulum (a hernia in the esophageal wall, allowing accumulation of food and debris and thus putrefaction) can cause significant breath odor because it is not separated from the oral cavity by a sphincter.[20]
- A gastric diaphragmatic hernia (where the fundus of the stomach protrudes through the diaphragm, with relative sphincter insufficiency, allowing gases to escape or contents to flow back in the esophagus) can cause reflux of the gastric contents up to the oropharynx. This is sometimes combined with ructus, in which air from the stomach suddenly regurgitates.
- Regurgitation esophagitis (ulceration of the mucosal lining of the esophagus by acidic stomach contents flowing back because of improper functioning of the sphincter) may be a cause.[60]
- Intestinal gas production: Some gases (e.g.,

> dimethyl sulfide) are absorbed but not metabolized by the intestinal endothelium and thus transported by the blood. These gases can then be exhaled through the lungs.[142]

Some disagreement exists in the literature over whether *Helicobacter pylori* infection is associated with halitosis.[57,81] In one report, *H. pylori* was shown to produce hydrogen sulfide and methylmercaptan, a finding suggesting that this microorganism can contribute to the development of halitosis.[71] Tangerman and colleagues[148] found no association between halitosis and *H. pylori* infection.[148]

Liver

Patients with various degrees of hepatocellular failure and/or portosystemic shunting of blood may acquire a sweet, musty, or even slightly fecal aroma of the breath, termed *fetor hepaticus,* which has been mainly attributed to the accumulation of dimethyl sulfide.[13,145,156] Moreover, if the metabolizing function of the liver fails, the concentrations of certain metabolites normally processed in the liver will increase, and they will enter the systemic circulation again and be exhaled.[21,154]

Kidney

Kidney insufficiency, primarily caused by chronic glomerulonephritis, leads to an increase of the amines dimethylamine and trimethylamine, causing a typical fishy odor of the breath.[134]

Systemic Metabolic Disorders

Uncontrolled diabetes mellitus results in the accumulation of ketones, which have a sweet smell, like the odor of rotten apples. Insulin resistance leads to an increase of triglycerides and free fatty acids, and ketones (e.g., acetone, acetoacetate, and hydroxybutyrate) are formed during lipolysis.[140]

Trimethylaminuria

Trimethylaminuria is a hereditary metabolic disorder that leads to a typical fishy odor of the breath, urine, sweat, and other bodily secretions. Trimethylaminuria is an enzymatic defect that prevents the transformation of trimethylamine to trimethylaminoxide, resulting in abnormal amounts of this molecule. The prevalence is unknown but approaches 1% in the United Kingdom.[77]

Hormonal Causes

At certain moments during the menstrual cycle, a typical breath odor can develop; partners are often well aware of this odor. Evidence also indicates that VSC levels in the expired air are increased twofold to fourfold around the day of ovulation and in the perimenstrual period. Increases in VSCs are smaller in midfollicular phases.[102]

Pseudo-halitosis or Halitophobia

If a patient presents with complaints but no objective halitosis can be detected, one speaks of pseudo-halitosis or *imaginary breath odor*, which can lead to *halitophobia*.[94] The latter is the case when, even after repeated diagnosis of an absence of bad breath, the patient cannot accept the absence of halitosis. This condition has been associated with obsessive-compulsive disorder and hypochondria. Well-established personality disorder questionnaires (e.g., Symptom Checklist 90) allow the clinician to assess the patient's tendency for illusional breath malodor.[28,29,31] Having a psychologist or psychiatrist at the malodor consultation can be especially helpful for such patients. Because of the complexity of this disorder, a malodor consultation is thus preferably multidisciplinary, combining the knowledge of a periodontologist or dentist, an ENT specialist, an internist (if necessary), and a psychologist or psychiatrist. In a study of 2000 patients, 16% were diagnosed with pseudo-halitosis or halitophobia.[107]

Key Fact

Only in a few cases is the cause of bad breath found outside the oral cavity. Thus, dentists play an important role in the diagnosis and treatment of halitosis.

Fundamentals of Malodor Detection

The breath of a person contains up to 150 different molecules.[100,102,155–157] The characteristics of the expired molecules determine whether we can smell them or not. Some gases can cause a striking odor at very low concentrations, whereas others need to be present in much higher quantities. The perception of the molecules depends on the following factors[43]:

1. The odor itself can be pleasant, unpleasant, or even repulsive *(olfactory response)*.
2. Each particular molecule has a specific concentration before it can be detected *(threshold concentration)*.
3. The *odor power* is the concentration that is necessary to increase the odor score by one unit.
4. The *volatility* of the compound: Malodorous molecules only express themselves when they become volatile.
5. The *substantivity:* The capacity of the molecule to stay present and thus remain the cause of smell.

eTable 49.1 provides an overview of these essential characteristics for the key malodorous compounds, clearly highlighting large interproduct variations. The odor power is the strongest for hydrogen sulfide and methylmercaptan; if the concentration of these products increases 5-fold to 10-fold, the odor will receive a higher organoleptic rating. For some other compounds, increases of 25 to 100 times are needed to reach a similar effect. Skatole and methylmercaptan are detected at the lowest concentrations (low threshold). The three sulfur molecules have the lowest volatility (i.e., will escape the liquid phase first).[43]

eTABLE 49.1

Odor Threshold and Odor Power of Key Malodorous Compounds

Compound	ODOR THRESHOLDS		ODOR POWER	VOLATILITY (HENRY'S CONSTANTS)
	Greenman (mol/dm^{-3})	Devos[a] (mol/dm^{-3})	Greenman (× increase to "up" score 1 unit)	Volatility (K_{cc}) in H_2O at 20° C
Butyrate	2.3×10^{-10}	2.4×10^{-10}	10-fold	3.9×10^{4}
Isovalerate	1.8×10^{-11}	2.5×10^{-11}	42-fold	2.5×10^{4}
Skatole	7.2×10^{-13}	1.0×10^{-12}	8-fold	4.1×10^{5}
Trimethylamine	1.8×10^{-11}	1.5×10^{-11}	96-fold (low affinity)	2.0×10^{2}
Putrescine	9.1×10^{-10}	1.0×10^{-9}	27-fold	4.1×10^{1}
CH_3SCH_3	5.9×10^{-8}	5.0×10^{-8}	10-fold	1.7×10^{1}
H_2S	6.4×10^{-10}	5.0×10^{-10}	4.8-fold	$\approx 1.7 \times 10^{1}$
CH_3SH	1.0×10^{-11}	1.0×10^{-11}	7.2-fold	$\approx 1.7 \times 10^{1}$

[a]Devos M, Patte F, Roualt J, et al: *Standardized human olfactory thresholds,* Oxford, 1990, IRL Press at Oxford University Press.

CH_3SH, Methylmercaptan; *CH_3SCH_3*, dimethyl sulfide; *H2S*, hydrogen sulfide; *K_{cc}*, unit for Henry's Law constant.

From Greenman J, Duffield J, Spencer P, et al: Study on the organoleptic intensity scale for measuring oral malodor. *J Dent Res* 83:81, 2004.

In a study by Kleinberg and Codipilly,[61] aqueous solutions of oral odoriferous volatiles were placed on the skin of the back of the hand. Afterward, odor scores were given (organoleptic score; see earlier). The results are shown in eTable 49.2. All metabolites caused an explicit odor, which decreased in intensity over time. Some molecules disappeared very fast (e.g., hydrogen sulfide and methylmercaptan), whereas others produced an unpleasant smell for a longer period of time (e.g., indole and skatole, for 10 minutes and longer).

eTABLE 49.2

Odor Scores at the Back of the Hand

	Start	1 Min	3 Min	10 Min
Hydrogen sulfide	3	1	0	0
Methylmercaptan	3	1	0	0
Acetic acid	3	4	0	0
Propionic acid	3	4	0	0
Butyric acid	4	4	2	2
Valeric acid	4	4	3	2
Indole	4	4	4	2
Skatole	4	4	4	2
Putrescine	4	4	3	1
Cadaverine	4	4	2	1

The olfactory response, rated by an organoleptic scale, follows an exponential curve when correlated with the concentration of different gases. In other words, when the concentrations of the molecules were compared with their organoleptic outcomes, an optimal fit was obtained only when the concentrations of the gases were transformed to log values. The latter implies that all types of breath "measurements" (gas chromatography [GC], portable breath analyzers [e.g., Halimeter, Interscan, Chatsworth, Calif]) require log transformation to be comparable with organoleptic scores.[43]

Diagnosis of Malodor

Preconsultation Approach

A proper diagnostic approach starts with providing the right information to the patient before the appointment. It is recommended that the patient does not eat garlic, onions, or spices for 2 days before the consultation because they can cause bad breath and body odor that can last from several hours to 2 days.[48] To remove confounding odors, the patient is also instructed to refrain from alcohol, coffee, and smoking during the 12-hour period before the consultation. For the same reason, it is advisable not to use chewing gum, mints, drops, or mouthrinses during the 8 hours preceding the appointment, both for the patient and for the oral malodor judge. The day of the consultation, the use of fragranced shampoo, body lotion, and perfume should also be avoided, so as not to disturb the organoleptic ratings. In most halitosis consultations, the patient is asked not to eat or drink on the morning of the examination. However, if breakfast is consumed, morning bad breath can be excluded.

Course of a Halitosis Consultation

Preconsultation patient information
Anamnesis
Organoleptic examination
Examination of the breath with portable sulfur monitor

Oropharyngeal examination
Explanation of halitosis and instructions for oral hygiene
If necessary, explanation of additional therapy

The patient should be encouraged to bring a confidant to the consultations who can identify whether the perceived odor is the one previously noticed. Some of these guidelines are crucial not only for the organoleptic evaluation, but also for a correct interpretation of the results obtained with certain breath analyzers (see later).

Anamnesis

Each consultation should start with thorough questioning about the breath malodor, eating habits, and medical and dental history. This can be done with a questionnaire that the patient fills out in the waiting room and/or verbally at the beginning of the consultation, depending on the preference of the examiner and the practical possibilities. To start with, the patient should be asked about the frequency of the halitosis (e.g., constantly, every day), the time of appearance during the day (e.g., after meals can indicate a stomach hernia), when the problem first appeared, and whether others have identified the problem (to exclude imaginary breath odor). In addition, the medical history has to be recorded, with an emphasis on medications and systemic diseases of the lungs, liver, kidneys, stomach, and pancreas. Concerning the ENT history, attention should be paid to the presence of nasal obstruction, mouth breathing, postnasal drip, allergy, tonsillitis, dysphagia, and previous ENT encounters. The dental history includes questions assessing the frequency of dental visits, the use of mouthrinses, the presence and maintenance of a dental prosthesis, and the frequency of and instruments used for toothbrushing, interdental cleaning, and tongue brushing and scraping. Finally, the patient is asked about smoking, drinking, and dietary habits.

Examinations

After obtaining a thorough anamnesis, the clinician checks whether an unpleasant odor can be perceived and inspects the mouth to

detect possible causes of bad breath. Different ways exist to examine the breath. The easiest and least expensive way is to smell the breath. However, several devices are on the market that mainly detect VSCs.

Organoleptic Rating

Even though devices are available, organoleptic assessment by a judge is still the gold standard in the examination of breath malodor. It is the easiest and most often used method because it gives a reflection of the everyday situation when halitosis is noticed. Moreover, the human nose can smell 10,000 different odors, many more than any device on the market.[48,51] In an organoleptic evaluation, a trained and preferably calibrated "judge" sniffs the expired air and assesses whether it is unpleasant by using an intensity rating.[124] Scoring is normally done according to the intensity scale of Rosenberg, where 0 represents the absence of odor, 1 is barely noticeable odor, 2 is slight malodor, 3 is moderate malodor, 4 is strong malodor, and 5 is severe malodor.[124] In this six-point system, 0 indicates a concentration of odorant below a threshold, 1 to 4 are increasing occupancy of receptor binding sites, and 5 is assumed to be close to saturation.[43,44] To avoid bias, it is advisable that the organoleptic assessment precedes all other measurements.

Before acting as a judge, clinicians must ensure they do not have *anosmia* (lost or impaired smelling capacity). A significant fraction of the adult population has partial loss of smelling acuity. After age 60, a decline of smelling acuity is common. Candidate odor judges should test their capacity to smell and recognize different odors (qualitative assessment), as well as to detect odors at low concentrations (quantitative assessment).[29] The first aspect can be checked by using, for example, a commercially available test (Smell Identification Test, Sensonic) that establishes a response curve based on the capacity to recognize and discriminate among smells. After scratching an odorous surface in a booklet, several options of smells are proposed. If the candidate judge lacks the capacity to recognize certain odors, it will reveal partial anosmia. The second aspect is tested by sniffing a series of dilutions of substances such as isovaleric acid, phenethyl alcohol, thiophene, and pyridine, which

are inexpensive organic components. These are presented to the candidate judge as dilutions, in one-log dilution steps from 1 to 10^{-1}.[12] Concentrations of the odorous substances are presented in ascending order until the person detects the substance, then in descending order until he or she no longer detects it. This is the "psychophysical staircase method" for determining the threshold level. The threshold corresponds to the average between ascending and descending levels. Clinicians can thus find out whether their smelling threshold level is acceptable. Abnormalities in the capacity to judge or perceive odors can be caused by a viral infection of the nasal cavities, a concussion, or smoking. Whereas an infection can have a transient effect on olfactory performance, concussion and smoking have permanent effects.

In an organoleptic assessment, the judge smells a series of air samples (Fig. 49.3), as follows:

FIG. 49.3 **(A) Organoleptic assessement of the oral cavity odor while the patients refrains from breathing. (B) assessment of the oral cavity odor when the patient counts out loud from 1 to 10. (C) A sample of the tongue coating is taken to smell afterward. (D) The nasal odor is rated.**

1. *Nasal breath odor:* The subject expires through the nose while keeping the mouth closed. When the nasal expiration is malodorous yet the air expired through the mouth is not, an ENT problem can be suspected.
2. *Oral cavity odor:* The subject opens the mouth and refrains from breathing while the judge places his or her nose close to the mouth opening (approximately 10 cm from the patient's mouth).
3. *Oral cavity odor:* The patient counts from 1 to 10. This reveals the same as described earlier, but favors oral malodor because of drying of the palatal and tongue mucosa.
4. *Tongue coating:* The judge smells a tongue scraping from the posterior part of the tongue, obtained with an odorless plastic spoon or tongue scraper, at a distance of approximately 5 cm from his or her nose. This odor resembles that emanating from the tongue dorsum.

Although the organoleptic assessment is still the gold standard for diagnosis of halitosis, the method also has some important drawbacks. The assessment can, for example, be influenced by several aspects, such as the position of the head, hunger, and the experience of the judge. Odor judges are also supposed to rest their nose for several minutes between tests to avoid habituation. The most important disadvantage of the method, however, is that it clearly has a degree of subjectivity. Researchers are trying to improve the reliability and reproducibility of the organoleptic method.[44] When using a panel of odor judges instead of one judge, the reliability is already considered to increase.[167] Furthermore, the agreement among judges may be improved by standardization of the sense of smell using an odor solution kit for measuring the olfactory response.[173] Training is also considered to reduce odor judges' errors.[82]

Portable Volatile Sulfur Monitor

The Halimeter (Interscan, Chatsworth, CA) is an electronic device that detects the presence of VSCs such as hydrogen sulfide and methylmercaptan in breath. The instrument cannot discriminate among the different sulfur compounds. The sensitivity for

methylmercaptan is five times lower than for hydrogen sulfide, and the device is almost insensitive to dimethyl sulfide.[37] Moreover, ethanol and other compounds can disturb the measurements.

To allow an increase in concentration of VSCs, the patient has to keep his or her mouth closed for 2 to 3 minutes before sampling. The mouth air is aspirated by inserting a drinking straw fixed on the flexible tube of the instrument (Fig. 49.4). The straw is kept inside the mouth, preferably above the posterior part of the tongue dorsum, not touching the oral mucosa or the tongue, while the subject keeps the mouth slightly open and breathes through the nose. The sulfur meter uses a voltametric sensor that generates a signal when exposed to sulfur-containing gases. Using a recorder or specific software, a graphic presentation can be obtained, called a *haligram* (Fig. 49.5), which gives the response as a function of time. For the most optimal results, the manufacturer recommends performing three measurements and using the average value. Between measurements, it is important to allow the meter to restabilize before repeating. The monitor needs regular calibration and replacement of the sensor biannually.

FIG. 49.4 **Halimeter.**

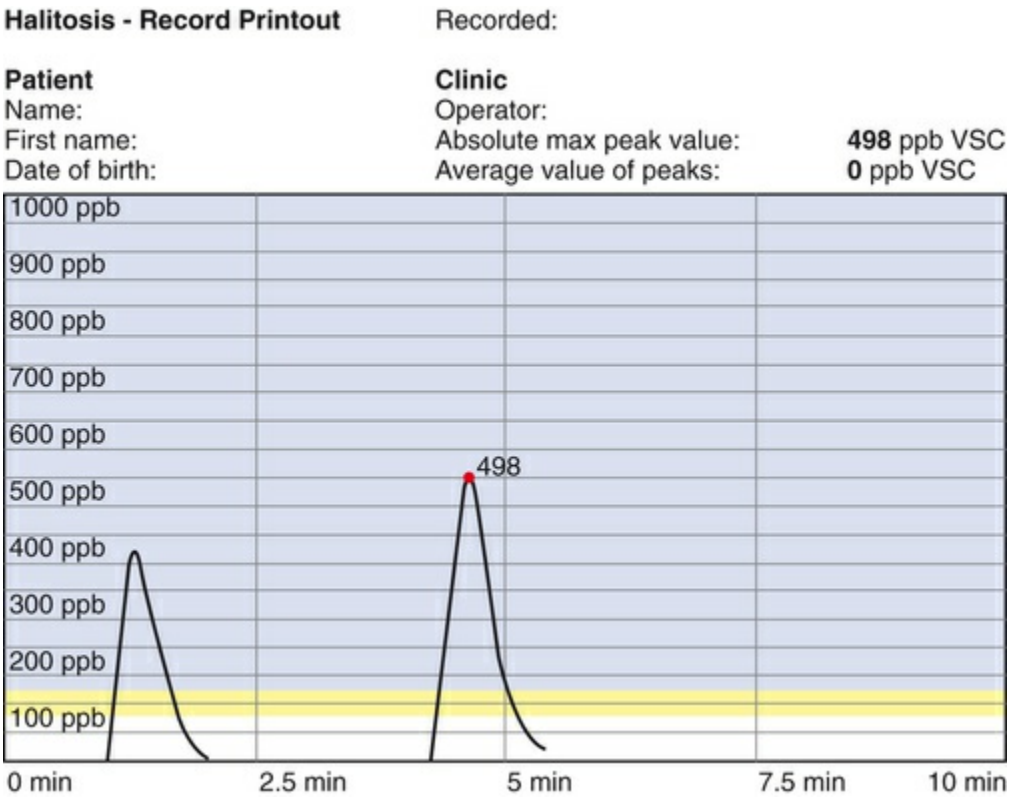

FIG. 49.5 Haligram.

The Halimeter is easy to use as a chair-side test and is relatively inexpensive. Patients are usually less embarrassed by this examination than by organoleptic assessment. Moreover the absence of odor in cases of halitophobia can be more convincingly proven than by an organoleptic assessment. Several studies have shown good correlations between the organoleptic measurement and the Halimeter.[122,125] An important drawback of the device is that it detects only sulfur compounds and thus is useful only for intraoral causes of halitosis. The absence of VSCs does not prove that no breath odor is present.

A wide range of threshold limits for halitosis has been proposed. Yaegaki and Sanade[168] recommended a value of 75 ppb as the limit for social acceptance, whereas the Halimeter's manufacturer proposes 150 ppb. Following this recommendation, the sensitivity and specificity of the device for the organoleptic score have been calculated to be 63% and 98%, respectively. Previous studies from our group showed that a reduction in this threshold to 120 ppb improves the sensitivity of the device without detriment to specificity.[159] In patients with oral malodor, VSC concentrations can easily reach 300 to 400 ppb.

Gas Chromatography

A gas chromatograph can analyze air, saliva, or crevicular fluid (Fig. 49.6). About 100 compounds have been isolated from the headspace of saliva and tongue coating, including ketones, alkanes, sulfur-containing compounds, and phenyl compounds.[17] In the expired air of a person, at least 150 compounds can be found.[100,155-157] The most important advantage of the technique is that when coupled with mass spectrometry, it can detect virtually any compound when using adequate materials and conditions. Moreover, it has very high sensitivity and specificity.

FIG. 49.6 Gas chromatography machinery, including thermal desorber (TD) to release molecules trapped in special collectors, gas chromatograph (GC) for separation of molecules, and mass spectrometer (MS) for identification of molecules.

Elaborate gas chromatography is available only in specialized centers but is especially useful for identifying nonoral causes.[54,99,142,154] It is expensive and requires trained personnel.

A small, portable "gas chromatograph" (OralChroma, Nissha FIS, Inc., Japan) has been introduced, which makes this technique available for periodontal clinics (Fig. 49.7). More recently, the second generation of this portable gas chromatograph was introduced: the OralChroma CHM-2. The CHM-2 is a little bit smaller than the first-generation OralChroma, the measurements only take half the time, and it comes with optimized software.

Sample collection is done by use of a disposable syringe, which is inserted two-thirds of the way into the oral cavity. The patient must close the mouth for 30 seconds before sample collection, and afterward the sample is injected into the gas chromatograph.

FIG. 49.7 OralChroma.

The analysis starts automatically. A software packet, OralChroma Data Manager, collects the data from the OralChroma and graphically displays the sensor responses on a computer screen. After 4 minutes for the OralChroma CHM-2, the process is completed, and the concentrations of the three gases are displayed in either ng/10 mL or ppb (nmol/mol) (Fig. 49.8). The accompanying software packet gives a clear overview of the VSC measurement. However, with the OralChroma CHM-1, sometimes these graphics are not correct because the place of the VSCs is incorrectly assigned in the chromatogram. The latter can be corrected by analyzing the chromatograph.[146,148]

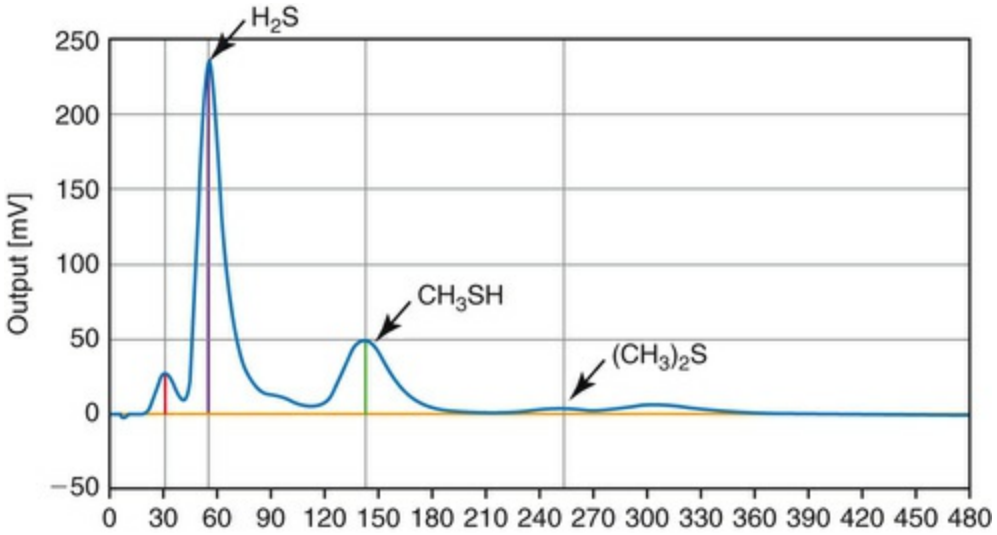

FIG. 49.8 **Graphic from the OralChroma. The first peak indicates the level of hydrogen sulfide *(HS)*, the second the level of methylmercaptan *(CHSH)*, and the third the level of dimethyl sulfide *([CH]S). 2332***

The OralChroma has the capacity to measure the concentration of the three key sulfur compounds (hydrogen sulfide, methylmercaptan, and dimethyl sulfide) separately. This can be helpful for a differential diagnosis. A high concentration of methylmercaptan compared with hydrogen sulfide indicates, for example, periodontitis.[169] If only hydrogen sulfide is increased, a problem with oral hygiene may exist. Dimethyl sulfide can indicate an extraoral cause.[145] Just like the Halimeter, the OralChroma cannot detect compounds other than sulfur compounds, and some intraoral and extraoral causes can thus be overlooked. The apparatus needs calibration and the sensor and column need to be replaced every 2 years.[159]

Halimeter Versus OralChroma

Halimeter	OralChroma
Easy to handle	Easy to handle
Affordable	More expensive
Displays results immediately	Takes 4 min (CHM-2) or 8 min (CHM-1) before measurements are shown
Cannot discriminate among different gases	Can discriminate among hydrogen sulfide, methylmercaptan, and dimethyl sulfide
Maintenance needed	Maintenance needed

Dark-Field or Phase-Contrast Microscopy

Oral malodor is typically associated with a higher incidence of motile organisms and spirochetes, so shifts in their proportions allow monitoring of therapeutic progress. Another advantage of direct microscopy is that the patient becomes aware of bacteria present in plaque, tongue coating, and saliva. Too often, patients confuse plaque with food remnants.

Oropharyngeal Examination

The oropharyngeal examination includes inspection of deep carious lesions, interdental food impaction, wounds, bleeding of the gums, periodontal pockets, tongue coating, dry mouth, and the tonsils and pharynx (for tonsillitis and pharyngitis).

The tongue coating can be scored with regard to thickness and surface. Several methods have been proposed for thickness; Gross and coworkers in 1975[47] proposed an index ranging from 0 (no coating) to 3 (severe coating). Miyazaki[78] (Fig. 49.9A) assessed tongue-coating status according to area: 0 = none visible, 1 = less than one-third of the tongue dorsum covered, 2 = less than two-thirds, and 3 = more than two-thirds.

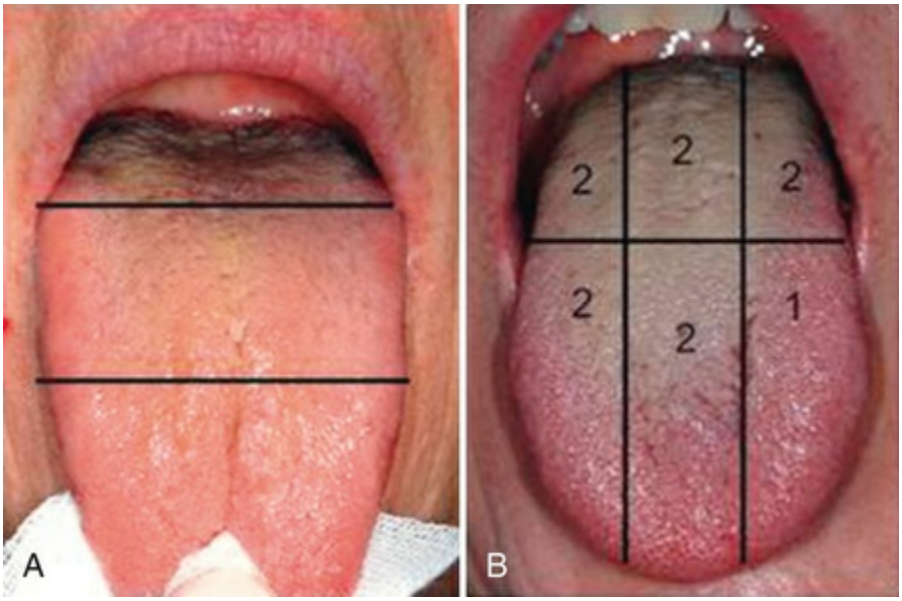

FIG. 49.9 (A) Miyazaki tongue coating index. Score 0 = none visible, score 1 = less than one-third of the tongue dorsum covered, score 2 = less than two-thirds, and score 3 = more than two-thirds; here score 2

applies because less than two-thirds of the tongue dorsum is covered. (B) Winkel tongue coating index. Divide the dorsum of the tongue into six areas, (i.e., three in the posterior and three in the anterior part of the tongue). The tongue coating in each sextant is scored as 0 = no coating, 1 = light coating, and 2 = severe coating.

Winkel and coworkers[165] considered both the extension and the thickness of the tongue coating. The dorsum of the tongue is divided into six areas, three in the posterior and three in the anterior of the tongue (see Fig. 49.9B). The tongue coating in each sextant is scored as follows: 0 = no coating, 1 = light coating, and 2 = severe coating. A score of 1 is given when the pink color underneath the coating is still visible; when this is not the case, 2 is given.

Attention should be paid to the morphology of the tongue. For example, the clinician should note whether the tongue looks normal or rough or has a deep sulcus or large papillae vallatae.[165]

Self-Examination

Smelling one's own breath by expiring into the hands in front of the mouth is not relevant because the nose becomes used to the odor,[141] and the smell of the skin and soap used for handwashing may interfere. Moreover, studies have shown that self-assessment of oral malodor is notoriously unreliable, and one should be careful with such information obtained from the patient.[6,30]

Clinician's Corner

When one of your patients complains of bad breath and he or she is periodontally healthy but has a thick tongue coating, what can you do?

You give the patient oral hygiene instruction and stress the importance of using a tongue scraper. Optionally, a mouthrinse can be advised, with active ingredients of proven efficacy such as chlorhexidine, cetylpyridinium chloride, or a zinc formulation.

Saliva Incubation Test

The analysis of the headspace above incubated saliva by gas chromatography reveals VSCs and other compounds such as indole, skatole, lactic acid, methylamine, diphenylamine, cadaverine, putrescine, urea, ammonia, dodecanol, and tetradecanol. By adding some proteins, such as lysine or cysteine, the production of cadaverine or hydrogen sulfide is dramatically increased. Organoleptic evaluation (or assessment of the VSCs) of the saliva headspace offers promising perspectives for monitoring treatment results.[109] It is a less invasive test, especially for the patient, than smelling breath in front of the oral cavity.

Electronic Nose

An electronic nose identifies the specific components of an odor and analyzes its chemical makeup. It consists of a mechanism for chemical detection, such as an array of electronic sensors, and a mechanism for pattern recognition. It is smaller, less expensive, and easier to use than, for example, gas chromatography, but can be developed only for specific applications if the important metabolites are already known. An artificial nose that has the same capacities as the human nose would be ideal. Currently, although significant improvements still need to be made, the first trials thus far have been promising.[144]

Chair-Side Test

A salivary chair-side test may be an alternative for the general practitioner for diagnosing halitosis. Currently, several tests based on the detection of bacteria and metabolites involved in the process of oral malodor are commercially available. All these tests have reported acceptable correlation with the organoleptic ratings, some even with the VSC level.[55,66,138] The BANA test is based on the ability of some bacterial species to hydrolyze a synthetic trypsin substrate (N-benzoyl-DL-arginine-2-naphthylamine).[66] In this way the test can detect three specific bacteria related to periodontal disease: *P. gingivalis*, *Bacteroides forsythus*, and *Treponema denticola*. As already mentioned, periodontitis is not the most common cause of oral malodor,[118] given that not all patients with periodontitis have bad

breath.

The β-galactosidase tests quantify, by means of chromogenic substrates, bacterial enzymes involved in the initial degradation of oral mucin. β-Galactosidase is one of the main enzymes responsible for the removal of carbohydrate side chains, a limiting step in the proteolysis of glycoproteins.[138] It has been demonstrated that the presence of the enzyme accounts for the presence of oral malodor independent of the VSC level.[137] The *ninhydrin* method is a colorimetric test to determine amino acids and low-molecular-weight amines. These compounds are, like VSCs, final products of bacterial proteolysis.[55]

A newer colorimetric test offers the possibility of assessing amines in saliva by means of a simple color scale.[23] In a first clinical study the test appeared to be able to distinguish between volunteers with and without malodor. Besides the correlation of the test results with the organoleptic rating, the independent contribution to the odor of the amines in saliva has been demonstrated.[24]

Treatment of Oral Malodor

The treatment of oral malodor (with an intraoral origin) should preferably be cause related. Because oral malodor is caused by the metabolic degradation of available proteins to malodorous gases by certain oral microorganisms, the following general treatment strategies can be applied:

- Mechanical reduction of intraoral nutrients (substrates) and microorganisms
- Chemical reduction of oral microbial load
- Rendering malodorous gases nonvolatile
- Masking the malodor

Treatment should be centered on reducing the bacterial load and micronutrients by effective mechanical oral hygiene procedures, including tongue scraping. Periodontal disease should be treated and controlled, and as an auxiliary aid, oral rinses containing

chlorhexidine and other ingredients may further reduce the oral malodor. If breath malodor persists after these approaches, other sources of the malodor, such as the tonsils, lung disease, gastrointestinal disease, or metabolic abnormalities (e.g., diabetes), should be investigated.

Mechanical Reduction of Intraoral Nutrients and Microorganisms

Because of the extensive accumulation of bacteria on the dorsum of the tongue, tongue cleaning should be emphasized.[15,126,168] Previous investigations demonstrated that tongue cleaning reduces both the amount of coating (and thus bacterial nutrients) and the number of bacteria and thereby improves oral malodor effectively.[25,40,41,47,111] Other reports indicated that the reduction of the microbial load on the tongue after cleaning is negligible and that the reduced malodor probably results from the reduction of bacterial nutrients.[76,106]

Cleaning of the tongue can be done with a normal toothbrush, but preferably with a tongue scraper if a coating is established.[93,95] Tongue cleaning using a tongue scraper reduces halitosis levels by 75% after 1 week.[95] This should be gentle cleaning to prevent soft tissue damage. It is best to clean as far backward as possible; the posterior portion of the tongue has the most coating.[123] Tongue cleaning should be repeated until almost no coating material can be removed.[16] The gagging reflex is often elicited, especially when using brushes[106]; practice helps to prevent this.[14] It can also be helpful to pull the tongue out with a gauze pad. Tongue cleaning has the additional benefit of improving taste sensation.[106,166]

Interdental cleaning and toothbrushing are essential mechanical means of dental plaque control. Both remove residual food particles and organisms that cause putrefaction. Clinical studies have shown that the mechanical action of toothbrushing alone has no appreciable influence on the concentration of VSCs.[143] In a short-term study, Tonzetich[150] showed a short-term effect on bad breath after brushing with a sodium monofluorophosphate toothpaste. However, the effect was half of what was observed when combined with tongue brushing (73% and 30% reduction in VSCs, respectively).[150]

When chronic oral malodor arises as a consequence of periodontitis, professional periodontal therapy is needed.[8,18,96,169] A one-stage full-mouth disinfection, combining scaling and root planing with the application of chlorhexidine, reduced organoleptic malodor levels up to 90% in one study.[108] In another study by the same investigators, initial periodontal therapy had only a weak impact on VSC levels, except when combined with a mouthrinse containing chlorhexidine.[109]

Chewing gum may control bad breath temporarily because it can stimulate salivary flow.[114] The salivary flow itself also has a mechanical cleaning capability. Not surprisingly, therefore, subjects with extremely low salivary flow rate have higher VSC ratings and tongue coating scores than those with normal saliva production.[64] Waler[161] showed that chewing gum without any active ingredient can reduce halitosis modestly.

Chemical Reduction of Oral Microbial Load

Together with toothbrushing, mouth rinsing has become a common oral hygiene practice.[38] Formulations have been modified to carry antimicrobial and oxidizing agents, impacting the process of oral malodor formation. The active ingredients usually include antimicrobial agents such as chlorhexidine, cetylpyridinium chloride (CPC), essential oils, chlorine dioxide, triclosan, amine fluoride and stannous fluoride, hydrogen peroxide, and baking soda. Some of these agents have only a temporary effect on the total number of microorganisms in the oral cavity.

Chlorhexidine

Chlorhexidine is considered the most effective antiplaque and antigingivitis agent.[1-3,5,56] Its antibacterial action can be explained by disruption of the bacterial cell membrane by the chlorhexidine molecules, thus increasing its permeability and resulting in cell lysis and death.[56,68] Because of its strong antibacterial effects and superior substantivity in the oral cavity, chlorhexidine rinsing provides significant reductions in VSC levels and organoleptic ratings.[12,120,122,153,171]

Rosenberg and associates[122] showed that a 0.2% chlorhexidine

regimen produced a 43% reduction in VSC values and >50% reduction in organoleptic mouth odor ratings. De Boever and Loesche[25] reported that 1 week of rinsing with 0.12% chlorhexidine gluconate, in combination with tooth and tongue brushing, significantly reduced VSC levels, mouth odor, and tongue odor by 73%, 69%, and 78%, respectively. Morning halitosis was reduced up to 90%.[153] Halita (Dentaid, Spain), a solution of 0.05% chlorhexidine, 0.05% CPC, and 0.14% zinc lactate, without alcohol, was even more efficient than chlorhexidine alone, suggesting that the other compounds are also important.[116,117,153] This is explained by a synergistic effect between chlorhexidine and CPC, and between chlorhexidine and zinc (Zn^{++}) (see following discussion). The latter was confirmed in a randomized controlled trial where amine fluoride/stannous fluoride solution showed improved outcomes when Zn^{++} was added.[22]

Unfortunately, as mentioned in some trials, chlorhexidine at a concentration of 0.2% or greater also has some disadvantages, such as increased tooth and tongue staining, unpleasant taste, and some temporary reduction in taste sensation.[32]

Essential Oils

Previous studies evaluated the short-term effect (3 hours) of a Listerine rinse (which contains essential oils) compared with a placebo rinse.[101] Listerine was found to be only moderately effective against oral malodor (±25% reduction vs. 10% for placebo of VSCs after 30 minutes) and caused a sustained reduction in the levels of odorigenic bacteria. Similar VSC reductions were found after rinsing for 4 days.[12]

Chlorine Dioxide

Chlorine dioxide (ClO_2) is a powerful oxidizing agent that can eliminate bad breath by oxidation of hydrogen sulfide, methylmercaptan, and the amino acids methionine and cysteine. Studies demonstrated that a single use of a chlorine dioxide–containing oral rinse slightly reduced mouth odor.[34,35]

Two-Phase Oil-Water Rinse

Rosenberg and colleagues[120] designed a two-phase oil-water rinse containing CPC. The efficacy of oil-water-CPC formulations is thought to result from the adhesion of a high proportion of oral microorganisms to the oil droplets that is further enhanced by the CPC. A twice-daily rinse with this product (before bedtime and in the morning) showed reductions in both VSC levels and organoleptic ratings. These reductions were superior to those seen with Listerine and were significantly superior to placebo.[65,120]

Triclosan

Triclosan, a broad-spectrum antibacterial agent, has been found to be effective against most oral bacteria and has good compatibility with other compounds used for oral home care. A pilot study demonstrated that an experimental mouthrinse containing 0.15% triclosan and 0.84% zinc (Zn^{++}) produced a stronger and more prolonged reduction in mouth odor than Listerine rinse.[113] The anti-VSC effect of triclosan, however, seems strongly dependent on the solubilizing agents.[170] Flavoring oils or anionic detergents and copolymers are added to increase the oral retention and decrease the rate of release in toothpaste formulations containing triclosan. The effects of these formulations in oral malodor have been illustrated in several studies.[53,89,90,132,133] Significant reduction of breath scores were observed after a single use as well as after a week (28% and >50%, respectively), with a similar effect on VSC levels (57% reduction after 1 week of using the paste).

Amine Fluoride or Stannous Fluoride

The association of amine fluoride with stannous fluoride resulted in encouraging reductions of morning breath odor, even when oral hygiene was insufficient.[105] More recent evidence supporting the use of this rinse has become available. The formulation showed not only short-term but also long-term effects on malodor indicators in patients with obvious malodor.[22]

Stannous fluoride has also been shown to be effective in the management of oral malodor as a component of a dentifrice, reducing both organoleptic scores and VSC levels.[39] A superior short-term and overnight benefit of a stannous-containing dentifrice versus a control dentifrice on morning bad breath was

demonstrated in a meta-analysis.[33]

Hydrogen Peroxide

Suarez and colleagues[143] reported that rinsing with 3% hydrogen peroxide (H_2O_2) produced impressive reductions (±90%) in sulfur gases that persisted for 8 hours.

Oxidizing Lozenges

Greenstein and associates[46] reported that sucking a lozenge with oxidizing properties reduced tongue dorsum malodor for 3 hours. This antimalodor effect may be caused by the activity of dehydroascorbic acid, which is generated by peroxide-mediated oxidation of ascorbate in the lozenges.

Baking Soda

Baking soda dentifrices have been shown to confer a significant odor-reducing benefit for up to 3 hours.[11,88] The mechanism by which baking soda produces its inhibition of oral malodor is related to its bactericidal effects.[103]

Conversion of Volatile Sulfur Compounds

Metal Salt Solutions

Metal ions with an affinity for sulfur are efficient in capturing the sulfur-containing gases. Zinc is an ion with two positive charges (Zn^{++}), which will bind to the twice-negatively loaded sulfur radicals and thus reduce the expression of VSCs. The same applies for other metal ions such as stannous, mercury, and copper. Clinically, the VSC inhibitory effect was copper chloride > stannous fluoride > zinc chloride ($CuCl_2 > SnF_2 > ZnCl_2$). In vitro, the inhibitory effect was mercury chloride = copper chloride = cadmium chloride > zinc chloride > stannous fluoride > tin chloride > lead chloride ($HgCl_2 = CuCl_2 = CdCl_2 > ZnCl_2 > SnF_2 > SnCl_2 > PbCl_2$).[172]

Compared with other metal ions, Zn^{++} is relatively nontoxic and noncumulative and gives no visible discoloration. Thus, Zn^{++} has

been one of the most-studied ingredients for the control of oral malodor.[161,172] Schmidt and Tarbet[127] reported that a rinse containing zinc chloride was remarkably more effective than a saline rinse (or no treatment) in reducing the levels of both VSCs (±80% reduction) and organoleptic scores (±40% reduction) for 3 hours.

As mentioned, Halita, a rinse containing 0.05% chlorhexidine, 0.05% CPC, and 0.14% zinc lactate, has been even more efficient than a 0.2% chlorhexidine formulation in reducing VSC levels and organoleptic ratings.[110,153] The special effect of Halita may result from the VSC conversion ability of Zn^{++}, besides its antimicrobial action. The combination of Zn^{++} and chlorhexidine seems to act synergistically.[171]

Similar observations have been reported for a chlorhexidine-free mouthrinse. The addition of zinc ions to a basic formulation containing amino fluoride and stannous fluoride caused short- and long-term reduction of oral malodor indicators in volunteers with morning bad breath[163,164] as well as in volunteers with obvious halitosis.[22]

In a study by Hoshi and van Steenberghe,[52] a zinc citrate/triclosan toothpaste applied to the tongue dorsum appeared to control morning breath malodor for 4 hours. If the flavor oil was removed, however, the antimalodor efficacy of the active ingredients decreased. Another clinical study reported up to a 41% reduction in VSC levels after 7 days' use of a dentifrice containing triclosan and a copolymer, but the benefit compared with a placebo was relatively small (17% reduction).[90] Similar reductions were also found in two other more recent studies.[53,89]

Chewing gum can be formulated with antibacterial agents, such as fluoride or chlorhexidine, helping to reduce oral malodor through both mechanical and chemical approaches. Tsunoda and associates[151] investigated the beneficial effect of chewing gum containing tea extracts for its deodorizing mechanism. *Epigallocatechin* is the main deodorizing agent among the tea catechins. The chemical reaction between epigallocatechin and methylmercaptan results in a nonvolatile product. Waler[161] compared different concentrations of Zn^{++} in a chewing gum and found that a 2-mg Zn^{++} acetate–containing chewing gum that remained in the mouth for 5 minutes resulted in an immediate

reduction in VSC levels of up to 45%, but the long-term effect was not mentioned.

Masking the Malodor

Treatment with rinses, mouth sprays, or lozenges containing volatiles with a pleasant odor has only a short-term effect.[114,115] Typical examples are mint-containing lozenges and the aroma of rinses without antibacterial components.[22]

Another pathway is to increase the solubility of malodorous compounds in the saliva by increasing the secretion of saliva; a larger volume allows the retention of larger volumes of soluble VSCs.[62] The latter can also be achieved by ensuring proper liquid intake or using chewing gum; chewing triggers the periodontal-parotid reflex, at least when the lower (pre)molars are still present.

Conclusion

Breath malodor has important socioeconomic consequences and can reveal important diseases. A proper diagnosis and determination of the etiology allow initiation of the proper etiologic treatment. Although tongue coating and (less frequently) periodontitis and gingivitis are by far the most common causes of malodor, a clinician cannot take the risk of overlooking other, more challenging diseases. This can be done with a multidisciplinary consultation or, if this is not feasible, a trial therapy to deal quickly with intraoral causes (e.g., full-mouth one-stage disinfection, including the use of proper mouthrinses, tongue scrapers, and toothpastes). For more detailed information, the reader is encouraged to consult review articles.[45,69,131]

Case Scenario 49.1

Patient:
A 63-year-old female

Chief Complaint:

The patient complains of bleeding gums. Her husband complains about her foul mouth odor.

Background Information:

The patient is allergic to penicillin. Medications: Asaflow 80 mg/day and omeprazole 20 mg/day.

Current Findings:

Generalized bleeding on probing and pockets >5 mm. For organoleptic scoring, her nasal breath odor is scored 2, and the oral cavity odor and tongue coating are scored 5. The Halimeter gives a score of 250 ppb volatile sulfur compounds.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Which is the most plausible cause of her bad breath? A. Tongue coating B. Periodontitis C. Stomach problems D. Tongue coating and periodontitis E. Stomach problems and periodontitis	**Answer: D** Tongue coating and periodontal disease are the most common causes of bad breath. In this patient, both are clearly present. Stomach problems are rarely a cause of bad breath. Although this patient uses omeprazole, it is prescribed for protection against gastric ulcers because she uses Asaflow, an acetylsalicylic acid formulation.
2. What do you do? A. Explanation of halitosis B. Oral	**Answer: D** For every patient who complains about halitosis, it is important to explain the etiology and give oral hygiene instruction (because in most people, oral hygiene is suboptimal). Because the patient has tongue coating, this includes a tongue scraper. The patient has

hygiene instruction C. Periodontal treatment D. All of the above	periodontitis, so this should also be treated.

Case Scenario 49.2

Patient:
A 25-year-old female

Chief Complaint:
The patient complains of bad breath.

Background Information:
The patient is systemically healthy. Her last dental check-up was 3 months ago, and she brushes twice a day using an electric toothbrush and interdental brushes.

Current Findings:
The patient has good oral hygiene and healthy periodontium and teeth. When questioning the patient, it is clear that only she thinks she has bad breath. She mentions that her partner and her siblings have never smelled anything. For organoleptic scoring, her nasal breath odor is scored 0, and the oral cavity odor and tongue coating are scored 1. The Halimeter gives a score of 36 ppb volatile sulfur compounds.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Which is the most plausible cause of her bad breath? A. Tongue coating B. Periodontitis C. Stomach ulcer D. The patient does not have bad breath.	**Answer: D.** Because all halitosis measurements, both organoleptic and with the Halimeter, are under the threshold limit, the patient does not have halitosis.
2. What is the diagnosis? A. Intraoral halitosis B. Extraoral halitosis C. Pseudo-halitosis D. Halitophobia	**Answer: C** Because no obvious oral malodor could be perceived, pseudo-halitosis is diagnosed.
3. What is the treatment? A. Explanation and oral hygiene instruction B. Explanation and oral hygiene instruction, explanation of examined data, education, and reassurance C. Explanation and oral hygiene instruction and prophylaxis D. Explanation and oral hygiene instruction and referral to psychology specialist	**Answer: B** In patients who think they have halitosis, this condition can be improved by carefully explaining the etiology of halitosis and the nature and results of all examinations of the breath and oral cavity. However, if the patient persists in believing that he or she has halitosis when no evidence exists, we call this halitophobia, and referral to a psychology specialist is required.

Case Scenario 49.3

Patient:
A 30-year-old female

Chief Complaint:
The patient and people around her complain about intermittent halitosis. The patient says that the bad breath seems related to white stones that appear to come from her throat.

Background Information:
The patient is in good health. She brushes once or twice a day and uses interdental cleaning aids daily.

Current Findings:
The patient has good oral hygiene and healthy periodontium and teeth. Her tonsils seem inflamed, and tonsil stones can be seen. For organoleptic scoring, her nasal breath odor and tongue coating odor are scored 1, and the oral cavity odor is scored 3. The Halimeter gives a score of 133 ppb volatile sulfur compounds.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Which is the most plausible cause of her bad breath? A. Tongue coating	**Answer: C** Tonsil stones, or tonsilloliths, are formed when debris trapped in the crypts of the tonsils calcifies.

B. Periodontitis C. Tonsil stones D. Stomach problems	
2. What do you do? A. Explanation of halitosis B. Oral hygiene instruction C. Periodontal treatment D. Refer the patient to an ear, nose, and throat specialist	**Answer: D**

CHAPTER 50

Scaling and Root Planing*

Anna M. Pattison, Gordon L. Pattison

CHAPTER OUTLINE

Classification of Periodontal Instruments
General Principles of Instrumentation *(e-only)*
Principles of Scaling and Root Planing *(e-only)*
Instrument Sharpening *(e-only)*

Periodontal instruments are designed for specific purposes, such as calculus removal, biofilm removal, and root planing. On first investigation, the variety of instruments available for similar purposes appears confusing. With experience, however, clinicians select a relatively small set that fulfills all requirements.

Classification of Periodontal Instruments

Periodontal instruments are classified according to the purposes they serve, as follows:

1. *Periodontal probes* are used to locate, measure, and mark pockets, as well as determine their course on individual tooth surfaces.
2. *Explorers* are used to locate calculus deposits and caries.
3. *Scaling, root-planing, and curettage instruments* are used for removal of biofilm and calcified deposits from the crown and root of a tooth, removal of altered cementum from the subgingival root surface, and debridement of the soft tissue lining the pocket. Scaling and curettage instruments are classified as follows:
    - *Sickle scalers* are heavy instruments used to remove supragingival calculus.
    - *Curettes* are fine instruments used for subgingival scaling, root planing, and removal of the soft tissue lining the pocket.
    - *Hoe, chisel, and file scalers* are used to remove tenacious subgingival calculus and altered cementum. Their use is limited compared with that of curettes.
    - *Implant instruments* are plastic or titanium scalers and curettes designed for use on implants and implant restorations.
    - *Ultrasonic and sonic instruments* are used for scaling and cleansing tooth surfaces and curetting the soft tissue wall of the periodontal pocket.[42,43,66]
4. *Periodontal endoscopes* are used for deep visualization into subgingival pockets and furcations, thereby allowing the detection of deposits.
5. *Cleansing and polishing instruments*, such as rubber cups, brushes, and dental tape, are used to clean and polish tooth surfaces. Air-powder abrasive systems are also available for supragingival and subgingival cleaning and polishing of tooth, root, and implant surfaces.

The wearing and cutting qualities of some types of steel used in

periodontal instruments have been tested,[88,89,157] but specifications vary among manufacturers.[157] Stainless steel is used most often in instrument manufacture. High–carbon content steel instruments are available and are considered by some clinicians to be superior. Newer advanced proprietary manufacturing processes for heat treating and cryogenically tempering stainless steel are producing blades that are sharper and longer lasting than ever before. In addition, other processes produce stainless steel instruments with titanium nitride or other surface coatings that are not embedded or diffused into the base material. Their cutting edges are sharp when new, but these coatings wear down during normal use and cannot be resharpened. Each group of instruments has characteristic features; individual therapists often develop variations with which they operate most effectively. Small instruments are recommended to fit into periodontal pockets without injuring the soft tissues.[116,118,119,174]

The parts of each instrument are referred to as the working end, shank, and handle (Fig. 50.1).

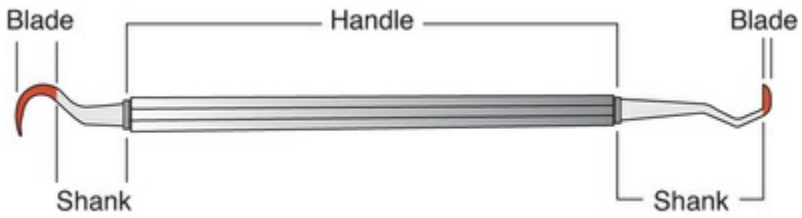

FIG. 50.1 **Parts of a typical periodontal instrument.**

Periodontal Probes

Periodontal probes are used to measure the depth of pockets and to determine their configuration. The typical probe is a tapered, rodlike instrument calibrated in millimeters, with a blunt, rounded tip (Fig. 50.2). Several other designs with various millimeter calibrations are available (Fig. 50.3). The World Health Organization probe has millimeter markings and a small, round ball at the tip (Fig. 50.3E). Ideally, these probes are thin, and the shank is angled to allow easy insertion into the pocket. Furcation areas can best be evaluated with the curved, blunt Nabers probe

(Fig. 50.4).

FIG. 50.2 Periodontal probe is composed of the handle, shank, and calibrated working end.

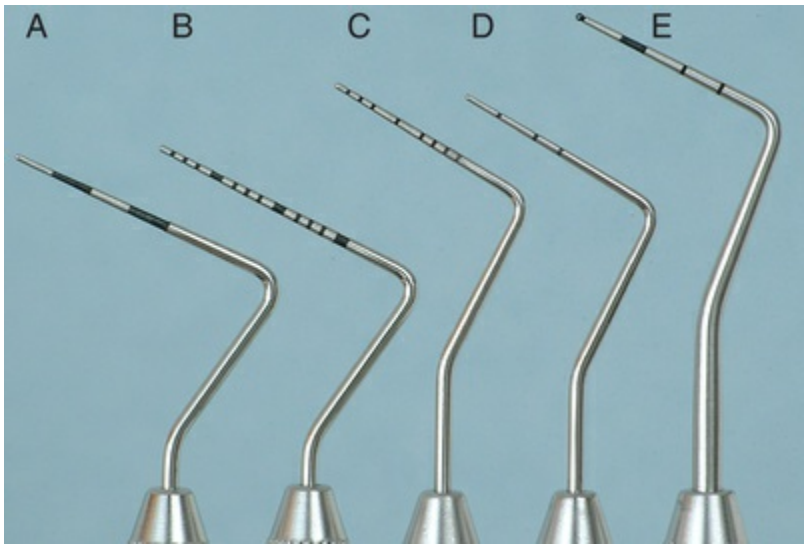

FIG. 50.3 **Types of periodontal probes. *A,* Marquis color-coded probe. Calibrations are in 3-mm sections. *B,* University of North Carolina 15 probe, a 15-mm long probe marked at each millimeter and color coded at the 5th, 10th, and 15th millimeters. *C,* University of Michigan "O" probe, with Williams markings (at 1, 2, 3, 5, 7, 8, 9, and 10 mm). *D,* Michigan "O" probe with markings at 3, 6, and 8 mm. *E,* World Health Organization probe, which has a 0.5-mm ball at the tip and markings at 3.5, 8.5, and 11.5 mm and color coding from 3.5 to 5.5 mm.**

FIG. 50.4 Curved #2 Nabers probe for detection of furcation areas, with color-coded markings at 3, 6, 9, and 12 mm.

Learning Box 50.1

Periodontal probes are used to measure the depth of pockets and to determine their configuration.

When measuring a pocket, the probe is inserted with firm, gentle pressure to the bottom of the pocket. The shank should be aligned with the long axis of the tooth surface to be probed. Several measurements are made to determine the level of attachment along the surface of the tooth.

Explorers

Explorers are used to locate subgingival deposits and carious areas and to check the smoothness of the root surfaces after root planing. Explorers are designed with different shapes and angles, with various uses (Fig. 50.5), as well as limitations (Fig. 50.6). The periodontal probe can also be useful in the detection of subgingival deposits (Fig. 50.6D).

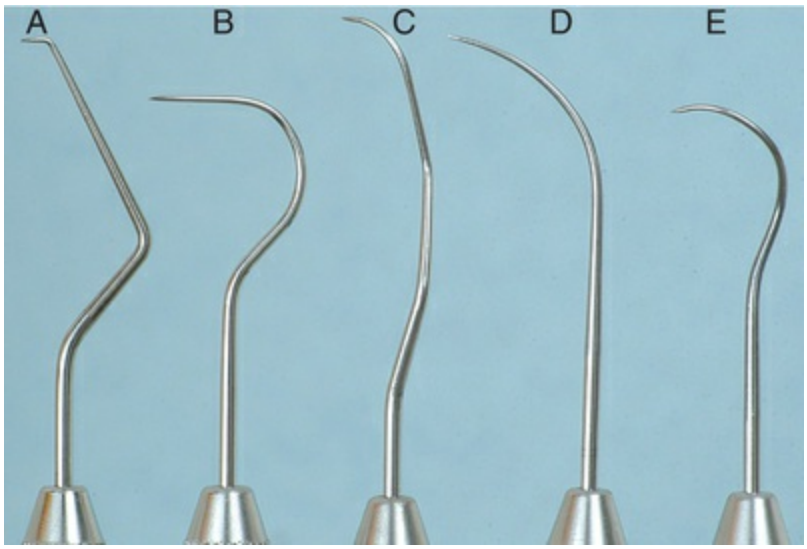

FIG. 50.5 **Five typical explorers. *A,* #17; *B,* #23; *C,* EXD 11-12; *D,* #3; *E,* #3CH pigtail.**

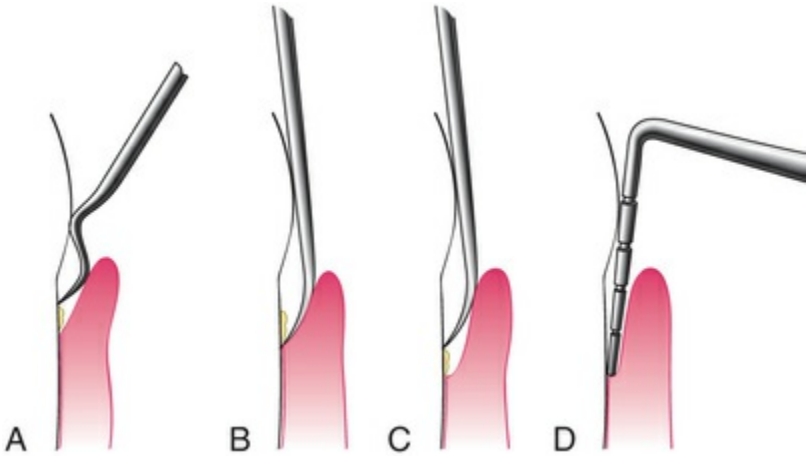

FIG. 50.6 **Insertion of two types of explorers and a periodontal probe in a pocket for calculus detection. (A) The limitations of the pigtail explorer in a deep pocket. (B) Insertion of the #3 explorer. (C) Limitations of the #3 explorer. (D) Insertion of the periodontal probe.**

Learning Box 50.2

Explorers are used to locate subgingival deposits and carious areas and to check the smoothness of the root surfaces after root planing.

Scaling and Curettage Instruments

Scaling and curettage instruments are illustrated in Fig. 50.7.

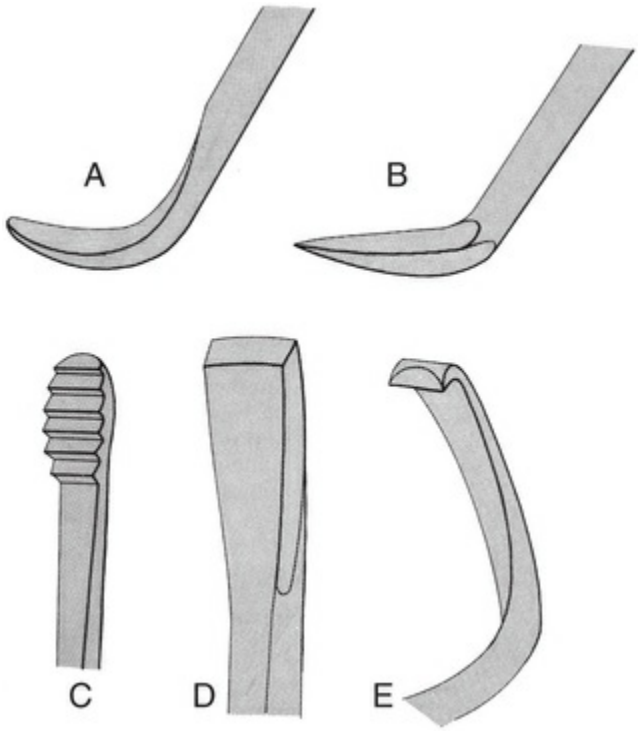

FIG. 50.7 **The five basic scaling instruments. (A) Curette; (B) sickle; (C) file; (D) chisel; (E) hoe.**

Sickle Scalers

Sickle scalers have a flat surface and two cutting edges that converge in a sharply pointed tip. The shape of the instrument makes the tip strong so that it will not break off during use (Fig. 50.8). The sickle scaler is used primarily to remove supragingival calculus (Fig. 50.9). Because of the design of this instrument, it is difficult to insert a large sickle blade under the gingiva without damaging the surrounding gingival tissues (Fig. 50.10). Small, curved sickle scaler blades such as the 204SD can be inserted under ledges of calculus several millimeters below the gingiva. Sickle scalers are used with a pull stroke.

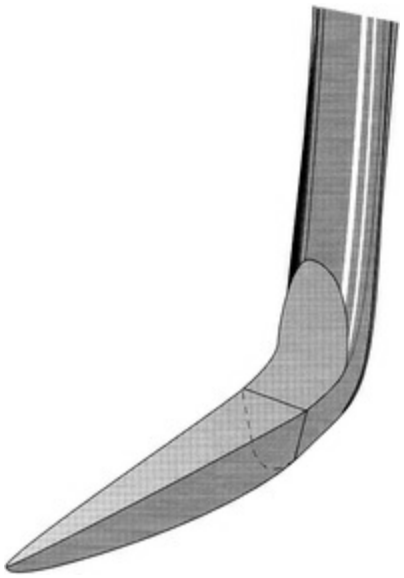

FIG. 50.8 Basic characteristics of a sickle scaler: triangular shape, double-cutting edge, and pointed tip.

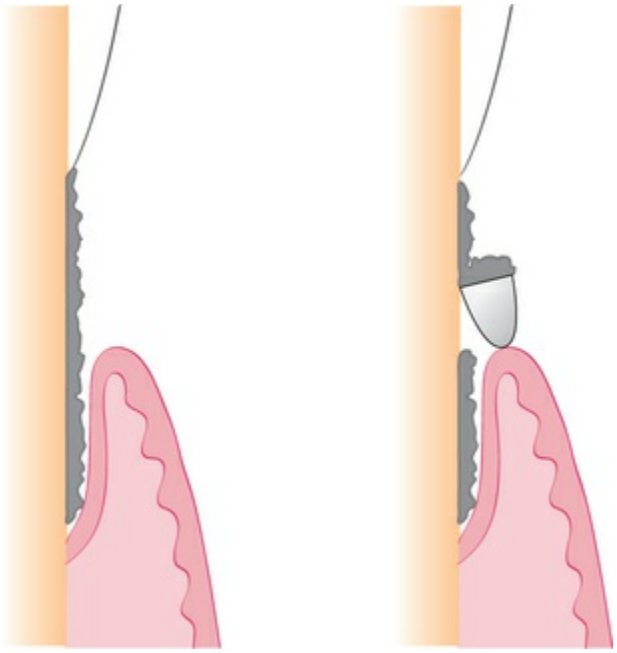

FIG. 50.9 **Use of a sickle scaler for removal of supragingival calculus.**

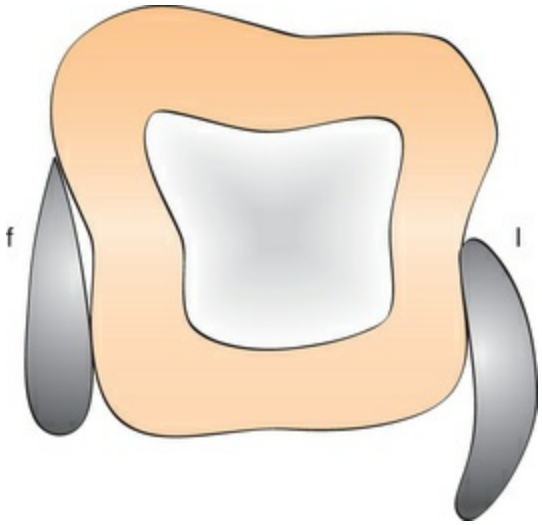

FIG. 50.10 Subgingival adaptation around the root is better with the curette than with the sickle. *f,* Facial; *l,* lingual.

Sickle scalers of the same basic design can be obtained with different blade sizes and shank types to adapt to specific uses. The U15/30 (Fig. 50.11), Ball, and Indiana University sickle scalers are large. Jaquette sickle scalers #1, #2, and #3 have medium-size blades. Curved 204 posterior sickle scalers are available with large, medium, or small blades (Fig. 50.12). The Montana Jack sickle scaler and the Nevi 2, Nevi 3, and Nevi 4 curved posterior sickle scalers are all thin enough to be inserted several millimeters subgingivally for removal of light to moderate ledges of calculus. The selection of these instruments should be based on the area to be scaled. Sickle scalers with straight shanks are designed for use on anterior teeth and premolars. Sickle scalers with contra-angled shanks adapt to posterior teeth.

FIG. 50.11 Both ends of a U15/30 scaler.

FIG. 50.12 Three different sizes of 204 sickle scalers.

Curettes

The curette is the instrument of choice for removing deep subgingival calculus, root planing altered cementum, and removing the soft tissue lining the periodontal pocket (Fig. 50.13). Each working end has a cutting edge on both sides of the blade and a rounded toe. Curettes are finer than sickle scalers and do not have any sharp points or corners other than the cutting edges of the blade (Fig. 50.14). Therefore curettes can be adapted for and provide good access to deep pockets, with minimal soft tissue trauma (see Fig. 50.10). In cross section, the blade appears semicircular with a convex base. The lateral border of the convex base forms a cutting edge with the face of the semicircular blade. Cutting edges are present on both sides of the blade. Both single- and double-end curettes may be obtained, depending on the preference of the operator.

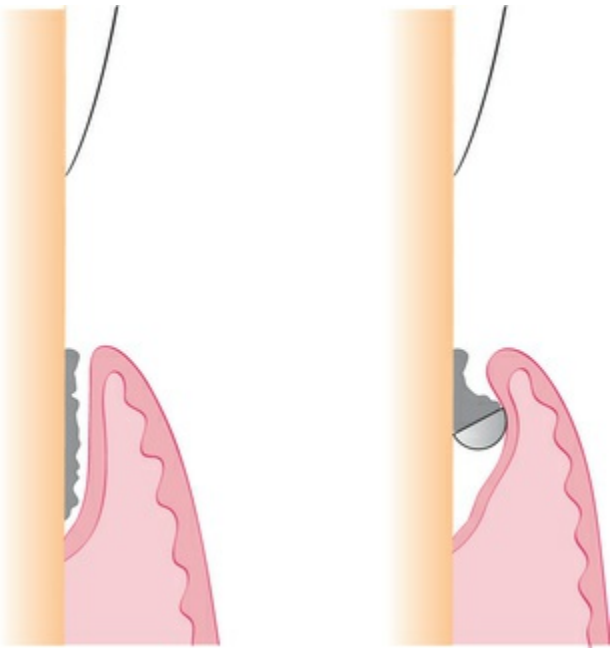

FIG. 50.13 The curette is the instrument of choice for subgingival scaling and root planing.

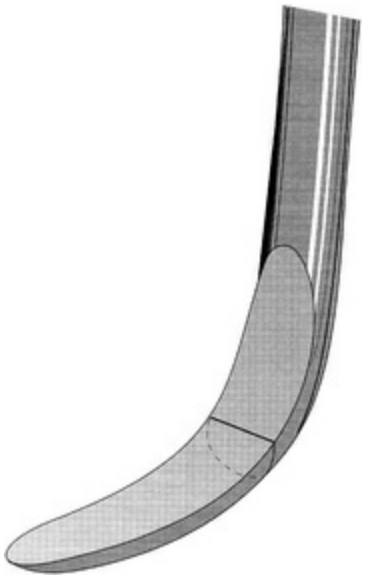

FIG. 50.14 **Basic characteristics of a curette: spoon-shaped blade and rounded tip.**

Learning Box 50.3

The curette is the instrument of choice for removing deep subgingival calculus, root planing altered cementum, and removing the soft tissue lining the periodontal pocket.

As shown in Fig. 50.10, the curved blade and rounded toe of the curette allow the blade to adapt better to the root surface, unlike the straight design and pointed end of a sickle scaler, which can cause tissue laceration and trauma. The two basic types of curettes are universal and area specific.

Universal Curettes

Universal curettes have cutting edges that may be inserted in most areas of the dentition by altering and adapting the finger rest, fulcrum, and hand position of the operator. The blade size and the angle and length of the shank may vary, but the face of the blade of every universal curette is at a 90-degree angle (perpendicular) to the lower shank when seen in cross section from the tip (Fig. 50.15A). The blade of the universal curette is curved in one direction from the head of the blade toward the toe. Barnhart curettes #1-2 and #5-6 and Columbia curettes #13-14, #2R-2L, and

#4R-4L (Figs. 50.16 and 50.17A) are examples of universal curettes. Other popular universal curettes are Younger-Good #7-8, McCall's #17-18, and Indiana University #17-18 (Fig. 50.17B).

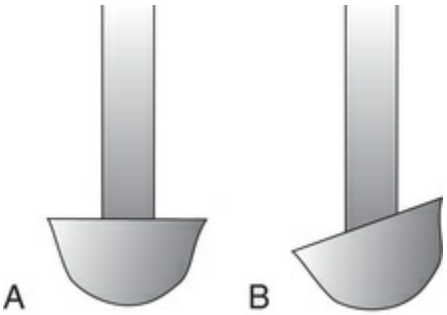

FIG. 50.15 **Principal types of curettes as seen from the toe of the instrument. (A) Universal curette. (B) Gracey curette. Note the offset blade angulation of the Gracey curette.**

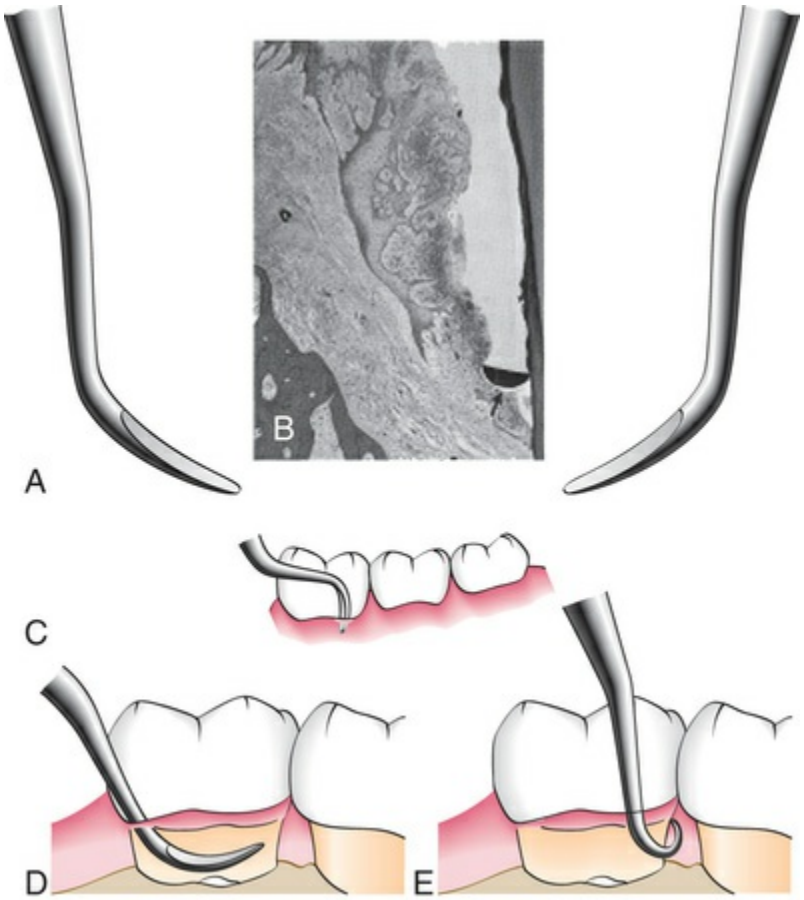

FIG. 50.16 (A) Double-ended curette for the removal of subgingival calculus. (B) Cross section of the curette blade *(arrow)* against the cemental wall of a deep

periodontal pocket. (C) Curette inserted in a pocket with the tip directed apically. (D) Curette in position at the base of a periodontal pocket on the facial surface of a mandibular molar. (E) Curette in position at the base of a pocket on the distal surface of the mandibular molar.

FIG. 50.17 (A) Columbia #4R-4L universal curette. (B) Younger-Good #7-8, McCall's #17-18, and Indiana University #17-18 universal curettes.

Learning Box 50.4

Universal curettes have cutting edges that may be inserted in most areas of the dentition by altering and adapting the finger rest, fulcrum, and hand position of the operator.

Area-Specific Curettes

Gracey Curettes.

Gracey curettes are representative of the area-specific curettes, a set of several instruments designed and angled to adapt to specific anatomic areas of the dentition (Fig. 50.18). These curettes and their modifications are probably the best instruments for subgingival scaling and root planing because they provide the best adaptation to complex root anatomy.

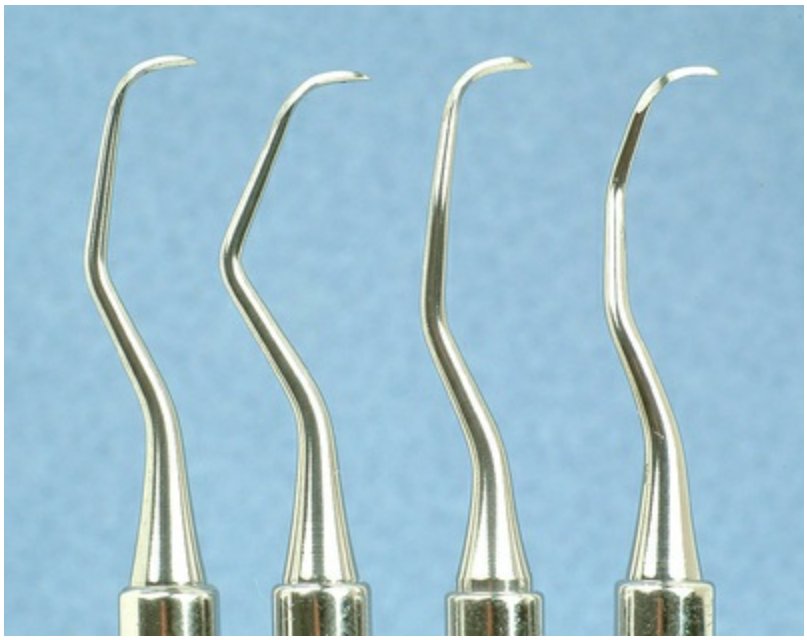

FIG. 50.18 **Reduced set of Gracey curettes. *Left to right,* #5-6, #7-8, #11-12, and #13-14.**

Learning Box 50.5

Gracey curettes are representative of the area-specific curettes, a set of several instruments designed and angled to adapt to specific anatomic areas of the dentition.

Double-ended Gracey curettes are paired in the following manner:

Gracey #1-2 and #3-4: Anterior teeth
Gracey #5-6: Anterior teeth and premolars
Gracey #7-8 and #9-10: Posterior teeth, facial and lingual

Gracey #11-12: Posterior teeth, mesial (Fig. 50.19)

FIG. 50.19 **Gracey #11-12 curette. For mesial surfaces.**

Gracey #13-14: Posterior teeth, distal (Fig. 50.20)

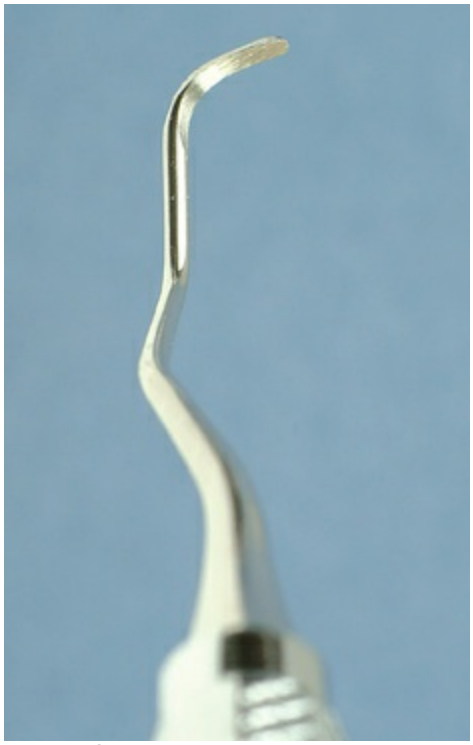

FIG. 50.20 **Gracey #13-14 curette. For distal surfaces.**

Single-ended Gracey curettes can also be obtained; a set comprises 14 instruments. Although these curettes are designed to be used in specific areas, an experienced operator can adapt each instrument for use in several different areas by altering the position of his or her hand and the position of the patient.

Gracey curettes also differ from universal curettes in that the blade is not at a 90-degree angle to the lower shank. The term *offset blade* is used to describe Gracey curettes because they are angled approximately 70 degrees from the lower shank (see Fig. 50.15B). This unique angulation allows the blade to be inserted in the precise position necessary for subgingival scaling and root planing, provided the lower shank is parallel to the long axis of the tooth surface being scaled.

Learning Box 50.6

Gracey curettes also differ from universal curettes in that the blade is not at a 90-degree angle to the lower shank.

Area-specific curettes also have curved blades. Whereas the blade of the universal curette is curved in one direction (Fig. 50.21A), the Gracey blade is curved from shank to toe and also appears to be curved along the side of the cutting edge (Fig. 50.21B). Table 50.1 lists some of the major differences between Gracey (area-specific) curettes and universal curettes.

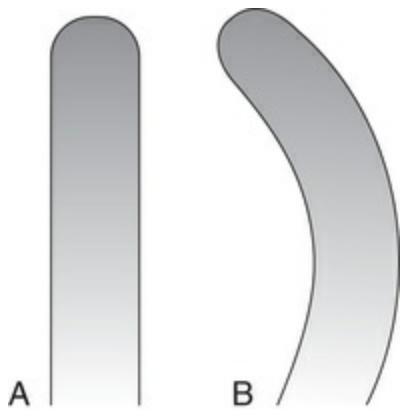

FIG. 50.21 (A) Universal curette as seen with the face of the blade parallel to the floor. Note that the blade is straight. (B) Gracey curette as seen with the face of the blade parallel to the floor. Only the outer convex cutting edge is used.

TABLE 50.1
Comparison of Area-Specific (Gracey) and Universal Curettes

	Gracey Curette	Universal Curette
Area of use	Set of many curettes designed for specific areas and surfaces	One curette designed for all areas and surfaces
Cutting Edge		
Use	One cutting edge used; work with outer edge only	Both cutting edges used; work with either outer or inner edge
Curvature	Blade curves from the shank toward the toe and also appears to curve to the side	Blade curves only from the shank toward the toe, not to the side
Blade angle	Offset blade; face of blade beveled at 60 degrees to shank	Blade not offset; face of blade beveled at 90 degrees to shank

Modified from Pattison G, Pattison A: *Periodontal instrumentation*, ed 2, Norwalk, CT, 1992, Appleton & Lange.

Gracey curettes are available with either a "rigid" or "finishing" type of shank. The rigid Gracey has a larger, stronger, and less flexible shank and blade than the standard finishing Gracey. The rigid shank allows the removal of moderate to heavy calculus without using a separate set of heavy scalers, such as sickles and hoes. Although some clinicians prefer the enhanced tactile sensitivity that the flexible shank of the finishing Gracey provides, both types of Gracey curettes are suitable for root planing.

More recent additions to the Gracey curette set have been #15-16 and #17-18. The Gracey #15-16 is a modification of the standard #11-12 and is designed for the mesial surfaces of posterior teeth (Fig. 50.22). It consists of a Gracey #11-12 blade combined with the more acutely angled #13-14 shank. When the clinician is using an intraoral finger rest, it is often difficult to position the lower shank of the Gracey #11-12 so that it is parallel to the mesial surfaces of the posterior teeth, especially on the mandibular molars. The newer shank angulation of the Gracey #15-16 allows better adaptation to posterior mesial surfaces from a front position with intraoral rests. If alternative fulcrums, such as extraoral or opposite-arch rests, are

used, the Gracey #11-12 works well and the #15-16 is not essential. The Gracey #17-18 is a modification of the #13-14. It has a terminal shank elongated by 3 mm and a more accentuated angulation of the shank to provide complete occlusal clearance and better access to all posterior distal surfaces. The horizontal handle position minimizes interference from opposing arches and allows a more relaxed hand position when scaling distal surfaces. In addition, the blade is 1 mm shorter to allow better adaptation of the blade to distal tooth surfaces.

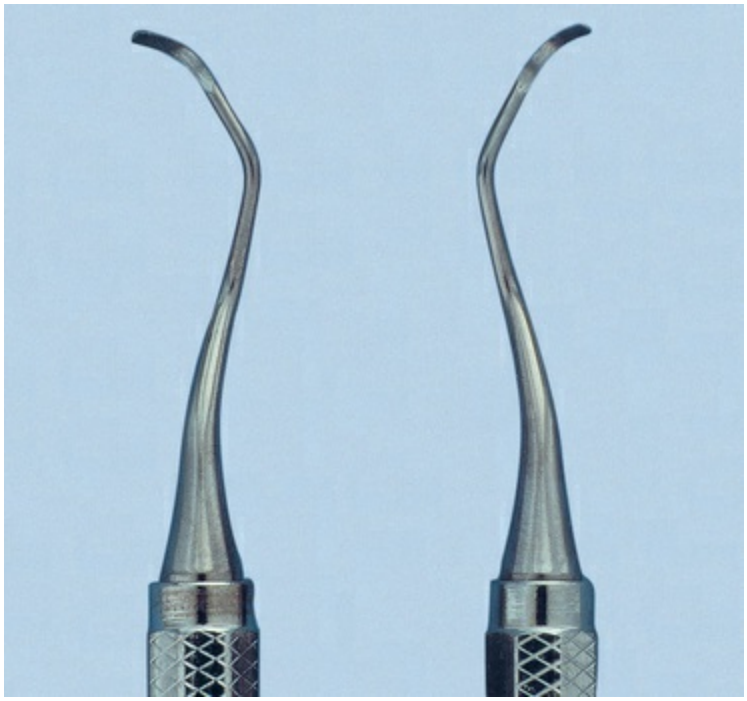

FIG. 50.22 Gracey #15-16. New Gracey curette, designed for mesioposterior surfaces, combines a Gracey #11-12 blade with a Gracey #13-14 shank. (Copyright A. Pattison.)

Extended-Shank Curettes.

Extended-shank curettes, such as *After Five* curettes (Hu-Friedy, Chicago, IL), are modifications of the standard Gracey curette design. The terminal shank is 3 mm longer, allowing extension into deeper periodontal pockets of 5 mm or more (Figs. 50.23 and 50.24). Other features of After Five curettes include a thinned blade for smoother subgingival insertion and reduced tissue distention and a large-diameter, tapered shank. All standard Gracey numbers except

for the #9-10 (i.e., #1-2, #3-4, #5-6, #7-8, #11-12, or #13-14) are available in the After Five series. After Five curettes are available in finishing or rigid designs. For heavy or tenacious calculus removal, rigid After Five curettes should be used. For light scaling or deplaquing in a periodontal maintenance patient, the thinner finishing After Five curettes will insert subgingivally more easily.

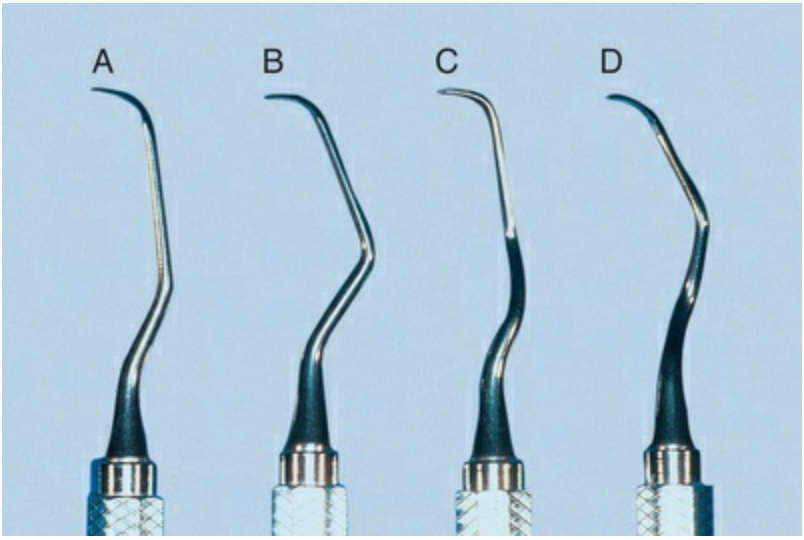

FIG. 50.23 **After Five curettes. Note the extra 3 mm in the terminal shank of After Five curettes compared with standard Gracey curettes. *A*, #5-6; *B*, #7-8; *C*, #11-12; *D*, #13-14. (Copyright A. Pattison.)**

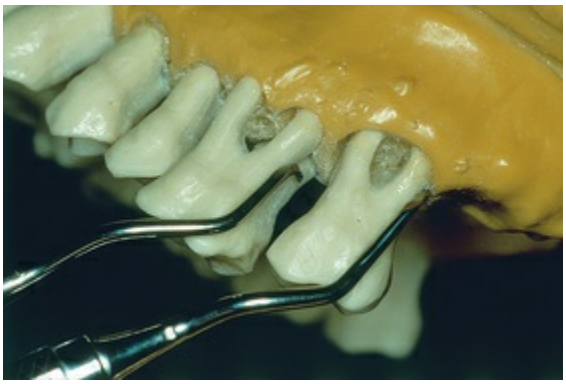

FIG. 50.24 **Comparison of After Five curette with standard Gracey curette. Rigid Gracey #13-14 adapted to the distal surface of the first molar and rigid After Five #13-14 adapted to the distal surface of the second molar. Notice the extralong shank of the After Five curette, which allows deeper insertion and better access. (Copyright A. Pattison.)**

Learning Box 50.7

Extended-shank curettes, such as After Five curettes (Hu-Friedy, Chicago, IL), are modifications of the standard Gracey curette design.

Mini-Bladed Curettes.

Mini-bladed curettes, such as Hu-Friedy *Mini Five* curettes, are modifications of the After Five curettes. Mini Five curettes feature blades that are half the length of After Five or standard Gracey curettes (Fig. 50.25). The shorter blade allows easier insertion and adaptation in deep, narrow pockets; furcations; developmental grooves; line angles; and deep, tight facial, lingual, or palatal pockets. In any area where root morphology or tight tissue prevents full insertion of the standard Gracey or After Five blade, Mini Five curettes can be used with vertical strokes, with reduced tissue distention and no tissue trauma (Fig. 50.26).

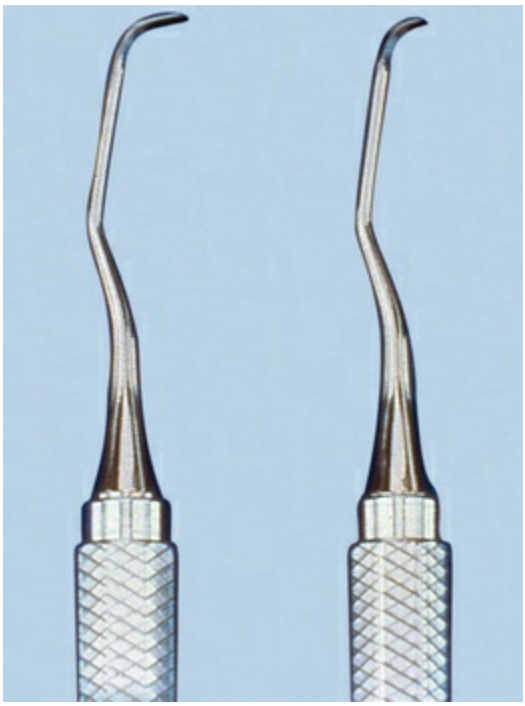

FIG. 50.25 Comparison of After Five curette and Mini Five curette. The shorter Mini Five blade (half the length) allows increased access and reduced tissue trauma.

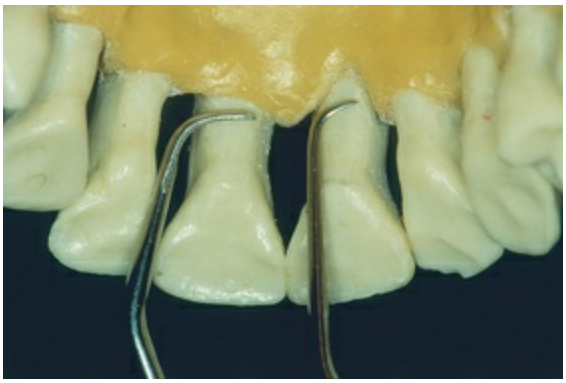

FIG. 50.26 **Comparison of standard rigid Gracey #5-6 with rigid Mini Five #5-6 on the palatal surfaces of the maxillary central incisors. Mini Five curette can be inserted to the base of these tight anterior pockets and used with a straight vertical stroke. The standard Gracey or After Five curette usually cannot be inserted vertically in this area because the blade is too long. (Copyright A. Pattison.)**

Learning Box 50.8

Mini Five curettes (Hu-Friedy, Chicago, IL) feature blades that are half the length of After Five or standard Gracey curettes. The shorter blade allows easier insertion and adaptation in deep, narrow pockets; furcations; developmental grooves; line angles; and deep, tight facial, lingual, or palatal pockets.

In the past the only solution in most of these areas of difficult access was to use Gracey curettes with a toe-down horizontal stroke. Mini Five curettes, along with other short-bladed instruments recently introduced, opened a new chapter in the history of root instrumentation by allowing access to areas that previously were extremely difficult or impossible to reach with standard instruments. Mini Five curettes are available in both finishing and rigid designs. Rigid Mini Five curettes are recommended for calculus removal. The more flexible shanked finishing Mini Five curettes are appropriate for light scaling and deplaquing in periodontal maintenance patients with tight pockets. As with the After Five series, Mini Five curettes are available in all standard Gracey numbers, except the #9-10.

The recently introduced *Micro Mini Five* Gracey curettes (Hu-Friedy) have blades that are 20% thinner and smaller than the Mini Five curettes (Figs. 50.27 and 50.28). These are the smallest of all

curettes, and they provide exceptional access and adaptation to tight, deep, or narrow pockets; narrow furcations; developmental depressions; line angles; and deep pockets on facial, lingual, or palatal surfaces. In areas where root morphology or tight, thin tissue prevents easy insertion of other mini-bladed curettes, Micro Mini Five curettes can be used with vertical strokes without causing tissue distention or tissue trauma.

FIG. 50.27 **Micro Mini Five Gracey curettes. *Left to right,* #1-2, #7-8, #11-12, #13-14. (Copyright A. Pattison.)**

FIG. 50.28 **Comparison of Gracey curette designs. *Left to right,* Standard #1-2, After Five #1-2, Mini Five #1-2, Micro Mini Five #1-2. (Courtesy Hu-Friedy, Chicago, IL.)**

Learning Box 50.9

Micro Mini Five Gracey curettes (Hu-Friedy, Chicago, IL) have blades that are 20% thinner and smaller than the Mini Five curettes These are the smallest of all curettes, and they provide exceptional access and adaptation to tight, deep, or narrow pockets; narrow furcations; developmental depressions; line angles; and deep pockets on facial, lingual, or palatal surfaces.

Gracey Curvettes comprise another set of four mini-bladed curettes; the Sub-0 and #1-2 are used for anterior teeth and premolars, the #11-12 is used for posterior mesial surfaces, and the #13-14 is used for posterior distal surfaces. The blade length of these instruments is 50% shorter than that of the conventional Gracey curette, and the blade is curved slightly upward (Fig. 50.29). This curvature allows Gracey Curvettes to adapt more closely to the tooth surface than any other curettes, especially on the anterior teeth and on line angles (Fig. 50.30). However, this curvature also carries the risk of gouging or "grooving" into the root surfaces on the proximal surfaces of the posterior teeth when #11-12 or #13-14 is used. Additional features that represent improvements on the standard Gracey curettes are a precision-balanced blade tip in direct alignment with the handle, a blade tip perpendicular to the handle, and a shank closer to parallel with the handle.

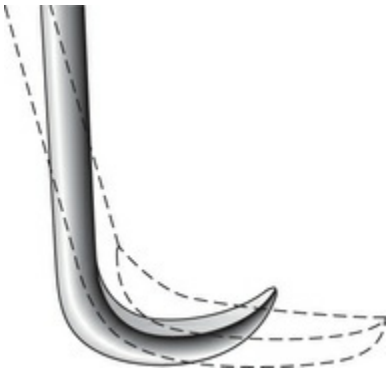

FIG. 50.29 Gracey Curvette blade. This diagram shows the 50% shorter blade of the Gracey Curvette superimposed on the standard Gracey curette blade *(dotted lines).* Notice the upward curvature of the Curvette blade and blade tip. (Redrawn from Pattison G, Pattison A: *Periodontal instrumentation,* ed 2, Norwalk, CT, 1992, Appleton & Lange.)

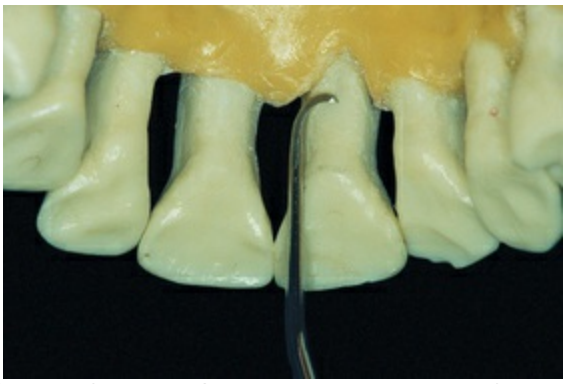

FIG. 50.30 **Gracey Curvette Sub-0 on the palatal surface of a maxillary central incisor. The long shank and short, curved, blunted tip make this a superior instrument for deep anterior pockets. This curette provides excellent blade adaptation to the narrow root curvatures of the maxillary and mandibular anterior teeth.** (Copyright A. Pattison.)

For many years, the *Morse scaler,* a miniature sickle, was the only mini-bladed instrument available. However, mini-bladed curettes have largely replaced this instrument (Fig. 50.31).

FIG. 50.31 **Comparison of three different mini-bladed instruments designed for use on the maxillary and mandibular anterior teeth. *A,* Hu-Friedy Mini Five #5-6; *B,* Hu-Friedy Curvette Sub-0; *C,* Hartzell Sub-0. (Copyright A. Pattison.)**

Periodontal Maintenance Curettes.

The most recent Gracey curette innovation is a category called periodontal maintenance Gracey curettes, introduced in November 2015. These instruments are specifically designed for patients with tight tissue, recession, and residual pocket depth following initial periodontal therapy or periodontal surgery. They can also be used on maintenance patients with healthier tight tissue without attachment loss or recession. In both cases, patients require a small, thin blade to allow subgingival insertion with ease (Fig. 50.32).

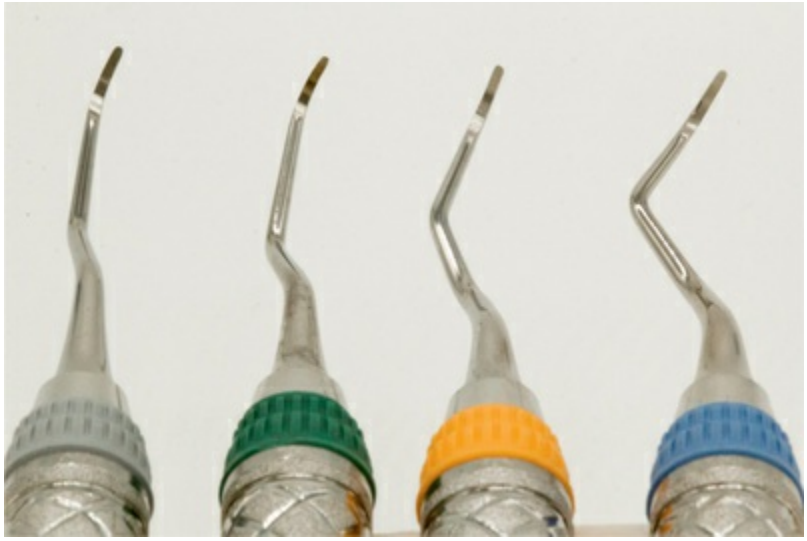

FIG. 50.32 Periodontal maintenance Gracey curettes (Hu-Friedy) Shorter, thinner three-quarter–sized Gracey curettes with modified rigid shanks. *Left to right,* Pattison Gracey Lite #1-2, Pattison Gracey Lite #7-8, Pattison Gracey Lite #11-12, Pattison Gracey Lite #13-14. (Copyright A. Pattison.)

Learning Box 50.10

The most recent Gracey curette innovation is a category called periodontal maintenance Gracey curettes, introduced in November 2015. These instruments are specifically designed for patients with tight tissue, recession, and residual pocket depth following initial periodontal therapy or periodontal surgery.

This newer blade is 1 mm shorter and 20% thinner, and the face of the blade is offset from the terminal shank at 60 degrees as

opposed to all other Gracey designs, which are offset at 70 degrees. This slight modification to the blade-to-shank angle and the thinner, narrow blade allow easier insertion and better access to root surfaces with tight tissue and loss of attachment. Working angulation can be achieved without as much tissue distention, thus increasing patient comfort. The three-quarter blade length of this new type of Gracey curette is between the blade lengths of the standard and mini-bladed Gracey curettes. The shorter blade adapts more easily to root anatomy and furcation areas and helps to prevent spanning across root depressions.

The shank length is 2 mm longer than that of the standard Gracey curette, but 1 mm shorter than that of the extended shank Gracey curette. This length enables better access to molar areas with attachment loss but still allows ease of use in the anterior areas where a very long shank is not necessary. The shank angle of the new Gracey #11-12 is between the regular Gracey #11-12 and the Gracey #15-16, and the shank angle of the new Gracey #13-14 is between the regular Gracey #13-14 and the Gracey #17-18. These shank angle modifications were developed to enhance access to the mesial and distal surfaces of the posterior teeth.

The shanks of these newer instruments are rigid so they can withstand firm pressure when removal of residual burnished calculus is necessary. However, they are not designed for moderate or heavy calculus removal. The clinician must be mindful that the instrument blade is at a slightly more closed angle than the traditional Gracey curette, so if more substantial or tenacious calculus is encountered, the clinician must slightly open the blade angulation, or switch to a rigid standard Gracey curette, or use a different manual or ultrasonic instrument.

Langer and Mini-Langer Curettes.

Langer and Mini Langer curettes comprise a set of three curettes combining the shank design of standard Gracey #5-6, #11-12, and #13-14 curettes with a universal blade honed at 90 degrees rather than the offset blade of the Gracey curette. This marriage of the Gracey and universal curette designs allows the advantages of the area-specific shank to be combined with the versatility of the universal curette blade. The Langer #5-6 curette adapts to the

mesial and distal surfaces of anterior teeth; the Langer #1-2 curette (Gracey #11-12 shank) adapts to the mesial and distal surfaces of mandibular posterior teeth; and the Langer #3-4 curette (Gracey #13-14 shank) adapts to the mesial and distal surfaces of maxillary posterior teeth (Fig. 50.33). These instruments can be adapted to both mesial and distal tooth surfaces without changing instruments. The standard Langer curette shanks are heavier than a finishing Gracey but less rigid than the rigid Gracey. Langer curettes are also available with either rigid or finishing shanks and can be obtained in extended-shank (After Five) and mini-bladed (Mini Five) versions.

FIG. 50.33 Langer curettes combine Gracey-type shanks with universal curette blades. *Left to right,* #5-6, #1-2, and #3-4. (Copyright A. Pattison.)

Schwartz Periotrievers

Schwartz Periotrievers comprise a set of two double-ended, highly magnetized instruments designed for retrieval of a broken instrument tip from the periodontal pocket (Fig. 50.34). They are indispensable when the clinician has broken a curette tip in a furcation or deep pocket.[148]

FIG. 50.34 **Broken instrument tip attached to the magnetic tip of a Schwartz Periotriever (Daness Dental Distributors, Nyack, N.Y.).** (From Pattison G, Pattison A: *Periodontal instrumentation,* ed 2, Norwalk, CT, 1992, Appleton & Lange.)

Plastic and Titanium Instruments for Implants

Several companies are manufacturing plastic and titanium instruments for use on titanium and other implant abutment materials. It is important that plastic or titanium instruments be used to avoid scarring and permanent damage to implants[a] (Figs. 50.35 through 50.37).

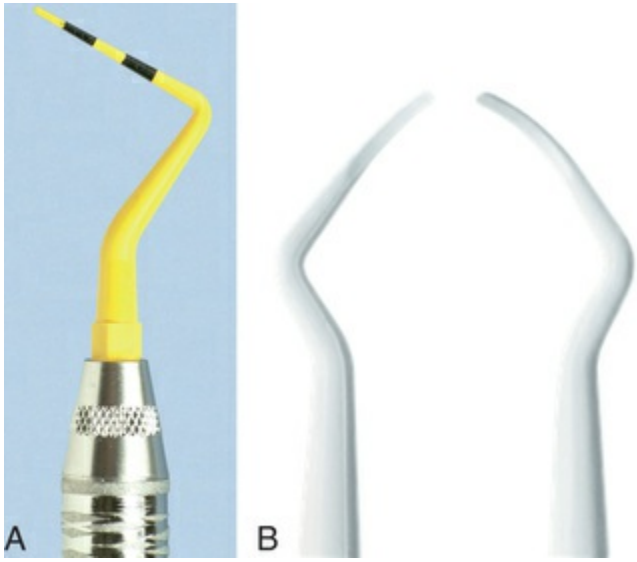

FIG. 50.35 **(A) Plastic probe: Colorvue. (B) New Implacare II Barnhart #5-6 cone socket plastic curette tips that screw into an autoclavable stainless steel handle.** (Courtesy Hu-Friedy, Chicago, IL.)

FIG. 50.36 **New Mini titanium implant scalers (Hu-Friedy, Chicago). *Left to right*, Mini Five Gracey #1-2, Mini Five Gracey #11-12, Langer #1-2, Mini Five Gracey #13-14, 204SD Sickle Scaler.**

FIG. 50.37 (A) Micro Mini titanium implant curettes (Paradise Dental Technologies, Missoula, MT). *Left to right,* Gracey #1-2 Micro Mini, Gracey #11-12 Micro Mini, Gracey #13-14 Micro Mini. (B) Mini-bladed titanium implant curettes (LM Instruments, Parainen, Finland) : Mini universal curette, Mini Gracey #1-2, Mini Gracey #13-14, Mini Gracey #11-12.

Mini-bladed titanium implant instruments are now available in both universal and Gracey curette designs (Fig. 50.37B). Although

most standard titanium implant instrument blades are large, the newer mini-bladed titanium curettes insert more easily under tight tissue and adapt more easily around implants and implant restorations. They may be used for implant maintenance with careful, light-pressured strokes for biofilm and light calculus removal. Moderate- or heavy-pressured strokes should be avoided to prevent scratching or roughening of implant surfaces. These instruments are not intended for removal of heavy calculus or cement. Such deposits are often found in cases of peri-implantitis with moderate to advanced bone loss and exposure of implant threads. Removal of tenacious deposits requires other forms of instrumentation and surgical treatment of the implant. (See Chapter 85 for information on treatment of peri-implantitis.)

Learning Box 50.11

Several companies are manufacturing plastic and titanium instruments for use on titanium and other implant abutment materials. It is important that plastic or titanium instruments be used to avoid scarring and permanent damage to implants

Hoe Scalers

Hoe scalers are used for scaling of ledges or rings of calculus (Fig. 50.38). The blade is bent at a 99-degree angle, and the cutting edge is formed by the junction of the flattened terminal surface with the inner aspect of the blade. The cutting edge is beveled at 45 degrees. The blade is slightly bowed so that it can maintain contact at two points on a convex surface. The back of the blade is rounded, and the blade has been reduced to minimal thickness to permit access to the roots without interference from the adjacent tissues.

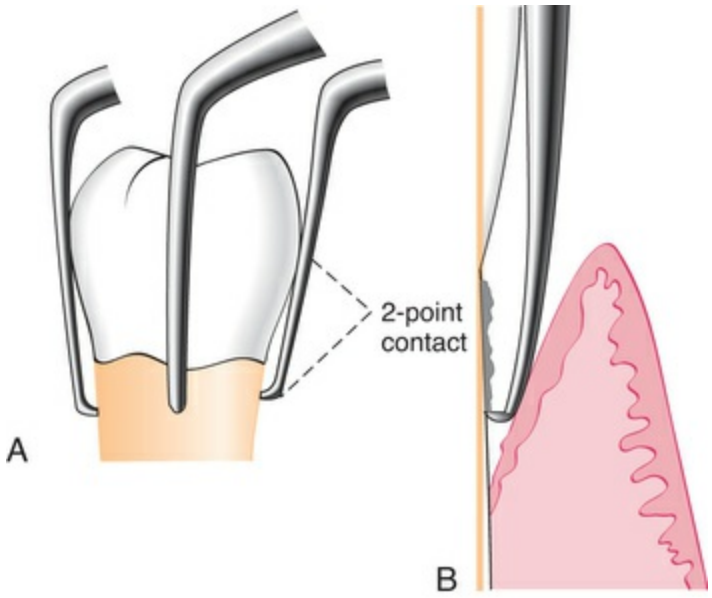

FIG. 50.38 (A) Hoe scalers designed for different tooth surfaces, showing "two-point" contact. (B) Hoe scaler in a periodontal pocket. The back of the blade is rounded for easier access. The instrument contacts the tooth at two points for stability.

Hoe scalers are used in the following manner:

1. The blade is inserted into the base of the periodontal pocket so that it makes two-point contact with the tooth (see Fig. 50.38). This stabilizes the instrument and prevents nicking of the root.
2. The instrument is activated with a firm pull stroke toward the crown, with every effort made to preserve the two-point contact with the tooth.

McCall's #3, #4, #5, #6, #7, and #8 comprise a set of six hoe scalers designed to provide access to all tooth surfaces. Each instrument has a different angle between the shank and the handle.

Files

Files have a series of blades on a base (Fig. 50.39). Their primary function is to fracture or crush large deposits of tenacious calculus or burnished sheets of calculus. Files can easily gouge and roughen root surfaces when they are used improperly. Therefore they are not suitable for fine scaling and root planing. Mini-bladed curettes

are currently preferred for fine scaling in areas where files were once used. Files are sometimes used for removing overhanging margins of dental restorations.

FIG. 50.39 (A) Chisel scaler and (B) file scaler.

Learning Box 50.12

Files have a series of blades on a base. Their primary function is to fracture or crush large deposits of tenacious calculus or burnished sheets of calculus.

Chisel Scalers

The chisel scaler, designed for the proximal surfaces of teeth too closely spaced to permit the use of other scalers, is usually used in the anterior part of the mouth. It is a double-ended instrument with a curved shank at one end and a straight shank at the other (see Fig. 50.39); the blades are slightly curved and have a straight cutting edge beveled at 45 degrees.

The chisel is inserted from the facial surface. The slight curve of the blade makes it possible to stabilize it against the proximal

surface, while the cutting edge engages the calculus without nicking the tooth. The instrument is activated with a push motion while the side of the blade is held firmly against the root.

Quétin Furcation Curettes

Quétin furcation curettes are actually hoes with a shallow, half-moon radius that fits into the roof or floor of the furcation. The curvature of the tip also fits into developmental depressions on the inner aspect of the roots. The shanks are slightly curved for better access, and the tips are available in two widths (Fig. 50.40). The BL1 *(buccal-lingual)* and MD1 *(mesial-distal)* instruments are small and fine, with a 0.9-mm blade width. The BL2 and MD2 instruments are larger and wider, with a 1.3-mm blade width.

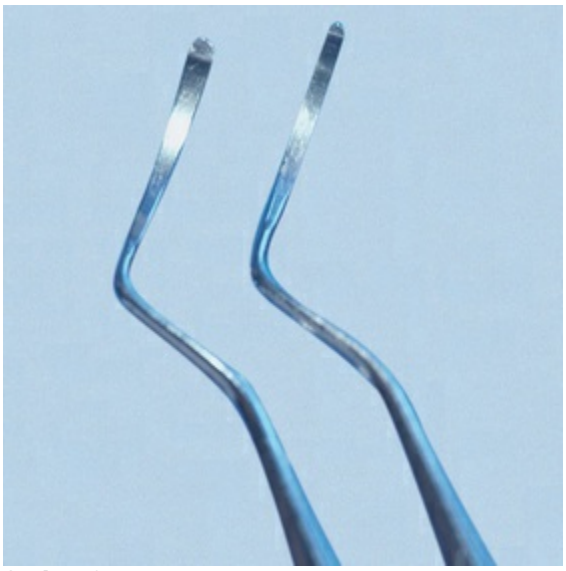

FIG. 50.40 **Quétin furcation curettes: BL2 (larger) and BL1 (smaller).**
(Copyright A. Pattison.)

These instruments remove burnished calculus from recessed areas of the furcation where curettes, even mini-bladed curettes, are often too large to gain access. Using mini-bladed Gracey curettes and Gracey Curvettes on the ceiling or floor of the furcation may unintentionally create gouges and grooves. The Quétin instruments, however, are well suited for this area and lessen the likelihood of root damage.

Diamond-Coated Files

Diamond-coated files are unique instruments used for final finishing of root surfaces. These files do not have cutting edges; instead, they are coated with very fine-grit diamond (Fig. 50.41). The most useful diamond files are the buccal-lingual instruments, which are used in furcations and also adapt well to many other root surfaces.

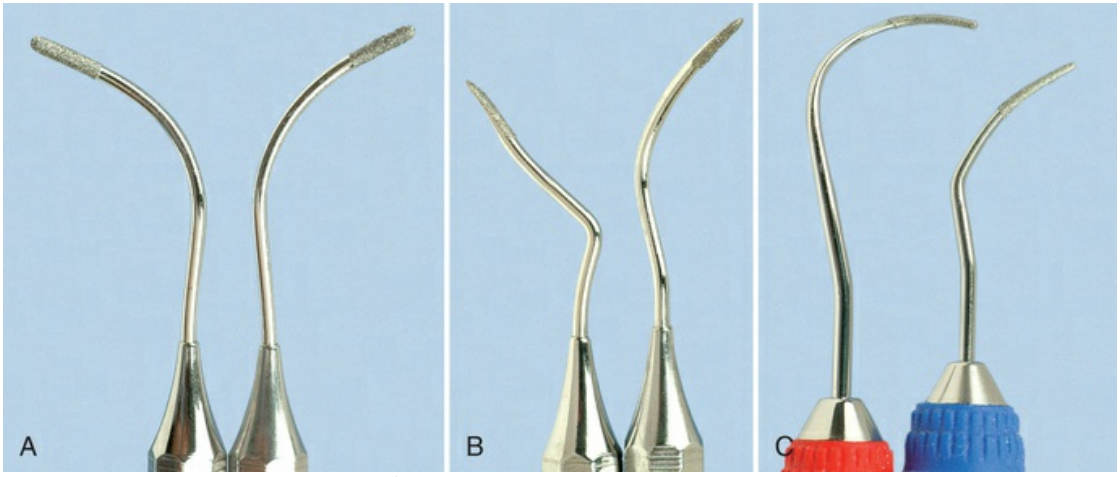

FIG. 50.41 **Diamond files. (A) #1, #2 and (B) #3, #4. (Brasseler, Savannah, GA.) (C) SDCN 7, SDCM/D 7. (Hu-Friedy, Chicago.) (Copyright A. Pattison.)**

New diamond files are sharply abrasive and should be used with light, even pressure against the root surface to avoid gouging or grooving. When viewing the root surface with the dental endoscope after all tactilely detectable deposits are gone, one can observe small embedded remnants of calculus in the root surface. Diamond files are used similar to an emery board to remove these minute remnants of calculus from the root, to create a surface that is free of all visible accretions. Diamond files can produce a smooth, even, clean, and highly polished root surface.

Diamond files must be used carefully because they can cause overinstrumentation of the root surface. They will remove too much root structure if they are used with excessive force, are poorly adapted to root morphology, or are used too long in one place.

Diamond files are particularly effective when used with the dental endoscope, which reveals residual deposits and directs the clinician to the exact area for instrumentation.

Ultrasonic and Sonic Instruments

Ultrasonic instruments may be used for removing biofilm, scaling, curetting, and removing stain (see Chapter 51).

Dental Endoscope

A dental endoscope has been introduced for use subgingivally in the diagnosis and treatment of periodontal disease (Fig. 50.42). The *Perioscopy* system (Perioscopy, Inc., Oakland, CA) consists of a 0.99-mm-diameter reusable fiberoptic endoscope over which is fitted a disposable sterile sheath. The fiberoptic endoscope fits onto periodontal probes and ultrasonic instruments that have been designed to accept it (Fig. 50.43). The sheath delivers water irrigation that flushes the pocket while the endoscope is being used, thereby keeping the field clear. The fiberoptic endoscope attaches to a medical-grade charge-coupled device (CCD) video camera and light source that produces an image on a flat-panel monitor for viewing during subgingival exploration and instrumentation. This device allows clear visualization deep into subgingival pockets and furcations (Fig. 50.44). It permits operators to detect the presence and location of subgingival deposits and guides them in the thorough removal of these deposits. Magnification ranges from 24 to 48 times, enabling visualization of even minute deposits of plaque and calculus. Using this device, operators can achieve levels of root debridement and cleanliness that are much more difficult or impossible to produce without it.[160,161,179,180] The Perioscopy system can also be used to evaluate subgingival areas for caries, defective restorations, root fractures, and resorption.

FIG. 50.42 **Perioscopy system, dental endoscope.** (Courtesy Perioscopy, Inc., Oakland, CA.)

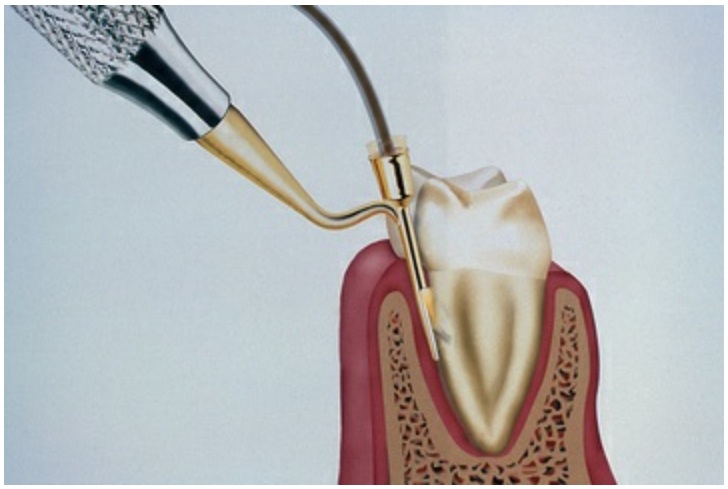

FIG. 50.44 Perioscopic instrumentation permits deep subgingival visualization in pockets and furcations. (Courtesy Perioscopy, Inc., Oakland, CA.)

Learning Box 50.13

Using this device, operators can achieve levels of root debridement and cleanliness that are much more difficult or impossible to produce without it. The Perioscopy system (Perioscopy, Inc., Oakland, CA) can also be used to evaluate subgingival areas for caries, defective restorations, root fractures, and resorption.

Cleansing and Polishing Instruments

Rubber Cups

Rubber cups consist of a rubber shell with or without webbed configurations in the hollow interior (Fig. 50.45). They are used in the handpiece with a special prophylaxis angle. The handpiece, prophylaxis angle, and rubber cup must be sterilized after each patient use, or a disposable plastic prophylaxis angle and rubber cup may be used and then discarded (Fig. 50.46). A good cleansing and polishing paste that contains fluoride should be used and kept moist to minimize frictional heat as the cup revolves. Polishing pastes are available in fine, medium, or coarse grit and are packaged in small, convenient, single-use containers. Aggressive use of the rubber cup with any abrasive may remove the layer of cementum, which is thin in the cervical area.

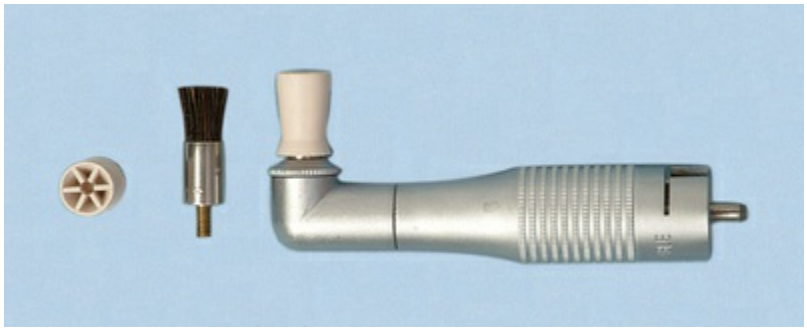

FIG. 50.45 Metal prophylaxis angle with rubber cup and brush.

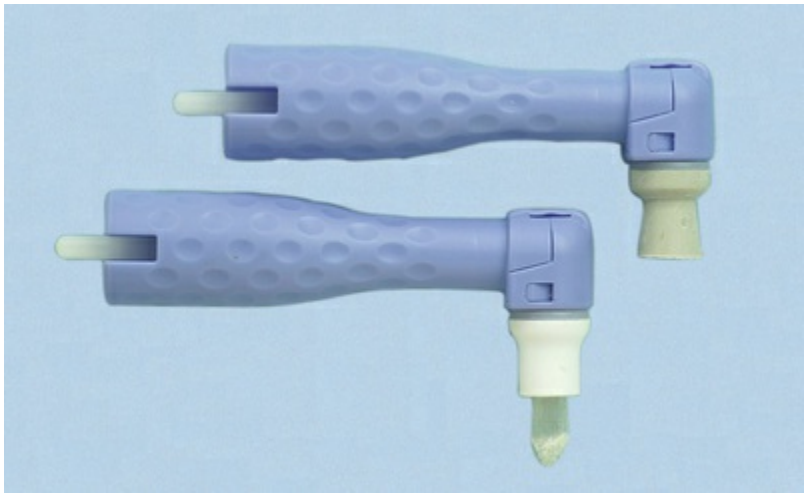

FIG. 50.46 Disposable plastic prophylaxis angle with rubber cup and with brush.

Bristle Brushes

Bristle brushes are available in wheel and cup shapes (see Fig. 50.45). The brush is used in the prophylaxis angle with a polishing paste. Because the bristles are stiff, use of the brush should be confined to the crown to avoid injuring the cementum and the gingiva.

Dental Tape

Dental tape with polishing paste is used for polishing proximal surfaces that are inaccessible to other polishing instruments. The tape is passed interproximally while being kept at a right angle to the long axis of the tooth and is activated with a firm labiolingual motion. Particular care is taken to avoid injury to the gingiva. The

area should be cleansed with warm water to remove all remnants of paste.

Air-Powder Polishing

The first specially designed handpiece to deliver an air-powered slurry of warm water and sodium bicarbonate for polishing was introduced in the early 1980s. This device, called the *Prophy-Jet* (Dentsply International, York, PA), is very effective for removing extrinsic stains and soft deposits (Fig. 50.47). The slurry removes stains rapidly and efficiently by mechanical abrasion and provides warm water for rinsing and lavage. The flow rate of the abrasive cleansing power can be adjusted to increase the amount of powder for heavier stain removal. Currently, many manufacturers produce air-powder polishing systems that use various powder formulas (Fig. 50.48).

FIG. 50.47 Cavitron ProphyJet air-powder polishing device. (Courtesy Dentsply International, York, PA.)

FIG. 50.48 Hu-Friedy EMS Air Flow Master air polishing device with perio and standard handpieces and tips for both supragingival and subgingival air polishing. Courtesy Hu-Friedy, Chicago, IL.)

The results of studies on the abrasive effect of the air-powder polishing devices using sodium bicarbonate and aluminum trihydroxide on cementum and dentin show that significant tooth substance can be lost.[2,20,117,125] Damage to gingival tissue is transient and insignificant clinically, but amalgam restorations, composite resins, cements, and other nonmetallic materials can be roughened.[13,44,72,94,172] Polishing powders containing glycine or erythritol rather than sodium bicarbonate are commonly used in Europe for subgingival biofilm removal from root surfaces.[103,124]

Both supragingival and subgingival air polishing with glycine or erythritol powder are safe and very effective for removal of biofilm from titanium implant surfaces and restorative materials[79,96,136] (Fig. 50.49).

FIG. 50.49 Hu-Friedy EMS Air Flow Perio Handy smaller air polishing device with subgingival air polishing tip for glycine or erythritol powder polishing.
(Courtesy Hu-Friedy, Chicago, IL.)

Learning Box 50.14

Both supragingival and subgingival air polishing with glycine or erythritol powder are safe and very effective for removal of biofilm from titanium implant surfaces and restorative materials.

No soft tissue abrasion occurs, and at probing depths of 1 mm to greater than 5 mm, the use of glycine or erythritol powder in an air-polishing device with a subgingival nozzle (Fig. 50.50) is more effective for subgingival biofilm removal than the use of either manual or ultrasonic instruments.[b]

FIG. 50.50 Hu-Friedy EMS Perio Flow Tip disposable plastic tip with millimeter markings for subgingival air polishing of implants or deep pockets with glycine or erythritol powder. (Courtesy Hu-Friedy, Chicago IL.)

Learning Box 50.15

The use of glycine or erythritol powder in an air-polishing device with a subgingival nozzle is more effective for subgingival biofilm removal than the use of either manual or ultrasonic instruments.

Patients with a medical history of respiratory illness or hemodialysis are not candidates for the use of the air-powder polishing device.[156,177] Powder containing sodium bicarbonate should not be used on patients with a history of hypertension, sodium-restricted diet, or medication use affecting electrolyte balance.[135] Patients with infectious diseases should not be treated with this device because of the large quantity of aerosol created. A preprocedural rinse with 0.12% chlorhexidine gluconate should be used to minimize the microbial content of the aerosol.[18] High-speed evacuation should also be performed to eliminate as much of the aerosol as possible.[61]

Summary

Various periodontal instruments and devices are specifically

designed for examination of the periodontium, removal of calculus and biofilm from tooth and implant surfaces, and root planing.

General Principles of Instrumentation

Effective instrumentation is governed by a number of general principles that are common to all periodontal instruments. Proper positioning of the patient and the operator, illumination and retraction for optimal visibility, and sharp instruments are fundamental prerequisites. A constant awareness of tooth and root morphologic features and of the condition of the periodontal tissues is also essential. Knowledge of instrument design enables the clinician to select the proper instrument for the procedure and the correct area in which it will be performed. In addition to these principles, the basic concepts of grasp, finger rest, adaptation, angulation, and stroke must be understood before clinical instrument-handling skills can be mastered.

Learning Box e50.1

Proper positioning of the patient and the operator, illumination and retraction for optimal visibility, and sharp instruments are fundamental prerequisites for effective instrumentation.

Accessibility: Positioning of Patient and Operator

Accessibility facilitates thoroughness of instrumentation. The position of the patient and the operator should provide maximal accessibility to the area of operation. Inadequate accessibility impedes thorough instrumentation, prematurely tires the operator, and diminishes his or her effectiveness.

The clinician should be seated on a comfortable operating stool that has been positioned so that his or her feet are flat on the floor, with the thighs parallel to the floor. The clinician should be able to observe the field of operation while keeping the back straight and the head erect.

The patient should be in a supine position and placed so that the mouth is close to the resting elbow of the clinician. For instrumentation of the maxillary arch, the patient should be asked to raise the chin slightly to provide optimal visibility and accessibility. For instrumentation on the mandibular arch, it may be necessary to raise the back of the chair slightly and request that the patient lower the chin until the mandible is parallel to the floor. This will especially facilitate work on the lingual surfaces of the mandibular anterior teeth.

Learning Box e50.2

The clinician should be seated on a comfortable operating stool that has been positioned so that his or her feet are flat on the floor, with the thighs parallel to the floor.

Visibility, Illumination, and Retraction

Whenever possible, *direct vision* with *direct illumination* from the dental light is most desirable (eFig. 50.1). If this is not possible, *indirect vision* may be obtained by using the mouth mirror (eFig. 50.2), and *indirect illumination* may be obtained by using the mirror to reflect light to where it is needed (eFig. 50.3). Indirect vision and indirect illumination are often used simultaneously (eFig. 50.4).

EFIG. 50.1 **Direct vision and direct illumination in the mandibular left premolar area.**

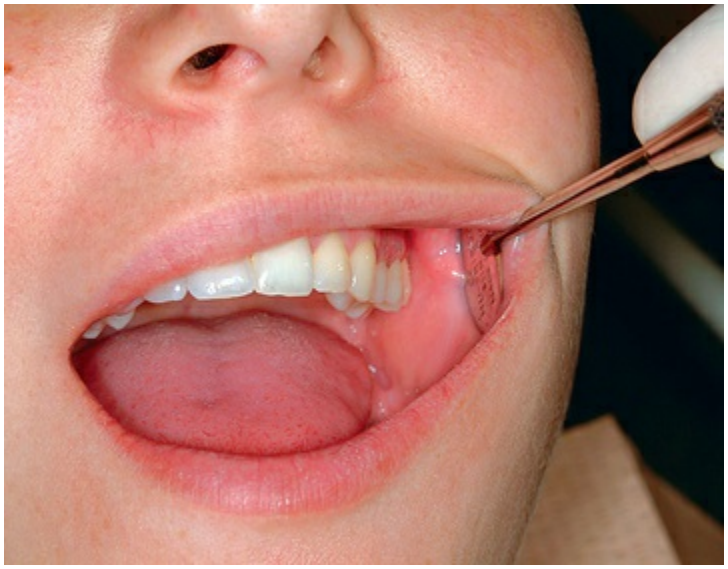
EFIG. 50.2 **Indirect vision using the mirror for the lingual surfaces of the mandibular posterior teeth.**

EFIG. 50.3 **Indirect illumination using the mirror to reflect light onto the maxillary left posterior lingual region.**

EFIG. 50.4 Combination of indirect illumination and indirect vision for the lingual surfaces of the maxillary anterior teeth.

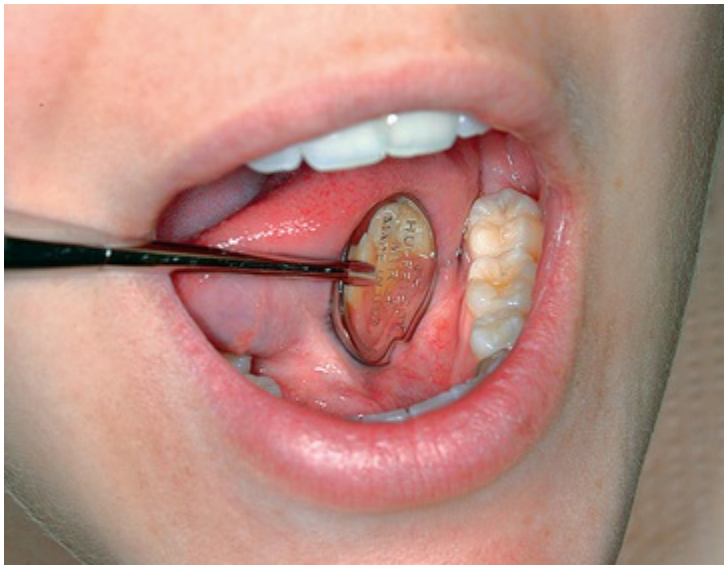
Retraction provides visibility, accessibility, and illumination. Depending on the location of the area of operation, the fingers or the mirror, or both, may be used for retraction. The *mirror* may be used for retraction of the cheeks or tongue; the *index finger* is used for retraction of the lips or cheeks. The following methods are effective for retraction:

1. Use of the mirror to deflect the cheek while the fingers of the nonoperating hand retract the lips and protect the angle of the mouth from irritation by the mirror handle.
2. Use of the mirror alone to retract the lips and cheek (eFig. 50.5).
3. Use of the fingers of the nonoperating hand to retract the lips (eFig. 50.6).
4. Use of the mirror to retract the tongue (eFig. 50.7).
5. Combinations of the preceding methods.



EFIG. 50.5 **Retracting the cheek with the mirror.**

EFIG. 50.6 **Retracting the lip with the index finger of the nonoperating hand.**



EFIG. 50.7 **Retracting the tongue with the mirror.**

When retracting, care should be taken to avoid irritating the angles of the mouth. If the lips and skin are dry, softening the lips with petroleum jelly before instrumentation is a helpful precaution against cracking and bleeding. Careful retraction is especially important for patients with a history of recurrent *herpes labialis* because these patients may easily develop herpetic lesions after instrumentation.

Learning Box e50.3

Whenever possible, *direct vision* with *direct illumination* from the dental light is most desirable.

Condition and Sharpness of Instruments

Before any instrumentation, all instruments should be inspected to make sure that they are clean, sterile, and in good condition. The working ends of pointed or bladed instruments must be sharp to be effective. Sharp instruments enhance tactile sensitivity and allow the clinician to work more precisely and efficiently (see later discussion). Dull instruments may lead to incomplete calculus removal and unnecessary trauma because of the excess force usually applied to compensate for their ineffectiveness.

Learning Box e50.4

Sharp instruments enhance tactile sensitivity and allow the clinician to work more precisely and efficiently. Dull instruments may lead to incomplete calculus removal and unnecessary trauma because of the excess force usually applied to compensate for their ineffectiveness.

Maintaining a Clean Field

Despite good visibility, illumination, and retraction, instrumentation can be hampered if the operative field is obscured by saliva, blood, or debris. The pooling of saliva interferes with visibility during instrumentation and impedes control because a firm finger rest cannot be established on wet, slippery tooth surfaces. Adequate suction is essential and can be achieved with a saliva ejector or, if working with an assistant, an aspirator.

Gingival bleeding is an unavoidable consequence of subgingival instrumentation. In areas of inflammation, bleeding is not necessarily an indication of trauma from incorrect technique but rather may indicate ulceration of the pocket epithelium. Blood and debris can be removed from the operative field with suction and by wiping or blotting with gauze squares. The operative field should also be flushed occasionally with water.

Compressed air and gauze squares can be used to facilitate visual inspection of tooth surfaces just below the gingival margin during instrumentation. A jet of air directed into the pocket deflects a retractable gingival margin. Retractable tissue can also be deflected away from the tooth by gently packing the edge of a gauze square into the pocket with the back of a curette. Immediately after the gauze is removed, the subgingival area should be clean, dry, and clearly visible for a brief interval.

Instrument Stabilization

Stability of the instrument and the hand is the primary requirement for controlled instrumentation. Stability and control are essential for effective instrumentation and avoidance of injury to the patient or

clinician. The two factors of major importance in providing stability are the instrument grasp and the finger rest.

Learning Box e50.5

Stability and control are essential for effective instrumentation and avoidance of injury to the patient or clinician.

Instrument Grasp

A proper grasp is essential for precise control of movements made during periodontal instrumentation. The most effective and stable grasp for all periodontal instruments is the *modified pen grasp* (eFig. 50.8). Although other grasps are possible, this modification of the *standard pen grasp* (eFig. 50.9) ensures the greatest control in performing intraoral procedures.

EFIG. 50.8 **Modified pen grasp. The pad of the middle finger rests on the shank.** (Copyright A. Pattison.)

EFIG. 50.9 Standard pen grasp. The side of the middle finger rests on the shank. (Copyright A. Pattison.)

Learning Box e50.6

The most effective and stable grasp for all periodontal instruments is the *modified pen grasp.*

The thumb, index finger, and middle finger are used to hold the instrument as a pen is held, but the middle finger is positioned so that the side of the pad next to the fingernail is resting on the instrument shank. The index finger is bent at the second joint from the fingertip and is positioned well above the middle finger on the same side of the handle.

The pad of the thumb is placed midway between the middle and index fingers on the opposite side of the handle. This creates a triangle of forces, or *tripod effect,* that enhances control because it counteracts the tendency of the instrument to turn uncontrollably between the fingers when scaling force is applied to the tooth. This stable modified pen grasp enhances control because it enables the clinician to roll the instrument in precise degrees with the thumb against the index and middle fingers to adapt the blade to the slightest changes in tooth contour. The modified pen grasp also enhances tactile sensitivity because slight irregularities on the tooth surface are best perceived when the tactile-sensitive pad of the

middle finger is placed on the shank of the instrument.

The *palm and thumb grasp* (eFig. 50.10) is useful for stabilizing instruments during sharpening and for manipulating air and water syringes, but it is not recommended for periodontal instrumentation. Maneuverability and tactile sensitivity are so inhibited by this grasp that it is unsuitable for the precise, controlled movements necessary for periodontal procedures.

EFIG. 50.10 Palm and thumb grasp, used for stabilizing instruments during sharpening. (Copyright A. Pattison.)

Finger Rest

The finger rest serves to stabilize the hand and the instrument by providing a firm fulcrum as movements are made to activate the instrument. A good finger rest prevents injury and laceration of the gingiva and surrounding tissues by poorly controlled instruments. The fourth (ring) finger is preferred by most clinicians for the finger rest. Although it is possible to use the third (middle) finger for the finger rest, this is not recommended because it restricts the arc of movement during the activation of strokes and severely curtails the use of the middle finger for both control and tactile sensitivity.

Maximal control is achieved when the middle finger is kept between the instrument shank and the fourth finger. This "built-up" fulcrum is an integral part of the wrist-forearm action that activates the powerful working stroke for calculus removal. Whenever possible, these two fingers should be kept together to work as a one-unit fulcrum during scaling and root planing. Separation of the middle and fourth fingers during scaling strokes results in a loss of power and control because it forces the clinician to rely solely on finger flexing for activation of the instrument.

Learning Box e50.7

The finger rest serves to stabilize the hand and the instrument by providing a firm fulcrum as movements are made to activate the instrument. A good finger rest prevents injury and laceration of the gingiva and surrounding tissues by poorly controlled instruments.

Finger rests may be generally classified as intraoral finger rests or extraoral fulcrums. Intraoral finger rests on tooth surfaces ideally are established close to the working area. Variations of intraoral finger rests and extraoral fulcrums are used whenever good angulation and a sufficient arc of movement cannot be achieved by a finger rest close to the working area. The following examples illustrate variations of the intraoral finger rest:

1. *Conventional:* The finger rest is established on tooth surfaces immediately adjacent to the working area (eFig. 50.11).
2. *Cross-arch:* The finger rest is established on tooth surfaces on the other side of the same arch (eFig. 50.12).
3. *Opposite arch:* The finger rest is established on tooth surfaces on the opposite arch (e.g., mandibular arch finger rest for instrumentation on the maxillary arch) (eFig. 50.13).
4. *Finger on finger:* The finger rest is established on the index finger or thumb of the nonoperating hand (eFig. 50.14).

EFIG. 50.11 **Intraoral conventional finger rest. The fourth finger rests on the occlusal surfaces of adjacent teeth.**

EFIG. 50.12 **Intraoral cross-arch finger rest. The fourth finger rests on the incisal surfaces of teeth on the opposite side of the same arch.**

EFIG. 50.13 **Intraoral opposite-arch finger rest. The fourth finger rests on the mandibular teeth while the maxillary posterior teeth are instrumented.**

EFIG. 50.14 **Intraoral finger-on-finger rest. The fourth finger rests on the index finger of the nonoperating hand.**

Extraoral fulcrums are essential for effective instrumentation of some aspects of the maxillary posterior teeth. When properly established, they allow optimal access and angulation while providing adequate stabilization. Extraoral fulcrums are not "finger rests" in the literal sense because the tips or pads of the fingers are not used for extraoral fulcrums as they are for intraoral finger rests. Instead, as much of the front or back surface of the fingers as

possible is placed on the patient's face to provide the greatest degree of stability. The two most common extraoral fulcrums are used as follows:

1. *Palm up:* The palm-up fulcrum is established by resting the backs of the middle and fourth fingers on the skin overlying the lateral aspect of the mandible on the right side of the face (eFig. 50.15).
2. *Palm down:* The palm-down fulcrum is established by resting the front surfaces of the middle and fourth fingers on the skin overlying the lateral aspect of the mandible on the left side of the face (eFig. 50.16).

EFIG. 50.15 **Extraoral palm-up fulcrum. The backs of the fingers rest on the right lateral aspect of the mandible while the maxillary right posterior teeth are instrumented.**

EFIG. 50.16 **Extraoral palm-down fulcrum. The front surfaces of the fingers rest on the left lateral aspect of the mandible while the maxillary left posterior teeth are instrumented.**

Both intraoral finger rests and extraoral fulcrums may be reinforced by applying the index finger or thumb of the nonoperating hand to the handle or shank of the instrument for added control and pressure against the tooth. The reinforcing finger is usually employed for an opposite-arch or extraoral fulcrum when precise control and pressure are compromised by the longer distance between the fulcrum and the working end of the instrument. eFig. 50.17 shows the index finger–reinforced rest, and eFig. 50.18 shows the thumb-reinforced rest.

EFIG. 50.17 **Index finger–reinforced rest. The index finger is placed on**

the shank for pressure and control in the maxillary left mesial and lingual region.

EFIG. 50.18 Thumb-reinforced rest. The thumb is placed on the handle for control in the maxillary right posterior lingual region.

Learning Box e50.8

Extraoral fulcrums are essential for effective instrumentation of some aspects of the maxillary posterior teeth.

Instrument Activation

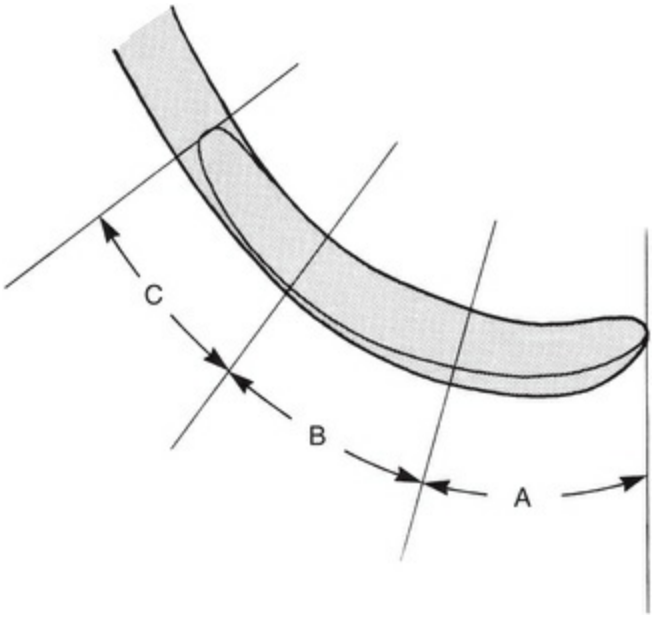
Adaptation

Adaptation refers to the manner in which the working end of a periodontal instrument is placed against the surface of a tooth. The objective of adaptation is to make the working end of the instrument conform to the contour of the tooth surface. Precise adaptation must be maintained with all instruments to avoid trauma to the soft tissues and root surfaces and to ensure maximum effectiveness of instrumentation.

Learning Box e50.9

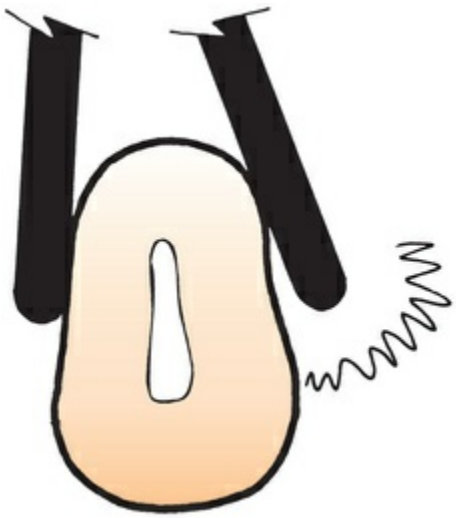
Precise adaptation must be maintained with all instruments to avoid trauma to the soft tissues and root surfaces and to ensure maximum effectiveness of instrumentation.

Correct adaptation of the probe is quite simple. The tip and side of the probe should be flush against the tooth surface as vertical strokes are activated within the crevice. Bladed instruments (e.g., curettes) and sharp-pointed instruments (e.g., explorers) are more difficult to adapt. The ends of these instruments are sharp and can lacerate tissue, so adaptation in subgingival areas becomes especially important. The lower third of the working end, which is the last few millimeters adjacent to the toe or tip, must be kept in constant contact with the tooth while it is moving over varying tooth contours (eFig. 50.19). Precise adaptation is maintained by carefully rolling the handle of the instrument against the index and middle fingers with the thumb. This rotates the instrument in slight degrees so that the toe or tip leads into concavities and around convexities. On convex surfaces such as line angles, it is not possible to adapt more than 1 or 2 mm of the working end against the tooth. Even on what appear to be broader, flatter surfaces, no more than 1 or 2 mm of the working end can be adapted because the tooth surface, although it may seem flat, is actually slightly curved.



EFIG. 50.19 **Gracey curette blade divided into three segments. *A,* The lower one-third of the blade, consisting of the terminal few millimeters adjacent to the toe; *B,* the middle one-third; and, *C,* the upper one-third, which is adjacent to the shank.**

If only the middle third of the working end is adapted on a convex surface so that the blade contacts the tooth at a tangent, the toe or sharp tip will jut out into soft tissue, thus causing trauma and discomfort (eFig. 50.20).



EFIG. 50.20 **Blade adaptation. The curette on the *left* is properly adapted to the root surface. The curette on the *right* is incorrectly adapted; the toe juts out, lacerating the soft tissues.**

If the instrument is adapted so that only the toe or tip is in contact, the soft tissue can be distended or compressed by the back

of the working end, also causing trauma and discomfort. A curette that is improperly adapted in this manner can be particularly damaging because the toe can gouge or groove the root surface.

Learning Box e50.10

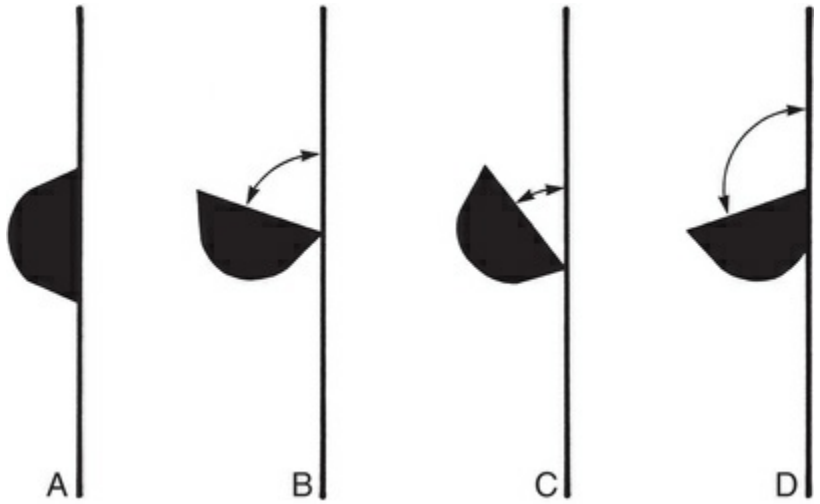
The lower third of the working end, which is the last few millimeters adjacent to the toe or tip, must be kept in constant contact with the tooth while the instrument is moving over varying tooth contours. Precise adaptation is maintained by carefully rolling the handle of the instrument against the index and middle fingers with the thumb.

Angulation

Angulation refers to the angle between the face of a bladed instrument and the tooth surface. It may also be called the *tooth-blade relationship.*

Correct angulation is essential for effective calculus removal. For subgingival insertion of a bladed instrument such as a curette, angulation should be as close to 0 degrees as possible (eFig. 50.21A). The end of the instrument can be inserted to the base of the pocket more easily with the face of the blade flush against the tooth. During scaling and root planing, optimal angulation is between 45 and 90 degrees (eFig. 50.21B). The exact blade angulation depends on the amount and nature of the calculus, the procedure being performed, and the condition of the tissue. Blade angulation is diminished or closed by tilting the lower shank of the instrument toward the tooth. It is increased or opened by tilting the lower shank away from the tooth. During scaling strokes on heavy, tenacious calculus, angulation should be just less than 90 degrees so that the cutting edge "bites" into the calculus. With angulation of less than 45 degrees, the cutting edge will not bite into or engage the calculus properly (eFig. 50.21C). Instead, it will slide over the calculus, smoothing or "burnishing" it. If angulation is more than 90 degrees, the lateral surface of the blade, rather than the cutting edge, will be against the tooth, and the calculus will not be removed and may become burnished (eFig. 50.21D). After the calculus has

been removed, angulation of just less than 90 degrees may be maintained, or the angle may be slightly closed as the root surface is smoothed with light root-planing strokes.



EFIG. 50.21 Blade angulation. (A) 0 degrees: correct angulation for blade insertion. (B) 45 to 90 degrees: correct angulation for scaling and root planing. (C) Less than 45 degrees: incorrect angulation for scaling and root planing. (D) More than 90 degrees: incorrect angulation for scaling and root planing, but correct angulation for gingival curettage.

Learning Box e50.11

Correct angulation is essential for effective calculus removal. During scaling and root planing, optimal angulation is between 45 and 90 degrees.

When gingival curettage is indicated, angulation greater than 90 degrees is deliberately established so that the cutting edge will engage and remove the pocket lining (see eFig. 50.21D).

Lateral Pressure

Lateral pressure refers to the pressure created when force is applied against the surface of a tooth with the cutting edge of a bladed instrument. The exact amount of pressure applied must be varied according to the nature of the calculus and whether the stroke is intended for initial scaling to remove calculus or for root planing to

smooth the root surface.

Learning Box e50.12

The exact amount of pressure applied must be varied according to the nature of the calculus and whether the stroke is intended for initial scaling to remove calculus or for root planing to smooth the root surface.

Lateral pressure may be firm, moderate, or light. When removing calculus, lateral pressure is initially applied firmly or moderately and is progressively diminished until light lateral pressure is applied for the final root-planing strokes. When insufficient lateral pressure is applied for the removal of heavy calculus, rough ledges or lumps may be shaved to thin, smooth sheets of burnished calculus that are difficult to detect and remove. This burnishing effect often occurs in areas of developmental depressions and along the cementoenamel junction.

Although firm lateral pressure is necessary for the thorough removal of calculus, indiscriminate, unwarranted, or uncontrolled application of heavy forces during instrumentation should be avoided. Repeated application of excessively heavy strokes often nicks or gouges the root surface.

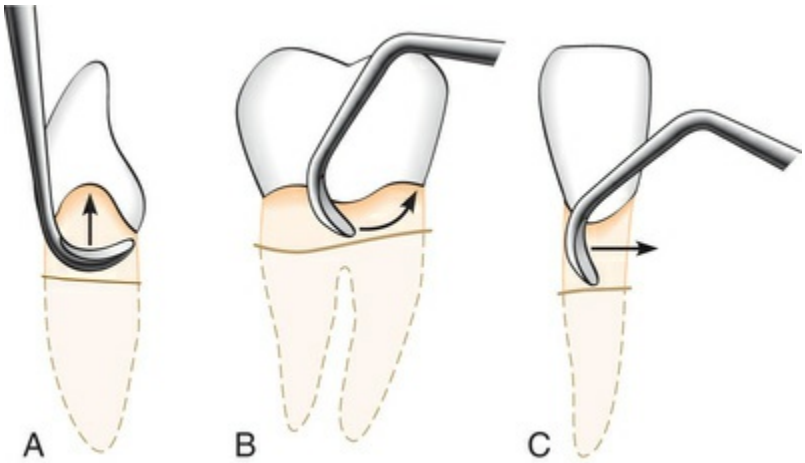
Careful application of varied and controlled amounts of lateral pressure during instrumentation is an integral part of effective scaling and root-planing techniques and is critical to the success of both of these procedures.

Learning Box e50.13

Careful application of varied and controlled amounts of lateral pressure during instrumentation is an integral part of effective scaling and root-planing techniques and is critical to the success of both of these procedures.

Strokes

Three basic types of strokes are used during instrumentation: the exploratory stroke, the scaling stroke, and the root-planing stroke. Any of these basic strokes may be activated by a pull or push motion in a vertical, oblique, or horizontal direction (eFig. 50.22). *Vertical* and *oblique* strokes are used most frequently. *Horizontal* strokes are used selectively on line angles or deep pockets that cannot be negotiated with vertical or oblique strokes. The direction, length, pressure, and number of strokes necessary for either scaling or root planing are determined by four major factors: (1) gingival position and tone, (2) pocket depth and shape, (3) tooth contour, and (4) the amount and nature of the calculus or roughness.



EFIG. 50.22 **Three basic stroke directions. (A) Vertical; (B) oblique; (C) horizontal.**

The **exploratory stroke** is a light "feeling" stroke that is used with probes and explorers to evaluate the dimensions of the pocket and to detect calculus and irregularities of the tooth surface. With bladed instruments such as the curette, the exploratory stroke is alternated with scaling and root-planing strokes for the same purposes of evaluation and detection. The instrument is grasped lightly and adapted with light pressure against the tooth to achieve maximal tactile sensitivity.

Learning Box e50.14

The **exploratory stroke** is a light "feeling" stroke that is used with

probes and explorers to evaluate the dimensions of the pocket and to detect calculus and irregularities of the tooth surface.

The **scaling stroke** is a short, powerful pull stroke that is used with bladed instruments for the removal of both supragingival and subgingival calculus. The muscles of the fingers and hands are tensed to establish a secure grasp, and lateral pressure is firmly applied against the tooth surface. The cutting edge engages the apical border of the calculus and dislodges it with a firm movement in a coronal direction. The scaling motion should be initiated in the forearm and transmitted from the wrist to the hand with a slight flexing of the fingers. Rotation of the wrist is synchronized with movement of the forearm. The scaling stroke is not initiated in the wrist or fingers, nor is it carried out independently without the use of the forearm.

Learning Box e50.15

The **scaling stroke** is a short, powerful pull stroke that is used with bladed instruments for the removal of both supragingival and subgingival calculus.

It is possible to initiate the scaling motion by rotating the wrist and forearm or flexing the fingers. The use of wrist and forearm action versus finger motion has long been debated among clinicians. Perhaps the strong opinions on both sides should be the most valid indication that each has a time and a place. Neither method can be advocated exclusively because a careful analysis of effective scaling and root-planing techniques reveals that both types of stroke activation are necessary for complete instrumentation. The wrist and forearm motion, pivoting in an arc on the finger rest, produces a more powerful stroke and is therefore preferred for scaling. *Finger flexing* is indicated for precise control over stroke length in areas such as line angles and when horizontal strokes are used on the lingual or facial aspect of narrow-rooted teeth.

The *push scaling* motion has been advocated by some clinicians. In the push stroke, the instrument engages the lateral or coronal

border of the calculus, and the fingers provide a thrust motion that dislodges the deposit. Because the push stroke may force calculus into the supporting tissues, its use, especially in an apical direction, is not recommended.

The **root-planing stroke** is a moderate to light pull stroke that is used for final smoothing and planing of the root surface. Although hoes, files, and ultrasonic instruments have been used for root planing, curettes are widely acknowledged to be the most effective and versatile instruments for this procedure.[c] The design of the curette, which allows it to be more easily adapted to subgingival tooth contours, makes it particularly suitable for root planing in periodontal patients. With a moderately firm grasp, the curette is kept adapted to the tooth with even, lateral pressure. A continuous series of long, overlapping shaving strokes is activated. As the surface becomes smoother and resistance diminishes, lateral pressure is progressively reduced.

Learning Box e50.16

The **root-planing stroke** is a moderate to light pull stroke that is used for final smoothing and planing of the root surface. Curettes are widely acknowledged to be the most effective and versatile instruments for this procedure.

Instruments for Scaling and Root Planing

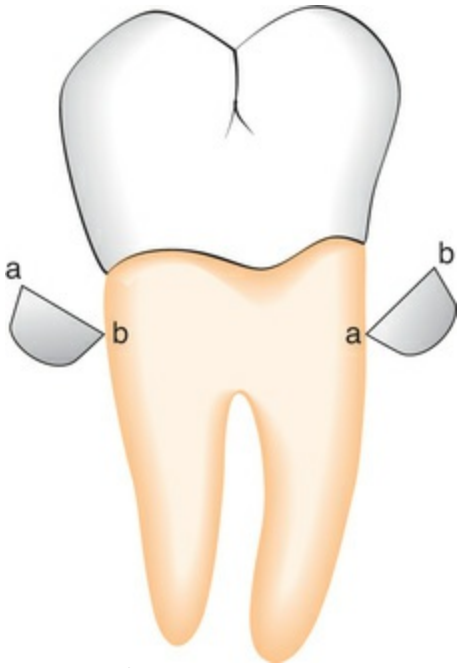
Universal Curettes

The working ends of the universal curette are designed in pairs so that all surfaces of the teeth can be treated with one double-ended instrument or a matched pair of single-ended instruments (see Fig. 50.16). Both cutting edges of the universal curette blade are used.

Learning Box e50.17

The working ends of the universal curette are designed in pairs so that all surfaces of the teeth can be treated with one double-ended instrument.

In any given quadrant, when approaching the tooth from the facial aspect, one end of the universal curette adapts to the mesial surfaces and the other end adapts to the distal surfaces. When approaching from the lingual aspect in the same quadrant, the double-ended universal curette must be turned end for end because the blades are mirror images. This means that the end that adapts to the mesial surfaces on the facial aspect also adapts to the distal surfaces on the lingual aspect, and vice versa. Both ends of the universal curette are used for instrumentation of the anterior teeth. On posterior teeth, however, because of the limited access to distal surfaces, a single working end can be used to treat both mesial and distal surfaces by using both of its cutting edges. To do this, the instrument is first adapted to the mesial surface with the handle nearly parallel to the mesial surface. Because the face of the universal curette blade is honed at 90 degrees to the lower shank, if the lower shank is positioned so that it is absolutely parallel to the surface being instrumented, the tooth-blade angulation is 90 degrees. To close this angle and thus obtain proper working angulation, the lower shank must be tilted slightly toward the tooth. The distal surface of the same posterior tooth can be instrumented with the opposite cutting edge of the same blade. This cutting edge can be adapted at proper working angulation by positioning the handle so that it is *perpendicular* to the distal surface (eFig. 50.23).



EFIG. 50.23 **Adaptation of the universal curette on a posterior tooth. Cross-sectional representations of the same universal curette blade as its cutting edges (*a* and *b*) are adapted to the mesial and distal surfaces of a posterior tooth.**

When adapting the universal curette blade, as much of the cutting edge as possible should be in contact with the tooth surface, except on narrow convex surfaces such as line angles. When the cutting edge is adapted to the tooth, pressure should be concentrated on the lower third of the blade during scaling and root planing strokes.

The primary advantage of these curettes is that they are designed to be used universally on all tooth surfaces, in all regions of the mouth. However, universal curettes have limited adaptability for the treatment of deep pockets in which apical migration of the attachment has exposed furcations, root convexities, and developmental depressions. For this reason, many clinicians prefer Gracey curettes and the newer modifications of Gracey curettes, which are area specific and specially designed for subgingival scaling and root planing in periodontal patients.

Learning Box e50.18

The primary advantage of these curettes is that they are designed to be used universally on all tooth surfaces, in all regions of the

mouth.

Gracey Curettes

As discussed earlier, Gracey curettes comprise a set of area-specific instruments that were designed by Dr. Clayton H. Gracey of Michigan in the mid-1930s (see Fig. 50.18). Four design features make Gracey curettes unique: (1) they are area specific, (2) only one cutting edge on each blade is used, (3) the blade appears to curve in two planes, and (4) the blade is "offset" (see Table 50.1.) Each of these features directly influences the manner in which Gracey curettes are used, as discussed next.

Area Specificity

Each set has seven pairs of curettes. Gracey curettes #1-2 and #3-4 are used on anterior teeth. The Gracey #5-6 may be used on both anterior and premolar teeth. The facial and lingual surfaces of posterior teeth are instrumented with Gracey curettes #7-8 and #9-10. The Gracey #11-12 is designed for mesial surfaces of posterior teeth, and the #13-14 adapts to the distal surfaces of posterior teeth. Although these guidelines for areas of use were originally established by Dr. Gracey, it is possible to use a Gracey curette in an area of the mouth other than the one for which it was specifically designed if the general principles regarding these curettes are understood and applied. Gracey curettes need not be reserved exclusively for periodontal patients. In fact, many clinicians prefer Gracey curettes for general scaling because of their excellent adaptability.

Single Cutting Edge Used

As with a universal curette, the Gracey curette has a blade with two cutting edges. Unlike the universal curette, however, the Gracey instrument is designed so that only one cutting edge is used. To determine which of the two is the correct cutting edge to adapt to the tooth, the blade should be held face up and parallel to the floor. When viewed from this angle, the blade appears to curve to the side. One cutting edge appears to be a larger outer curve, and the other appears to be a shorter, small inner curve. The larger outer

curve, which has also been described as the “inferior cutting edge” or the cutting edge farther away from the handle, is the correct cutting edge (eFig. 50.24).

EFIG. 50.24 Determining the correct cutting edge of a Gracey curette. When viewed from directly above the face of the blade, the correct cutting edge is the one forming the larger outer curve on the right.

Learning Box e50.19

The Gracey instrument is designed so that only one cutting edge is used.

Blade Appears to Curve in Two Planes

Like the universal curette, the Gracey curette blade curves from the shank toward the toe The blade of the Gracey curette also appears to curve to the side when viewed with the face of the blade parallel to the floor.

Offset Blade

Gracey curette blades are honed at an *offset angle,* which means that the face of the blade is not perpendicular to the lower shank, as it is on a universal curette. Instead, Gracey curettes are designed so that the tooth-blade working angulation is 60 to 70 degrees when the lower shank is held parallel to the tooth surface. Gracey curettes were originally designed to be used with *push strokes* and were beveled to provide a tooth-blade angulation of 40 degrees when the lower shank was parallel to the tooth surface; for many years,

Gracey curettes were available only in this form. Currently, Gracey curettes are available not only in the original push design but also in a modified version to be used with pull strokes. It is important to understand this when purchasing Gracey curettes to avoid obtaining instruments that are not properly designed for *pull strokes.* If Gracey curettes that are designed to be used with push strokes are used with pull strokes instead, they are likely to burnish calculus rather than completely remove it. The design of the Gracey curette was modified in response to requests from clinicians who liked the shank design and adaptability of the original Gracey instruments but were opposed to the use of push strokes for scaling and root planing. The push stroke is not recommended, especially for the novice clinician, because it is likely to cause undue trauma to the junctional epithelium and to embed fragments of dislodged calculus in the soft tissues.

Learning Box e50.20

Gracey curette blades are honed at an *offset angle* so that the tooth-blade working angulation is 60 to 70 degrees when the lower shank is held parallel to the tooth surface.

Principles of Use

The following general principles for use of Gracey curettes are essentially the same as those for the universal curette; italicized principles apply only to Gracey curettes:

1. *Determine the correct cutting edge.* The correct cutting edge should be determined by visually inspecting the blade and confirmed by lightly adapting the chosen cutting edge to the tooth with the lower shank parallel to the surface of the tooth. With the toe pointed in the direction to be scaled (e.g., mesially with a #7-8 curette), only the back of the blade can be seen if the correct cutting edge has been selected (eFig. 50.25). If the wrong cutting edge has been adopted, the flat, shiny face of the blade will be seen instead (eFig. 50.26).
2. *Make sure the lower shank is parallel to the surface to be*

instrumented. The lower shank of a Gracey curette is the portion between the blade and the first bend in the shank. Parallelism of the handle or upper shank is not an acceptable guide with Gracey curettes because the angulations of the shanks vary. On anterior teeth the lower shank of the Gracey #1-2, #3-4, or #5-6 should be parallel to the mesial, distal, facial, or lingual surfaces of the teeth (eFig. 50.27). On posterior teeth the lower shank of the #7-8 or #9-10 should be parallel to the facial or lingual surfaces of the teeth (eFig. 50.28); the lower shank of the #11-12 should be parallel to the mesial surfaces of the teeth (eFig. 50.29); and the lower shank of the #13-14 should be parallel to the distal surfaces of the teeth (eFig. 50.30).

Learning Box e50.21

Make sure the lower shank is parallel to the surface to be instrumented. The lower shank of a Gracey curette is the portion between the blade and the first bend in the shank.

3. When using intraoral finger rests, keep the fourth and middle fingers together in a built-up fulcrum for maximum control and wrist-arm action.
4. Use extraoral fulcrums or mandibular finger rests for optimal angulation when working on the maxillary posterior teeth.
5. Concentrate on using the lower third of the cutting edge for calculus removal, especially on line angles or when attempting to remove a calculus ledge by breaking it away in sections, beginning at the lateral edge.
6. Allow the wrist and forearm to carry the burden of the stroke, rather than flexing the fingers.
7. Roll the handle slightly between the thumb and fingers to keep the blade adapted as the working end is advanced around line angles and into concavities.
8. Modulate lateral pressure from firm to moderate to light depending on the nature of the calculus, and reduce

pressure as the transition is made from scaling to root-planing strokes.

Extended-Shank Gracey Curettes

Extended-shank Gracey curettes, such as After Five curettes, are 3 mm longer in the terminal shank than standard Gracey curettes but are used with the same technique (see Fig. 50.23). They are most useful for deep pockets on maxillary and mandibular posterior teeth, where the longer terminal shank allows better access, especially to deep mesial and distal pockets (see Fig. 50.24). Although the longer lower shank makes access easier while using a conventional intraoral finger rest, the use of an extraoral fulcrum allows better access and adaptation to all the maxillary posterior teeth. Extended-shank Gracey curettes with rigid shanks should be used for scaling of heavy calculus; curettes with regular finishing shanks should be used for periodontal maintenance patients with deep residual pockets.

Learning Box e50.22

Extended-shank Gracey curettes are most useful for deep pockets on maxillary and mandibular posterior teeth, where the longer terminal shank allows better access, especially to deep mesial and

distal pockets.

Mini-Bladed Gracey Curettes

Mini-bladed Gracey curettes, such as Mini Five curettes and Gracey Curvettes, have a terminal shank that is 3 mm longer than the standard Gracey curettes and a blade that is 50% shorter. Micro Mini Five curette blades are 20% smaller than Mini Five curette blades (see Figs. 50.28 and 50.29). These mini-bladed instruments are generally used in the same manner as the Gracey curettes, except for the following specific differences:

1. Mini-bladed curettes should not be used routinely in place of standard Gracey or extended-shank Gracey curettes. Instead, they should be used to supplement conventional curettes and ultrasonic instruments in areas difficult to access, such as furcations, line angles, and deep, tight, or narrow pockets (see Fig. 50.30).

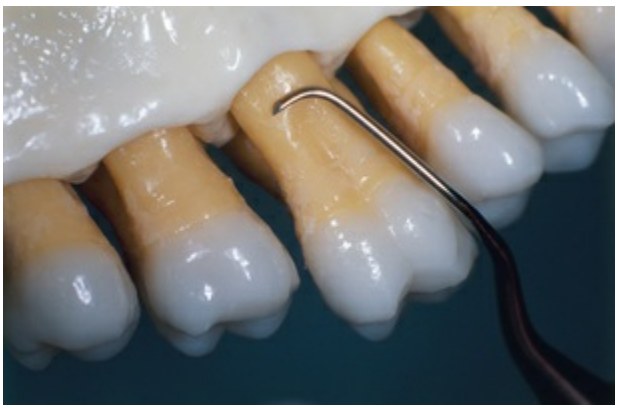
Learning Box e50.23

Mini-bladed curettes should be used to supplement conventional curettes and ultrasonic instruments in areas difficult to access.

2. Large #4 handles are recommended for any mini-bladed instruments because the larger diameter of the handles allows better control of the small blades.
3. Mini-bladed curettes can be used to scale with the toe directed either mesially or distally. In fact, these curettes often adapt more effectively to the root curvatures of many posterior teeth when the blade is inserted with the toe pointed distally and when strokes are activated from the mesial toward the distal line angle (eFig. 50.31).
4. Use rigid-shank mini-bladed curettes for calculus removal. Use the thinner, standard-shank mini-bladed curettes for deplaquing during maintenance.
5. When using mini-bladed curettes for calculus removal, use intraoral finger rests close to the working area. When

performing light root planing or deplaquing, either intraoral rests or extraoral fulcrums may be used. Extraoral fulcrums are usually necessary to gain access to deep pockets on maxillary second and third molars.

6. Mini-bladed curettes are generally used with straight, vertical strokes. They may also be used with oblique or horizontal strokes, but because of the shortness of the blade, these strokes may not extend far enough subgingivally unless the tissue is very retractable. Horizontal strokes with mini-bladed curettes are most effective when used in the cementoenamel junction or in developmental depressions just below it.



EFIG. 50.31 Mini Five #13-14 curette adapted to the palatal surface of a maxillary molar with the toe directed distally. (Copyright A. Pattison.)

Learning Box e50.24

Mini-bladed curettes are generally used with straight, vertical strokes with the toe directed either mesially or distally.

When properly used, mini-bladed Gracey curettes allow unprecedented access and effectiveness for both nonsurgical and surgical root debridement. One study showed that Gracey Curvettes performed better than standard Gracey curettes in deep anterior pockets.[81] In areas such as line angles, furcations, and narrow, curved, facial, or palatal root surfaces, these miniature curettes provide excellent adaptation with better tactile sensitivity

than modified slim ultrasonic tips. Studies also demonstrated that Gracey Curvette curettes performed better than ultrasonic slim tips on deep mandibular anterior pockets, furcations, and furcation entrances.[118,119] No comparison of hand instruments and modified slim ultrasonic tips can be made unless mini-bladed curettes have been fully employed. To date, some research has been done to compare the effectiveness of mini-bladed instruments with the modified slim ultrasonic tips. More of these studies need to be performed in vivo to guide clinicians in the optimal utilization of these newer types of instruments.[123]

Mini-bladed Gracey curettes allow unprecedented access and effectiveness for both nonsurgical and surgical root debridement.

Principles of Scaling and Root Planing

Definitions and Rationale

Scaling is the process by which biofilm and calculus are removed from both supragingival and subgingival tooth surfaces. No deliberate attempt is made to remove tooth substance along with the calculus. *Root planing* is the process by which residual embedded calculus and portions of cementum are removed from the roots to produce a smooth, hard, clean surface.

Learning Box e50.26

Scaling is the process by which biofilm and calculus are removed from both supragingival and subgingival tooth surfaces. No deliberate attempt is made to remove tooth substance along with the calculus.

Learning Box e50.27

Root planing is the process by which residual embedded calculus and portions of cementum are removed from the roots to produce a smooth, hard, clean surface.

The primary objective of scaling and root planing is to restore gingival health by completely removing elements that provoke gingival inflammation (i.e., biofilm, calculus, and endotoxin) from the tooth surface (eFig. 50.32). Instrumentation has been shown to reduce dramatically the numbers of subgingival microorganisms and produce a shift in the composition of subgingival biofilm from one with high numbers of gram-negative anaerobes to one dominated by gram-positive facultative bacteria compatible with health.[d] After thorough scaling and root planing, a profound reduction in spirochetes, motile rods, and putative pathogens, such

as *Actinobacillus actinomycetemcomitans, Porphyromonas gingivalis,* and *Prevotella intermedia,* and an increase in coccoid cells occur.[e] These changes in the microbiota are accompanied by a reduction or elimination of inflammation clinically.[f] This positive microbial change must be sustained by the periodic scaling and root planing performed during supportive periodontal therapy.[10,19,90,123,151,176]

EFIG. 50.32 **Results of phase I therapy. (A) to (F) Moderate chronic periodontitis. (A) Patient presenting with moderate attachment loss and probe depths in the 4- to 6-mm range. Note that the gingiva appears pink because it is fibrotic and the inflammation is deep in the periodontal pockets. (B) Lingual view before treatment, with more visible inflammation and heavy deposits of calculus. (C) and (D) The same areas with significant improvement in gingival health 18 months after scaling, root planing, and plaque control therapy were provided;**

the patient returned for regular maintenance visits. (E) and (F) Presenting radiographs of the lower anterior teeth. Radiograph taken 18 months after phase I therapy and maintenance shows no increase in bone loss.

Learning Box e50.28

The primary objective of scaling and root planing is to restore gingival health by completely removing elements that provoke gingival inflammation (i.e., biofilm, calculus, and endotoxin) from the tooth surface

Scaling and root planing are not separate procedures; all the principles of scaling apply equally to root planing. The difference between scaling and root planing is only a matter of degree. The nature of the tooth surface determines the degree to which the surface must be scaled or planed.

Biofilm and calculus on enamel surfaces provoke gingival inflammation. Unless they are grooved or pitted, enamel surfaces are relatively smooth and uniform. When biofilm and calculus form on enamel, the deposits are usually superficially attached to the surface and are not locked into irregularities. Scaling alone is sufficient to completely remove biofilm and calculus from enamel, leaving a smooth, clean surface.

Root surfaces exposed to biofilm and calculus pose a different problem. *Deposits of calculus on root surfaces are frequently embedded in cemental irregularities.*[1,27,106,150,182] Subgingival calculus is porous and harbors bacteria and endotoxin and therefore should be removed completely.[25,26,164] When dentin is exposed, biofilm bacteria may invade dentinal tubules.[1] Therefore scaling alone is insufficient to remove them, and a portion of the root surface must be removed to eliminate these deposits. Furthermore, when the root surface is exposed to biofilm and the pocket environment, its surface is contaminated by toxic substances, notably endotoxins.[3,4,62] Evidence suggests that these toxic substances are only superficially attached to the root and do not permeate it deeply.[8] Removal of extensive amounts of dentin and cementum is not necessary to render the roots free of toxins and should be avoided.[50,93,123] In areas where

cementum is thin, however, instrumentation may expose dentin. Although this is not the aim of treatment, such exposure may be unavoidable.[145,170]

Learning Box e50.29

Deposits of calculus are frequently embedded in cemental irregularities; therefore scaling alone is insufficient, and a portion of the root surface must be removed to eliminate these deposits.

Learning Box e50.30

Removal of extensive amounts of dentin and cementum is not necessary to render the roots free of toxins and should be avoided.

Scaling and root planing should not be viewed as separate procedures unrelated to the rest of the treatment plan. These procedures belong in the initial phase of an orderly sequence of treatment. After careful analysis of a case, the number of appointments needed to complete this phase of treatment is estimated. Patients with small amounts of calculus and relatively healthy tissues can be treated in one appointment. Most other patients require several treatment sessions. The dentist should estimate the number of appointments needed on the basis of the number of teeth in the mouth, severity of inflammation, amount and location of calculus, depth and activity of pockets, presence of furcation invasions, patient's comprehension of and compliance with oral hygiene instructions, and need for local anesthesia.

When the rationale for scaling and root planing is thoroughly understood, it becomes apparent that mastering these skills is essential to the ultimate success of any course of periodontal therapy. Of all clinical dental procedures, subgingival scaling and root planing in deep pockets are the most difficult and exacting skills to master. It has been argued that such proficiency in instrumentation cannot be attained, and therefore periodontal surgery is necessary to gain access to root surfaces. Others have argued that although proficiency is possible, it need not be

developed because access to the roots can be gained more easily with surgery. However, without mastering subgingival scaling and root-planing skills, the clinician will be severely hampered and unable to treat adequately those patients for whom surgery is contraindicated.

Learning Box e50.31

Mastery of scaling and root planing is essential to the ultimate success of any course of periodontal therapy.

Learning Box e50.32

Of all clinical dental procedures, subgingival scaling and root planing in deep pockets are the most difficult and exacting skills to master.

Detection Skills

Good visual and tactile detection skills are required for the accurate initial assessment of the extent and nature of deposits and root irregularities before scaling and root planing. Valid evaluation of the results of instrumentation depends on these detection skills.

Visual examination of supragingival and subgingival calculus just below the gingival margin is not difficult with good lighting and a clean field. Light deposits of supragingival calculus are often difficult to see when they are wet with saliva. Compressed air may be used to dry supragingival calculus until it is chalky white and readily visible. Air also may be directed into the pocket in a steady stream to deflect the marginal gingiva away from the tooth so that subgingival deposits near the surface can be seen.

Tactile exploration of the tooth surfaces in subgingival areas of pocket depth, furcations, and developmental depressions is much more difficult than visual examination of supragingival areas and requires the skilled use of a fine-pointed explorer or probe. The explorer or probe is held with a light but stable modified pen grasp. This provides maximal tactile sensitivity for detection of

subgingival calculus and other irregularities. The pads of the thumb and fingers, especially the middle finger, should perceive the slight vibrations conducted through the instrument shank and handle as irregularities in the tooth surface are encountered.

After a stable finger rest is established, the tip of the instrument is carefully inserted subgingivally to the base of the pocket. Light exploratory strokes are activated vertically on the root surface. When calculus is encountered, the tip of the instrument should be advanced apically over the deposit until the termination of the calculus on the root is felt. The distance between the apical edge of the calculus and the bottom of the pocket usually ranges from 0.2 to 1.0 mm. The tip is adapted closely to the tooth to ensure the greatest degree of tactile sensitivity and avoid tissue trauma. When a proximal surface is being explored, strokes must be extended at least halfway across the surface past the contact area to ensure complete detection of interproximal deposits. When an explorer is used at line angles, convexities, and concavities, the handle of the instrument must be rolled slightly between the thumb and fingers to keep the tip constantly adapted to the changes in tooth contour.

Although exploration technique and good tactile sensitivity are important, *interpreting various degrees of roughness and making clinical judgments based on these interpretations* also require much expertise. The beginning student usually has difficulty detecting fine calculus and altered cementum. Such detection must begin with the recognition of ledges, lumps, or spurs of calculus, then smaller spicules, then slight roughness, and finally a slight graininess that feels like a sticky coating or film covering the tooth surface. Overhanging or deficient margins of dental restorations, caries, decalcification, and root roughness caused by previous instrumentation are all typically found during exploration. These and other irregularities must be recognized and differentiated from subgingival calculus. Because this requires a great deal of experience and a high degree of tactile sensitivity, many clinicians agree that the development of detection skills is as important as the mastery of scaling and root-planing technique.

Learning Box e50.33

The development of detection skills is as important as the mastery of scaling and root-planing technique.

Supragingival Scaling Technique

Supragingival calculus is generally less tenacious and less calcified than subgingival calculus. Because instrumentation is performed coronal to the gingival margin, scaling strokes are not confined by the surrounding tissues. This makes adaptation and angulation easier. It also allows direct visibility, as well as a freedom of movement not possible during subgingival scaling.

Sickles, curettes, and ultrasonic and sonic instruments are most often used for the removal of supragingival calculus; hoes and chisels are less frequently used. To perform supragingival scaling, the sickle or curette is held with a modified pen grasp, and a firm finger rest is established on the teeth adjacent to the working area. The blade is adapted with an angulation of slightly less than 90 degrees to the surface being scaled. The cutting edge should engage the apical margin of the supragingival calculus while short, powerful, overlapping scaling strokes are activated coronally in a vertical or oblique direction. The sharply pointed tip of the sickle can easily lacerate marginal tissue or gouge exposed root surfaces, so careful adaptation is especially important when this instrument is being used. The tooth surface is instrumented until it is visually and tactilely free of all supragingival deposits. If the tissue is retractable enough to allow easy insertion of the bulky blade, the sickle may be used slightly below the free gingival margin. If the sickle is used in this manner, final scaling and root planing with the curette should always follow.

Learning Box e50.34

Supragingival calculus is generally less tenacious and less calcified than subgingival calculus. Sickles, curettes, and ultrasonic and sonic instruments are most often used for the removal of supragingival calculus.

Subgingival Scaling and Root-Planing Technique

Subgingival scaling and root planing are much more complex and difficult to perform than supragingival scaling. *Subgingival calculus* is usually harder than supragingival calculus and is often locked into root irregularities, thus making it more tenacious and more difficult to remove.[27,106,150,182] The overlying tissue creates significant problems in subgingival instrumentation. Vision is obscured by the bleeding that inevitably occurs during instrumentation and by the tissue itself. The clinician must rely heavily on tactile sensitivity to detect calculus and irregularities, guide the instrument blade during scaling and root planing, and evaluate the results of instrumentation.

Learning Box e50.35

Subgingival calculus is usually harder than supragingival calculus and is often locked into root irregularities, making it more tenacious and therefore more difficult to remove.

In addition, the adjacent pocket wall limits the direction and length of the strokes. The confines of the soft tissue make careful adaptation to tooth contours imperative to avoid trauma. Such precise adaptation cannot be accomplished without thorough knowledge of tooth morphologic features. The clinician must form a mental image of the tooth surface to anticipate variations in contour, continually confirming or modifying the image in response to tactile sensations and visual cues, such as the position of the instrument handle and shank. The clinician then must instantaneously adjust the adaptation and angulation of the working end to the tooth. It is this complex and precise coordination of visual, mental, and manual skills that makes subgingival instrumentation one of the most difficult of all dental skills. *The curette is preferred by most clinicians for subgingival scaling and root planing because of the advantages afforded by its design.* Its curved blade, rounded toe, and curved back allow the curette to be inserted to the base of the pocket and adapted to variations in tooth

contour with minimal tissue displacement and trauma.

Learning Box e50.36

The curette is preferred for subgingival scaling and root planing because its design allows it to be inserted to the base of the pocket and adapted to variations in tooth contour with minimal tissue displacement and trauma.

Sickles, hoes, files, and ultrasonic instruments also are used for subgingival scaling of heavy calculus. Some small files (e.g., Hirschfeld file) may be inserted to the base of the pocket to crush or initially fracture tenacious deposits. Larger files, hoes, sickles, and standard ultrasonic tips for supragingival use are too bulky and cannot be inserted easily into deep pockets or areas where tissue is firm and fibrotic. Hoes and files cannot be used to produce as smooth a surface as curettes. Hoes, files, and standard large ultrasonic tips are all more hazardous than curettes in terms of trauma to the root surface and surrounding tissues.[16,116,145] Although thin ultrasonic tips designed for scaling of deep pockets and furcations can be inserted more easily subgingivally, they must be used on low power.[42,43,65] When low-power scaling is performed on heavy calculus or tenacious sheets of calculus, thin ultrasonic tips are likely to burnish the calculus rather than thoroughly remove it. Therefore ultrasonic scaling should be followed by careful assessment with an explorer and further instrumentation with curettes when necessary.

Learning Box e50.37

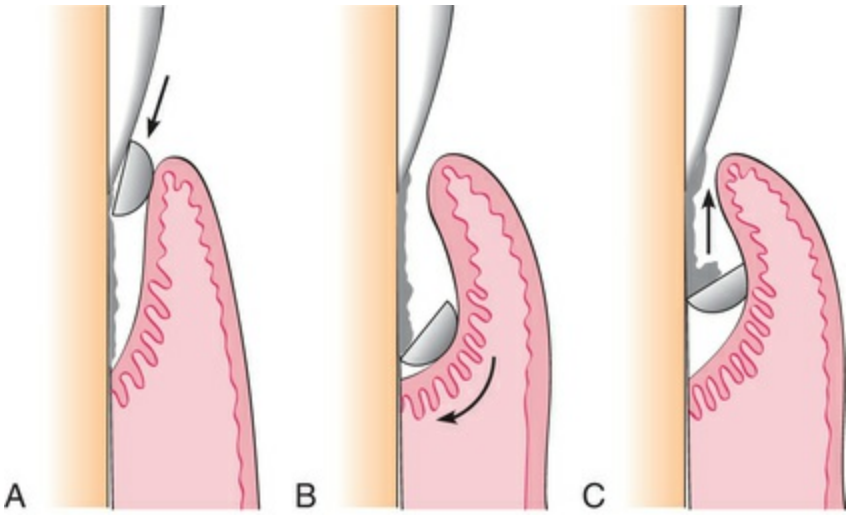
A Hirschfeld file may be inserted to the base of the pocket to crush or initially fracture tenacious deposits.

Learning Box e50.38

Ultrasonic scaling should be followed by careful assessment with

an explorer and further instrumentation with curettes when necessary.

Subgingival scaling and root planing are accomplished with either universal or area-specific (Gracey) curettes by using the following basic procedure. The curette is held with a modified pen grasp, and a stable finger rest is established. The correct cutting edge is slightly adapted to the tooth, with the lower shank kept parallel to the tooth surface. The lower shank is moved toward the tooth so that the face of the blade is nearly flush with the tooth surface. The blade is then inserted under the gingiva and advanced to the base of the pocket by a light exploratory stroke. When the cutting edge reaches the base of the pocket, a working angulation of between 45 and 90 degrees is established, and pressure is applied laterally against the tooth surface. Calculus is removed by a series of controlled, overlapping, short, powerful strokes primarily using wrist-arm motion (eFig. 50.33). As calculus is removed, resistance to the passage of the cutting edge diminishes until only a slight roughness remains. Longer, lighter root-planing strokes are then activated with less lateral pressure until the root surface is completely smooth and hard. The instrument handle must be rolled carefully between the thumb and fingers to keep the blade adapted closely to the tooth surface as line angles, developmental depressions, and other changes in tooth contour are followed. Scaling and root-planing strokes should be confined to the portion of the tooth where calculus or altered cementum is found; this area is known as the *instrumentation zone.* Sweeping the instrument over the crown where it is not needed wastes operating time, dulls the instrument, and causes loss of control.



EFIG. 50.33 **Subgingival scaling procedure. (A) Curette inserted with the face of the blade flush against the tooth. (B) Working angulation (45 to 90 degrees) is established at the base of the pocket. (C) Lateral pressure is applied, and the scaling stroke is activated in the coronal direction.**

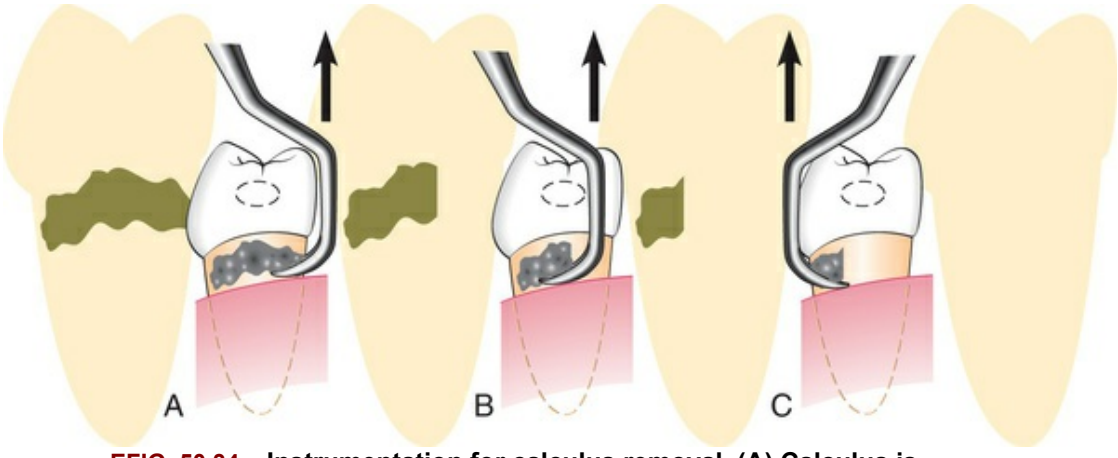
Learning Box e50.39

Calculus is removed by a series of controlled, overlapping, short, powerful strokes. Longer, lighter root-planing strokes are then activated with less lateral pressure until the root surface is completely smooth and hard.

The amount of lateral pressure applied to the tooth surface depends on the nature of the calculus and whether the strokes are for initial calculus removal or final root planing. If heavy lateral pressure is continued after the bulk of calculus has been removed and the blade is repeatedly readapted with short, choppy strokes, the result will be a root surface roughened by numerous nicks and gouges, resembling the rippled surface of a washboard.[122] If heavy lateral pressure is continued with long, even strokes, the result will be excessive removal of root structure, producing a smooth but "ditched" or "riffled" root surface. To avoid these hazards of overinstrumentation, a deliberate transition from short, powerful scaling strokes to longer, lighter root-planing strokes must be made as soon as the calculus and initial roughness have been eliminated.

When scaling strokes are used to remove calculus, force can be

maximized by concentrating lateral pressure onto the lower third of the blade (see eFig. 50.19). This small section, the terminal few millimeters of the blade, is positioned slightly apical to the lateral edge of the deposit, and a short vertical or oblique stroke is used to split the calculus from the tooth surface. Without withdrawing the instrument from the pocket, the lower third of the blade is advanced laterally and repositioned to engage the next portion of the remaining deposit. Another vertical or oblique stroke is made, slightly overlapping the previous stroke. This process is repeated in a series of powerful scaling strokes until the entire deposit has been removed. The overlapping of these pathways or "channels" of instrumentation[122] ensures that the entire instrumentation zone is covered (eFig. 50.34).



EFIG. 50.34 Instrumentation for calculus removal. (A) Calculus is removed by engaging the apical or lateral edge of the deposit with the cutting edge of a scaler; vertical movement of the instrument will remove the fragment of calculus engaged by the instrument, as seen in the *shaded drawing.* (B) The instrument is moved laterally and again engages the edge of the calculus, thus overlapping the previous stroke to some extent; the *shaded drawing* shows further removal. (C) The final portion of the deposit is engaged and removed. Note how the procedure is performed in an interdental space by entering facially and lingually.

Learning Box e50.40

When scaling strokes are used to remove calculus, force can be maximized by concentrating lateral pressure onto the lower third

of the blade.

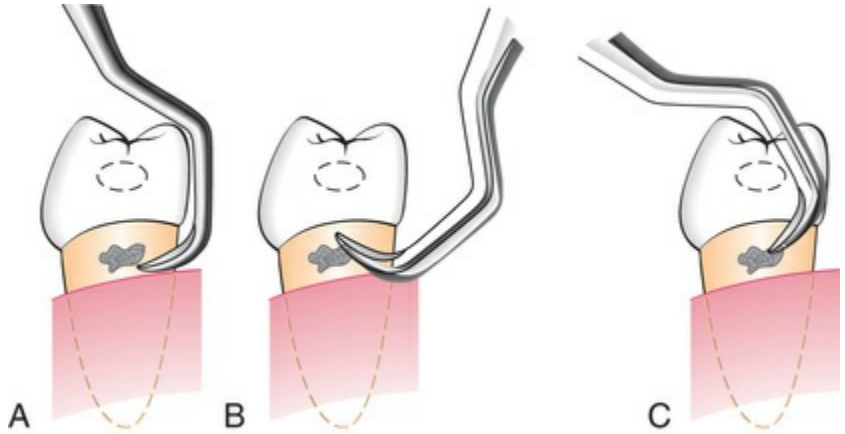
Learning Box e50.41

Overlapping of "channels" of instrumentation ensures that the entire instrumentation zone is covered.

Engaging a large, tenacious ledge or piece of calculus with the entire length of the cutting edge is not recommended because the force is distributed through a longer section of the cutting edge rather than concentrated. Much more lateral pressure is required to dislodge the entire deposit in one stroke. Although some clinicians may possess the strength to remove calculus completely in this manner, the heavier forces required diminish tactile sensitivity and contribute to a loss of control that results in tissue trauma. A single heavy stroke usually is not sufficient to remove calculus entirely. Instead, the blade skips over or skims the surface of the deposit. Subsequent strokes made with the entire cutting edge tend to shave the deposit down layer by layer. When a series of these repeated whittling strokes is applied, the calculus may be reduced to a thin, smooth, burnished sheet that is difficult to distinguish from the surrounding root surface.

A common error in instrumenting proximal surfaces is failing to reach the midproximal region apical to the contact. This area is relatively inaccessible, and the technique requires more skill than instrumentation of buccal or lingual surfaces. It is extremely important to extend strokes at least halfway across the proximal surface so that no calculus or roughness remains in the interproximal area. With properly designed curettes, this can be accomplished by keeping the lower shank of the curette parallel with the long axis of the tooth (eFig. 50.35A). With the lower shank parallel to the long axis, the blade of the curette will reach the base of the pocket and the toe will extend beyond the midline as strokes are advanced across the proximal surface. This extension of strokes beyond the midline ensures thorough exploration and instrumentation of these surfaces. If the lower shank is angled or tilted away from the tooth, the toe will move toward the contact

area. Because this prevents the blade from reaching the base of the pocket, calculus apical to the contact will not be detected or removed. Strokes will be hampered because the toe tends to become lodged in the contact. If the instrument is angled or tilted too far toward the tooth, the lower shank will hit the tooth or the contact area, thereby preventing extension of strokes to the midproximal region (eFig. 50.35B and C).



EFIG. 50.35 **Shank position for scaling proximal surfaces. (A) Correct shank position, parallel to the long axis of the tooth. (B) Incorrect shank position, tilted away from the tooth. (C) Incorrect shank position, tilted too far toward the tooth. Sextant: lingual aspect.**

Learning Box e50.42

Extension of strokes beyond the midline of proximal surfaces ensures thorough exploration and instrumentation apical to the contact area.

The relationship between the location of the finger rest and the working area is important for two reasons. First, the finger rest or fulcrum must be positioned to allow the lower shank of the instrument to be parallel or nearly parallel to the tooth surface being treated. This parallelism is a fundamental requirement for optimal working angulation. Second, the finger rest must be positioned to enable the operator to use wrist-arm motion to activate strokes. On some aspects of the maxillary posterior teeth, these requirements can be met only with the use of extraoral or

opposite-arch fulcrums. When intraoral finger rests are used in other regions of the mouth, the finger rest must be close enough to the working area to fulfill these two requirements. A finger rest that is established too far from the working area forces the clinician to separate the middle finger from the fourth finger in an effort to obtain parallelism and proper angulation. Effective wrist-arm motion is possible only when these two fingers are kept together in a built-up fulcrum. Separation of the fingers commits the clinician to the exclusive use of finger flexing for the activation of strokes.

Learning Box e50.43

The finger rest or fulcrum must be positioned to allow the lower shank of the instrument to be parallel to the tooth surface and enable wrist-arm motion to activate strokes.

As instrumentation proceeds from one tooth to the next, the body position of the operator and the location of the finger rest must be frequently adjusted or changed to allow parallelism and wrist-arm motion. Various approaches to instrumentation in different areas of the mouth are illustrated here. The examples shown provide maximal efficiency for the clinician and comfort for the patient. For most areas, more than one approach is presented. Other approaches are possible and are acceptable if they provide equal efficiency and comfort. The following approaches may be used:

Maxillary right posterior sextant: Facial aspect (eFig. 50.36).
- Operator position: Side position.
- Illumination: Direct.
- Visibility: Direct (indirect for distal surfaces of molars).
- Retraction: Mirror or index finger of the nonoperating hand.
- Finger rest: Extraoral, palm up. Backs of the middle and fourth fingers on the lateral aspect of the mandible on the right side of the face.

Maxillary right posterior sextant, premolar region only: Facial

aspect (eFig. 50.37).

Operator position: Side or back position.
Illumination: Direct.
Visibility: Direct.
Retraction: Mirror or index finger of the nonoperating hand.
Finger rest: Intraoral, palm up. Fourth finger on the occlusal surfaces of the adjacent maxillary posterior teeth.

Maxillary right posterior sextant: Lingual aspect (eFig. 50.38).

Operator position: Side or front position.
Illumination: Direct and indirect.
Visibility: Direct or indirect.
Retraction: None.
Finger rest: Extraoral, palm up. Backs of the middle and fourth fingers on the lateral aspect of the mandible on the right side of the face.

Maxillary right posterior sextant: Lingual aspect (eFig. 50.39).

Operator position: Front position.
Illumination: Direct.
Visibility: Direct.
Retraction: None.
Finger rest: Intraoral, palm up, finger on finger. Index finger of the nonoperating hand on the occlusal surfaces of the maxillary right posterior teeth; fourth finger of the operating hand or the index finger of the nonoperating hand.

Maxillary anterior sextant: Facial aspect, surfaces away from the operator (eFig. 50.40).

Operator position: Back position.
Illumination: Direct.
Visibility: Direct.
Retraction: Index finger of the nonoperating hand.
Finger rest: Intraoral, palm up. Fourth finger on the incisal edges or occlusal surfaces of adjacent maxillary teeth.

Maxillary anterior sextant: Facial aspect, surfaces toward the operator (eFig. 50.41).

Operator position: Front position.
Illumination: Direct.
Visibility: Direct.
Retraction: Index finger of the nonoperating hand.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal or facial surfaces of adjacent maxillary teeth.

Maxillary anterior sextant: Lingual aspect, surfaces away from the operator (surfaces toward the operator are scaled from a front position) (eFig. 50.42).

Operator position: Back position.
Illumination: Indirect.
Visibility: Indirect.
Retraction: None.
Finger rest: Intraoral, palm up. Fourth finger on the incisal edges or the occlusal surfaces of adjacent maxillary teeth.

Maxillary left posterior sextant: Facial aspect (eFig. 50.43).

Operator position: Side or back position.
Illumination: Direct or indirect.
Visibility: Direct or indirect.
Retraction: Mirror.
Finger rest: Extraoral, palm down. Front surfaces of the middle and fourth fingers on the lateral aspect of the mandible on the left side of the face.

Maxillary left posterior sextant: Facial aspect (eFig. 50.44).

Operator position: Back or side position.
Illumination: Direct or indirect.
Visibility: Direct or indirect.
Retraction: Mirror.
Finger rest: Intraoral, palm up. Fourth finger on the incisal edges or the occlusal surfaces of adjacent maxillary teeth.

Maxillary left posterior sextant: Lingual aspect (eFig. 50.45).

Operator position: Front position.
Illumination: Direct.
Visibility: Direct.
Retraction: None.

Finger rest: Intraoral, palm down, opposite arch, reinforced. Fourth finger on the incisal edges of the mandibular anterior teeth or the facial surfaces of the mandibular premolars, reinforced with the index finger of the nonoperating hand.

Maxillary left posterior sextant: Lingual aspect (eFig. 50.46).

Operator position: Front position.
Illumination: Direct and indirect.
Visibility: Direct and indirect.
Retraction: None.
Finger rest: Extraoral, palm down. Front surfaces of the middle and fourth fingers on the lateral aspect of the mandible on the left side of the face. The nonoperating hand holds the mirror for indirect illumination.

Maxillary left posterior sextant: Lingual aspect (eFig. 50.47).

Operator position: Side or front position.
Illumination: Direct.
Visibility: Direct.
Retraction: None.
Finger rest: Intraoral, palm up. Fourth finger on the occlusal surfaces of adjacent maxillary teeth.

Mandibular left posterior sextant: Facial aspect (eFig. 50.48).

Operator position: Side or back position.
Illumination: Direct.
Visibility: Direct or indirect.
Retraction: Index finger or mirror of the nonoperating hand.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal or facial surfaces of adjacent mandibular teeth.

Mandibular left posterior sextant: Lingual aspect (eFig. 50.49).

Operator position: Front or side position.
Illumination: Direct and indirect.
Visibility: Direct.
Retraction: Mirror retracts tongue.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent

mandibular teeth.

Mandibular anterior sextant: Facial aspect, surfaces toward the operator (eFig. 50.50).

Operator position: Front position.
Illumination: Direct.
Visibility: Direct.
Retraction: Index finger of the nonoperating hand.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Mandibular anterior sextant: Facial aspect, surfaces away from the operator (eFig. 50.51).

Operator position: Back position.
Illumination: Direct.
Visibility: Direct.
Retraction: Index finger or thumb of the nonoperating hand.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Mandibular anterior sextant: Lingual aspect, surfaces away from the operator (eFig. 50.52).

Operator position: Back position.
Illumination: Direct and indirect.
Visibility: Direct and indirect.
Retraction: Mirror retracts tongue.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Mandibular anterior sextant: Lingual aspect, surfaces toward the operator (eFig. 50.53).

Operator position: Front position.
Illumination: Direct and indirect.
Visibility: Direct and indirect.
Retraction: Mirror retracts tongue.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Mandibular right posterior sextant: Facial aspect (eFig. 50.54).

Operator position: Side or front position.
Illumination: Direct.
Visibility: Direct.
Retraction: Mirror or index finger of the nonoperating hand.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Mandibular right posterior sextant: Lingual aspect (eFig. 50.55).

Operator position: Front position.
Illumination: Direct and indirect.
Visibility: Direct and indirect.
Retraction: Mirror retracts tongue.
Finger rest: Intraoral, palm down. Fourth finger on the incisal edges or the occlusal surfaces of adjacent mandibular teeth.

Ultrasonic and Sonic Scaling

Instruments

Ultrasonic scalers may be used for removing plaque and stain, scaling, root planing, curetting, and surgical debridement. The two types of ultrasonic units are magnetostrictive and piezoelectric. In both types, alternating electrical current generates oscillations in materials in the handpiece that cause the scaler tip to vibrate. Depending on the manufacturer, the ultrasonic vibrations at the tip of both types of instruments range from 18,000 to 50,000 cycles per second (cps; also referred to as Hertz [Hz]). In magnetostrictive units the pattern of vibration is elliptical, which means that all sides of the tip are active and will work when adapted to the tooth. In piezoelectric units the pattern of vibration is linear, or back and forth, meaning that the two sides of the tip are the most active.

Learning Box e50.44

Ultrasonic scalers may be used for removing plaque and stain, scaling, root planing, curetting, and surgical debridement. The two types of ultrasonic units are magnetostrictive and piezoelectric.

Sonic units consist of a handpiece that attaches to a compressed-

air line and uses a variety of specially designed tips. Vibrations at the sonic tip range from 2500 to 7000 cps, which provides less power for calculus removal than ultrasonic units.

Ultrasonic and sonic tips of different shapes and sizes are available. Larger tips are used for removal of heavy supragingival calculus and heavy subgingival calculus where tissue is inflamed and retractable. Thinner tips are designed for more definitive subgingival debridement. All tips are designed to operate in a wet field with a water spray directed at the end of the tip. Vibrational energy dislodges calculus and biofilm from the tooth surfaces, and acoustic streaming and acoustic turbulence of the water serve to flush these deposits from the pocket. Magnetostrictive ultrasonic inserts generate heat and require water for cooling. Sonic and piezoelectric units do not generate heat but still use water for cooling of frictional heat and for flushing away debris.

Learning Box e50.45

Larger tips are used for removal of heavy supragingival calculus and heavy subgingival calculus where tissue is inflamed and retractable. Thinner tips are designed for more definitive subgingival debridement.

Ultrasonic Instruments

Ultrasonic instruments have been used as a valuable adjunct to conventional hand instrumentation for many years. In the early era of ultrasonic scaling, most tips were large and bulky, making them generally suitable only for supragingival scaling. Currently, many thinner ultrasonic tips allow better access to subgingival areas that were previously accessible only with hand instruments.[41] It is important to understand this historical perspective when attempting to interpret the literature comparing the effects of hand and ultrasonic instruments on root surfaces. Earlier studies using older tip designs generally showed that ultrasonic instruments left a rougher, more damaged surface than curettes.[h] More recent studies, especially those using the newer, thinner tips, show that ultrasonic instruments can produce root surfaces as smooth as or

smoother than those produced by curettes.[41,42,49,138] Whether these relative degrees of smoothness are important has not been clearly established.[i] It is evident, however, that both methods of instrumentation are able to provide satisfactory clinical results, as measured by removal of biofilm and calculus, reduction of bacteria, reduction of inflammation and pocket depth, and gain in clinical attachment.[j]

Ultrasonic instruments have been shown to be more effective than hand instruments at reducing spirochetes and motile rods in class II and III furcations.[86] Two in vitro studies found that ultrasonic and sonic scalers do not kill periodontal pathogenic bacteria by cavitation; rather, they suggest an antimicrobial effect from an increase in temperature or from acoustic streaming.[113,146] Other in vitro studies found that mini-bladed Gracey Curvettes were more effective than slim ultrasonic inserts in debriding root trunks, furcation entrances, and furcation areas of mandibular first molars.[118,119] Mini-bladed hand instruments (e.g., Gracey Curvettes and mini-bladed or micro mini-bladed Gracey Curvettes) allow excellent, unprecedented access to narrow furcations, and they can be followed by thin, curved ultrasonic inserts for final debridement and lavage.

The selection of either ultrasonic or hand instrumentation should be determined by the clinician's preference and experience and the needs of each patient. The success of either treatment method is determined by the time devoted to the procedure and the thoroughness of root debridement. In practice, clinicians typically use a combination of both ultrasonic and hand instrumentation to achieve thorough debridement.

Learning Box e50.46

Clinicians typically use a combination of both ultrasonic and hand instrumentation to achieve thorough debridement.

The vibrational energy produced by the ultrasonic instrument makes it useful for removing heavy, tenacious deposits of calculus and stain. Such deposits can be removed more quickly and with

less effort ultrasonically than manually. When ultrasonic instruments are properly manipulated, less tissue trauma and therefore less postoperative discomfort occur. This makes ultrasonic instrumentation useful for initial debridement in patients with acute painful conditions such as necrotizing ulcerative gingivitis. This same quality can be used to advantage with the newer thin ultrasonic tips for subgingival root debridement and deplaquing in maintenance patients with residual pocket depth. Ultrasonic scaling devices also have been used for gingival curettage and to remove overhangs and excess cement after cementing orthodontic appliances. Opinions differ regarding the effectiveness of ultrasonic instruments for removing stains compared with conventional polishing methods.[24]

The use of ultrasonic and sonic scaling devices has some contraindications. Magnetostrictive devices have been reported to interfere with the function of older cardiac pacemakers.[183] In an independent study, a piezoelectric dental scaler produced no electromagnetic interference with defibrillators.[22] Patients with newer pacemakers can be treated safely; however, a risk may exist if the patient is medically fragile or if electronically defective ultrasonic devices are used.[98,167,183] Medical consultation is advised when treating patients with such conditions.

Patients with known communicable diseases that can be transmitted by aerosols should not be treated with ultrasonic or sonic scaling devices. The water spray creates a contaminated aerosol that fills the operating area, exposing personnel and surfaces.[82,108] Even when treating patients without known communicable diseases, it is especially important that proper infection control measures be observed (i.e., use of protective clothing, eyewear, masks, and gloves) and proper surface decontamination be performed afterward. Prerinsing for 1 minute with an antimicrobial mouthwash such as 0.12% chlorhexidine significantly reduces the number of bacteria in the aerosol for approximately 1 hour.[171]

Learning Box e50.47

Patients with known communicable diseases that can be

transmitted by aerosols should not be treated with ultrasonic or sonic scaling devices.

Patients at risk for respiratory disease should not be treated with ultrasonic or sonic devices, including patients who are immunosuppressed or have chronic pulmonary disorders.[152,163] Finally, metal ultrasonic and sonic inserts are contraindicated for titanium implants, which can be etched or gouged, and for porcelain or bonded restorations, which can be fractured or removed.[21,40,83,134,172] Magnetostrictive and piezoelectric plastic-tipped ultrasonic inserts that do not cause damage to titanium implants are available.[80] In addition, plastic and Teflon-coated sonic scaler tips have been developed for titanium implants and for deplaquing and subgingival polishing of root surfaces.[77,78,142]

Technique

Ultrasonic instrumentation is accomplished with a light-to-moderate grasp and varying pressure depending on the amount and tenacity of the deposit. Excessive pressure is not recommended because it can cause dampening of the vibration of the tip. The tip should be kept in constant motion and parallel to the tooth surface.[42,65,127] Leaving the tip in one place for too long or using the point of the tip against the tooth can produce gouging and roughening of the root surface or overheating of the tooth.[41] Using a lower-power setting and applying only slight pressure reduces the volume and depth of tooth structure removal.[32,127]

The ultrasonic tip must come in direct physical contact with calculus to fracture and remove it. The tip must also contact all aspects of the root surface to remove biofilm and toxins thoroughly. Although as much as 10 mm or more of the length of the ultrasonic tip vibrates, only the terminal few millimeters of the tip produce maximum vibration. At any point in time, it is only possible for this terminal 1- to 2-mm portion of the tip to be in contact with the tooth because of the curved anatomy of teeth. On convex surfaces such as depressions or line angles, it is not possible to adapt more than 1 or 2 mm of the tip against the tooth. Even on what appear to be broader, flatter surfaces, no more than this small terminal portion of the tip can be adapted because the tooth surface, although it may

seem flat, is actually slightly curved.

If a longer portion of the tip is adapted to a convex surface so that it contacts the tooth at a tangent, this less effective part of the tip is likely to burnish calculus or miss it altogether. Additionally, the tip will jut out into the soft tissue, thus possibly causing trauma and discomfort.

A series of focused, overlapping strokes must be activated to keep this small active portion of the tip adapted to the root surface at all times.[65] The handpiece and the blunt working end of the ultrasonic tip impair tactile sensitivity, and the constant water spray hampers visibility. For these reasons, during ultrasonic instrumentation, the tooth surface should be frequently examined with an explorer to evaluate the completeness of debridement.

Learning Box e50.48

The ultrasonic tip must come in direct physical contact with calculus to fracture and remove it.

Learning Box e50.49

Only the terminal 1 to 2 mm of the tip will produce maximum vibration. The curved anatomy of teeth dictates that only this small portion of the tip can possibly contact a tooth at any point in time.

Learning Box e50.50

During ultrasonic instrumentation, the tooth surface should be frequently examined with an explorer to evaluate the completeness of debridement.

The aerosol produced by sonic and ultrasonic instrumentation may contain potentially infectious blood-borne and airborne pathogens.[k] Pneumococci, staphylococci, α-hemolytic streptococci, and *Mycobacterium tuberculosis* are among the bacteria that have been found in dental aerosols.[73,87] Aerosols also subject dental

personnel and patients to many viruses, including herpes simplex, hepatitis, influenza, common cold, Epstein-Barr, and cytomegalovirus.[30,33-36,97,165] Of additional concern are pathogens that do not originate from patients but from the contaminated water lines of the dental unit or the ultrasonic device.[38,45,120] Putative pathogens such as *Pseudomonas* species and *Legionella pneumophila* have been isolated from dental unit water and can become aerosolized by an ultrasonic scaler.[33,45,54,115] Aerosol from ultrasonic instrumentation always contains blood,[15,99] and it lingers in the air for 30 minutes or longer in the entire operatory and in areas of the dental office outside the operatory.[82,84,100,101] Unprotected patients may be more susceptible to infection from the aerosol than are dental personnel who are wearing protective barriers, such as masks, gloves, eyewear, and clinical clothing.[17,30,152] High-speed evacuation, preprocedural rinsing with chlorhexidine, flushing of the handpiece and water lines or a self-contained sterile water source, thorough disinfection of environmental surfaces, and use of adequate ventilation and air filtration units with high-efficiency particulate air (HEPA) filters are all important precautions to minimize the potential hazards of ultrasonic aerosols.[58–60,143]

Learning Box e50.51

Aerosols from ultrasonic instrumentation always contain blood, potentially infectious blood-borne and airborne pathogens, and linger in the air for 30 minutes or longer.

With these points in mind, the ultrasonic device is used in the following manner:

1. Thoroughly wipe the ultrasonic unit with a disinfectant. Use a sterile, autoclavable ultrasonic handpiece, or wipe the handpiece with disinfectant. Cover the ultrasonic unit or control knobs and the handpiece with plastic or latex barriers. Flush the water lines and handpiece for 2 minutes to decrease the number of microorganisms in the lines.[177] Use water line filters or sterile water whenever possible.

2. Direct the patient to rinse for 1 minute with an antimicrobial oral rinse such as 0.12% chlorhexidine to reduce the contaminated aerosol.[171,177]
3. The clinician and the assistant should wear protective eyewear or face shields and masks. Use high-speed evacuation to minimize contaminated aerosol produced during instrumentation.[58–60]
4. Turn on the unit, select an insert, place it into the handpiece, and then adjust the water control knob to produce a light mist of water at the working tip. Adequate aspiration is necessary to remove the water as it accumulates in the mouth. The power setting should begin on low and be adjusted no higher than necessary to remove calculus. Medium- to high-power settings have been shown to cause damage to roots when the tip is not parallel to the root surface.
5. The instrument is grasped with a light to moderate pen or modified pen grasp, and a finger rest or extraoral fulcrum should be established to allow a light touch. Extraoral hand rests should be used for the maxillary teeth. For the mandibular teeth, either intraoral or extraoral fulcrums may be used.
6. Use short, light, vertical, horizontal, or oblique overlapping strokes. Keep the working tip adapted to the tooth surface as it passes over the deposit. Heavy lateral pressure is unnecessary because the vibrational energy of the instrument dislodges the calculus. However, the working end must touch the deposit for this to occur.
7. The working end should be kept in constant motion, and the tip should be kept parallel to the tooth surface or at no more than a 15-degree angle to avoid etching or grooving the tooth surface.[177]
8. The instrument should be switched off periodically to allow for aspiration of water, and the tooth surface should be examined frequently with an explorer.
9. Any remaining irregularities of the root surface may be removed with sharp standard or mini-bladed curettes if necessary.

10. See Chapter 51 for additional information on ultrasonic and sonic scaling.

Evaluation

The adequacy of scaling and root planing is evaluated when the procedure is performed and again later, after a period of soft tissue healing.

Immediately after instrumentation, the tooth surfaces should be carefully inspected visually with optimal lighting and the aid of a mouth mirror and compressed air; surfaces also should be examined with a fine explorer or probe. Subgingival surfaces should be hard and smooth. Although complete removal of calculus is definitely necessary for the health of the adjacent soft tissue,[176] little documented evidence for the necessity of root smoothness is available.[50,53,166] Nevertheless, relative smoothness is still the best immediate clinical indication that calculus has been completely removed.[50]

Although smoothness is the criterion by which scaling and root planing are immediately evaluated, the ultimate evaluation is based on *tissue response*.[173] Clinical evaluation of the soft tissue response to scaling and root planing, including probing, should not be conducted earlier than 2 weeks postoperatively. Reepithelialization of the wounds created during instrumentation takes 1 to 2 weeks.[131,158,159] Until then, gingival bleeding on probing can be expected even when calculus has been completely removed because the soft tissue wound is not epithelialized. Any gingival bleeding on probing noted after this interval is more likely the result of persistent inflammation produced by residual deposits not removed during the initial procedure or inadequate plaque control. Positive clinical changes after instrumentation often continue for weeks or months. Therefore a longer period of evaluation may be indicated before deciding whether to intervene with further instrumentation or surgery.[31]

Learning Box e50.52

Although smoothness is the criterion by which scaling and root

planing are immediately evaluated, the ultimate evaluation is based on tissue response.

Learning Box e50.53

Positive clinical changes after instrumentation often continue for weeks or months. Therefore a longer period of evaluation may be indicated before deciding whether to intervene with further instrumentation or surgery.

Occasionally, the clinician may find that some slight root roughness remains after scaling and root planing.[40,97,111] If sound principles of instrumentation have been followed, the roughness may not be calculus. Because calculus removal, not root smoothness, has been shown to be necessary for tissue health, it may be more prudent in such a case to stop short of perfect smoothness and reevaluate the patient's tissue response after 2 to 4 weeks or longer. This avoids overinstrumentation and removal of excessive root structure in the pursuit of smoothness for its own sake. If the tissue is healthy after an interval of 2 to 4 weeks or longer, no further root planing is necessary. If the tissue is inflamed, the clinician must determine to what extent this is caused by biofilm accumulation or the presence of residual calculus and to what degree further root planing is necessary.

Instrument Sharpening

It is impossible to carry out periodontal procedures efficiently with dull instruments. A sharp instrument cuts more precisely and quickly than a dull instrument. To do its job at all, a dull instrument must be held more firmly and pressed harder than a sharp instrument. This reduces tactile sensitivity and increases the possibility that the instrument will inadvertently slip. *Therefore, to avoid wasting time and operating haphazardly, clinicians must be thoroughly familiar with the principles of sharpening and able to apply them to produce a keen cutting edge on the instruments they are using.* Developing this skill requires patience and practice, but clinical

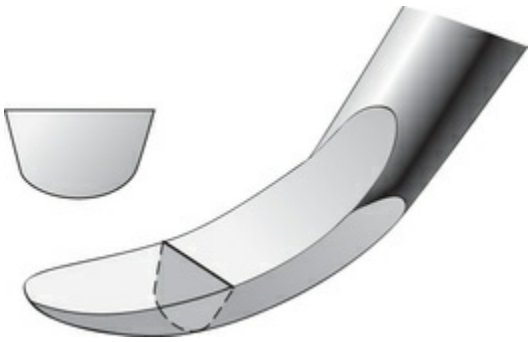
excellence cannot be attained without it.

Learning Box e50.54

It is impossible to carry out periodontal procedures efficiently with dull instruments.

Evaluation of Sharpness

The *cutting edge* of an instrument is formed by the angular junction of two surfaces of its blade. The cutting edges of a curette, for example, are formed where the face of the blade meets the lateral surfaces (eFig. 50.56).



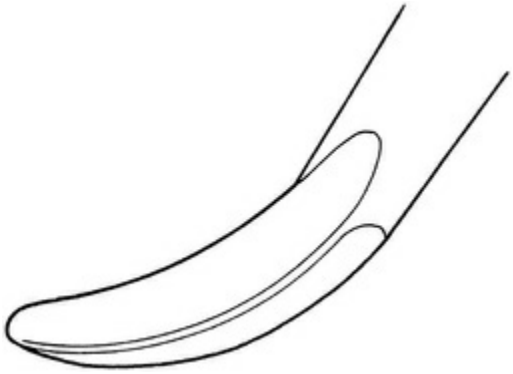
EFIG. 50.56 The cutting edge of a curette is formed by the angular junction of the face and the lateral surfaces of the instrument. When the instrument is sharp, the cutting edge is a fine line.

When the instrument is sharp, this junction is a fine line running the length of the cutting edge. As the instrument is used, metal is worn away at the cutting edge, and the junction of the face and lateral surface becomes rounded or dulled[6,89] (eFig. 50.57). Thus the cutting edge becomes a rounded surface rather than an acute angle, which is why a dull instrument cuts less efficiently and requires more pressure to do its job.[51]

EFIG. 50.57 The cutting edge of a dull curette is rounded.

Sharpness can be evaluated by sight and touch in one of the following ways:

1. When a dull instrument is held under a light, the rounded surface of its cutting edge reflects light back to the observer. It appears as a bright line running the length of the cutting edge (eFig. 50.58). The acutely angled cutting edge of a sharp instrument, conversely, has no surface area to reflect light. When a sharp instrument is held under a light, no bright line can be observed (see eFig. 50.56).
2. Tactile evaluation of sharpness is performed by drawing the instrument lightly across an acrylic rod known as a "sharpening test stick." A dull instrument will slide smoothly, without "biting" into the surface and raising a light shaving, as a sharp instrument would.[177]



EFIG. 50.58 Light reflected from the rounded cutting edge of a dull instrument appears as a bright line.

Objective of Sharpening

The objective of sharpening is to restore the fine, thin, linear cutting edge of the instrument. This is done by grinding the surfaces of the blade until their junction is once again sharply angular rather than rounded. For any given instrument, several sharpening techniques may produce this result. A technique is acceptable if it produces a

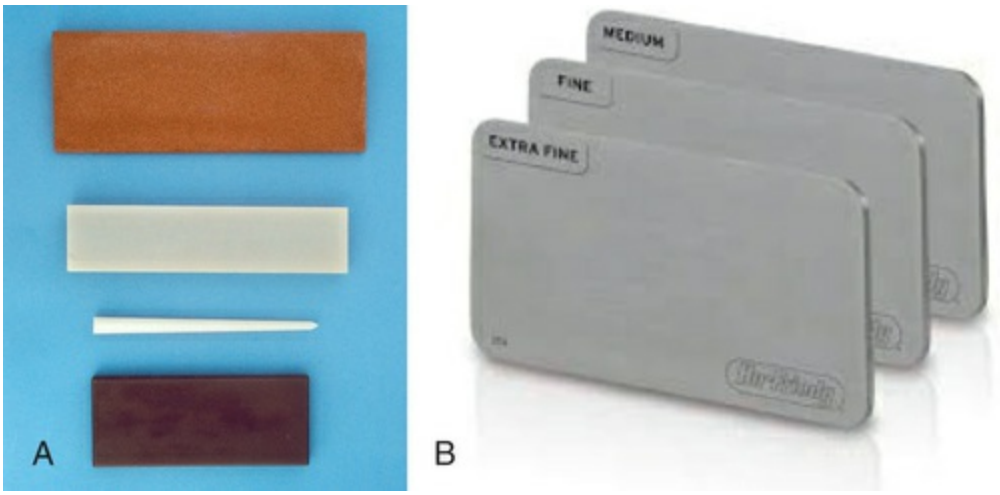
sharp cutting edge without unduly wearing down the instrument or altering its original design. To maintain the original design, the operator must understand the location and course of the cutting edges and the angles between the surfaces that form them. It is important to restore the cutting edge without distorting the original angles of the instrument. When these angles have been altered, the instrument does not function as it was designed to function, and this limits its effectiveness.

Learning Box e50.55

The objective of sharpening is to restore the fine, thin, linear cutting edge of the instrument without distorting its original angles.

Sharpening Stones

Sharpening stones may be quarried from natural mineral deposits or produced artificially. In either case, the surface of the stone is made up of abrasive crystals that are harder than the metal of the instrument to be sharpened. Coarse stones have larger particles and cut more rapidly; they are used on instruments that are dull. Finer stones with smaller crystals cut more slowly and are reserved for final sharpening to produce a finer edge and for sharpening instruments that are only slightly dull.[141,155] India and Arkansas oilstones are examples of natural abrasive stones. Carborundum, ruby, and ceramic stones are synthetically produced (eFig. 50.59).



EFIG. 50.59 (A) Sharpening stones. *Top* to *bottom,* A flat India stone, a flat Arkansas stone, a cone-shaped Arkansas stone, and a ceramic stone. (B) Diamond sharpening cards. Left to right: Extra fine grit, fine grit and medium grit one-sided diamond sharpening cards.
(Courtesy Hu-Friedy, Chicago, IL.)

Sharpening stones can also be categorized by their method of use.

Mounted Rotary Stones

These stones are mounted on a metal mandrel and used in a motor-driven handpiece. They may be cylindrical, conical, or disc shaped. These stones are generally not recommended for routine use because they (1) are difficult to control precisely and can ruin the shape of the instrument, (2) tend to wear down the instrument quickly, and (3) can generate considerable frictional heat, which may affect the temper of the instrument.

Unmounted Stones or Sharpening Cards

Unmounted stones come in a variety of sizes and shapes. Some are rectangular with flat or grooved surfaces, whereas others are cylindrical or cone shaped. Diamond sharpening cards are rectangular and similar in size and shape to a credit card. Unmounted stones or sharpening cards can be used in two ways: the instrument can be stabilized and held stationary while the stone or card is drawn across it, or the stone or card can be stabilized and held stationary while the instrument is drawn across it.

Diamond Sharpening Cards

The abrasive surface of the diamond sharpening card is made up of small, industrial-grade diamonds coated onto one or both sides of a stainless steel card. Three grits are available: extra fine, fine, and medium (eFig. 50.59B). The medium card has somewhat larger diamond crystals. These sharpen faster and are used to recondition instruments that are very dull. Fine-grit cards are used for routine sharpening, and extra fine is used to further refine an already sharp instrument. One advantage of diamond sharpening cards is that the surface does not wear away with use the way conventional stones do. The durable surface remains flat even after repeated use. Another advantage is that these cards do not require lubrication. They can be used dry or moistened with water. Oil is not required. Diamond sharpening cards can be cleaned in an ultrasonic instrument cleaner or scrubbed and rinsed with water to remove metal filings. They are sterilized in a steam autoclave between uses.

Principles of Sharpening

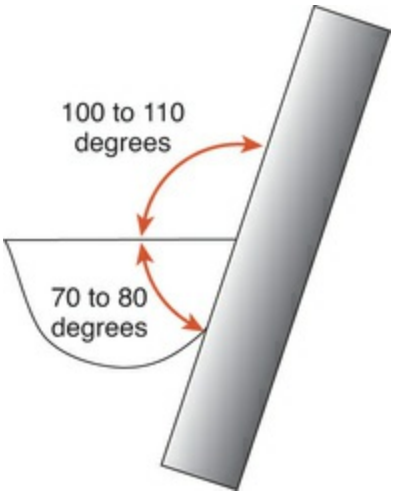
1. Choose a stone or sharpening card suitable for the instrument to be sharpened—one that has an appropriate shape and abrasiveness.
2. Use a sterilized sharpening stone or card if the instrument to be sharpened will not be resterilized before it is used on a patient.
3. Establish the proper angle between the sharpening stone or card and the surface of the instrument based on an understanding of its design.
4. Maintain a stable, firm grasp of both the instrument and the sharpening stone. This ensures that the proper angulation is maintained throughout the controlled sharpening stroke. In this manner, the entire surface of the instrument can be reduced evenly and the cutting edge is not improperly beveled.
5. Avoid excessive pressure. Heavy pressure causes the stone to grind the surface of the instrument more quickly and may shorten the instrument's life unnecessarily.

6. Avoid the formation of a "wire edge," characterized by minute filamentous projections of metal extending as a roughened ledge from the sharpened cutting edge.[6,52,121,177] When the instrument is used on root surfaces, these projections produce a grooved surface rather than a smooth surface. A wire edge is produced when the direction of the sharpening stroke is away from, rather than into or toward, the cutting edge.[6,121] When back-and-forth or up-and-down sharpening strokes are used, formation of a wire edge can be avoided by finishing with a down stroke toward the cutting edge.[88,89]
7. When using a stone, lubricate it during sharpening. This minimizes clogging of the abrasive surface of the stone with metal particles removed from the instrument.[52,121,177] It also reduces heat produced by friction. Oil should be used for natural stones and water for synthetic stones.
8. Sharpen instruments at the first sign of dullness. A grossly dull instrument is inefficient and requires more pressure when used, which hinders control. Furthermore, sharpening such an instrument requires removing a great deal of metal to produce a sharp cutting edge. This shortens the effective life of the instrument.

Sharpening Individual Instruments

Universal Curettes

Several techniques will produce a properly sharpened curette. Regardless of the technique used, the clinician must keep in mind that the angle between the face of the blade and the lateral surface of any curette is 70 to 80 degrees (eFig. 50.60). This is the most effective design for removing calculus and root planing (eFig. 50.61, *left*). Changing this angle distorts the design of the instrument and makes it less effective. A cutting edge of less than 70 degrees is quite sharp but also thin (eFig. 50.61, *center*). It wears down quickly and becomes dull. A cutting edge of 90 degrees or more requires heavy lateral pressure to remove deposits (eFig. 50.61, *right*). Calculus removal with such an instrument is often incomplete, and root planing cannot be done effectively.



EFIG. 50.60 When the sharpening stone forms a 100- to 110-degree angle with the face of the blade, the 70- to 80-degree angle between the face and the lateral surface is automatically preserved.

EFIG. 50.61 *Left,* Properly sharpened curette maintains a 70- to 80-degree angle between its face and lateral surface. *Center,* Curette has been sharpened so that one of its cutting edges is less than 70 degrees. This fine edge is quite sharp but dulls easily. *Right,* One of the cutting edges of the curette has been sharpened to 90 degrees. Heavy lateral pressure must be applied to the tooth to remove deposits with such an instrument.

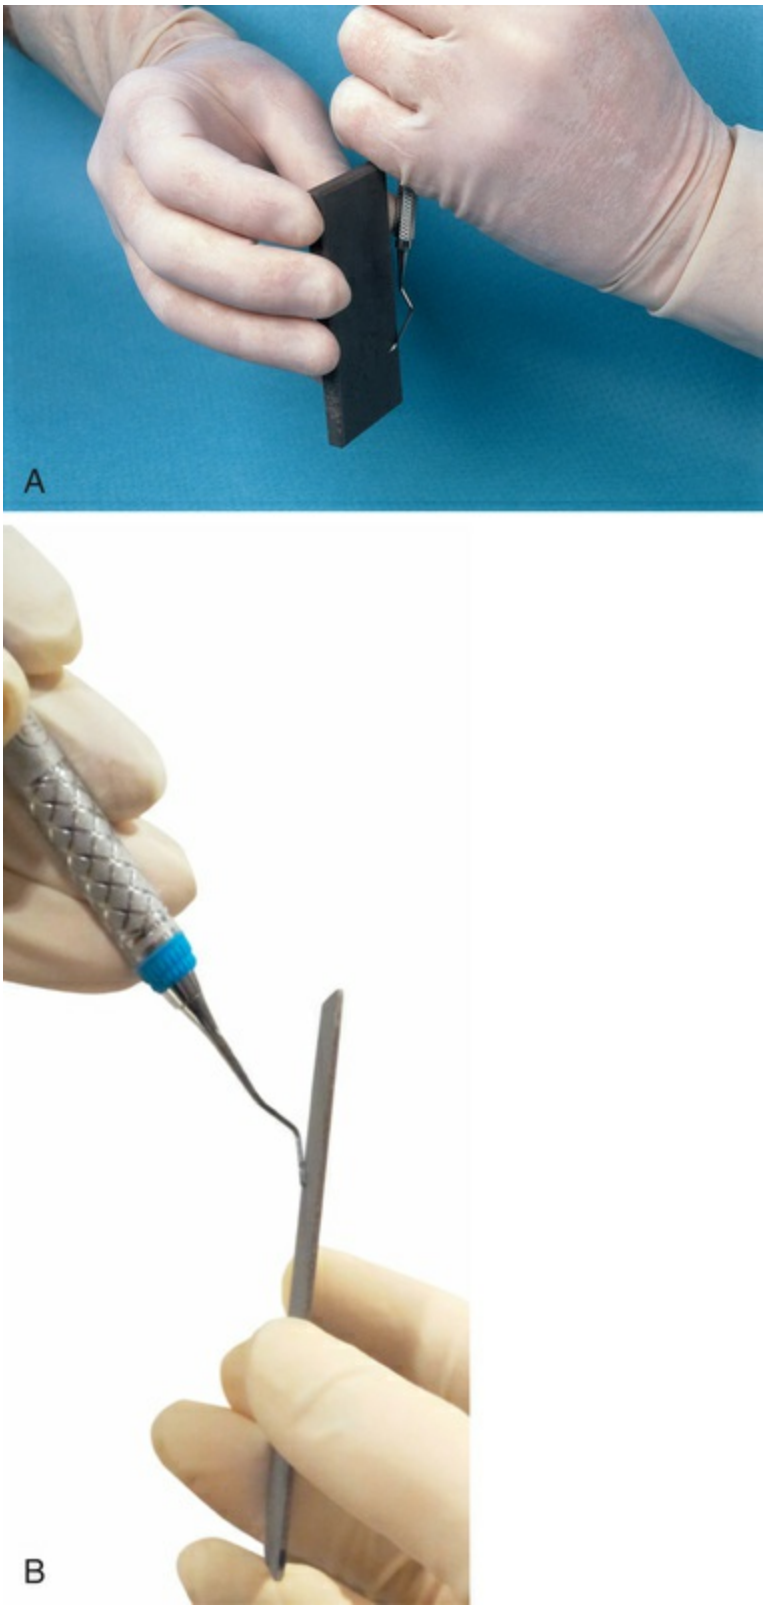
The following technique is recommended because it enables the clinician to visualize the critical 70- to 80-degree angle easily and thereby consistently restores an effective cutting edge:

Sharpening the Lateral Surface

When a flat, handheld stone or card is correctly applied to the lateral surface of a curette to maintain the 70- to 80-degree angle, the angle between the face of the blade and the surface of the stone will be 100 to 110 degrees (see eFig. 50.60). This can best be visualized by holding the curette so that the face of the blade is

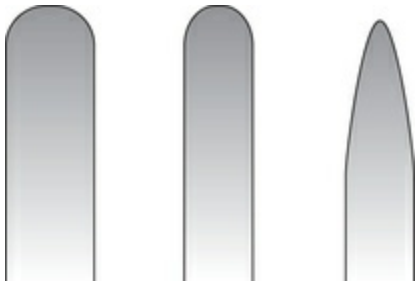
parallel with the floor. A palm grasp should be used and the upper arm braced against the body for support.

1. Apply the sharpening stone or card to the lateral surface of the curette so that the angle between the face of the blade and the stone is 100 to 110 degrees (eFig. 50.62; see also eFig. 50.60).
2. Beginning at the shank end of the cutting edge and working toward the toe, activate the stone with short up-and-down strokes. Use consistent, light pressure and keep the stone or card continuously in contact with the blade. Make sure that the 100- to 110-degree angle is constantly maintained (see eFig. 50.62).
3. Check for sharpness as previously described, and continue sharpening as necessary. To prevent the toe of the curette from becoming pointed, sharpen the entire blade from shank end to toe. When approaching the toe, be sure to sharpen around it to preserve its rounded form (eFig. 50.63).
4. As the stone or card is moved along the cutting edge, finish each section with a down stroke into or toward the cutting edge; this will minimize formation of a wire edge. Check the cutting edge under a light.
5. Sharpening the curette in this manner tends to flatten the lateral surface. This can be corrected by lightly grinding the lateral surface and the back of the instrument, away from the cutting edge, each time the instrument is sharpened.
6. When one edge has been properly sharpened, the opposite cutting edge can be sharpened in the same manner.



EFIG. 50.62 Using a palm grasp, the operator holds the universal curette so that the face of the blade is parallel to the floor. The stone makes a 100- to 110-degree angle with the face of the blade. (B) Sharpening the universal curette with a diamond sharpening card: Hold the curette so that the face of

the blade is parallel to the floor. The sharpening card makes a 100- to 110 degree angle with the face of the blade. (Courtesy Hu-Friedy, Chicago, IL.)



EFIG. 50.63 *Left,* New, unsharpened curette viewed from directly above the face of the blade. *Center,* Curette has been correctly sharpened to maintain the rounded toe. *Right,* Curette has been incorrectly sharpened, producing a pointed toe.

Sharpening the Face of the Blade

This may be done by moving a handheld cylindrical or cone-shaped stone back and forth across the face of the blade. A similar stone mounted in a handpiece may also be used by applying it to the face of the blade with the stone rotating toward the toe. These methods are not recommended for routine use for the following reasons:

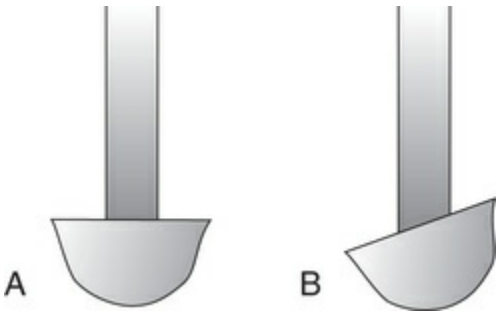
1. The angulation between the instrument and the stone is difficult to maintain, and therefore the blade may be improperly beveled[6] (eFig. 50.64, *left*).
2. Sharpening the face of the blade narrows the working end from face to back. This weakens the blade and makes it likely to bend or break while in use[6,89,121,148] (eFig. 50.64, *right*).
3. Sharpening the face of the blade with a handheld stone using a back-and-forth motion produces a wire edge that interferes with the sharpness of the blade.[6]

EFIG. 50.64 *Left,* Angulation is difficult to control when sharpening the face of the blade and often results in unwanted beveling. *Right,* Sharpening the face also weakens the blade by narrowing it from face to back.

Area-Specific (Gracey) Curettes

As with a universal curette, a Gracey curette has an angle of 70 to 80 degrees between the face and lateral surface of its blade. Therefore the technique described for sharpening a universal curette can be used to sharpen a Gracey curette. However, several unique design features that distinguish a Gracey from a universal curette must be understood to avoid distorting the design of the instrument while sharpening (see earlier discussion).

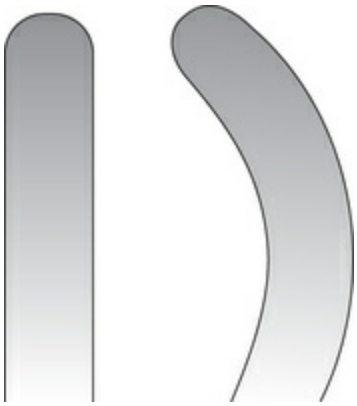
As previously noted, Gracey curettes have an offset blade; that is, the face of the blade is not 90 degrees (perpendicular) to the shank of the instrument, as it is on a universal curette, but is offset at a 70-degree angle (eFig. 50.65). Like a universal curette, the Gracey curette has two cutting edges, but only the lower cutting edge is used for scaling and root planing. Thus only this cutting edge needs to be sharpened.



EFIG. 50.65 (A) Face of a universal curette is at 90 degrees to its shank. (B) Face of a Gracey curette is offset, forming a 70-degree angle with its shank.

When viewing the face of a universal curette blade from directly above with the face of the blade positioned parallel to the floor, the cutting edges extend in straight lines from shank to toe. In contrast,

when the face of a Gracey curette is viewed from directly above with the face of the blade positioned parallel to the floor, the cutting edges emerge from their origin in the lower shank, where they form a gentle curve. This is most evident on posterior Gracey curettes such as the #13-14 and less evident on anterior Gracey curettes such as the #1-2. On all Gracey curettes, the working cutting edge becomes straight toward the middle and lower thirds of the blade, where it forms a straight line until it curves again around the toe of the instrument (eFig. 50.66).



EFIG. 50.66 Cutting edges of a universal curette extend straight from shank to toe. The cutting edges of a Gracey curette appear to curve gently from shank to toe. Only the larger, outer cutting edge on the right is used for scaling and needs to be sharpened.

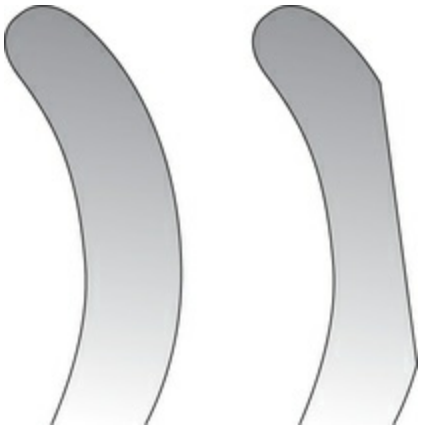
With these points in mind, a Gracey curette is sharpened in the following manner:

1. Hold the curette so that the face of the blade is parallel with the floor. Because the blade is offset, the shank of the instrument will not be perpendicular to the floor, as it is with universal curettes (eFig. 50.67).
2. Identify the edge to be sharpened. Remember that only one cutting edge is used, so only that edge must be sharpened (eFig. 50.68, *left*). Apply the stone or card to the lateral surface so that the angle between the face of the blade and the stone is 100 to 110 degrees.
3. Activate short up-and-down strokes, working from the

shank end of the blade to the curved toe. Finish with a down stroke.

4. Although the cutting edge is curved near the shank, the working portion of the middle and lower cutting edge is actually straight. Remember to preserve the original contour of the blade. If the stone is kept in one place for too many strokes, the blade will be flattened (eFig. 50.68, *right*).
5. Evaluate sharpness as previously described. Continue sharpening as necessary.

EFIG. 50.67 Note that when a Gracey curette is held in proper sharpening position, its shank is not perpendicular to the floor because of its offset blade angle. The stone meets the blade at an angle of 100 to 110 degrees. Compare this position with the sharpening position of a universal curette, as shown in eFig. 50.62.



EFIG. 50.68 Gracey curette on the *left* has been properly sharpened to maintain the original contour. For the curette on the *right,* the sharpening stone was activated too long in one place, thereby flattening the blade.

Extended-Shank, Mini-Bladed, and Periodontal Maintenance Gracey Curettes

Extended-shank Gracey curettes, such as After Five curettes, are sharpened in exactly the same manner as standard Gracey curettes. Although the terminal shank is 3 mm longer, the blade size and shape are very similar, and thus no difference exists in the sharpening technique.

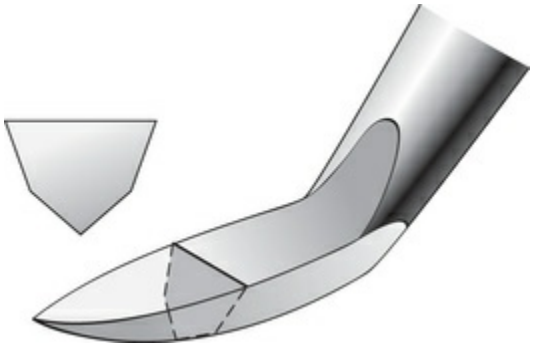
Mini-bladed Gracey curettes, such as Mini Five curettes, Micro Mini curettes, and Gracey Curvettes, are also sharpened with the same technique. These blades are only half the length of a standard Gracey blade, but the angle between the face of the blade and the lateral surface of the blade is still 70 to 80 degrees. Similarly, Periodontal Maintenance Gracey curettes have the same 70 to 80 degree angle between the face of the blade and the lateral surface, and are therefore sharpened with the same technique. They also have a shorter blade, being only three-fourths the length of a standard Gracey curette. With any of these modified Gracey curettes, sharpening too heavily or too often around the toe should be avoided to prevent excessive shortening of the blade.

Sickle Scalers

The two types of sickle scalers are the straight sickle and curved

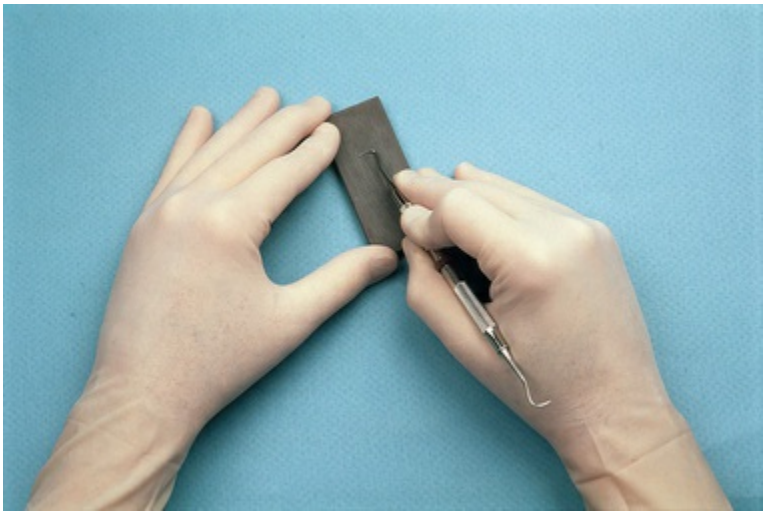
sickle. On a straight sickle the face of the blade is flat from shank to tip, whereas on a curved sickle the face of the blade forms a gentle curve (eFig. 50.69). However, straight and curved sickles have similar cross-sectional designs. As in the curette, the angle between the face of the blade and the lateral surface of a sickle is 70 to 80 degrees (eFig. 50.70). When a sharpening stone or card is correctly applied to the lateral surface to preserve this angle, the angle between the face of the blade and the surface of the stone or card is 100 to 110 degrees. With this in mind, the sickle scaler can be sharpened in a manner similar to that described for the curette, except that the sickle has a sharp pointed toe that must not be rounded.

EFIG. 50.69 Face of the blade on a straight sickle is flat from shank to tip *(left)*, whereas on the curved sickle the blade face forms a gentle arc *(right)*.



EFIG. 50.70 As with the curette, the sickle has an angle of 70 to 80 degrees between the face of the blade and the lateral surface.

A large flat stone may also be used to sharpen sickles (eFig. 50.71). The stone is stabilized on a table or cabinet with the left hand. The sickle is held in the right hand with a modified pen grasp and applied to the stone so that the angle between the face of the blade and the stone is 100 to 110 degrees. The fourth finger is placed on the right-hand edge of the stone to stabilize and guide the sharpening movement. The right hand then pushes and pulls the sickle across the surface of the stone.



EFIG. 50.71 A large flat stone may also be used to sharpen the sickle. The stone is stabilized on a flat surface. The fourth finger of the right hand guides the sharpening stroke as the instrument is pulled across the face of the stone toward the operator.

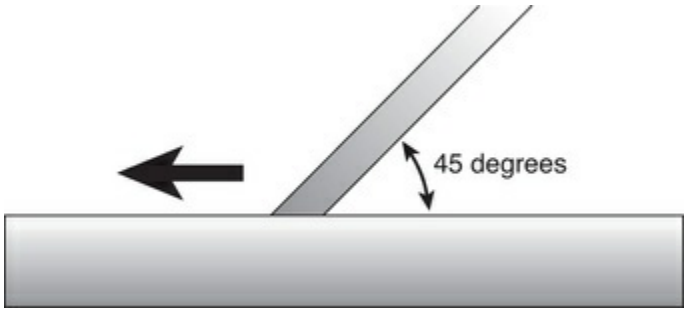
To avoid a wire edge, the operator finishes with a pull stroke, making sure that the proper angulation is always maintained

Chisels and Hoes

Chisels have a single straight cutting edge that is perpendicular to the shank. The face of the blade is continuous with the shank of the instrument, which may be directly in line with the handle or slightly curved. The end of the blade is beveled at 45 degrees to form the cutting edge.

To sharpen a chisel, stabilize a flat sharpening stone on a flat surface. Grasp the instrument with a modified pen grasp. Establish a finger rest with the pads of the third and fourth fingers against

the straight edge of the sharpening stone. Apply the flat beveled surface of the chisel to the surface of the stone. If the entire surface of the bevel is contacting the stone, the 45-degree angle between the beveled surface and the face of the blade will be maintained, and the design of the instrument will not be altered (eFigs. 50.72 and 50.73).



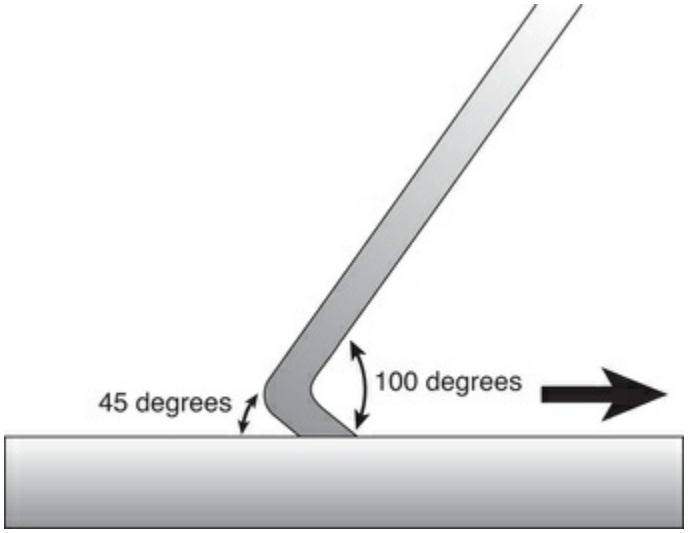
EFIG. 50.72 When the entire bevel on a chisel contacts the sharpening stone, the angle between the instrument and the stone is 45 degrees. The cutting edge will be properly sharpened if this angle is maintained as the instrument is pushed across the stone.

EFIG. 50.73 A chisel also can be sharpened on a stationary flat sharpening stone.

Using moderate, steady pressure, with the hand and arm acting as a unit and the finger resting on the edge of the stone as a guide,

push the instrument across the surface of the sharpening stone. Release pressure slightly, and draw the instrument back to its starting point. Repeat the sharpening stroke until a sharp edge has been obtained. Remember to finish with a push stroke to prevent the formation of a wire edge. Check for sharpness as previously described. Examine the instrument carefully to be sure that its design has not been inadvertently altered.

Back-action surgical chisels and hoe scalers are sharpened with exactly the same technique described for chisels, except that a pull stroke is used rather than a push stroke (eFig. 50.74).



EFIG. 50.74 Back-action chisels and hoes are sharpened with a pull stroke.

Periodontal Knives

Two general types of periodontal knives are available. The first type includes disposable scalpel blades that come prepackaged and are presharpened and sterilized by the manufacturer. These knives are not resharpened when they become dull but are discarded and replaced.

The second type of periodontal knife is reusable and must be sharpened when it becomes dull. The most common knives in this group are the flat-bladed gingivectomy knives (e.g., Kirkland knives #15K and #16K) and the narrow, pointed interproximal knives.

Flat-Bladed Gingivectomy Knives

These knives have broad, flat blades that are nearly perpendicular to the lower shank of the instrument. The curved cutting edge extends around the entire outer edge of the blade and is formed by bevels on both the front and back surface of the blade (eFig. 50.75).

EFIG. 50.75 Flat-bladed gingivectomy knives, such as this Kirkland knife, have a cutting edge that extends around the entire blade. The entire cutting edge must be sharpened.

When sharpening these instruments, only the bevel on the back surface of the instrument needs to be ground. This can be done by drawing the blade across a stationary, flat sharpening stone or by holding the instrument stationary and drawing the stone across its blade.

Interproximal Knives

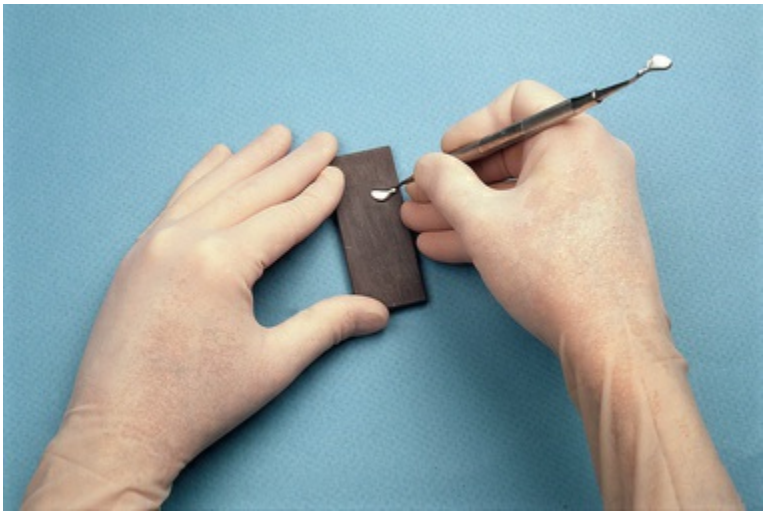
The blades of interproximal knives have two long, straight cutting edges that come together at the sharply pointed tip of the instrument. The cutting edges are formed by bevels on the front and back surfaces of the blade. The entire blade is roughly perpendicular to the lower shank of the instrument (eFig. 50.76).

EFIG. 50.76 The two cutting edges of an interproximal knife are formed by bevels on the front and back surfaces of the blade.

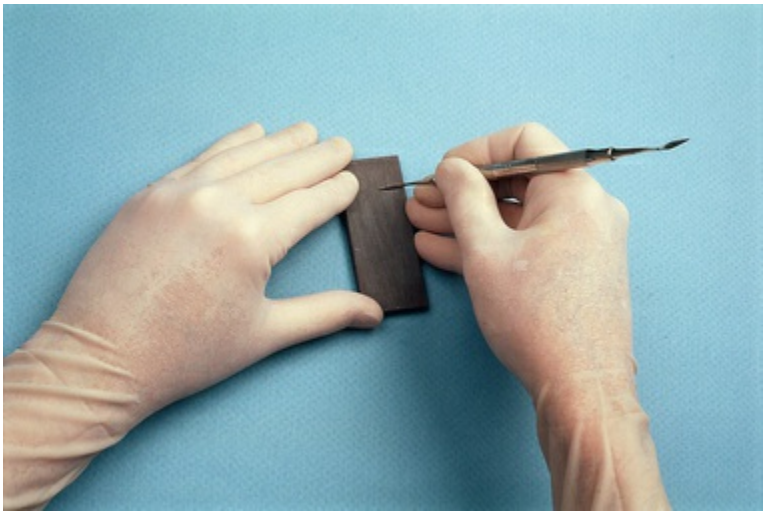
As with flat-bladed gingivectomy knives, only the bevels on the back surface of interproximal knives need to be sharpened. Again, this can be accomplished by drawing the instrument across a stationary stone or by holding the instrument stationary and moving the stone across it.

Stationary Stone Technique

Stabilize a flat sharpening stone on a flat surface. Grasp the handle of the instrument with a modified pen grasp, and apply the bevel on the back surface of the blade to the flat surface of the sharpening stone. With moderate pressure, pull the instrument toward you (eFigs. 50.77 and 50.78). Release pressure slightly, and return to the starting point. Begin at one end of the cutting edge and continue around the blade by rolling the handle of the instrument slightly between the thumb and the first and second fingers. Finish each section of the blade with a pull stroke to prevent formation of a wire edge. Check for sharpness as described previously.



EFIG. 50.77 A gingivectomy knife may be sharpened on a stationary flat stone. The instrument is held with a modified pen grasp. The fourth finger guides the sharpening stroke as the instrument is rolled between the fingers so that all sections of the blade are sharpened.



EFIG. 50.78 An interproximal knife may be sharpened on a flat stationary stone. The blade is drawn toward the operator.

Stationary Instrument Technique

Grasp the instrument with the palm. Apply the flat surface of a handheld sharpening stone to the bevel on the back surface of the blade (eFig. 50.79). Begin at one end of the cutting edge, and with

moderate pressure, draw the stone back and forth across the instrument. To prevent the formation of a wire edge, finish each section with a stroke into or toward the cutting edge. Proceed around the entire length of the cutting edge by gradually rotating the instrument and the stone in relation to one another.

EFIG. 50.79 An interproximal knife may also be sharpened with a handheld stone. The instrument is held with a palm grasp, and the stone is applied to the entire cutting edge.

Case Scenario 50.1

The patient is a 55-year-old mechanical engineer with diabetes who was diagnosed 5 years ago after his dentist noticed severe periodontitis with multiple abscesses, which were treated at that time. He takes 20 units of insulin every morning and is also taking glyburide, atorvastatin (Lipitor), and losartan. He is overweight, has hypertension, and reports that his blood sugar is sometimes over 200 even with medication. His chief complaint today is pain in tooth #5 and discomfort on chewing with tooth #18. Several molars have furcation invasions with severe bone loss, suppuration, and bleeding on probing but no severe swelling on the buccal or lingual gingiva. He has not had any periodontal treatment since he underwent scaling 5 years ago and wants a "recall" scaling. You

find that he has poor oral hygiene, generalized severe periodontitis, probing depths of 4 to 9 mm, and moderate to heavy calculus throughout the mouth.

CASE-BASED QUESTIONS	SOLUTIONS
1. The best instruments to adapt to the furcations and tight, deep pockets on this patient are: A. Rigid Gracey curettes B. Langer curettes C. Gracey Curvette Sub-0 curettes D. Mini-bladed or micro mini-bladed Gracey curettes	**Answer: D** **Explanation:** All furcations, whether Class I, II, III, or IV, are best scaled with Mini or MicroMini bladed Gracey curettes because they adapt to the contours of the roots better than any other hand instruments.
2. The Gracey Curvette Sub-0 was described as being the most effective instrument for deep pockets on which of the following? A. Maxillary or mandibular anterior teeth B. Maxillary molar furcations C. Molar line angles D. Maxillary premolars	**Answer: A** **Explanation:** The Gracey Curvette Sub-0 has a straight shank and a very short curved blade that is designed for the narrow root surfaces of the maxillary and mandibular anterior teeth.
3. On this patient, which of the following curettes would be the most effective for scaling a thin sheet of tenacious calculus in the 6-mm pocket on the palatal surface of the maxillary	**Answer: D** **Explanation:** All three of the mini-bladed Gracey curette designs listed in Answer D are better choices for scaling tenacious calculus on a deep palatal root surface with tight tissue than the others. All the other choices include standard Gracey curettes, which would be too large for

right central incisor (#8), which has very firm, tight tissue? A. Gracey #7-8, Gracey #13-14 B. Gracey #11-12, Gracey #5-6, Gracey #7-8 C. Gracey #13-14, Mini Five #13-14, Micro Mini #13-14 D. Gracey Curvette Sub-0, Mini Five #5-6, or Micro Mini #1-2	use on this palatal surface.
4. In which of the following areas would you select an extraoral fulcrum for use with Gracey curettes? A. Labial of maxillary anteriors with tight tissue B. Lingual of mandibular anteriors with heavy calculus C. Buccal of mandibular molars with furcations D. Mesial of maxillary molars with deep pockets	**Answer: D** **Explanation:** An extraoral fulcrum would work best for the mesial surfaces of the maxillary molars. Intraoral fulcrums would work best for the areas described in A, B, and C, and these areas should be scaled with mini-bladed Gracey curettes.
5. To remove a heavy ledge of interproximal calculus most effectively, it is best to begin by engaging the edge of the ledge with the: A. Upper one-third of the cutting edge B. Middle one-third of the cutting edge C. Lower one-third of the cutting edge D. Entire length of the cutting edge	**Answer: C** **Explanation:** Always engage the edge of any ledge of calculus with the lower one-third of the cutting edge to efficiently fracture the calculus away from the tooth. All other choices would most likely shave away at the calculus, resulting in incomplete removal or burnishing of the ledge.
6. The working stroke for removing a heavy ledge of interproximal calculus should be: A. Short, vertical with firm pressure B. Short, horizontal with moderate pressure C. Long, vertical with light pressure D. Long, oblique with firm pressure	**Answer: A** **Explanation:** Short and controlled vertical strokes that engage the interproximal calculus ledge with firm pressure are the most effective. Strokes should be 1-3 mm long and advance only 1 mm at a time in a series of overlapping strokes to remove the ledge completely.
7. Final root planing strokes to achieve a smooth surface should be: A. Short with light pressure B. Short with firm pressure	**Answer: C** **Explanation:** Long strokes with moderate to light pressure are best for finishing root planing strokes. Short overlapping strokes are for calculus or biofilm removal. Long strokes with firm pressure can result in overinstrumentation of the root surface, removing too

C. Long with moderate to light pressure D. Long with firm pressure	much cementum or dentin, or trauma to the soft tissue; they can also cause root hypersensitivity.
8. The maximum width of the active stroke of any hand instrument when it is properly adapted to the tooth or root surface is: A. 1 to 2 mm B. 2 to 4 mm C. 4 to 6 mm D. 6 to 8 mm	**Answer: A** **Explanation:** Only 1-2 mm of any hand instrument or ultrasonic tip will adapt to the tooth during any stroke because of the curvature of the tooth or root surface. This is true regardless of the design of the instrument or the length of the blade. It is the anatomy of the tooth that dictates the very narrow width of each stroke.
9. The maximum width of the active stroke of any ultrasonic tip when it is properly adapted to the tooth or root surface is: A. 1 to 2 mm B. 2 to 4 mm C. 4 to 6 mm D. 6 to 8 mm	**Answer: A** **Explanation:** Only 1-2 mm of any ultrasonic tip or hand instrument will adapt to the tooth during any stroke because of the curvature of the tooth or root surface. This is true regardless of the design or length of the ultrasonic tip. It is the anatomy of the tooth that dictates the very narrow width of each stroke.
10. When reevaluating the results of scaling and root planing after 4 weeks, the best indication of success is: A. Reduction of pocket depth B. Lack of bleeding on probing C. Root smoothness D. Absence of plaque	**Answer: B** **Explanation:** Lack of bleeding on probing is the most reliable indication of success after scaling and root planing. Presence of bleeding on probing is almost always a sign that residual subgingival calculus remains on the root surface, especially in areas of pocket depth. Reduction of pocket depth, root smoothness, and absence of plaque can be positive outcomes, but they are not significant if bleeding on probing persists.

CHAPTER 51

Sonic and Ultrasonic Instrumentation and Irrigation

Carol A. Jahn

CHAPTER OUTLINE

Power-Driven Instruments: Overview
Mechanism of Action of Power Scalers
Type and Benefit of Power Instruments
Clinical Outcomes of Power-Driven Instruments
Principles of Instrumentation
Home and Self-Applied Irrigation
Mechanism of Action of Irrigation
Clinical Outcomes of Irrigation
Individuals With Special Considerations
Action of a Tip With Filaments Cleaning Around an Implant
Conclusion

Scaling and root planing are considered the initial nonsurgical treatments of choice for chronic periodontitis.[60] Practitioners often try to enhance and prolong the outcomes from scaling and root planing. In the office setting, technologic advances and new designs of ultrasonic and sonic power scalers have transformed the role of power-driven oscillating instruments in periodontal therapy. At home, the pulsating oral irrigator has been clinically proven to help patients maintain periodontal health by removing biofilm supragingivally and subgingivally and reducing inflammation.

Power-Driven Instruments: Overview

Power-driven instruments are everyday mainstays in periodontal therapy and maintenance. They may be used alone or combination with hand instruments. Evidence indicates that power-driven instruments provide clinical outcomes similar to those derived from hand instruments.[49,50,64,68] Power instrumentation has the potential to make scaling less demanding and more time efficient.[11,64] Potential hazards from using power-driven devices include rough root surfaces, production of bioaerosols, and interference with cardiac pacemakers.[40,63]

Clinical Correlation

Power instruments are useful tools that can be used alone or in combination with hand instruments. Evidence indicates that power and hand instruments have similar clinical outcomes. Although power instruments can make scaling less demanding, thorough debridement takes time regardless of the type of instrument used.

Mechanism of Action of Power Scalers

Various physical factors play a role in the mechanism of action of power scalers. These factors include frequency, stroke, and water flow. In addition to rate of flow, the physiologic effects of water

may contribute to the efficacy of power instruments.

Water contributes to three physiologic effects that play a role in the efficacy. These are acoustic streaming, acoustic turbulence, and cavitation. Acoustic steaming is unidirectional fluid flow caused by ultrasound waves. Acoustic turbulence is created when the movement of the tip causes the coolant to accelerate, producing an intensified swirling effect. This turbulence continues until cavitation occurs. Cavitation is the formation of bubbles in water caused by the high turbulence. The bubbles implode and produce shock waves in the liquid, thus creating further shock waves throughout the water.[40,66] In vitro, the combination of acoustic streaming, acoustic turbulence, and cavitation has been shown to disrupt biofilm.[36,67]

Type and Benefit of Power Instruments

Sonic units work at a frequency of 2000 to 6500 cycles per second and use a high- or low-speed air source from the dental unit. Water is delivered via the same tubing used to deliver water to a dental handpiece. Sonic scaler tips are large in diameter and universal in design. A sonic scaler tip travels in an elliptical or orbital stroke pattern. This stroke pattern allows the instrument to be adapted to all tooth surfaces. Box 51.1 outlines the advantages and disadvantages of mechanized instruments compared with manual instruments.

Box 51.1

Advantages and Disadvantages of Mechanized Instruments Compared With Manual Instruments

Advantages

Increased efficiency

Multiple surfaces of tip are capable of removing deposits
No need to sharpen
Less chance for repetitive stress injuries
Large handpiece size
Reduced lateral pressure
Less tissue distention
Water
Lavage
Irrigation
Acoustic microstreaming

Disadvantages

More precautions and limitations
Client comfort (water spraying)
Aerosol production
Temporary hearing shifts
Noise
Less tactile sensation
Reduced visibility

From Darby ML, Walsh MM: *Dental hygiene,* ed 3, St. Louis, 2010, Saunders.

Magnetostrictive ultrasonic devices work in a frequency range of 18,000 to 50,000 cycles per second (Figs. 51.1 and 51.2). Metal stacks that change dimension when electrical energy is applied power the magnetostrictive technology. Vibrations travel from the metal stack to a connecting body that causes the vibration of the working tip. Tips move in an elliptical or orbital stroke pattern. This gives the tip four active working surfaces (Fig. 51.3).

FIG. 51.1 **Magnetostrictive ultrasonic device.** (Courtesy Dentsply Sirona, York, PA.)

FIG. 51.2 **A magnetostrictive ultrasonic device.** (Courtesy Hu-Friedy, Chicago, IL.)

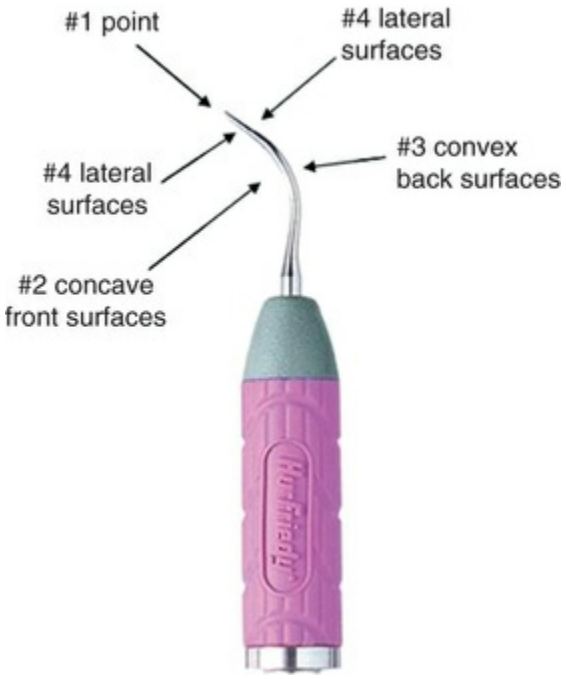

FIG. 51.3 Working sides of a magnetostrictive tip. (Courtesy Hu-Friedy, Chicago, IL.)

Piezoelectric ultrasonic units work in a frequency range of 18,000 to 50,000 cycles per second (Fig. 51.4). Ceramic disks located in the handpiece power the piezoelectric technology and change in dimension as electric energy is applied. Piezoelectric tips move primarily in a linear pattern, giving the tip two active surfaces (Fig. 51.5). Various insert tip designs and shapes are available for use.

FIG. 51.4 **A piezoelectric ultrasonic device.** (Courtesy Hu-Friedy, Chicago, IL.)

FIG. 51.5 **Working sides of a piezoelectric tip.** (Courtesy Hu-Friedy, Chicago, IL.)

Efficiency

Modified tip designs allow for improved access in many areas, including furcations. Newer, slimmer designs operate effectively at lower power settings, thus improving patients' comfort. Flat-edged tips (rectangular in cross section) or bladed designs seem to engage deposits and remove them more efficiently than conical (in cross section) tips.

Tip Designs

Some tips are designed to remove heavy supragingival calculus or debride periodontal pockets definitively. Large-diameter tips are created with a universal design and are indicated for the removal of large, tenacious deposits. A medium to medium-high power setting is generally recommended. Thinner-diameter tips may be site specific in design. The straight-tip design is ideal for use in treating patients with gingivitis and deplaquing maintenance patients[51] (Fig. 51.6). The right and left contra-angled instruments allow for greater access and adaptation to root morphology. These inserts are designed to work on a low-power setting. A deactivated tip can be used for exploration. The amount of water delivered for lavage can be controlled through the selection of either traditional flow or focused-tip delivery flow. Contra-angled designs and larger ergonomic grips enhance comfort and ergonomics (Figs. 51.7 and 51.8).

FIG. 51.8 **Site-specific designed insert.** (Courtesy Dentsply Sirona, York, PA.)

Clinical Outcomes of Power-Driven Instruments

Numerous clinical outcomes have been evaluated from the use of power-driven instruments. Reviews of the literature have found the effectiveness of subgingival debridement using ultrasonic or sonic scalers to be similar to that achieved with hand instruments.[2,50,64,68]

It is well established that power-driven instruments remove

bacterial biofilm and calculus through mechanical action.[26,32,39,58,62] With the advent of newer designs and thinner tips, deplaquing of root surfaces may be effectively accomplished by power scalers.[51] Power-driven instruments have been shown to be effective in removing calculus, similar to hand instrumentation.[39,58] Ultrasonic instruments, through high-speed action, produce cavitational activity and acoustic microstreaming that some believe may help enhance the disruption of bacteria in subgingival biofilm.

Key Fact

Power-driven instruments are not just for heavy calculus removal. Depending on tip design and size, they are beneficial for supragingival calculus removal, subgingival debridement, and general deplaquing.

The primary expected clinical outcomes from scaling and root planing are reductions in bleeding and probing depth and a gain in clinical attachment.[60] Comparing power scalers with hand instruments, both types demonstrate similar outcomes for reductions in bleeding on probing and probing depth and gains in clinical attachment.[16,43,49] Because the opening of a furcation is narrower than with conventional hand instruments, power scalers may be recommended as a means to improve access when scaling this type of defect.[3]

Special Considerations

Power-driven instruments must be used with some caution. Roots may be rougher post scaling than with hand instruments. Due to aerosol production, proper infection control procedures need to be implemented. Power-driven instruments may be contraindicated for people with pacemakers.

Root Surface Roughness

The data are mixed on whether power-driven instruments cause more root surface roughness than hand instruments.[38,40,41,59]

Although it could be assumed that using the device at a higher power may cause more roughness, this is not been proven.[39] It is also not known how much root surface roughness affects the healing process.[40] Power-driven instruments may increase the roughness of resin or glass ionomer restorative materials; therefore, repolishing post scaling is recommended.[20]

Aerosol Production

Power-driven devices produce bioaerosols and splatter, which can contaminate the operator and remain in the air for up to 30 minutes.[65] Good infection control practices can minimize the hazard. Data have shown that preprocedural rinsing with 0.12% chlorhexidine and high-speed evacuation are the most efficient ways to reduce bioaerosols.[46]

Key Fact

Bioaerosols from power-driven devices can remain in the air for up to 30 minutes. If the operator's face mask becomes damp during the procedure, it should be changed. A face shield may be required. To help minimize bioaerosols, preprocedural rinsing and high-speed evacuation have been shown to be effective.

Cardiac Pacemakers

The use of ultrasonics on patients with cardiac pacemakers is somewhat controversial.[63] Newer models of pacemakers often have bipolar titanium insulation that is believed to make ultrasonic and sonic instruments generally safe for use. An in vivo study supports this; 12 patients underwent continuous electrocardiogram monitoring during piezoelectric ultrasonic scaling and had no abnormal pacemaker functions.[45] Conversely, an in vitro study found that ultrasonic scalers interfered with the activity of dual-system pacemakers.[52] If in doubt, consult with the physician regarding any precautions or warnings from the manufacturer of the product. Box 51.2 outlines the indications, precautions, and contraindications of using mechanized instrumentation.

Box 51.2

Indications, Precautions, and Contraindications for Use of Mechanized Instruments

Indications

- Supragingival debridement of dental calculus and extrinsic stains
- Subgingival debridement of calculus, oral biofilm, root surface constituents, and periodontal pathogens
- Removal of orthodontic cement
- Gingival and periodontal conditions and diseases
- Surgical interventions
- Margination (reduces amalgam overhangs)

Precautions

- Unshielded pacemakers
- Infectious diseases: human immunodeficiency virus, hepatitis, tuberculosis (active stages)
- Demineralized tooth surface
- Exposed dentin (especially associated with sensitivity)
- Restorative materials (porcelain, amalgam, gold, composite)
- Titanium implant abutments unless using special insert (e.g., Quixonic SofTip Prophy Tips)
- Children (primary teeth)
- Immunosuppression from disease or chemotherapy
- Uncontrolled diabetes mellitus

Contraindications

- Chronic pulmonary disease: asthma, emphysema, cystic

fibrosis, pneumonia
- Cardiovascular disease with secondary pulmonary disease
- Swallowing difficulty (dysphagia)

From Darby ML, Walsh MM: *Dental hygiene,* ed 3, St. Louis, 2010, Saunders.

Principles of Instrumentation

Ultrasonic technique is different from instrumentation with hand scalers. A pen grasp is used with an ultrasonic scaler, along with an extraoral fulcrum (Fig. 51.9). The purpose of the extraoral fulcrum is to allow the operator to maintain a light grasp and have easier access physically and visually to the oral cavity. Alternate cross-arch or opposite-arch fulcrums are acceptable alternatives.

FIG. 51.9 **Pen grasp of tip.** (Courtesy Hu-Friedy, Chicago, IL.)

Clinical Correlation

Instrumentation with the ultrasonic device is different from hand instrumentation. A pen grasp with light pressure is preferred, as is using an extraoral fulcrum. Deposits are removed coronally to apically. For deposits in the embrasure area, a horizontal or transverse stroke is recommended.

Light pressure is needed with a power instrument. The tip is traveling at a set frequency in a set stroke pattern. Increased clinician pressure on the tip causes decreased clinical efficacy.

Sonic or ultrasonic instrumentation requires removal from the coronal to the apical portion of the deposit. This stroke pattern allows the insert to work at its optimal stroke pattern and frequency for quick, effective deposit removal. For coronal deposits located in the embrasure area, a horizontal or transverse tip orientation is recommended. A deplaquing stroke should be used when the focus is removal of biofilm and soft debris for the resolution of gingival inflammation. This stroke entails accessing every square millimeter of the tooth surface during ultrasonic deplaquing as a result of the limited lateral dispersion of the lavage subgingivally (Videos 51.1 and 51.2).

Home and Self-Applied Irrigation

The oral irrigator (also called a dental water jet or water flosser) was introduced in 1962. Contrary to myth and misunderstanding, the body of evidence on this device has consistently shown that it safely and effectively improves periodontal health.[33,35] Emerging evidence indicates that the oral irrigator effectively removes biofilm[28,29] and is as effective as dental floss when added to toothbrushing.[4,44,54,57]

« Flash Back

The oral irrigator has had many different names throughout the years. It has been referred to as a water jet or dental water jet. Today, the more common name is water flosser. The term is supported by clinical evidence and has been shown to be useful in helping patients understand the benefit of the device.

Mechanism of Action of Irrigation

The mechanism of action of irrigation is through pulsation and pressure.[5,7,55] Pulsation creates a decompression phase that allows

the water or solution to penetrate subgingivally. It is followed by a compression phase that expels bacteria and debris from the pocket (Fig. 51.10). Physiologically, pulsation, along with pressure and water velocity, creates shear hydraulic forces that are capable of removing bacterial biofilm from treated areas.[28] Clinical efficacy of home irrigation has been found for units that pulsate from 1200 to 1400 pulses per minute set at a minimum of 60 psi.[33] The oral irrigator is safe to use at higher pressure settings.[5,7,55] Many types of oral irrigators are commercially available, but as with other self-care products, research available from one product brand should not be extrapolated to other brands, because they may have used different pressure settings and pulsation rates (Figs. 51.11 and 51.12).

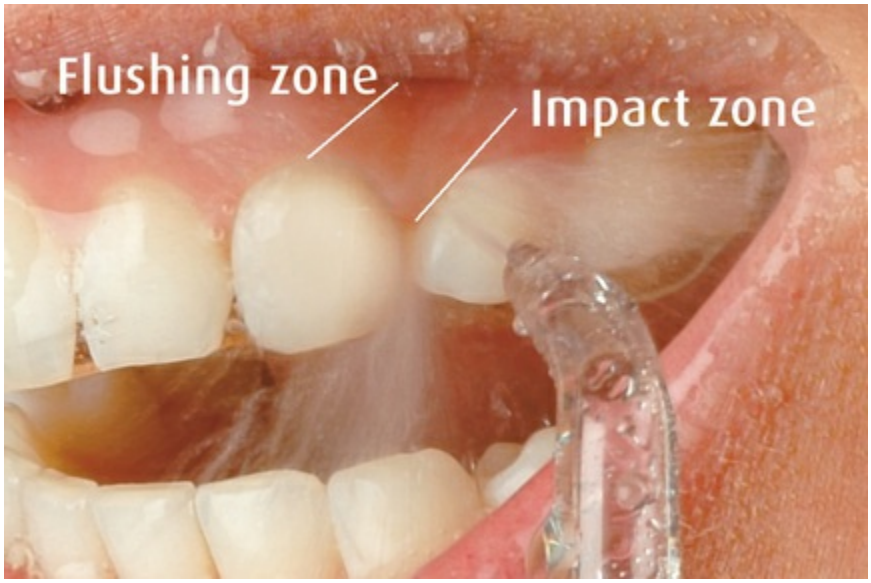

FIG. 51.10 Pulsation creates two zones of hydrokinetic activity: the impact zone and the flushing zone. (Courtesy Water Pik, Inc., Fort Collins, CO.)

FIG. 51.11 **A dental water jet with 1200 ppm and a pressure setting that ranges from 20 to 90 psi.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

FIG. 51.12 **A cordless dental water jet, which also has 1200 ppm.**
(Courtesy Water Pik, Inc., Fort Collins, CO.)

Key Fact

Pulsation and pressure create a compression-decompression phase that allows for both penetration of the agent into the sulcus or pocket and expelling of bacteria and debris. Unlike simple rinsing, pulsation, pressure, and water velocity create shear hydraulic forces capable of removing biofilm.

A variety of tips can be used with an oral irrigator. One type of tip is placed supragingivally at a 90-degree angle, and the other is placed slightly subgingivally. Tips placed above the gingival margin result in a pocket penetration of 50% on average[19] (Fig. 51.13). The soft, site-specific subgingival tip (Pik Pocket subgingival irrigation tip, Water Pik, Inc., Fort Collins, CO) (Fig. 51.14) penetrates to about 90% of the depth of pockets that are 6 mm or less and 64% of pockets that are 7 mm or greater[8] (Videos 51.3 and 51.4).

FIG. 51.13 **Jet tip.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

FIG. 51.14 **Site-specific tip.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

Tips that are placed supragingivally are recommended for full-mouth irrigation or cleansing. These tips include a traditional jet tip along with jet tips of this configuration that have been enhanced with bristles or filaments to assist in biofilm removal[54,57] (Figs. 51.15 and 51.16). The subgingival tip is generally used after full-mouth

cleaning for localized irrigation of a specific site that is difficult to access, such as a deep pocket, a furcation, an implant, or a crown and bridge (Fig. 51.17).

FIG. 51.15 **Tip with soft tapered bristles.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

FIG. 51.16 **Tip with soft filaments.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

FIG. 51.17 **The Pik Pocket tip is gently placed slightly subgingivally.**
(Courtesy Water Pik, Inc., Fort Collins, CO.)

Safety

Oral irrigation is supported by a large body of scientific evidence and has been used by people since the 1960s.[35] Clinical studies on oral irrigation evaluate for adverse events, and none have been reported. Despite the scientific evidence, myths about trauma to soft tissue, penetration of bacteria into the pocket, increased pocket depth, and rates of bacteremia still exist.

Key Fact

Using an oral irrigation is both safe and effective. "Stories" about trauma to soft tissue, penetration of bacteria into the pocket, and increased pocket depth are not supported by clinical evidence. The device has been recommended by dental professionals and used by the general population since the 1960s.

Trauma to tissue and penetration of bacteria were evaluated in a study that used scanning electron microscopy to assess the differences between irrigated and nonirrigated untreated chronic periodontal pockets. Examination with scanning electron microscopy showed no observable differences between the irrigated and nonirrigated pocket tissue with regard to physical features and appearance of the epithelium. The investigators also found that irrigated pockets had significantly fewer bacteria up to 6 mm, compared with nonirrigated pockets.[15] These findings are supported by other investigations. Histologic studies have shown that irrigated tissue has less inflammation.[12,37] Researchers who have looked at the reduction of bacteria agree that irrigation reduces pathogens and that irrigation for a period of 3 to 6 months results in reduced periodontal bacteria.[13,23,48]

Probing pocket depth has been evaluated in several studies.[a] None have found that the use of an oral irrigator increases pocket depth. The findings consistently show small improvements in probing depth.[b]

One long-held assumption is that using an oral irrigator will

result in a higher incidence of bacteremia compared with flossing. However, the data show that the incidence of bacteremia can range from 7% in people with gingivitis[53] to 50% in those with periodontitis.[21] Other investigators have found similar results, with one study finding no incidence of bacteremia[61] post irrigation and another study noting a rate of 27%.[6] In comparison, the incidence of bacteremia from string flossing has been shown to be 40% in people with periodontitis and 41% in periodontally healthy individuals.[17]

Clinical Outcomes of Irrigation

Table 51.1 highlights the body of evidence on the oral irrigator. Evaluated outcomes include removal of plaque biofilm and reductions in calculus, gingivitis, bleeding on probing, probing depth, periodontal pathogens, and inflammatory mediators.[c] Home irrigation has been studied and found safe and effective for those with gingivitis,[d] implants,[22,44] crown and bridge,[37] orthodontics,[10,57] and diabetes,[1] as well as in periodontal maintenance.[18,23,24,27,35,47]

Emerging evidence indicates that using an oral irrigator can lead to oral health improvements over what has been traditionally seen with string floss.[4,29,44,54,57] When an oral irrigator was added to either manual or power toothbrushing and compared with manual brushing and flossing, subjects who added the oral irrigator, regardless of toothbrush type, had significantly better reductions in both bleeding and gingivitis.[4] This finding is supported by other studies that have found the oral irrigator to be more effective than string floss in reducing bleeding.[44,54,57]

Clinical Correlation

Nearly 70 studies have been conducted on the oral irrigator. Consistent clinical outcomes demonstrate reductions in biofilm, periodontal pathogens, bleeding on probing, gingivitis, and probing depth. The device has been tested on people in periodontal maintenance and in those with gingivitis, orthodontic appliances, implants, crowns, bridges, and diabetes.

As early as the 1960s, it was shown that oral irrigation with water added to toothbrushing reduced gingivitis by 52% compared with a 30% reduction for toothbrushing alone.[42] Throughout the years, other researchers have found concurring results with the use of plain water.[e] The use of an antimicrobial agent, such as diluted chlorhexidine (Table 51.2), or an essential oil generally enhances reductions in gingivitis and bleeding.[9,13,14,22–25,35]

TABLE 51.2

Chlorhexidine Dilutions (Based on 0.12% Concentration) Shown Effective in Clinical Trials

Concentrations	Amount of Water	Amount of Chlorhexidine
0.04%[13,35]	3 parts	1 part
0.06%[9,22,25,48]	1 part	1 part

The oral irrigator has been demonstrated to remove biofilm.[f] The combination of pulsation, pressure, and water velocity creates shear hydraulic forces that can significantly remove biofilm. Researchers who assessed the action of the oral irrigator with scanning electron microscopy found that a 3-second application at medium pressure removed 99.9% of biofilm from treated areas[28] (Figs. 51.18 and 51.19).

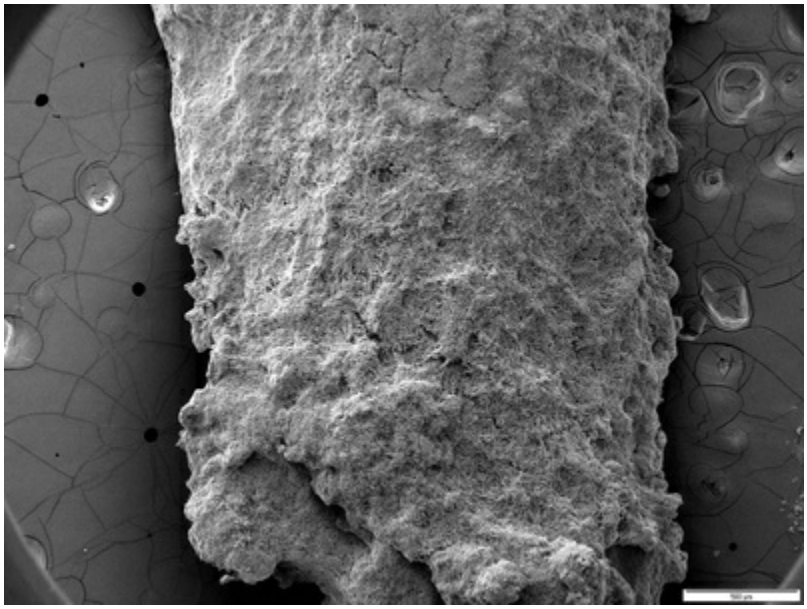

FIG. 51.18 **Control tooth with no irrigation.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

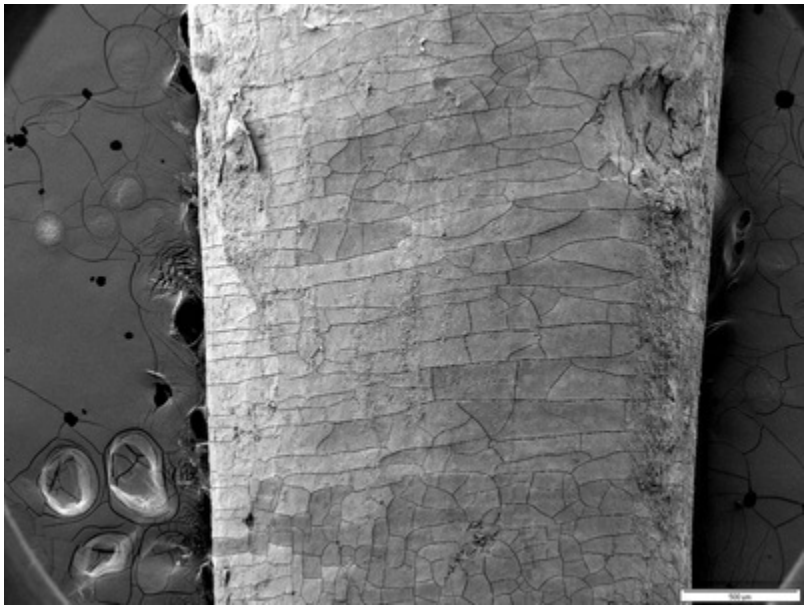

FIG. 51.19 **Tooth after a 3-second pulsating lavage with a jet tip at medium pressure.** (Courtesy Water Pik, Inc., Fort Collins, CO.)

Individuals With Special Considerations

Some clinical trials have focused on groups with special oral or

medical health needs. Both children and adults undergoing orthodontic therapy have shown significant benefits from using a dental water jet.[10,57] A newer small brush tip that cleans and irrigates simultaneously has been shown to remove 3.76 times more plaque than brushing and flossing with a floss threader.[57] For individuals with implants, a modified jet tip with filaments has been found to be both safe and effective. Patients who used the oral irrigator at 60 psi with warm water had twice the reduction in bleeding around implants compared with patients who used floss. No adverse events were reported.[44] The site-specific subgingival tip has also been shown to be safe and effective for use on implants.[22] The oral irrigator has also been found to improve periodontal health in people with type 1 or 2 diabetes.[1] For patients who prefer natural products, subjects who used the oral irrigator for 30 days post scaling and root planing effectively reduced the clinical parameters of periodontitis and periodontal bacteria similar to scaling and root planing followed by the placement of 1 mg of minocycline hydrochloride. Any differences between the two therapies was not statistically significant (Videos 51.5 and 51.6).[27]

Action of a Tip With Filaments Cleaning Around an Implant

Video 51.7 shows the action of the site-specific tip in a periodontal pocket.

Conclusion

Power scalers have emerged from being adjuncts for removing heavy supragingival calculus to a tool that may be used for all aspects of scaling: deplaquing, supragingival scaling, and subgingival scaling. The clinical outcomes achieved are similar to those seen with hand instrumentation. The advantages gained from using power instruments are potentially greater access subgingivally and in furcation areas and increased efficiency in time needed for scaling.

Home irrigation is safe and effective for a wide variety of

patients, including those in periodontal maintenance; those with calculus buildup, gingivitis, orthodontic appliances, maxillary fixation, crown and bridge, implants, or diabetes; and those who are noncompliant with floss. Clinical outcomes include reductions of plaque, calculus, gingivitis, bleeding on probing, probing depth, periodontal pathogens, and inflammatory mediators.

Case Scenario 51.1

Patient:
A 65-year-old female patient

Chief Complaint:
Tenderness and bleeding around her implant, which replaced tooth #30.

Background and History:
Tooth #30 was extracted 2 years ago due to a root fracture on a tooth with previous endodontic therapy. The patient is in overall good health. Her only medication is calcium for osteopenia. She underwent knee replacement due to osteoarthritis 9 months earlier. She reports that her recovery has gone well and she is back to normal activities. The patient also mentions that her hands are affected by osteoarthritis, and due to this, she is finding it increasingly difficult to use dental floss. She is concerned because she has always tried to take very good care of her smile.

Current Findings:
The patient presents with mucositis around the implant restoring tooth #30. The rest of the mouth exhibits moderate gingivitis in more than 30% of sites. Light to moderate plaque and bleeding are present. Calculus buildup is light. Probing depths range from 2 to 4 mm, with the majority of the 4-mm readings occurring in posterior teeth. The patient was diagnosed with gingivitis and was treated with therapeutic scaling to bring the periodontium back to health. Because the patient struggles with floss, a water flosser was recommended for daily use.

Case-Based Questions	Solutions and Explanations
1. Due to the patient's history of joint replacement, at what setting should she use the water flosser? A. 30 psi B. 60 psi C. The use of a water flosser is contraindicated in a patient with joint replacement.	**Answer: B** **Explanation:** Studies have found the incidence of bacteria from a water flosser to range from 0% to 50%; this is comparable to string floss, which has been shown to have an incidence of bacteria at around 40%. Therefore, the most appropriate setting is the one that has been clinically demonstrated to be effective with implants—60 psi. Individuals who used the water flosser at 60 psi for a period of 30 days found that the water flosser was twice as effective as string floss at reducing bleeding.
2. As an alternative to string floss, the water flosser has been found to be: A. As effective at reducing bleeding and gingivitis B. Less effective at reducing bleeding and gingivitis C. More effective at reducing bleeding and gingivitis	**Answer: C** **Explanation:** Multiple studies have demonstrated that the water flosser is more effective at reducing bleeding and gingivitis than string floss. Many factors likely contribute to this outcome. For many people, the water flosser is easier to use than string floss. The water flosser has been shown to reduce bacteria up to 6 mm, and this may benefit patients with pockets or hard-to-access areas.
3. Because the patient has light calculus buildup, the use of ultrasonic instrumentation is not necessary. True False	**Answer: False** **Explanation:** New thinner tip designs are ideal for deplaquing and treating gingivitis. The most important consideration for this patient is the implant. Metal tips are generally contraindicated with implants. Because the tools for scaling implants are continually improving, it is best to check with both the manufacturer of the implant and the manufacturer of the ultrasonic device before using this device with implants.

CHAPTER 52

Systemic Anti-infective Therapy for Periodontal Diseases

Sebastian G. Ciancio, Angelo J. Mariotti

CHAPTER OUTLINE

Definitions
Systemic Administration of Antibiotics
Serial and Combination Antibiotic Therapy
Conclusion

Learning Objectives

- Evaluate the rationale for use of anti-infective agents as adjuncts to periodontal therapy.
- List the clinical indications for use of anti-infective agents.
- Evaluate the pharmacology of anti-infective agents indicated as

adjuncts to periodontal therapy.

It has been well established that the various periodontal diseases are caused by bacterial infection. Bacteria begin reattaching to tooth surfaces soon after the teeth have been cleaned and start to form a *biofilm.* Over time, this supragingival plaque biofilm becomes more complex, which leads to a succession of bacteria that are more pathogenic. Bacteria grow in an apical direction and become subgingival. Eventually, as bone is destroyed, a periodontal pocket is formed. In a periodontal pocket, the bacteria form a highly structured and complex biofilm. As this process continues, the bacterial biofilm extends so far subgingivally that the patient cannot reach it during oral hygiene efforts. In addition, this complex biofilm may now offer some protection from the host's immunologic mechanisms in the periodontal pocket as well as from antibiotics used for treatment. It has been suggested that an antibiotic strength that is 500 times greater than the usual therapeutic dose may be needed to be effective against bacteria that have become arranged in biofilms.[26]

Systemic Administration of Antibiotics

Tetracyclines
Metronidazole
Penicillins
Cephalosporins
Clindamycin
Ciprofloxacin
Macrolides

It is therefore logical to treat periodontal pockets by mechanically removing local factors (including the calculus that harbors bacteria) and by disrupting the subgingival plaque biofilm itself. Mechanical removal includes manual instrumentation (e.g., scaling and root planing) and machine-driven instrumentation (e.g., ultrasonic scalers), and these procedures can be considered “anti-infective therapy.” Many chemotherapeutic agents are now available to

clinicians who treat periodontal diseases. *Systemic* anti-infective therapy (oral antibiotics) and *local* anti-infective therapy (placing anti-infective agents directly into the periodontal pocket) can reduce the bacterial challenge to the periodontium. It is also possible that systemically administered nonsteroidal antiinflammatory agents may play a role in future adjunctive therapy.[42,58]

Bacteria and their toxic products may cause a loss of attachment and a loss of bone. Ultimately, however, the host's own immunologic response to this bacterial infection can cause even more bone destruction (i.e., indirect bone loss) than that caused by pathogenic bacteria and their by products. This immunologic response can be influenced by environmental (e.g., tobacco use), acquired (e.g., systemic disease), or genetic risk factors.[49] Chemotherapeutic agents can modulate the host's immune response to bacteria and reduce the host's self-destructive immunologic response to bacterial pathogens, thereby reducing bone loss.[45-47] It is also incumbent on health care providers to counsel patients about the detrimental effects of systemic factors, including medications, stress, and tobacco use.[26]

This chapter reviews the indications and protocols for optimizing the use of systemically administered anti-infective agents during the treatment of periodontal diseases. It is important to note that there has been significant work with the use of a systematic *evidence-based approach* to evaluate the various anti-infective and host modulation therapies.[64] A meta-analysis of similar research studies has given power to statistical analysis to evaluate anti-infective chemotherapeutic agents for the treatment of periodontal disease. Unfortunately, a standardized research protocol has not yet been implemented. As a result, some studies, although relevant, have not been used in the evidence-based approach because of their study design. Further evidence-based and similar research is needed to define protocols more precisely for the use of anti-infective agents to treat various periodontal diseases.

Key Fact

Bacteriostatic Versus Bactericidal Antibiotics

Pharmacologic agents that prevent the growth of bacteria are bacteriostatic antibiotics, whereas pharmacologic agents that actually kill the bacteria are bactericidal antibiotics. Examples of bacteriostatic antibiotics include tetracycline and clindamycin, and penicillin and metronidazole are good examples of bactericidal antibiotics.

Definitions

An anti-infective agent is a *chemotherapeutic agent* that acts by reducing the number of bacteria present. An antibiotic is a naturally occurring, semisynthetic, or synthetic type of anti-infective agent that destroys or inhibits the growth of select microorganisms, generally at low concentrations. An antiseptic is a chemical antimicrobial agent that can be applied topically or subgingivally to mucous membranes, wounds, or intact dermal surfaces to destroy microorganisms and inhibit their reproduction or metabolism. In dentistry, antiseptics are widely used as the active ingredient in antiplaque and antigingivitis oral rinses and dentifrices. Disinfectants (a subcategory of antiseptics) are antimicrobial agents that are generally applied to inanimate surfaces to destroy microorganisms.[13]

When anti-infective agents are administered orally, many of these agents can be found in the gingival crevicular fluid (GCF). The purpose of a *systemic administration* of antibiotics is to reduce the number of bacteria present in the diseased periodontal pocket; this is often a necessary adjunct for controlling bacterial infection, because bacteria can invade periodontal tissues, thereby making mechanical therapy alone sometimes ineffective.[2,11,12,21,48]

A single chemotherapeutic agent can also have a dual mechanism of action. For example, tetracyclines (especially doxycycline) are chemotherapeutic agents that can reduce collagen and bone destruction via their ability to inhibit the enzyme collagenase. As antibiotic agents, they can also reduce periodontal pathogens in periodontal tissues.[12]

Systemic Administration of Antibiotics

Background and Rationale

The treatment of periodontal diseases is based on their infectious nature (Table 52.1). Ideally, the causative microorganisms should be identified, and the most effective agent should be selected with the use of antibiotic-sensitivity testing. Although this appears simple, the difficulty lies primarily in identifying the specific etiologic microorganisms rather than the microorganisms that are simply associated with various periodontal disorders.[12]

TABLE 52.1

Antibiotics Used to Treat Periodontal Diseases

Category	Agent	Major Features
Penicillin[a]	Amoxicillin	Extended spectrum of antimicrobial activity; excellent oral absorption; used systemically
	Augmentin[b]	Effective against penicillinase-producing microorganisms; used systemically
Tetracyclines	Minocycline	Effective against a broad spectrum of microorganisms; used systemically and applied locally (subgingivally)
	Doxycycline	
	Tetracycline	Effective against a broad spectrum of microorganisms; used systemically and applied locally (subgingivally)
		Chemotherapeutically used in subantimicrobial doses for host modulation (Periostat)
		Effective against a broad spectrum of microorganisms
Quinolone	Ciprofloxacin	Effective against gram-negative rods; promotes health-associated microflora
Macrolide	Azithromycin	Concentrates at sites of inflammation; used systemically
Lincomycin derivative	Clindamycin	Used in penicillin-allergic patients; effective against anaerobic bacteria; used systemically
Nitroimidazole[c]	Metronidazole	Effective against anaerobic bacteria; used systemically and applied locally (subgingivally) as gel

[a]Indications: localized aggressive periodontitis, generalized aggressive periodontitis, medically related periodontitis, and refractory periodontitis.

[b]Amoxicillin and clavulanate potassium.

[c]Indications: localized aggressive periodontitis, generalized aggressive periodontitis, medically related periodontitis, refractory periodontitis, and necrotizing ulcerative periodontitis.

An ideal antibiotic for use in the prevention and treatment of periodontal disease should be specific for periodontal pathogens,

allogenic, nontoxic, substantive, not in general use for the treatment of other diseases, and inexpensive.[22] Currently, however, an ideal antibiotic for the treatment of periodontal disease does not exist.[32] Although oral bacteria are susceptible to many antibiotics, no single antibiotic at the concentrations achieved in body fluids inhibits all putative periodontal pathogens.[61] Indeed, a combination of antibiotics may be necessary to eliminate all putative pathogens from some periodontal pockets[43] (Table 52.2).

TABLE 52.2

Common Antibiotic Regimens Used to Treat Periodontal Diseases[a]

	Regimen	Dosage/Duration
Single Agent		
Amoxicillin	500 mg	Three times daily for 8 days
Azithromycin	500 mg	Once daily for 4 to 7 days
Ciprofloxacin	500 mg	Twice daily for 8 days
Clindamycin	300 mg	Three times daily 10 days
Doxycycline or minocycline	100 mg to 200 mg	Once daily for 21 days
Metronidazole	500 mg	Three times daily for 8 days
Combination Therapy		
Metronidazole + amoxicillin	250 mg of each	Three times daily for 8 days
Metronidazole + ciprofloxacin	500 mg of each	Twice daily for 8 days

[a]These regimens are prescribed after a review of the patient's medical history, periodontal diagnosis, and antimicrobial testing. Clinicians must consult pharmacology references such as *Mosby's GenRx*[41] or the manufacturer's guidelines for warnings, contraindications, and precautions.

Data from Jorgensen MG, Slots J: Practical antimicrobial periodontal therapy. *Compend Contin Educ Dent* 21:111, 2000.

As always, the clinician, in concert with the patient, must make the final decision regarding any treatment. Thus the treatment of an individual patient must be based on the patient's clinical status, the nature of the colonizing bacteria, the ability of the agent to reach the site of infection, and the risks and benefits associated with the proposed treatment plan. The clinician is responsible for choosing the correct antimicrobial agent. Some adverse reactions include allergic or anaphylactic reactions, superinfections of opportunistic bacteria, development of resistant bacteria, interactions with other medications, upset stomach, nausea, and vomiting.[3] Most adverse reactions take the form of gastrointestinal upset.[32] Other concerns include the cost of the medication and the patient's willingness and

ability to comply with the proposed therapy.

No consensus exists regarding the magnitude of risk for the development of bacterial resistance. The common and indiscriminate use of antibiotics worldwide has contributed to increasing numbers of resistant bacterial strains since the late 1990s, and this trend is likely to continue given the widespread use of antibiotics.[10,18,62] The overuse, misuse, and widespread prophylactic application of anti-infective drugs are some of the factors that have led to the emergence of resistant microorganisms. Increasing levels of resistance of subgingival microflora to antibiotics have been correlated with the increased use of antibiotics in individual countries.[10,57] However, researchers have noted that the subgingival microflora tends to revert to similar proportions of antibiotic-resistant isolates 3 months after therapy.[20,28]

Tetracyclines

Tetracyclines have been widely used for the treatment of periodontal diseases. They have been frequently used to treat refractory periodontitis, including *localized aggressive periodontitis* (LAP)[31,63] (see Table 52.1). Tetracyclines have the ability to concentrate in the periodontal tissues and inhibit the growth of *Aggregatibacter actinomycetemcomitans.* In addition, tetracyclines exert an anticollagenase effect that can inhibit tissue destruction and may help with bone regeneration.[9,37,60]

Pharmacology

The tetracyclines are a group of antibiotics that are produced naturally from certain species of *Streptomyces* or derived semisynthetically. These antibiotics are bacteriostatic and are effective against rapidly multiplying bacteria. They generally are more effective against gram-positive bacteria than against gram-negative bacteria. Tetracyclines are effective for the treatment of periodontal diseases in part because their concentration in the gingival crevice is 2 to 10 times that found in serum.[1,4,24] This allows a high drug concentration to be delivered into the periodontal pockets. In addition, several studies have demonstrated that tetracyclines at a low GCF concentration (i.e., 2 μg/ml to 4 μg/ml)

are very effective against many periodontal pathogens.[5,6]

Clinical Use

Tetracyclines have been investigated as adjuncts for the treatment of LAP.[31,51] *A. actinomycetemcomitans* is a microorganism that is frequently associated with LAP, and it invades tissue. Therefore the mechanical removal of calculus and plaque from root surfaces may not eliminate this bacterium from the periodontal tissues. Systemic tetracycline can eliminate tissue bacteria and has been shown to arrest bone loss and suppress *A. actinomycetemcomitans* levels in conjunction with scaling and root planing.[50] This combination therapy allows for the mechanical removal of root surface deposits and the elimination of pathogenic bacteria from within the tissues.[53] Increased posttreatment bone levels have been noted with the use of this method (Figs. 52.1 to 52.4).

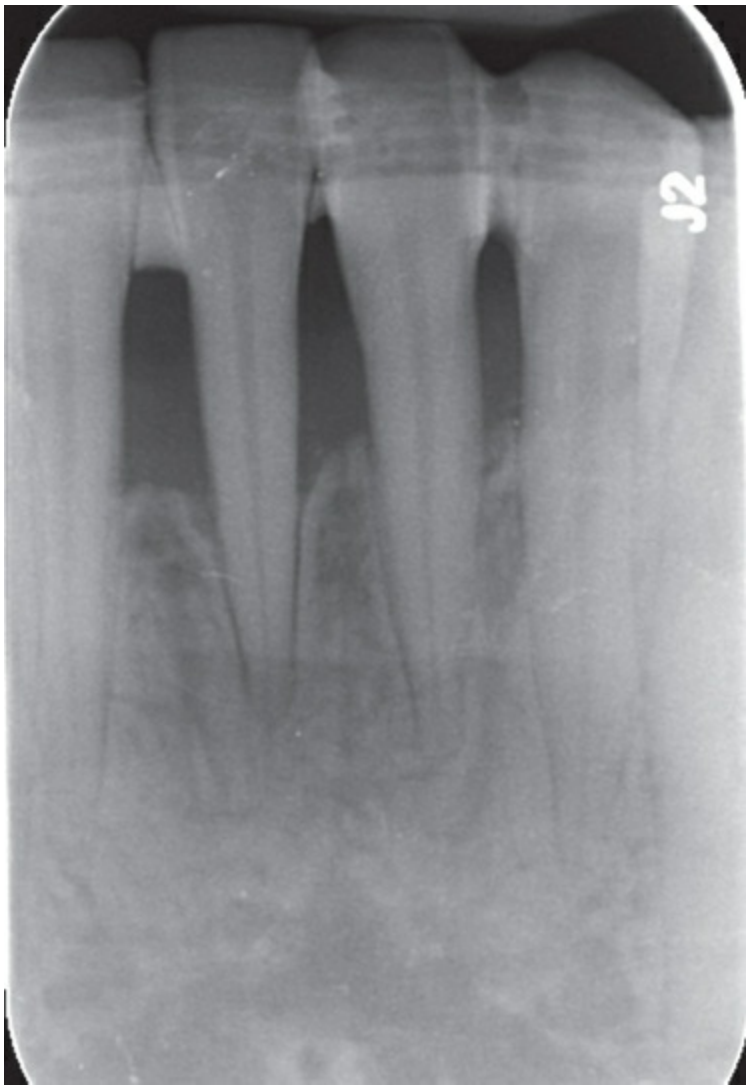

FIG. 52.4 Postoperative radiograph of anterior mandible in localized aggressive periodontitis patient treated with a combination of antibiotic therapy, scaling and root planing, and surgical intervention. (Photo courtesy Dr. Sasi Sunkari.)

As a result of increased resistance to tetracyclines, metronidazole or amoxicillin with metronidazole has been found to be more effective for the treatment of aggressive periodontitis in children and young adults. Some investigators think that metronidazole in combination with amoxicillin–clavulanic acid is the preferable antibiotic.[59]

Long-term use of low antibacterial doses of tetracyclines has been advocated in the past. One long-term study of patients taking low doses of tetracycline (i.e., 250 mg/day for 2 to 7 years) demonstrated the persistence of deep pockets that did not bleed after probing.

These sites contained high proportions of tetracycline-resistant gram-negative rods *(Fusobacterium nucleatum).* After the antibiotic was discontinued, the flora was characteristic of sites with disease.[32] Therefore it is not advisable to prescribe a long-term regimen of tetracyclines because of the possible development of resistant bacterial strains.[34] Although tetracyclines were often used in the past as anti-infective agents, especially for LAP and other types of aggressive periodontitis, they are now frequently replaced by more effective combination antibiotics.[32]

Specific Agents

Tetracycline, minocycline, and doxycycline are semisynthetic members of the tetracycline group that have been used in periodontal therapy.

Tetracycline

Treatment with tetracycline hydrochloride requires the administration of 250 mg four times daily. It is inexpensive, but compliance may be reduced by the need to take the medication so frequently. Side effects include gastrointestinal disturbances, photosensitivity, hypersensitivity, increased blood urea nitrogen levels, blood dyscrasias, dizziness, and headache. In addition, tooth discoloration occurs when this drug is administered to children who are 12 years old or younger.

Key Fact

Tetracycline and Tooth Discoloration

Tetracycline has the ability to chelate with calcium and therefore gets deposited in mineralized tissues such as bone or teeth during the mineralization process, resulting in yellow to brown discoloration of teeth.

Minocycline

Minocycline is effective against a broad spectrum of microorganisms. In patients with adult periodontitis, it suppresses

spirochetes and motile rods as effectively as scaling and root planing, with suppression evident up to 3 months after therapy. Minocycline can be given twice daily, thereby facilitating compliance as compared with tetracycline. Although it is associated with less phototoxicity and renal toxicity than tetracycline, minocycline may cause reversible vertigo. Minocycline administered at a dose of 200 mg/day for 1 week results in a reduction of total bacterial counts, complete elimination of spirochetes for up to 2 months, and improvement of all clinical parameters.[13,14]

Side effects are similar to those of tetracycline; however, there is an increased incidence of vertigo. It is the only tetracycline that can permanently discolor erupted teeth and gingival tissue when administered orally.

Doxycycline

Doxycycline has the same spectrum of activity as minocycline and can be equally effective.[12] Because doxycycline can be given only once daily, patients may be more compliant. Compliance is also improved because its absorption from the gastrointestinal tract is only slightly altered by calcium, metal ions, or antacids, as is absorption of other tetracyclines. Side effects are similar to those of tetracycline hydrochloride; however, it is the most photosensitizing agent in the tetracycline category.

The recommended dosage when doxycycline is used as an anti-infective agent is 100 mg twice daily the first day, which is then reduced to 100 mg daily. To reduce gastrointestinal upset, 50 mg can be taken twice daily after the initial dose. When given as a sub-antimicrobial dose (to inhibit collagenase), 20 mg of doxycycline twice daily is recommended.[9,16]

Metronidazole

Pharmacology

Metronidazole is a nitroimidazole compound that was developed in France to treat protozoal infections. It is bactericidal to anaerobic organisms and is thought to disrupt bacterial DNA synthesis in conditions with a low reduction potential. Metronidazole is not the

drug of choice for treating *A. actinomycetemcomitans* infections. However, metronidazole is effective against *A. actinomycetemcomitans* when used in combination with other antibiotics.[43,44] Metronidazole is also effective against anaerobes such as *Porphyromonas gingivalis* and *Prevotella intermedia*.[25]

Clinical Use

Metronidazole has been used clinically to treat acute necrotizing ulcerative gingivitis, chronic periodontitis, and aggressive periodontitis. It has been used as monotherapy and also in combination with root planing and surgery or with other antibiotics. Metronidazole has been used successfully to treat necrotizing ulcerative gingivitis.[39]

Studies in humans have demonstrated the efficacy of metronidazole for the treatment of periodontitis.[38] A single dose of metronidazole (250 mg orally) appears in both serum and GCF in sufficient quantities to inhibit a wide range of suspected periodontal pathogens. When it is administered systemically (i.e., 750 mg/day to 1000 mg/day for 2 weeks), metronidazole reduces the growth of anaerobic flora, including spirochetes, and it decreases the clinical and histopathologic signs of periodontitis.[38] The most common regimen is 250 mg 3 times daily for 7 days.[39] Currently, the critical level of spirochetes that is needed to diagnose an anaerobic infection, the appropriate time to give metronidazole, and the ideal dosage or duration of therapy are unknown.[25] As monotherapy (i.e., with no concurrent root planing), metronidazole is inferior and at best only equivalent to root planing. Therefore if it is used, metronidazole should not be administered as monotherapy.

Soder and colleagues[52] demonstrated that metronidazole was more effective than placebo for the management of sites that were unresponsive to root planing. Nevertheless, many patients still had sites that bled with probing, despite metronidazole therapy. The existence of refractory periodontitis as a diagnostic consideration indicates that some patients do not respond to conventional therapy, which may include root planing, surgery, or both.

Studies have suggested that when it is combined with amoxicillin or amoxicillin–clavulanate potassium (Augmentin), metronidazole may be of value for the management of patients with LAP or

refractory periodontitis. This is discussed in more detail later in this chapter.

Side Effects

Metronidazole has an Antabuse effect when alcohol is ingested. The response is generally proportional to the amount ingested and can result in severe cramps, nausea, and vomiting. Products that contain alcohol should be avoided during therapy and for at least 1 day after therapy is discontinued. Metronidazole also inhibits warfarin metabolism. Patients who are undergoing anticoagulant therapy should avoid metronidazole, because it prolongs prothrombin time.[39] It also should be avoided in patients who are taking lithium. This drug produces a metallic taste in the mouth, which may affect compliance.

Penicillins

Pharmacology

Penicillins are the drugs of choice for the treatment of many serious infections in humans and are the most widely used antibiotics. Penicillins are natural and semisynthetic derivatives of broth cultures of the *Penicillium* mold. They inhibit bacterial cell wall production and therefore are bactericidal.

Clinical Use

Penicillins other than amoxicillin and amoxicillin–clavulanate potassium (Augmentin) have not been shown to increase periodontal attachment levels, and their use in periodontal therapy does not appear to be justified.

Side Effects

Penicillins may induce allergic reactions and bacterial resistance.

Key Fact

Penicillin Allergy

Up to 10% of patients may be allergic to penicillin. Reactions to ingestion of penicillin or its derivatives, such as amoxicillin, in allergic patients can range from skin rash to life-threatening anaphylaxis.

Amoxicillin

Amoxicillin is a semisynthetic penicillin with an extended anti-infective spectrum that includes gram-positive and gram-negative bacteria. It demonstrates excellent absorption after oral administration. Amoxicillin is susceptible to penicillinase, which is a β-lactamase produced by certain bacteria that breaks the penicillin ring structure and thus renders penicillins ineffective.

Amoxicillin may be useful for the management of patients with aggressive periodontitis in both localized and generalized forms. The recommended dosage is 500 mg 3 times daily for 8 days.[32,33]

Amoxicillin–Clavulanate Potassium

The combination of amoxicillin with clavulanate potassium makes this anti-infective agent resistant to penicillinase enzymes produced by some bacteria. Amoxicillin with clavulanate (Augmentin) may be useful for the management of patients with LAP or refractory periodontitis.[42] Bueno and colleagues[8] reported that Augmentin arrested alveolar bone loss in patients with periodontal disease that was refractory to treatment with other antibiotics, including tetracycline, metronidazole, and clindamycin.

Cephalosporins

Pharmacology

The family of β-lactams known as cephalosporins is similar in action and structure to the penicillins. These drugs are frequently used in medicine, and they are resistant to a number of β-lactamases that are normally active against penicillin.

Clinical Use

Cephalosporins are generally not used to treat dental-related infections. The penicillins are superior to cephalosporins with

regard to their range of action against periodontal pathogenic bacteria.

Side Effects

Patients who are allergic to penicillins must be considered to be allergic to all β-lactam products. More specifically, up to 10% of patients who have an allergy to penicillin may also have an adverse reaction to cephalosporins. Rashes, urticaria, fever, and gastrointestinal upset have all been associated with cephalosporins.[62]

Clindamycin

Pharmacology

Clindamycin is effective against anaerobic bacteria and has a strong affinity for osseous tissue.[56] It is effective for situations in which the patient is allergic to penicillin.

Clinical Use

Clindamycin has demonstrated efficacy in patients with periodontitis that is refractory to tetracycline therapy. Walker and colleagues[62] showed that clindamycin helped stabilize refractory patients; the dosage used was 150 mg 4 times daily for 10 days. Jorgensen and Slots[33] recommend a regimen of 300 mg twice daily for 8 days.

Side Effects

Clindamycin has been associated with pseudomembranous colitis, but the incidence is higher with cephalosporins and ampicillin. When needed, however, clindamycin can be used with caution, but it is not indicated for patients with a history of colitis. Diarrhea or cramping that develops during clindamycin therapy may be indicative of colitis, and it should be discontinued. If symptoms persist, the patient should be referred to an internist.

Ciprofloxacin

Pharmacology

Ciprofloxacin is a quinolone that is active against gram-negative rods, including all facultative and some anaerobic putative periodontal pathogens.[41]

Clinical Use

Because it demonstrates a minimal effect on *Streptococcus* species, which are associated with periodontal health, ciprofloxacin therapy may facilitate the establishment of a microflora that is associated with periodontal health. At present, ciprofloxacin is the only antibiotic in periodontal therapy to which all strains of *A. actinomycetemcomitans* are susceptible. It has also been used in combination with metronidazole.[43]

Side Effects

Nausea, headache, metallic taste in the mouth, and abdominal discomfort have been associated with ciprofloxacin. Quinolones inhibit the metabolism of theophylline, and caffeine and concurrent administration can produce toxicity. Quinolones have also been reported to enhance the effects of warfarin and other anticoagulants.[62]

Macrolides

Pharmacology

Macrolide antibiotics contain a many-membered lactone ring to which one or more deoxy sugars are attached. They inhibit protein synthesis by binding to the 50S ribosomal subunits of sensitive microorganisms. Macrolides can be bacteriostatic or bactericidal, depending on the concentration of the drug and the nature of the microorganism. The macrolide antibiotics used for periodontal treatment include erythromycin, spiramycin, and azithromycin.

Clinical Use

Erythromycin does not concentrate in GCF and is not effective against most putative periodontal pathogens. For these reasons, erythromycin is not recommended as an adjunct to periodontal

therapy.

Spiramycin is active against gram-positive organisms; it is excreted in high concentrations in saliva. It is used as an adjunct to periodontal treatment in Canada and Europe but is not available in the United States. Spiramycin has a minimal effect on attachment levels.

Azithromycin is a member of the azalide class of macrolides. It is effective against anaerobes and gram-negative bacilli. After an oral dosage of 500 mg 4 times daily for 3 days, significant levels of azithromycin can be detected in most tissues for 7 to 10 days.[7,30] The concentration of azithromycin in tissue specimens from periodontal lesions is significantly higher than that of normal gingiva.[40] It has been proposed that azithromycin penetrates fibroblasts and phagocytes in concentrations that are 100 to 200 times greater than that of the extracellular compartment. Azithromycin is actively transported to sites of inflammation by phagocytes, where it is released directly into the sites of inflammation as the phagocytes rupture during phagocytosis.[23] Therapeutic use requires a single dose of 250 mg/day for 5 days after an initial loading dose of 500 mg.[62]

Data have suggested that azithromycin may be an effective adjunctive therapy for increasing attachment levels in patients with aggressive periodontitis[27] as well as for reducing the degree of gingival enlargement.[15] These data must be carefully considered, because they were derived from small subject populations. Currently, the literature presents conflicting reports regarding the efficacy of this antibiotic as an adjunct to periodontal therapy. One study concluded that adjunctive azithromycin provides no additional benefit over nonsurgical periodontal treatment for the parameters investigated in patients with severe generalized chronic periodontitis. Furthermore, an additional study reported that there was an increase in cardiovascular deaths among patients who received azithromycin; this increase was most pronounced among patients with a high baseline risk of cardiovascular disease. As a result of this study, the US Food and Drug Administration issued a warning that the drug can alter the electrical activity of the heart, which may lead to a potentially fatal heart rhythm known as *prolonged QT interval.* This rhythm causes the timing of the heart's

contractions to become irregular. The warning stated that physicians should use caution when giving the antibiotic to patients who are known to have this condition or who are at risk for cardiovascular problems.

To ascertain the efficacy of azithromycin for the management of periodontal diseases, future studies will need to increase the number of subjects, improve diagnostic methods and tools, and determine the appropriate dose, duration, and frequency of azithromycin therapy.

Serial and Combination Antibiotic Therapy

Rationale

Because periodontal infections may contain a wide variety of bacteria, no single antibiotic is effective against all putative pathogens. Indeed, differences exist in the microbial flora associated with the various periodontal disease syndromes.[63] These "mixed" infections can include a variety of aerobic, microaerophilic, and anaerobic bacteria, which may be both gram negative and gram positive. In these cases, it may be necessary to use more than one antibiotic, either serially or in combination.[44] Before combinations of antibiotics are used, however, the periodontal pathogens being treated should be identified and antibiotic-susceptibility testing performed.[65]

Clinical Use

Antibiotics that are bacteriostatic (e.g., tetracycline) generally require rapidly dividing microorganisms to be effective. They do not function well if a bactericidal antibiotic (e.g., amoxicillin) is given concurrently. *When both types of drugs are required, they are best given serially rather than in combination.*

Rams and Slots[44] reviewed combination therapy involving the use of systemic metronidazole along with amoxicillin, amoxicillin–clavulanate (Augmentin), or ciprofloxacin. The metronidazole–amoxicillin and metronidazole–Augmentin combinations provided

excellent elimination of many organisms in adults with LAP who had been treated unsuccessfully with tetracyclines and mechanical debridement. These drugs have an additive effect that involves the suppression of *A. actinomycetemcomitans*. Tinoco and colleagues[55] found metronidazole and amoxicillin to be clinically effective for the treatment of LAP, although 50% of patients who were treated with this regimen harbored *A. actinomycetemcomitans* 1 year later. The metronidazole–ciprofloxacin combination is effective against *A. actinomycetemcomitans;* metronidazole targets obligate anaerobes, and ciprofloxacin targets facultative anaerobes. This is a powerful combination against mixed infections. Studies of this drug combination for the treatment of refractory periodontitis have documented marked clinical improvement. This combination may provide a therapeutic benefit by reducing or eliminating pathogenic organisms and a prophylactic benefit by giving rise to a predominantly streptococcal microflora.[43]

Systemic antibiotic therapy in combination with mechanical therapy appears to be valuable for the treatment of recalcitrant periodontal infections and LAP infections that involve *A. actinomycetemcomitans*. Antibiotic treatment should be reserved for specific subsets of periodontal patients who do not respond to conventional therapy. The selection of specific agents should be guided by the results of cultures and sensitivity tests for subgingival plaque microorganisms.

Pharmacologic Implications

Principles of antibiotic therapy for the proper selection of an antibiotic minimally require identification of the causative organism, determination of the antibiotic sensitivity, and an effective method of administration.[29] The use of antibiotics to treat gingival diseases is contraindicated, because this is a local infection that can be easily treated with scaling and appropriate home care by the patient.[54] With regard to destructive periodontal diseases, there are limited data to support the use of systemic antibiotic treatment. Although bacterial infections of the periodontium are considered to be important to initiation of the disease, currently no one microbe or group of microbes has been demonstrated to be the

cause of these diseases. It is therefore not surprising that systemic antibiotics have had only a modest effect on the management of periodontal diseases. At this time, systemic antibiotics for the treatment of periodontal diseases have been indicated primarily for adjunctive use in the treatment of aggressive periodontal diseases[26,28] (Table 52.3).

TABLE 52.3

Therapeutic Uses of Systemic Antimicrobial Agents for Various Periodontal Diseases

Disease	Systemic Antimicrobial Agents	Adjunct or Stand-Alone Therapy
Gingival diseases	Antibiotic use not recommended	Not applicable
Necrotizing ulcerative gingivitis	Antibiotic use not recommended unless there are systemic complications (e.g., fever, swollen lymph nodes)	As an adjunct when necessary
Chronic periodontitis	Limited benefit; antibiotic use not recommended	Not applicable
Aggressive periodontitis	Antibiotic use recommended; for greatest benefit, therapeutic levels of antibiotics should be achieved by the time scaling and root planing are completed (all debridement should be completed within a week); the optimal antibiotic type, dose, frequency, and duration have not been identified	As an adjunct
Necrotizing ulcerative periodontitis	Antibiotic use dependent on the systemic condition of the patient	As an adjunct when necessary
Periodontitis as a manifestation of systemic disease	Antibiotic use dependent on the systemic condition of the patient	As an adjunct when necessary
Periodontal abscess	Antibiotic use not recommended	Not applicable

Guidelines for the use of antibiotics in periodontal therapy include the following:

1. The clinical diagnosis and situation dictate the need for possible antibiotic therapy as an adjunct for controlling active periodontal disease (Fig. 52.5). The patient's diagnosis can change over time. For example, a patient who presents

with generalized mild chronic periodontitis can return to a diagnosis of periodontal health after initial therapy. However, if the patient has been treated and continues to have active disease, the diagnosis may change to generalized severe chronic periodontitis.

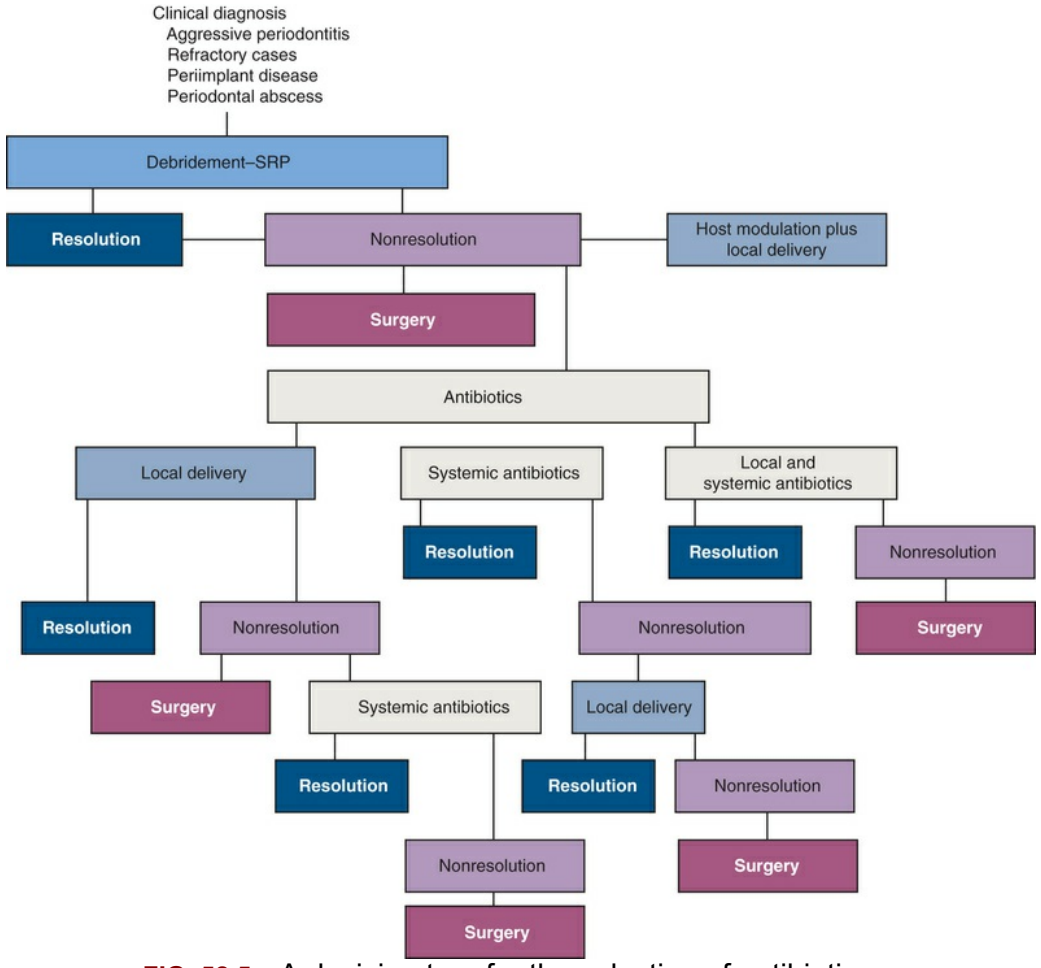

FIG. 52.5 A decision tree for the selection of antibiotic therapy.

2. Disease activity as measured by continuing attachment loss, purulent exudate, and bleeding on probing[35,36] may be an indication for periodontal intervention and possible microbial analysis through plaque sampling.
3. When they are used to treat periodontal disease, antibiotics are selected on the basis of the patient's medical and dental status and current medications,[32] and the results of microbial analysis, if it is performed.
4. Microbiologic plaque sampling may be performed according

to the instructions of the reference laboratory. The samples are usually taken at the beginning of an appointment, before instrumentation of the pocket. Supragingival plaque is removed, and an endodontic paper point is inserted subgingivally into the deepest pockets to absorb bacteria in the loosely associated plaque. This endodontic point is placed in reduced transfer fluid or a sterile transfer tube and sent to the laboratory. The laboratory will then send the referring dentist a report that includes the pathogens that are present and any appropriate antibiotic regimen. At this time, there are scant data to suggest that microbial identification from a plaque sample can be used to clinically improve the periodontal condition of the patient.

5. Meta-analyses of randomized clinical trials and quasi-experimental studies have shown that systemic antibiotics can improve attachment levels when they are used as adjuncts to scaling and root planing. The same benefits could not be demonstrated when antibiotics were used as a stand-alone therapy.[28]
6. When systemic antibiotics were used as adjuncts to scaling and root planing, improvements were observed in the attachment levels of patients with chronic and aggressive periodontitis, although patients with aggressive periodontitis experienced greater benefits.[28] The mean attachment level change depended on the antibiotic used and ranged from 0.09 mm to 1.10 mm.[28]
7. The identification of which antibiotics were most effective for the treatment of destructive periodontal diseases was limited by the insufficient sizes of the samples found in the randomized clinical trials used as part of a systematic review.[28] A meta-analysis evaluating eight different antibiotics or antibiotic combinations showed that only tetracycline and metronidazole significantly improved attachment levels when they were used as adjuncts to scaling and root planing for patients with destructive periodontal diseases.[28]
8. Debridement of root surfaces, optimal oral hygiene, and frequent periodontal maintenance therapy are important

parts of comprehensive periodontal therapy. As mentioned previously, an antibiotic strength that is 500 times greater than the systemic therapeutic dose may be required to be effective against bacteria that have been arranged into biofilm. It is therefore important to disrupt the biofilm physically so that the antibiotic agents can have access to the periodontal pathogens.[26]

9. Although there are adequate data to suggest that systemic antibiotics can be of benefit for the treatment of destructive periodontal diseases, there are limited data available to identify which antibiotics are suitable for which infection; the optimum dosage, frequency, and duration of antibiotic therapy; when the regimen should be introduced during the treatment schedule; the long-term outcomes of antibiotic use; the potential hazards of these agents (e.g., antibiotic resistance, changes in oral microflora)[28]; and the economic ramifications of this type of pharmacologic intervention.

The selection of an antibiotic must be made on the basis of factors other than the empirical decisions made by the clinician. Unfortunately, there is no one best choice of antibiotic at present (i.e., there is no “silver bullet”). Therefore the clinician must integrate the history of the patient's disease, the clinical signs and symptoms, and the results of radiographic examinations and possibly microbiologic sampling to determine the course of periodontal therapy. The clinician must obtain a thorough medical history, including current medications and the possible adverse effects of combining these medicines, before prescribing any antibiotic therapy. The clinician must make the final decision with the patient. Risks and benefits concerning antibiotics as adjuncts to periodontal therapy should be discussed with the patient before antibiotics are used.

Conclusion

Scaling and root planing alone are effective for reducing pocket depths, gaining increases in periodontal attachment levels, and decreasing inflammation levels (i.e., bleeding with probing). When

systemic antibiotics are used as adjuncts to scaling and root planing, the evidence indicates that some systemic antibiotics (e.g., metronidazole, tetracycline) provide additional improvements in attachment levels (0.35 mm for metronidazole; 0.40 mm for tetracycline) when used as adjuncts to scaling and root planing.[28] The use of anti-infective chemotherapeutic treatment adjuncts does not result in significant adverse effects for patients.

The decision regarding when to use systemic antimicrobials should be made on the basis of the clinician's consideration of the clinical findings, the patient's medical and dental history,[17,19] the patient's preferences, and the potential benefits of adjunctive therapy with these agents.

Chapter Highlights

- The *systemic administration* of antibiotics may be a necessary adjunct for controlling bacterial infection, because bacteria can invade periodontal tissues, thereby making mechanical therapy alone sometimes ineffective.
- Although oral bacteria are susceptible to many antibiotics, no single antibiotic at the concentrations achieved in body fluids inhibits all putative periodontal pathogens.
- The protocol for use of anti-infective agents depends on the mechanism of action, the patient's health status and history, and the clinical presentation.

Case Scenario 52.1

Patient:
27-year-old Caucasian female

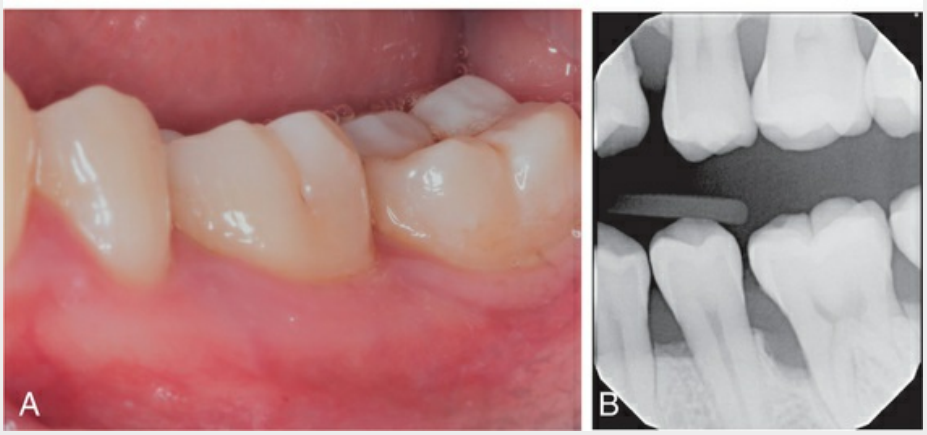
Chief Complaint:
"My gums bleed when I brush my teeth."

Background Information
The patient is a nonsmoker with no systemic medical conditions,

but she is allergic to penicillin. She reports that her sister, who is 32 years old, has a similar gum condition. The patient says that she brushes twice a day and flosses three or four times in a week.

Current Findings:

Probing depths are in the range of 1 to 8 mm. The deeper (>6 mm) probing depths are confined to maxillary incisors and first molars (Fig. A). Oral hygiene is optimal. Radiographically, vertical defect is noted mesial to all first molars. A representative radiographic vertical defect mesial to #19 is shown in Fig. B.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Based on the history and clinical presentation, what is the likely diagnosis? A. Chronic periodontitis B. Acute necrotizing ulcerative gingivitis (ANUG) C. Localized aggressive periodontitis (LAP) D. Necrotizing ulcerative periodontitis (NUP)	**Answer: C** **Explanation:** Considering the patient's age, family history, clinical presentation (severe attachment loss confined to first molars and incisors in spite of good oral hygiene), and radiographic findings (vertical bone loss around first molars), a diagnosis of LAP can be made.
2. Can you prescribe a combination of amoxicillin and metronidazole for this patient while performing scaling and root planing? A. Yes B. No	**Answer: B** **Explanation:** This patient is allergic to penicillin, and because amoxicillin is a derivative of penicillin, it should not be given to a penicillin-allergic patient. In such cases, metronidazole can be given alone or combined with other antibiotics, such as ciprofloxacin.

3. In North America, when compared with Caucasians, LAP is more prevalent in patients of African descent. A. True B. False	**Answer: A** **Explanation:** Several epidemiologic studies point to a higher prevalence of LAP (approximately 10 times more) in people of African descent when compared with Caucasians.

CHAPTER 53

Locally Delivered, Controlled-Release Antimicrobials

Richard D. Finkelman, Hector L. Sarmiento, Alan M. Polson

CHAPTER OUTLINE

Background and Objectives
Drug Development and Registration
Clinical Use
Case Reports
Conclusions

Background and Objectives

Chronic periodontitis is a bacterial infection. The focus of most nonsurgical periodontal therapy, including mechanical therapy such as scaling and root planing (SRP), is to combat infection. Chemical antibacterial strategies include systemic drug delivery,

oral rinses or toothpastes, and irrigating devices, but none of these therapies has provided significant clinical benefit in reducing the signs of chronic periodontitis.

In the past few decades, a new strategy has emerged. Several controlled-release delivery systems have been developed to deposit antimicrobials directly into the periodontal pocket and maintain effective concentrations of drug for an extended period. After extensive study, these agents have been declared safe and effective for the treatment of chronic adult periodontitis. In some cases, they are used as monotherapy, and in other cases, they are administered adjunctively with SRP, which is generally considered by the professional community to be the best approach.

Evidence-based practice, which provides dental treatment based on research, produces optimal care for the greatest number of patients.[123,124] Locally delivered, controlled-release antimicrobials may have the most robust data of any periodontal therapy to support their clinical use. This chapter considers the available clinical data that support the use of these agents for the treatment of chronic periodontitis and provides evidence-based guidance for their use. In this discussion, locally delivered, controlled-release antimicrobials are considered as a drug class rather than individually.

Because appropriate comparative trials have not been performed, there are insufficient data on which to base comparisons of agents or consider differential indications for use. The indications for use of each product are described in their respective full prescribing information. Some commentary is provided regarding these agents and available research for potentially new indications that have not been evaluated by the U.S. Food and Drug Administration (FDA) (Box 53.1).

Box 53.1

Adjunctive Therapy

- Adjunctive therapy makes scaling and root planing (SRP) more effective.

- Because most pockets are quiescent, mean changes are modest when all pockets are included.
- Significantly more patients show large pocket depth reductions with adjunctive therapy.
- Clinical responses are evident only after time and with clinical pocket measurements.
- The greatest clinical benefit is likely to result when adjunctive agents are routinely included as part of SRP procedures and in a long-term periodontal maintenance program.

U.S. Locally Delivered, Controlled-Release Antimicrobials

Three locally delivered, controlled-release antimicrobial products are available for dental use in the United States (Table 53.1): a chlorhexidine-containing chip (PerioChip), a doxycycline gel (Atridox), and minocycline microspheres (Arestin). A fourth product, an ethylene or vinyl acetate copolymer fiber containing the antibiotic tetracycline (Actisite as a 12.7-mg, 9-inch filament), was the first product introduced into the U.S. market in the early 1990s and was the prototypic system. The tetracycline fiber is no longer commercially available in the United States, and its clinical use is not further considered, but it is included because data generated from clinical studies of the product are pertinent to a discussion of the general effects of locally delivered, controlled-release antimicrobials.

TABLE 53.1

Locally Delivered, Controlled-Release Antimicrobials Developed and FDA Approved for Dental Use in the United States

Product	Antimicrobial Agent
Actisite[a]	Tetracycline
PerioChip	Chlorhexidine
Arestin	Minocycline
Atridox	Doxycycline

[a]No longer commercially available in the United States.

Chlorhexidine Chip

The chlorhexidine chip is a small chip (4.0 × 5.0 × 0.35 mm) that contains 2.5 mg of the active ingredient chlorhexidine gluconate in a resorbable, biodegradable matrix of hydrolyzed gelatin that is cross-linked with glutaraldehyde and packaged in individual foil containers (Fig. 53.1A). The chip is stored at 20° to 25° C (68° to 77° F), with excursions permitted to 15° to 30° C (59° to 86° F). The chlorhexidine chip is placed into the pocket directly from the foil container using a forceps (see Fig. 53.1B).

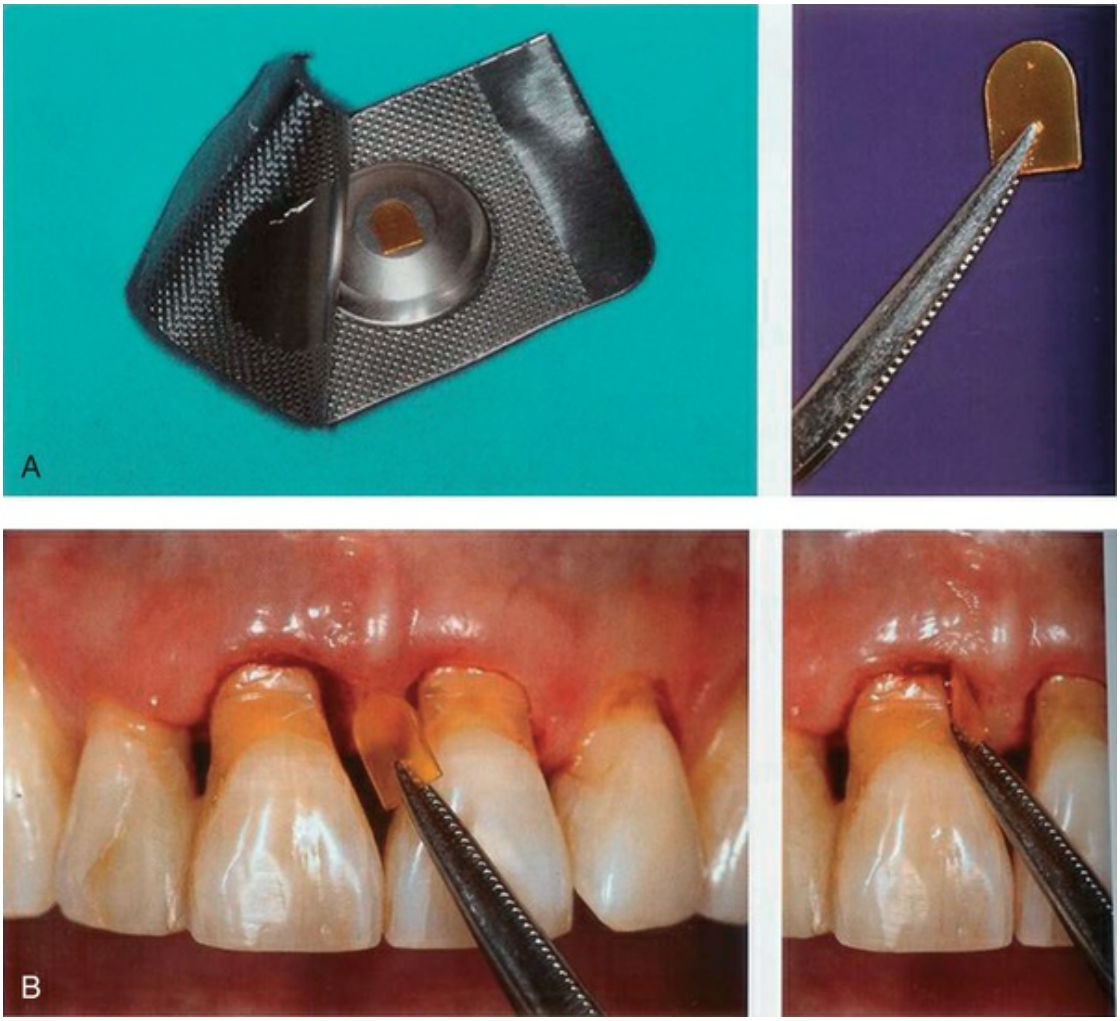

FIG. 53.1 Chlorhexidine gluconate chip (PerioChip). (A) The chip is packaged in a foil packet *(left)*. The chip is removed from the foil container with a suitable forceps *(right)*. (B) The chip is inserted into the pocket, curved end first *(left)*. After insertion, the chip is pressed apically to the base of the pocket *(right)*. (Reprinted from Wolf HF, Hassell TM: *Color atlas of dental hygiene: periodontology*, ed 1, Stuttgart, Germany, 2006, Thieme, with permission.)

The chlorhexidine chip is indicated as an adjunct to SRP

procedures for the reduction of pocket depth in adults with periodontitis, and it can be used as part of a periodontal maintenance program, which includes good oral hygiene and SRP.[145] After placement in the pocket, the chip has been reported to release chlorhexidine into the gingival crevicular fluid (GCF) over 7 to 10 days.[184] Chlorhexidine is active against a broad range of microbes. It disrupts the cell membrane and causes precipitation of the cytoplasm, resulting in cell death. No adverse alterations in the oral microbial flora or overgrowth of opportunistic microorganisms have been observed.[145] The chip is biodegradable and does not require removal, but dental floss should be avoided for 10 days to avoid dislodging it.

Doxycycline Gel

Doxycycline gel is a subgingival, controlled-release delivery product composed of a two-syringe mixing system (Fig. 53.2A). Syringe A contains 450 mg of a bioabsorbable polymeric formulation of 36.7% poly(D,L,-lactide) dissolved in 63.3% *N*-methyl-2-pyrrolidone. Syringe B contains 50 mg of doxycycline hyclate, equivalent to 42.5 mg of doxycycline. The two syringes are stored at 2° to 30° C (36° to 86° F). When mixed, the product is a viscous liquid of 500 mg, which contains 50 mg (10%) of doxycycline hyclate.

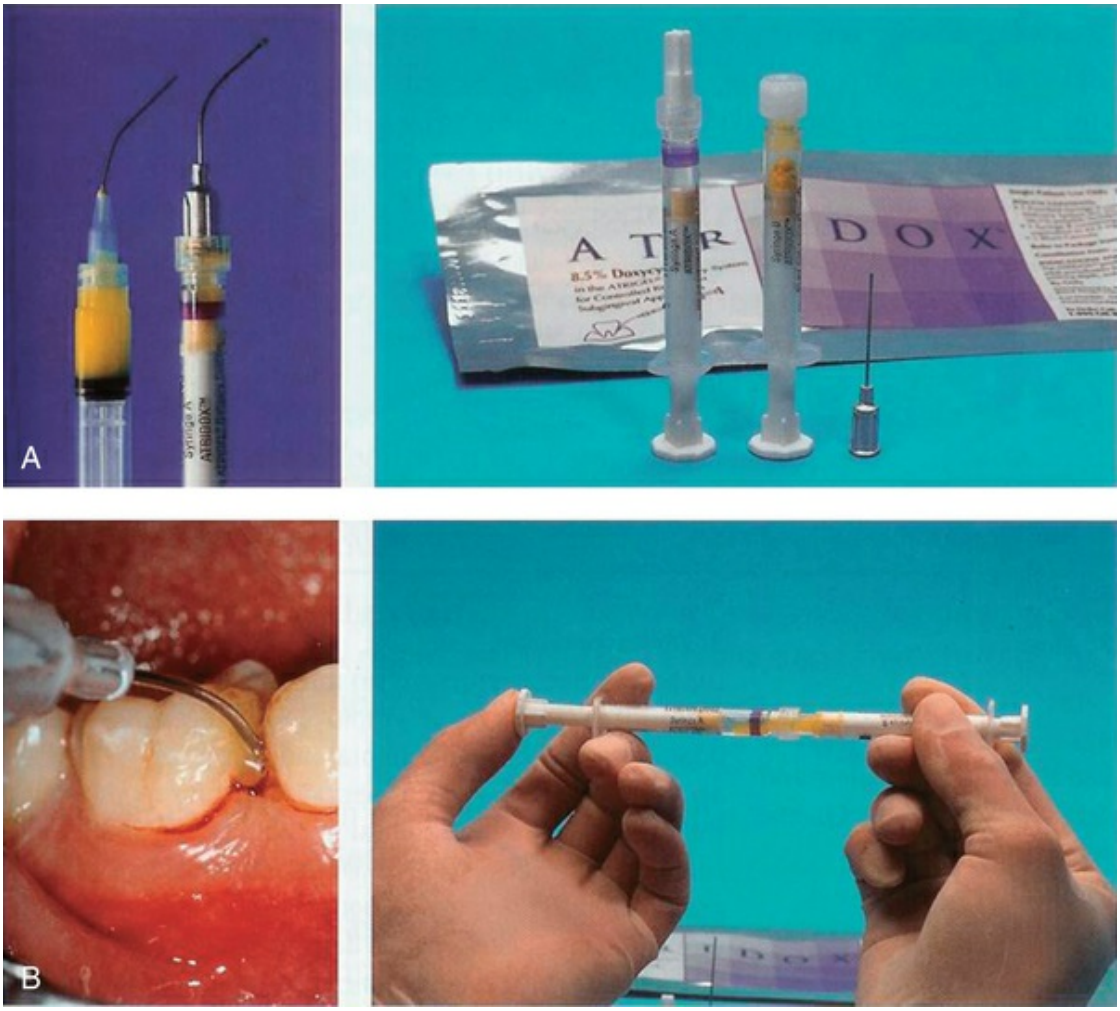

FIG. 53.2 **Doxycycline hyclate gel (Atridox). (A) Doxycycline gel is packaged as a two-syringe mixing system *(right)*. After mixing the gel, a cannula is attached for injection *(left)*. (B) The two syringes are coupled, and the liquid contents of syringe A are injected into the powder within syringe B; the contents are mixed within the two syringes for 100 cycles (1 cycle/sec) and then left within syringe A *(right)*. The mixed solution is injected into the pocket through the cannula attached to syringe A until the pocket is completely filled *(left)*. The pocket contents are covered with a periodontal dressing or a cyanoacrylate dental adhesive.** (Reprinted from Wolf HF, Hassell TM: *Color atlas of dental hygiene: periodontology*, ed 1, Stuttgart, Germany, 2006, Thieme, with permission.)

Doxycycline gel is indicated for the treatment of chronic adult periodontitis for a gain in clinical attachment, reduction in probing depth, and reduction of bleeding on probing.[17] Doxycycline, a broad-spectrum semisynthetic tetracycline, is bacteriostatic, inhibiting bacterial protein biosynthesis by interfering with transfer RNA (tRNA) and messenger RNA (mRNA) at the ribosome. No overgrowth of opportunistic organisms was observed after use of the doxycycline gel.[17]

The gel has been reported to release doxycycline in the GCF over

7 days.[192] The doxycycline gel is biodegradable and does not require removal. If not used immediately, the mixed contents in syringe A can be stored in an airtight container at room temperature for a maximum of 3 days. The doxycycline gel is used by injecting the mixed contents of the two syringes directly into the pocket (see Fig. 53.2B). The pocket contents are then covered with a periodontal dressing or a cyanoacrylate dental adhesive.

Minocycline Microspheres

The minocycline microspheres product is a subgingival, controlled-release delivery system containing the antibiotic minocycline hydrochloride incorporated into a bioresorbable poly(glycolide-co-D,L-lactide) polymer in unit-dose cartridges (Fig. 53.3). Each cartridge delivers minocycline hydrochloride equivalent to 1 mg of minocycline free base. Minocycline microspheres are indicated as an adjunct to SRP for the reduction of pocket depth in patients with adult periodontitis and as part of a periodontal maintenance program, which includes good oral hygiene and SRP.[16]

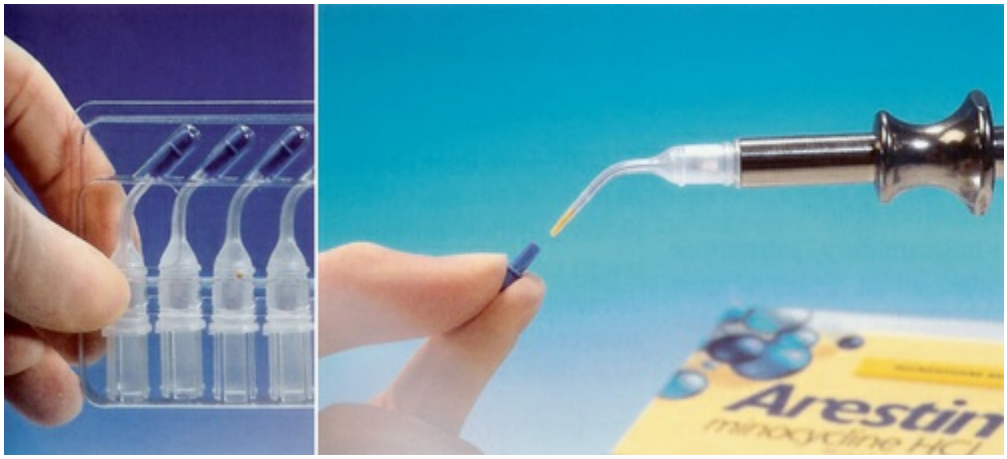

FIG. 53.3 Minocycline hydrochloride microspheres (Arestin). Minocycline microspheres are packaged into unit-dose cartridges *(left)*. Microspheres are used by injecting the cartridge contents directly with a syringe into the periodontal pocket *(right)*. (Reprinted from Wolf HF, Hassell TM: *Color atlas of dental hygiene: periodontology*, ed 1, Stuttgart, Germany, 2006, Thieme, with permission.)

Minocycline belongs to the tetracycline class of antibiotics and has a broad spectrum of activity. Its bacteriostatic, antimicrobial activity results from the inhibition of protein biosynthesis. No

overgrowth of opportunistic microorganisms was reported from clinical studies. No changes in the number of minocycline-resistant bacteria, *Candida albicans* or *Staphylococcus aureus*, in the gastrointestinal tract were detected at the end of a 56-day study, although there was a slight increase in the numbers of minocycline-resistant bacteria in periodontal pocket plaque samples after 9 months.[16] The clinical significance of the changes is unknown.

Patients should avoid hard or sticky foods at the treated teeth for 1 week and interproximal cleaning devices for about 10 days. The minocycline microspheres formulation is biodegradable and does not require removal. The cartridges are stored at 20° to 25° C (68° to 77° F), with excursions permitted to 15° to 30° C (59° to 86° F). Excessive heat should be avoided. The minocycline microspheres are used by injecting the contents of a unit-dose cartridge into the pocket. Neither a periodontal dressing nor an adhesive is needed.

Complete details on the use of locally delivered, controlled-release antimicrobials and their safety profiles are available in the full prescribing information for each product.[16,17,145]

Non-U.S Locally Delivered, Controlled-Release Antimicrobials

After approval by the FDA of locally delivered, controlled-release antimicrobials for clinical use in the United States, several products were approved for use in other countries. These products typically use antimicrobial agents that were discussed earlier for U.S. products.

Chlorhexidine-Based Products

PerioCol-CG

PerioCol-CG is a small, 10-mg chip (4 × 5 × 0.25–0.32 mm) designed as a collagen matrix into which chlorhexidine gluconate (2.5 mg) is incorporated from a 20% chlorhexidine solution that is its active ingredient. The chip is designed for insertion into the periodontal pocket and resorbs after 30 days, but its coronal edge degrades within 10 days.[14,34] It releases chlorhexidine in vitro at a rate of approximately 40% to 45% in the first 24 hours, followed by a linear

release for 7 to 8 days, and it has a shelf life of 2 years.[14,68]

Chlo-Site

Chlo-Site is a xanthan gel, consisting of a saccharide polymer as a three-dimensional mesh containing 1.5% chlorhexidine in 0.5 mL of gel, which is injected into the periodontal pocket (Fig. 53.4). The gel product is sterilized by gamma radiation at 2.5 Mrad and is individually packed for delivery in 0.25-mL prefilled syringes fitted with a blunt side-exit needle.[12,34,44]

FIG. 53.4 Chlo-Site gel packaging is shown *(left)*. The xanthan gel with chlorhexidine is inserted into the periodontal pocket *(right)*. (Reprinted from Gill, et al: Nonsurgical management of chronic periodontitis with two local drug delivery agents—a comparative study. *J Clin Exp Dent* 3:e424–e429, 2011.)

The gel contains two types of chlorhexidine: a slow-release chlorhexidine digluconate (0.5%) and a rapid-release chlorhexidine dihydrochloride (1.0%).[12] The gel is retained within the pocket and is not easily dislodged by the GCF or saliva. The gel disappears from the pocket in 10 to 30 days and is reported to achieve a chlorhexidine concentration in GCF of more than 100 µg/mL for an average of 6 to 9 days and to maintain an effective concentration for at least 15 days.[34,69]

Tetracycline-Based Products

PerioCol-TC

As reported by the manufacturer,[48] each PerioCol-TC vial contains fish type I collagen (approximately 25 mg) impregnated with approximately 2.0 mg of tetracycline hydrochloride, which is sterilized by gamma radiation (Fig. 53.5). PerioCol-TC releases tetracycline in vitro for 8 to 10 days. A periodontal dressing should be placed to avoid dislodging the fibers.

FIG. 53.5 PerioCol-TC fibers are packaged in an individual vial. (Courtesy Eucare Pharmaceuticals, Ltd., Chennai, India. http://www.eucare.in/dental-regeneration-concepts.html.)

PerioCol-TC is indicated for the treatment of adult periodontitis as an adjunct to SRP for pockets more than 5 mm deep, and it can be administered every 3 months. The fibers are moistened with saline and placed into the periodontal pocket to the depth of the pocket base; they are biodegradable and do not have to be removed. PerioCol-TC is stored in a dry place between 5° C (41° F) and 25° C (77° F) and has a shelf life of 2 years with proper storage.

Periodontal Plus AB

Periodontal Plus AB is a bioresorbable tetracycline fiber. It is 25 mg of pure fibrillar collagen evenly impregnated with approximately 2 mg of tetracycline hydrochloride (Fig. 53.6).[174] The fibers are packaged as a strip containing four individually packed and separable sterile product packs. The fiber biodegrades in the

periodontal pocket within 7 days.[34] The fiber should be retained with a periodontal dressing or covered with a dental adhesive for 10 days.

FIG. 53.6 Periodontal Plus AB packaging (*left*). Fibers are Inserted into the periodontal pocket *(right)*. (Reprinted from Gill, et al: *J Clin Exp Dent* 3:e424–e429, 2011.)

Doxycycline-Based Products

Ligosan Slow Release

Ligosan Slow Release is a 14% (w/w), resorbable doxycycline gel for periodontal application provided in a laminate pouch and stored under refrigeration. It contains 1, 2, 4, 8, 10, or 16 single-application cylinder cartridges, each containing 260 mg of Ligosan Slow Release (Fig. 53.7).[107]

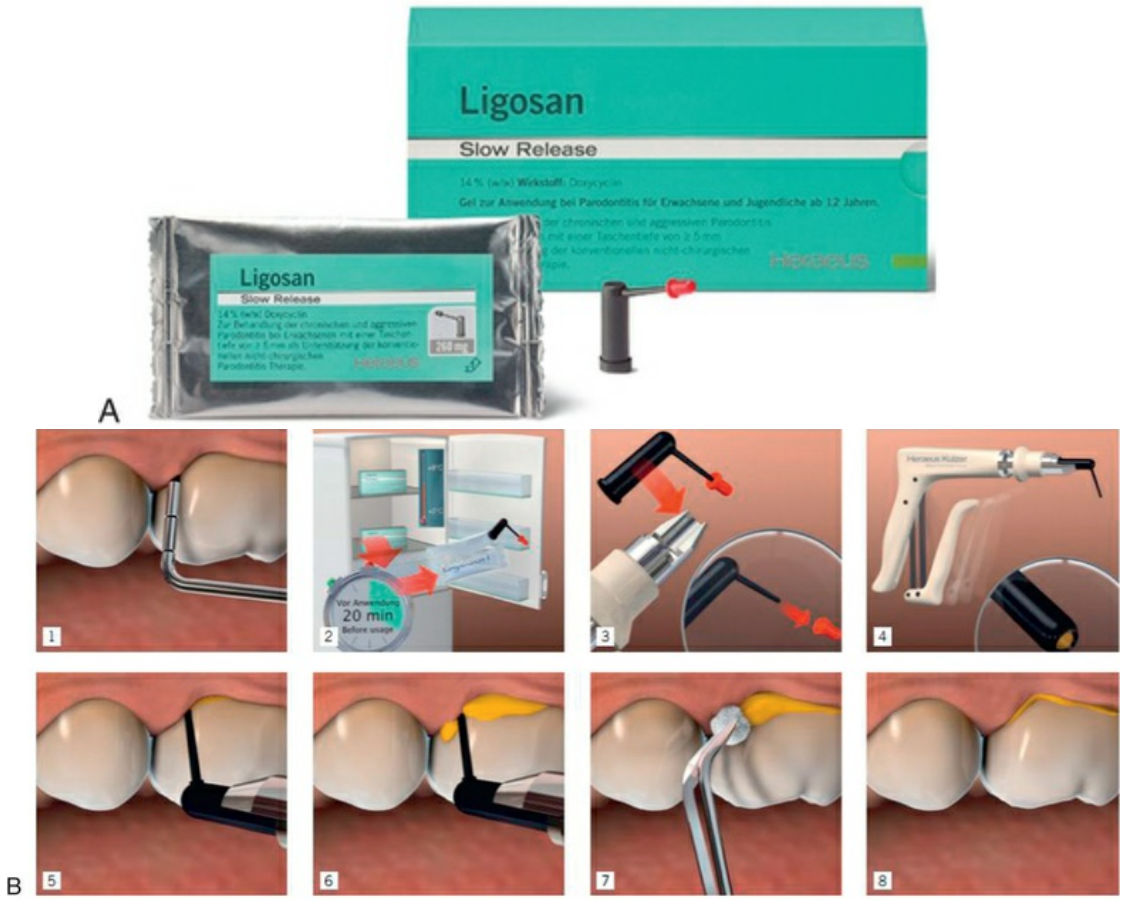

FIG. 53.7 (A) Ligosan Slow Release; box, laminate pouch and caulking gun tip. (From http://www.zm-online.de/markt/heraeus-kulzer/produkte/Ligosan-Slow-Release-in-Einer-Packung_69583.html). (B) Steps 1 through 8 in the placement procedure. (From http://heraeus-kulzer.de/media/webmedia_local/downloads_new/ligosan_4/Ligosan_Produktinformation_DE.pdf.)

The product is used by inserting the cartridge into the caulking gun, opening the spray nozzle, and then discharging the gel to the bottom of the pocket. The doxycycline release profile was studied in 20 patients.[107] The maximal value in the GCF within the first 5 hours (i.e., at 15 minutes) was 19.97 ± 5.58 mg/mL; after 3 days, the concentration was 577.1 ± 127.3 μg/mL. Concentrations in the GCF remained above 16 μg/mL for at least 12 days. Mechanical hygiene in the area should be avoided for 7 days.

Rationale for Local Delivery and Controlled Release

Chronic adult periodontitis is a multifactorial disease (Fig. 53.8). The first requirement is a susceptible host, largely due to genetics and not modifiable. Another nonmodifiable risk factor is age.

Disease risks that may be modifiable include pathogenic oral plaque microorganisms and behavioral or environmental factors such as tobacco use. Mediating the pathogenesis are host-derived elements, including immune and inflammatory responses that can affect soft and hard tissue metabolism and feed back on the pathogenic flora.

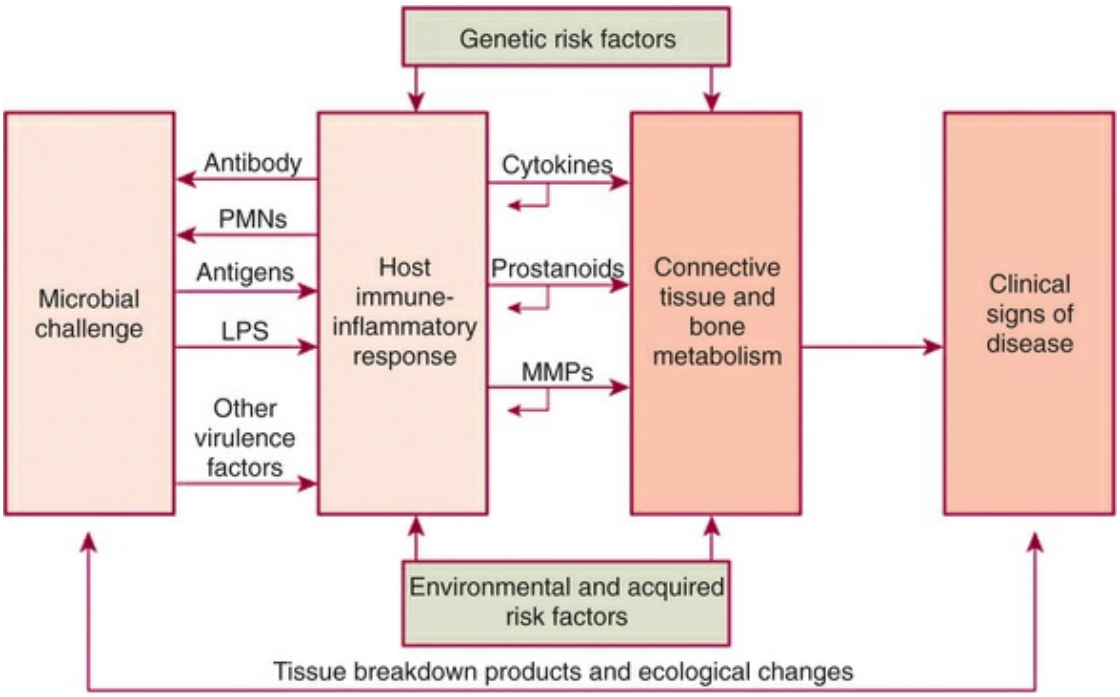

FIG. 53.8 Schematic representation of the pathogenesis of periodontal diseases and possible avenues for prevention or treatment. Through several virulence factors such as antigens or lipopolysaccharides *(LPS)*, pathogenic microorganisms stimulate a host immune-inflammatory response. Immune elements, including polymorphonuclear leukocytes *(PMNLs)* and antibodies, can inhibit the offending microorganisms, and various cytokines, prostanoids, or enzymes can affect connective tissue and bone metabolism, ultimately resulting in the clinical signs of periodontitis initiation and progression. Genetic factors or environmental/acquired factors can separately affect disease risk. Potential avenues for intervention include scaling and root planing and use of antimicrobial agents to inhibit pocket microorganisms (i.e., affecting the microbial challenge), nonsteroidal or other antiinflammatory agents to inhibit cytokines or

prostanoids (i.e., affecting the host immune-inflammatory response), antiresorptive agents (e.g., bisphosphonates) to inhibit osteoclastic bone resorption, and host-modulation therapy (e.g., low-dose oral doxycycline) to inhibit matrix-metalloproteinase *(MMP)* activity (i.e., affecting connective tissue and bone metabolism). (Modified from Page RC, Kornman KS: The pathogenesis of human periodontitis: an introduction. *Periodontology* 2000 14:9–11, 1997.)

From the most basic perspective, periodontal diseases are bacterial infections; the requirement for bacteria to initiate the periodontal lesion is well recognized. The antibacterial effect of SRP or other mechanical therapy generally results from a reduction of the bacterial load or an alteration of the composition of the bacterial flora at the periodontal site, but the antibacterial effect of mechanical treatment alone is insufficient, providing the rationale for chemically augmenting the mechanical therapy.

Many strategies have been used to deliver antimicrobial agents to the periodontal pocket at effective doses to reduce the bacterial microflora, including systemic administration or local administration by local irrigation of fluid formulations or placement of various gels or ointments. None of these strategies has proved as effective as controlled-release antimicrobials.

A drawback of antimicrobials delivered to the pocket but not in controlled-release formulations results from the dynamics of the GCF. The GCF fills the periodontal pocket space, but the copious flow out of the pocket continuously moves GCF contents to the oral cavity.[57,65] The flow rate can be markedly enhanced in the setting of inflammation. Antimicrobials delivered to the pocket are quickly washed out of the pocket by the GCF, rapidly reducing the concentration of drug locally to sub-antimicrobial levels (Figs. 53.9 and 53.10). GCF drug concentrations may need to be elevated above usual levels because microorganisms in the pocket can exist within a protective biofilm structure in the periodontal ecosystem[38,187] (for reviews of periodontal microbiology and biofilms, see Palmer,[134] Teughels et al,[194] or Kuboniwa and Lamont[105]). Bacterial biofilms can be highly resistant to penetration by fluids,[47] emphasizing the critical need for high GCF concentrations of active antimicrobials,

which are achievable only with locally delivered, controlled-release agents (see Pharmacokinetics) but not possible with locally delivered antimicrobials not in controlled-release formulations or by systemic routes. Drisko[45] suggested that the high antimicrobial concentrations in the GCF as a result of local delivery could help to reach infected sites within the root or tissue.

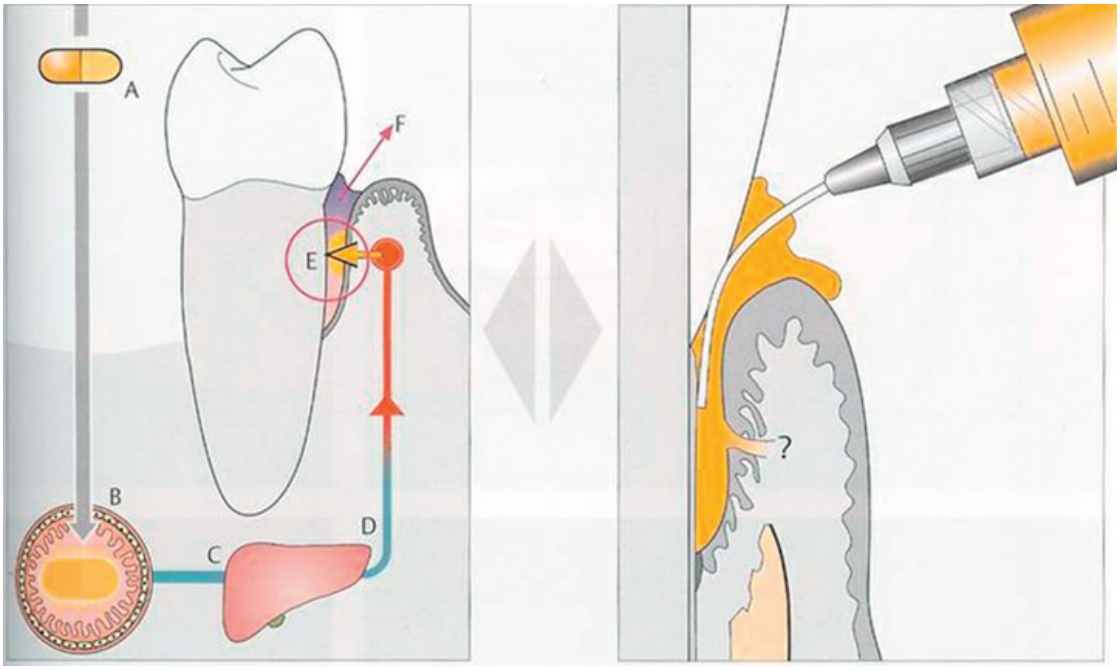

FIG. 53.9 Schematic representation of the inability to achieve therapeutically sufficient concentrations in the periodontal pocket for sufficient time with antimicrobials delivered systemically or locally but not in controlled-release formulations. *Left,* Orally administered drug *(A)* is absorbed in the gastrointestinal tract *(B)*, transported by the portal pathway to the liver *(C),* and enters the circulatory system *(D)*, from which drug exits the vasculature into the periodontal pocket *(E)*. Drug is quickly eliminated from the pocket into the oral cavity by the copious flow of gingival crevicular fluid (GCF) *(F)*. Locally administered drugs not in controlled-release formulations suffer from the same limitation. *Right,* Locally delivered, controlled-release antimicrobial is administered into the periodontal pocket, where it remains until it degrades, continuously releasing drug into the GCF over time. Antimicrobial drug may be active against plaque bacteria that have invaded the

surrounding periodontal tissues. (Reprinted from Wolf HF, Hassell TM: *Color atlas of dental hygiene: periodontology*, ed 1, Stuttgart, Germany, 2006, Thieme, with permission.)

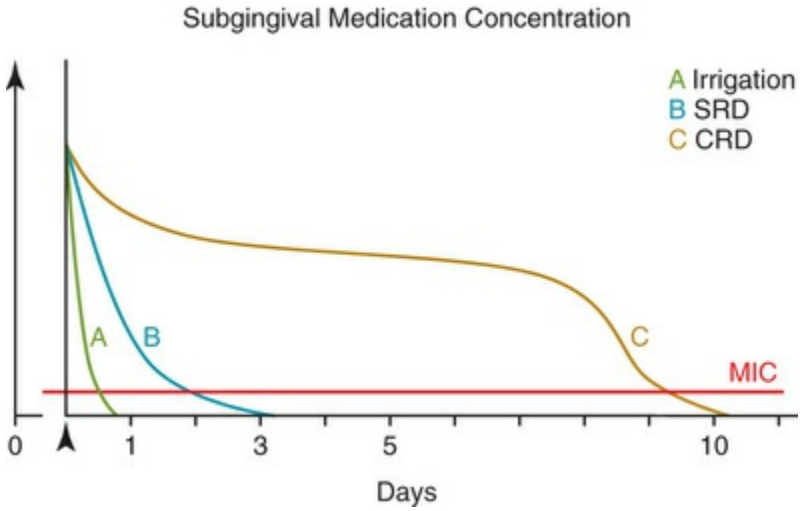

FIG. 53.10 Graph shows the release profile of locally delivered, sustained-release or controlled-release antimicrobials by irrigation. Drug concentration in the gingival crevicular fluid (GCF) is diminished rapidly after irrigation *(A)*. Drug concentration can be extended for several days with drug administered in a modified, sustained-release formulation *(B)*. Drug concentration in the GCF can be maintained at therapeutically relevant concentrations for up to 10 days with controlled-release formulations *(C)*. Area under the curve but above the minimal inhibitory concentration *(MIC)* line represents drug concentration in the gingival crevicular fluid greater than MIC values. The MIC for subgingival plaque bacteria may be substantially greater than typically reported bacterial MIC values because of the potentially protective effect of a subgingival biofilm formation. *CRD*, Controlled-release delivery; *SRD*, sustained-release delivery; *arrowhead*, administration of locally delivered agent. (Adapted from Wolf HF, Hassell TM: *Color atlas of dental hygiene: periodontology*, ed 1, Stuttgart, Germany, 2006, Thieme, with permission.)

Drug concentrations of systemically delivered antimicrobials in the GCF are orders of magnitude less than those achievable with

controlled-release local delivery, and they cannot provide equivalent therapy.[175,192] Drug that is transferred from the plasma compartment to the GCF in the periodontal pocket is quickly washed away by the GCF flow (see Fig. 53.9). It was previously thought that systemically delivered tetracyclines markedly concentrated drug in the GCF compared with plasma,[62,143] but the hypothesis was not supported by later studies.[175,192] Some investigators have suggested that systemic therapies, rather than locally delivered agents, should be considered when there are multiple pocket sites for the sake of convenience and to save costs,[64,167] but if high concentrations of an antimicrobial drug are desired in the periodontal pockets, systemic delivery is not the appropriate therapy. Other benefits of locally delivered, controlled-release antimicrobials include decreased systemic, off-target effects and a decreased risk for promoting microbial resistance.

Pharmacokinetics

The pharmacokinetic principles of controlled-release local delivery are illustrated in Fig. 53.10. Drug delivered locally to the periodontal pocket but not in a controlled-release formulation (e.g., by irrigation) is washed out of the pocket by the GCF flow, quickly reducing the concentration of drug in the GCF.[57] Locally delivered, controlled-release antimicrobials have been designed to maintain high and clinically relevant concentrations of drug in the GCF for extended periods. The pharmacokinetics of the chlorhexidine chip, doxycycline gel, and minocycline microspheres have been studied in clinical trials.

Clinical Correlation

Controlled-release agents maintain clinically effective intrapocket concentrations of antimicrobial for an extended period of time.

Chlorhexidine Chip

The release profile of the chlorhexidine chip was evaluated in a single-center, 10-day clinical trial in 19 patients with chronic adult periodontitis.[184] Each patient received a single chip administered

into each of four pocket sites, and concentrations of chlorhexidine were determined in GCF, plasma, and urine at various times after dosing. Peak GCF concentrations were achieved 2 hours after dosing (2007 ± 422 μg/mL), with GCF concentrations maintained between approximately 1300 and 1900 μg/mL to 4 days after dosing. Mean chlorhexidine concentrations then steadily decreased to 57 ± 13 μg/mL at 9 days. Chlorhexidine was below detectable limits in plasma and urine at all time points. For perspective, Wilson and colleagues[208] reported that chlorhexidine (125 μg/mL) killed 99.9% of cultivable bacteria from plaque samples from patients with chronic periodontitis within 15 minutes.

Doxycycline Gel

The release profile of the doxycycline gel was evaluated in a single-center, 28-day clinical trial in 32 patients with adult periodontitis and compared with oral doxycycline.[192] All patients assigned to receive local delivery had doxycycline gel administered to all pocket sites with probing depths of 5 mm or more that bled on probing. Drug was retained after placement with a noneugenol (NE) periodontal dressing (n = 13) or 2-octyl cyanoacrylate (2-O) (n = 13). Mean GCF concentrations peaked 2 hours after dosing (1473 ± 328 μg/mL for NE; 1986 ± 445 μg/mL for 2-O). At day 7, mean concentrations were 309 ± 127 μg/mL (NE) and 148 ± 49 μg/mL (2-O). Mean salivary concentrations peaked at 2 hours (4.05 ± 1.24 μg/mL for NE; 8.78 ± 1.48 μg/mL for 2-O) and were 2 μg/mL or less at 24 hours. Serum concentrations after local administration remained at 0.1 μg/mL or less.

For oral doxycycline (200 mg on day 0 and then 100 mg/day for 7 days; n = 6), GCF concentrations peaked at 12 hours after dosing (2.53 ± 1.56 μg/mL), and serum concentrations ranged from 0.91 to 2.26 μg/mL for the 8 days of data collection. Salivary concentrations never exceeded 0.11 μg/mL.

Minocycline Microspheres

The release profile of minocycline microspheres was studied in 18 patients with moderate to advanced chronic periodontitis.[15,16] Minocycline microspheres (mean dose, 46.2 mg; 25 to 112 unit doses) were administered to eligible periodontal pocket sites with a

5 mm or more probing depth (i.e., minimum of 30 sites on at least eight teeth; 1 mg/treatment site) after SRP. Serum and saliva samples were collected before dosing and at various times after dosing to 14 days. The mean dose-normalized saliva area under the curve and maximal concentration (C_{max}) were approximately 125 and 1000 times that of serum parameters, respectively. In saliva, the minocycline C_{max} was 254.0 ± 139.3 mg/mL at 0.75 ± 0.56 hours after dosing, with a half-life of 44.7 ± 19.2 hours.[15] In serum, the mean minocycline concentrations peaked at 4.8 ± 1.8 hours after dosing (C_{max}: 216.4 ± 122.9 µg/mL) and were undetectable by 7 days. Minocycline concentrations in saliva and GCF were sufficient (>1 µg/mL) to kill bacteria associated with periodontal disease in vitro.[15] These concentrations were evident for up to 14 days without significant systemic exposure.[15]

Drug Development and Registration

An investigational drug is typically studied in many clinical trials before it can be approved for clinical use, and locally delivered, controlled-release antimicrobials are no exception. These products have been rigorously studied in multiple trials to confirm their safety and efficacy for the indication of chronic adult periodontitis. Beyond the discussion of their effectiveness in the following sections, more information on drug development and registration, safety evaluation, informed consent, trial design, and information specific to periodontal studies is provided later in this chapter.

Locally Delivered, Controlled-Release Antimicrobials: Magnitude of the Effect

To consider results of clinical trials of the locally delivered, controlled-release antimicrobials available in the U.S., a literature search for published trials was conducted in Ovid Medline from 1990 to 2012 using the search terms (1) chlorhexidine, minocycline, doxycycline, or tetracycline; (2) clinical trial, delayed action preparations/tetracycline/drug delivery systems/periodontal diseases/periodontitis/minocycline/local delivery, double-blind

methods/placebo, parallel group, local drug delivery or pharmaceutical preparations/drug delivery systems/polymers/delayed-action preparations/drug carriers; and (3) periodontitis/chronic periodontitis, gingivitis/periodontal diseases/dental scaling/periodontal attachment loss/alveolar bone loss/periodontal pocket, planing, gingival crevicular fluid, periodontal index, periodontal treatment, or dental plaque. A total of 1216 articles were identified; of these, 186 were reviewed as potentially relevant. An additional search for later publications using a similar search strategy was conducted to identify additional pertinent trials to mid-2016; 101 additional articles were identified, of which 16 papers were reviewed. Overviews of results of reviewed trials of the doxycycline gel, minocycline microspheres, or the chlorhexidine chip used adjunctively or as monotherapy are presented in Tables 53.2, 53.3, and 53.4.

TABLE 53.2

Clinical Trials of Locally Delivered, Controlled-Release Antimicrobials (*N* ≥ 60/Treatment Group)

Drug	Study Design	Inclusion Criteria	Treatment Groups	Treatment	Study Duration
DOX[173]	Randomized, multicenter (10 ctrs), parallel-group, single-blind, monotherapy	Mod-sev periodontitis in ≥2 quads. Each quad had ≥4 pocket sites with PD ≥5 mm with BOP. Two sites had to be ≥7 mm	DOX (1) Nonsmokers *N* = 52 (2) Former smokers *N* = 65 (3) current smokers *N* = 60 SRP (1) Nonsmokers *N* = 48 (2) Former smokers *N* = 72 (3) Current smokers	All pts received OH. SRP pts rec'd SRP in the 2 treated quads, repeated at 4 mo (SRP until hard & smooth; local anesthesia PRN; no time restraints). DOX & veh at baseline	9 mo

			N = 61	and 4 mo applied to all qualifying pockets	
DOX[25]	Randomized, multicenter (3 ctrs), parallel-group, single-blind, adjunctive	≥15 natural teeth, ≥4 w PD ≥5 mm, previously treated for moderate/advanced chronic periodontitis, recall programs for SPT ≥1 yr	(1) SPT alone, *N* = 65 (2) SPT + DOX, *N* = 63	SRP at baseline, no time limit, anesthesia if requested. In group (2), DOX in all sites w PD, PD ≥5 mm. 0.1% chlorhexidine rinse for 1 mo. Returned to clinic for SPT q 6 mo. At 1 & 2 yr, DOX in sites w PD ≥5 mm	3 yr
TET[46]	Randomized, multicenter (3 ctrs), split-mouth, single-blind, adjunctive and monotherapy	≥1 site in each of 4 quads with PD ≥5 mm with BOP	(1) SRP alone (2) TET alone (3) TET alone administered twice, 10 d apart (4) SRP + TET *N* = 122	Supragingival scaling 2 wk before baseline. SRP w anesthesia for 5 min/tooth. Scaling at 10 d to remove any residual calc	12 mo, maintenance period
TET[125]	Multicenter (7 private practices) randomized, split-mouth, single-blind, adjunctive	Maintenance pts receiving regular SPT in private practice. Two nonadjacent sites in separate quadrants w PD 5–8 mm + BOP	(1) SRP alone (2) SRP + TET fiber *N* = 113	Full-mouth SRP (no more SRP info); TET placed in test teeth	6 mo
TET[58]	Multicenter (5 ctrs), randomized, split-mouth, single-blind, monotherapy	4 nonadjacent teeth w PD 6–10 mm w BOP	*N* = 113 (1) TET (2) plc (3) SRP (4) No tx	Prebaseline prophy; SRP for each tooth ≥5 min, local anesthesia 10 d, fiber removal	60 d

MIN[207]	Parallel-group; double-blind; adjunctive therapy; multicenter (18 ctrs)	ADA type III (mod) or type IV (sev) periodontitis. ≥4 teeth w PD 6–9 mm w BOP	(1) SRP alone, *N* = 250; (2) SRP + vehicle, *N* = 249; (3) SRP + MIN, *N* = 249; All sites ≥5 mm received study drug or vehicle at baseline, 3 & 6 mo	Full-mouth SRP at baseline; no limits: time or local anesthesia	9 mo
CHX[136]	Split-mouth; single-blind; adjunctive therapy; multicenter (4 ctrs)	Two sites per pt; PD ≥5 mm; BOP	(1) SRP alone (1 site); (2) SRP + CHX chip (1 site) *N* = 116	Two 2-hr sessions within 48 hr; w local anesthesia; full-mouth subgingival prophy at 3 mo	6 mo
CHX[185]	Randomized, single-blind, multicenter (3 ctrs), adjunctive therapy, split-mouth	≥1 pocket, PD 5–8 mm, w BOP, in each max quadrant	(1) SRP alone; *N* = 118 pts; 485 pockets (2) SRP + CHX chip *N* = 118 pts; 474 pockets	Full mouth SRP (tx time limited to 1 hr). At 3 mo, full-mouth supragingival prophy per clin need. CHX inserted if PD 5–8 mm	6 mo
CHX[82]	Two multicenter, randomized, double-blind, parallel-group, adjunctive therapy (5 ctrs each)	≥10 teeth, ≥4 teeth w PD ≥5 mm, BOP. Stratified by smoking status	Group 1 pts (active chip) SRP + CHX chip (Tx 1) SRP alone, *N* = 225 Group 2 pts (plcb chip) SRP + plcb (Tx 2); SRP alone (Tx 3), *N* = 222	Supragingival prophy for 1 hr. SRP for 1 hr for all teeth. Chips in test sites at baseline, at 3 & 6 mo if PD still ≥5 mm. Exit prophy at 9 mo	9 mo
DOX[52] Study 1	Randomized, multicenter (10 ctrs), parallel-group, single-blind, monotherapy	Mod-sev periodontitis in ≥2 quads. Each quad had ≥4 pocket sites with PD ≥5 mm with BOP. Two sites had to be ≥7	(1) DOX, *N* = 95 (2) Veh, *N* = 94 (3) OH, *N* = 95 (4) SRP, *N* =	All pts received OH. SRP pts rec'd SRP in the 2 treated	9 mo

		mm.	99	quads, repeated at 4 mo (SRP until hard & smooth; local anesthesia PRN; no time restraints). DOX & veh at baseline and 4 mo applied to all qualifying pockets	
DOX[52] Study 2	Randomized, multicenter (10 ctrs), parallel-group, single-blind, monotherapy	Mod-sev periodontitis in ≥2 quads. Each quad had ≥4 pocket sites with PD ≥5 mm with BOP. Two sites had to be ≥7 mm.	(1) DOX, *N* = 95; (2) Veh *N* = 94 (3) OH *N* = 95 (4) SRP *N* = 99	All pts received OH. SRP pts rec'd SRP in the 2 treated quads, repeated at 4 mo (SRP until hard & smooth; local anesthesia PRN; no time restraints). DOX & veh at baseline and 4 mo applied to all qualifying pockets	9 mo
CHX[186]	Open-label, 8 private dental offices, phase IV	≥30 yr age; pockets w PD ≥5 mm; no perio sx or SRP by periodontist within 2 yr of entrance	SRP group Non-SRP group (already on active RPMT) *N* = 835 enrolled; 595 completed at 24 mo	SRP (SRP group only) 1 mo before baseline. RPMT q 3 mo. All sites receiving CHX chip at baseline got CHX q 3 mo if PD ≥5 mm	2 yr
MIN[24,59]	Multicenter, single-blind, randomized, parallel-group, phase IV	30–65 yr age; ≥16 teeth; 5 sites w PD ≥5 mm in 5 nonadjacent interproximal spaces (excluding	(1) SRP alone, *N* = 65 (2) SRP + MIN, *N* = 62	Full-mouth SRP in ≤2 visits ≤10 d apart w hand, ultrasonic instruments, &	30 d

		distal of terminal teeth; no perio tx or antibiotics within 3 mo		local anesthesia permitted. MIN administered for group 2 to sites w PD ≥5 mm	

AL, Attachment level; *BOP*, bleeding on probing; *calc*, calculus; *CHX*, chlorhexidine chip; *cln*, clinical; *ctr*, center; *d*, day; *DOX*, doxycycline hyclate gel; *est*, estimated; *h*, hour; *info*, information; *MIN*, minocycline microspheres; *mo*, month(s); *mod*, moderate; *NA*, not applicable; *NR*, not reported; *OH*, oral hygiene; *PD*, probing depth; *perio*, periodontal; *plcb*, placebo; *prophy*, prophylaxis; *pt*, patient; *quad*, quadrant; *rec'd*, received; *RPMT*, routine periodontal maintenance therapy; *sev*, severe; *SPT*, supportive periodontal therapy; *SRP*, scaling and root planing; *sx*, surgery; *tx*, treatment; *veh*, vehicle; *vs*, versus; *w*, with; *wk*, week; *yr*, year.

TABLE 53.3

Clinical Trials of Locally Delivered, Controlled-Release Antimicrobials (*N* = 20–59/Treatment Group)

Drug	Study Design	Inclusion Criteria	Treatment Groups	Treatment	Study Duration	PD OUTCOM Absolute Reduction from Baseline (mm)
TET, MIN, MET[100]	Randomized, single-blind, parallel-group, single-center, adjunctive	≥4 nonadjacent teeth w PD ≥5 mm w BOP or suppuration	(1) SRP alone. *N* = 20 (2) SRP + MIN. *N* = 21 (3) SRP + TET. *N* = 19 (4) SRP + MET. *N* = 19	Full mouth SRP w local anesthesia (target teeth for ~5 min) MIN or MET applied at baseline and 2 & 4 wk. Clinical Trials of Locally Delivered, Controlled-Release Antimicrobials (*N* ≤ 19/Treatment Group)

Drug	Study Design	Inclusion Criteria	Treatment Groups	Treatment	Study Duration
CHX[89]	Randomized, double-blind, parallel-group, single-center, adjunctive	≥12 teeth w PD ≥5 mm w BOP	(1) SRP + placebo chip. *N* = 12 (2) SRP + CHX. *N* = 12	2 supraging scaling at d 7 & 14. CHX or placebo placed (max 2 chips/tooth if >1 site/tooth w PD ≥5 mm. At d 24, SRP on test teeth & on teeth w PD >3 mm w BOP in 1 app't for 1 hr. New chip placed per randomization	6 mo
CHX[118]	Randomized, single-blind, parallel-group, single-center, adjunctive	≥15 natural teeth, ≥2 sites w PD ≥5 mm, radiographic bone loss	(1) SRP alone. *N* = 17 (2) SRP + CHX. *N* = 17	Supraging scaling ≥2 wk before study. SRP at baseline (methods NR). Group 2, CHX at baseline & at 3 mo if PD ≥5 mm	6 mo
MIN[56]	Randomized,	≥2 sites on different	(1) No tx.	SRP (methods	6 mo

	single-blind, parallel-group, single-center, adjunctive, & monotherapy	teeth w PD ≥7 mm in 1 quad w culture of ≥1 of *Porphyromonas gingivalis*, *Prevotella intermedia*, or *Aggregatibacter actinomycetemcomitans*. Exclusion if ≥class II mobility or hopeless bone loss	*N* = 10 (2) SRP alone. *N* = 6 (3) SRP + MIN. *N* = 11 (4) MIN only. *N* = 12	NR) in study quad. MIN at baseline only	
TET, MIN, MET[86]	Randomized, single-blind, parallel-group, single-center, adjunctive	≥4 nonadjacent teeth w PD ≥5 mm w BOP or suppuration	(1) SRP alone. *N* = 13 (2) SRP + MIN. *N* = 14 (3) SRP + TET. *N* = 13 (4) SRP + MET. *N* = 14	Full-mouth SRP w local anesthesia (target teeth for ~5 min) MIN or MET applied at baseline and 2 & 4 wk. TET fiber placed for 10 d.	6 wk after last treatment
DOX[158]	Randomized, controlled, single-blind, parallel-group; single-center, adjunctive	Mod to adv periodontitis. ≥20 teeth. ≥10 w PD ≥5 mm w BOP. No subging instrumentation within 12 mo of baseline	(1) Ultrasonic + DOX gel *N* = 19 (2) ultrasonic *N* = 14	Full-mouth ultrasonic debridement 3 mo before baseline. Baseline exam. Reinstrumentation w ultrasonic (no time limit). Local analgesia if requested. Supraging plaque control at 1 & 3 mo	9 mo
TET[195]	Single-center, split-mouth	≥20 teeth. In each quad, 2–3 interprox sites w PD ≥6 mm & BOP	(1) untreated (2) TET alone (3) SRP alone (4) SRP + TET *N* = 10	Before screening: OHI, supraging calc removal, polishing. Tx 1 at baseline: Subging SRP. Tx 2 at 10 d: SRP again for groups 3 & 4. TET again for 2 & 4. 0.2% CHX rinse. q 2 wk, OHI & supraging, cleaning	62 d
CHX[74]	Split-mouth,	1 tooth per treatment	(1) SRP +	SRP w anesthesia	1 mo

	single-center; single-blind	group, PD 6–7 mm	CHX chip; (2) SRP alone; *N* = 13	for ≥10 min per tooth	
CHX[40]	Split-mouth; single-center; single-blind	≥4 teeth w PD 4–5 mm & BOP. No furcations, third molars or incisors	(1) SRP + TET fiber. (2) SRP alone *N* = 19	SRP w anesthesia. Time NR. Fiber placed, then cyanoacrylate adhesive. CHX rinse for 10 days. Maintenance scaling at 3, 6, & 9 months.	12 mo
CHX, MET[176]	Parallel-group; single-center; single-blind	≥2 teeth w PD ≥5 mm & BOP	(1) CHX chip, *N* = 15; (2) DOX gel, *N* = 16 (3) MET gel, *N* = 16	SRP 2–4 mo prior to baseline. Drug placed at baseline	4 mo
CHX[6]	Randomized, single-blind, parallel-group design. Number of centers not reported	≥4 pockets, PD ≥5 mm, BOP	(1) SRP alone *N* = 9 (2) SRP + CHX chip, *N* = 10	SRP at baseline w local anesthesia. At 3 & 6 mo, all sites w PD ≥5 mm received subgingival retreatment. Test group received a new CHX chip. Full-mouth supragingival prophylaxis monthly for both groups until the end of the study	9 mo
MIN[37]	Double-blind, randomized, single-center, adjunctive therapy	Nontreated chronic periodontitis, nonsmoker, 2 sites (no molars) from each pt w PD ≥6 mm (no furcation involvement	(1) SRP + MIN, *N* = 13 (2) SRP + veh, *N* = 13	Local anesthesia, then full-mouth SRP (supraging & subging) + MIN or veh at baseline and again at 90, 180, & 270 days	24 mo
TET[66]	Nonrandomized, single-center, adjunctive, and monotherapy	Periodontal maintenance w ≥1 site w PD ≥4.0 mm & BOP	(1) TET alone, *N* = 16 (2) SRP + TET, *N* = 6	SRP w local anesthesia, 5 min/tooth. TET fiber placed	6 mo
TET[31]	Single-center, single-blind,	Mod to adv perio disease; ≥2 sites in	(1) SRP alone	SRP, then TET for group 2 target	7 wk

	randomized, adjunctive, split-mouth	each quad w PD 5 mm + BOP	(2) SRP + TET *N* = 17	teeth	
MIN[210]	Single-center, single-blind, randomized, adjunctive, split-mouth	Mod to sev chronic periodontitis; 2 pairs of adjacent teeth on opposite sides of mouth w adjacent interproximal sites of PD 6–9 mm, smooth surfaces only w ≥3 mm attachment loss; no antibiotics for 3 mo or perio tx for 6 mo	(1) SRP alone (adjacent to MIN site) (2) SRP alone (opposite side from MIN site) (3) SRP + MIN *N* = 15	Full-mouth SRP w sonic/ultrasonic or hand instruments w local anesthesia as needed, then MIN administration	6 mo
DOX[4]	Single-center, parallel group	Chronic periodontitis; ≥5 nonadjacent pockets w PD ≥5 mm	(1) SRP alone, N = 6 (30 sites); (2) SRP + DOX, N = 6 (30 sites); All sites were 6–7 mm	Through SRP, then ± DOX	6 mo

Key Fact

Phase III clinical trials are the gold standard for evidence-based decision making. Evidence-based practice leads to the greatest clinical benefit for the greatest number of patients. Locally delivered, controlled-release antimicrobials have been studied in multiple adequate and well-controlled phase III clinical trials.

Although somewhat arbitrary, trials have been organized into

three tables based on the number of patients per treatment group: $n \geq 60$ (see Table 53.2), $n = 20$ to 59 (see Table 53.3), and $n \leq 19$ (see Table 53.4). This was an attempt to group trials based on size and therefore approximately on robustness for ease of consideration. The trials have a wide range of designs. Many suffer from design features that lessen the robustness of the data, including relatively small sample sizes, lack of blinding, or split-mouth design.

Results of trials with patient numbers per group of 60 or less and largely with phase III–like designs are presented in Table 53.2. Regulatory decisions are generally based on the clinical results of these types of trials, and they provide the outcomes on which treatment decisions should be based. As seen in Table 53.2, the results of published trials with treatment period endpoints and with antimicrobial agents administered according to the registration trials and the full prescribing information consistently show that outcomes obtained with SRP plus a locally delivered, controlled-release antimicrobial are significantly improved compared with mechanical therapy alone.

Mean differences of probing depth reductions from baseline in trials of adjunctive locally delivered, controlled-release antimicrobials compared with SRP alone range from approximately 0.20 to 0.70 mm. Potential clinical benefits are discussed later. The important consideration is that the changes were significant; trials met their primary objectives. Trials designed to consider monotherapy have shown outcomes with local delivery that are at least equivalent to those with SRP.

Results from smaller trials are presented in Tables 53.3 and 53.4. The results from these trials are mixed. Some have shown an increased benefit with adjunctive therapy compared with SRP alone, but others have shown no such increase. Many trials suffer from design features that are less robust than those in Table 53.2 and cannot provide conclusions that can support treatment decisions. These trials mostly have to be considered hypotheses-generating studies. In contrast, many of the trials reported in Table 53.2 can be considered as hypothesis-testing studies, and they have reached conclusive outcomes that supported regulatory approvals and can support treatment decision making. These trials found that clinical outcomes after SRP plus adjunctive use of a locally

delivered, controlled-release antimicrobial were significantly enhanced compared with SRP alone.[71]

Statistical Versus Clinical Significance

At least six multicenter, randomized, phase III–style trials[82,125,136,185,207] showed that SRP plus adjunctive treatment resulted in a significantly greater probing depth reduction from baseline compared with SRP alone. Probing depth is thought to be a clinically meaningful endpoint for periodontitis trials,[140,146] an appropriate outcome measure of inflammation,[92,140] and predictive of further disease progression,[166] although the progression of periodontitis may be most meaningfully measured by loss of attachment or alveolar bone.[10,42,132,162,170] The improvement in probing depth reduction with SRP plus adjunctive therapy versus SRP alone is statistically significant. The more relevant question is whether the difference is clinically significant and meaningful for patient benefit.

The mean differences in clinical trials between the probing depth reduction from baseline between treated (i.e., SRP plus adjunctive agent) and control (i.e., SRP plus placebo or SRP alone) groups were reported as approximately 0.2 to 0.7 mm.[82,125,136,185,207] The changes numerically seem small and of little clinical significance, but they need to be viewed from several perspectives. For example, it is commonly thought that only a low percentage of periodontitis sites are active at any time (i.e., actively evidencing tissue breakdown) and that most sites are relatively stable and inactive.[61,70,132,182] Because most sites may be stable at most times, unless a trial is enriched for active sites, it seems likely that there would not be much difference between treated and control sites in most patients. Many of the data points used to define a mean difference are small or near zero (i.e., no difference versus control). To increase the magnitude of mean changes in a clinical trial, the trial would have to be enriched for active sites, and to our knowledge no such trial has been reported.

Clinical trials for FDA registration are typically performed using an intent-to-treat analysis. The data from all entered patients are included in the analysis regardless of whether they complete the

trial; the anticipated small mean changes may be even further diluted by data recorded before the planned endpoint. The expected small mean outcomes highlight the importance of the statistical analyses. Adjunctive locally delivered, controlled-release antimicrobials have consistently shown this statistical benefit in multiple, well-designed, phase III–style clinical trials. For example, the mean probing depth reduction improved across all tested sites entered, including in patients with incomplete treatment, in a number of trials from about 22% to about 68% compared with controls (see Table 53.2), a magnitude of change that seems clinically significant.

A significant mean percentage change versus the control implies that the response curve is significantly shifted toward increased benefit for the population under study. The efficacy of local adjuncts was subsequently supported at the 2003 Workshop on Contemporary Science in Clinical Periodontics, which also concluded that the clinical result obtained after SRP that included the adjunctive use of a locally delivered, controlled-release antimicrobial was significantly enhanced compared with that after SRP alone.[71]

A mean probing depth reduction of 2 mm or more from baseline is commonly considered clinically significant.[82,156,207] Use of adjunctive locally delivered, controlled-release antimicrobials resulted in a significantly greater percentage of patients or sites with a probing depth reduction of 2 mm or more compared with SRP alone in adequate and well-controlled trials (see Table 53.2). This level of reduction may ultimately translate into a clinical outcome of fewer lost teeth, but this hypothesis requires testing in clinical trials with tooth mortality as the primary objective rather than surrogate endpoints.[78]

Available data support that adjunctive therapy is statistically and clinically significant. The clinical significance of the adjunctive benefit was also acknowledged at a symposium considering locally delivered chemotherapeutic agents in periodontal therapy sponsored by the Periodontal Research Group at the 1998 Annual Meeting of the American Association for Dental Research (AADR).[95] A later review confirmed that available trial evidence supported the adjunctive use of locally delivered, controlled-release

antimicrobials but commented that the data must be interpreted with caution.[120]

Clinical Correlation

Significantly more patients showed PD reductions 2 mm or more following SRP plus adjunctive therapy versus SRP alone.[82,87]

To consider the results from another perspective, surgery is a common treatment for patients with chronic adult periodontitis, but the mean differences in probing depth reduction between sites treated surgically and those treated with SRP alone have been in the neighborhood of several tenths of a millimeter.[75,133] The mean difference in probing depth reduction as a result of SRP plus adjunctive therapy compared with SRP alone is similar to the mean difference of probing depth reduction as a result of surgical procedures compared with SRP. The clinical significance of adjunctive therapy parallels that of periodontal surgery. The 1996 World Workshop in Periodontics concluded that "[o]utcomes [after surgical and nonsurgical therapy] after several years are generally similar."[209] As stated about the clinical significance of locally delivered antimicrobials at the 2001 Annual Meeting of the AADR, "[t]he case is stronger for local delivery than for surgery."[98] The use of locally delivered, controlled-release antimicrobials in the surgical setting is discussed later.

An example from the medical literature further illustrates the value of examining percentage changes rather than concentrating on absolute changes. Osteoporosis is a substantial public health concern because of the morbidity and mortality that result from osteoporotic fractures. Bisphosphonates have long been a mainstay of pharmacologic treatment for osteoporosis. Boonen and coworkers[27] reported that the rate of new morphometric vertebral fracture was 1.6% with zoledronic acid treatment versus 4.9% with placebo over 24 months. Although the absolute percentage of fractures was low, the change was a 67% risk reduction as a result of therapy (relative risk = 0.33; 95% confidence interval, 0.16–0.70; P = .002).

The available data confirm that adjunctive therapy is statistically

significant and support that it is clinically significant. When used routinely, practitioners can expect an enhanced mean clinical result. More clinical trials are necessary to expand knowledge regarding locally delivered, controlled-release antimicrobials, including additional clinical indications.

Clinical Correlation

Data support the idea that adjunctive therapy is both clinically significant and statistically significant.[71]

Phases of Drug Development

The typical investigational drug is studied in many clinical trials before an application (i.e., new drug application [NDA]) can be submitted to the U.S. Food and Drug Administration (FDA) for clearance for commercial marketing in the United States. Clinical trials before registration are often conducted in three phases. Phase I trials usually enroll small numbers of healthy volunteers to determine preliminary safety and dosing. Phase II trials typically enroll larger numbers of patients to characterize preliminary safety in patients and to determine dosing that is evaluated in later trials. Large phase III trials often are called pivotal or registration trials and usually are multicenter, blinded, and randomized studies that enroll sufficiently large numbers of patients to provide conclusive evidence of safety and efficacy to support the submission of an NDA to the FDA for registration for marketed use.

After FDA registration, phase IV trials may be performed to provide additional information about drug products, including longer-term safety and efficacy in a broader number of patients or in alternative practice settings. The objectives of the phases of clinical research as described by the National Institutes of Health[202] are given in Table 53.5. The typical phases of drug development seem less distinct when trials are considered in exploratory or confirmatory stages.[201] Specialized clinical pharmacology trials may be conducted at any phase to provide specific information such as pharmacokinetics or to address treatment conditions such as specific patient populations (e.g., geriatric or pediatric patients,

patients with hepatic or renal impairment) or the effect of the drug on cardiac electrophysiology (e.g., QT prolongation). The drug development process has been reviewed by Tonkens[199] and by Mathieu and Milne.[113] The FDA offers an overview of the drug review process to ensure that drugs are safe and effective (https://www.fda.gov/Drugs/ResourcesForYou/Consumers/ucm143

TABLE 53.5

Phases of Clinical Research

Phase	Description
I	Researchers test a new drug or treatment in a small group of people for the first time to evaluate its safety, determine a safe dosage range, and identify side effects.
II	The drug or treatment is given to a larger group of people to see if it is effective and to further evaluate its safety.
III	The drug or treatment is given to large groups of people to confirm its effectiveness, monitor side effects, compare it with commonly used treatments, and collect information that will allow the drug or treatment to be used safely.
IV	Studies are done after the drug or treatment has been marketed to gather information on the drug's effect in various populations and side effects associated with long-term use.

Key Fact

Regulatory Clearance for Controlled Release Antimicrobials

- Investigational drugs are typically studied in many clinical trials before clearance for marketing. Data from adequate and well-controlled clinical trials (e.g., phase III) are required for regulatory decision making.
- Drugs must be shown to be safe and effective before they can be marketed.
- FDA labels provide complete information for the proper use of locally delivered, controlled-release antimicrobials.

Trial Design Considerations

Regulatory decisions depend on the data produced by adequate and well-controlled phase III clinical trials providing evidence that a drug is safe and effective when used as intended. These trials are usually large and conducted in many investigational centers to enroll a sufficient number of patients to give the proper statistical power and to complete the trial within a reasonable length of time. Multicenter trials are enormously expensive and difficult to perform. Clinical trials must be designed appropriately to test the hypotheses. Some important design features of trials that are considered adequate and well controlled are listed in Table 53.6 and discussed in the following sections.

TABLE 53.6

Characteristics of Adequate and Well-Controlled (Phase III) Clinical Trial Designs

1. Type I error rate control
2. Clear statement of the proposed and actual objectives
3. Methods of analysis in the protocol, statistical analysis plan, and reports
4. Methods of adequate assurance of patient selections
5. Patient assignments that minimize bias and group comparability
6. Methods to minimize bias for all parties: patients, investigators, and data analysts
7. Well-defined endpoints that address the primary hypothesis
8. Analysis of results that allows for interpretation of the effects of the study drug

Modified from U.S. Food and Drug Administration: Electronic Code of Federal Regulations. §314.126 https://www.ecfr.gov/cgi-bin/text-idx?SID=6d23d836424edd2eeb76d932e75aca7b&mc=true&node=se21.5.314_1126&rgn

Type I Error Rate Control

A type I error occurs when the investigator rejects the null hypothesis when it is true (i.e., rejecting the null hypothesis that there is no effect of the treatment or drug in question and concluding that there is an effect). The probability of a type I error is the level of significance of the statistical test of the hypothesis and is denoted by *alpha*. This error contrasts with a type II error, when the alternative hypothesis (i.e., fails to reject the null hypothesis) is rejected although the alternative hypothesis is actually true. A clinical trial should be adequately designed so that the *alpha* level is set at $P \leq .05$, the value that is most commonly used as the cutoff for

statistical significance.

Statement of the Proposed and Actual Objectives

The primary and secondary objectives of the trial must be clearly defined in the protocol at the start of the study. The stated objectives should adequately address the study hypotheses. Exploratory objectives may also be included in the trial protocol, but they are typically considered as hypothesis-generating rather than hypothesis-testing objectives. Analyses not predefined and generated during the course of the study or assessed at the end of the study are typically denoted as post hoc analyses and are usually not appropriate for regulatory evaluation or decision.

Analysis in the Protocol, Statistical Plan, and Reports

The statistical methods planned for the analysis of trial data should be prespecified in the protocol and perhaps expanded in a statistical analysis plan, ideally before the start of the trial but at least before locking of the study data. In this fashion, all methods are predefined and not subject to bias as a result of the trial outcomes. Manuscripts or reports arising from the trial should adequately describe the analytic methods so that readers can appropriately consider and interpret the results of the trial.

Patient Selection and Assignment

The protocol should include methods for appropriately enrolling patients to ensure the study population represents the broader population and that study outcomes can be generalized to a broader population of similar patients. Multicenter trials (versus a single center or a few centers) increase the heterogeneity of the study population and make the study results more generalizable. There must be adequate procedures in place to ensure that patients are randomly included and not specifically selected, which can skew study results.

Patients should be randomly assigned to treatment groups to minimize the chances for systematic differences between groups. Treatment groups should be as comparable as possible so that any differences in study outcomes between groups can confidently be

ascribed to the study treatment. Treatment assignments should be sequential and generated by appropriate randomization schemes (usually computer generated) to eliminate the potential for bias in treatment selection by investigators or sponsors. For particular characteristics of interest (e.g., smoking status for periodontal trials), treatment assignments can be stratified to ensure an equal distribution of the characteristics among all treatment groups.

Dental studies often use teeth randomized to different treatment assignments in the same patient (i.e., split-mouth designs), using patients to serve as their own controls. This type of assignment should be discouraged because the units of statistical analysis are no longer independent. With this intrapatient design, there are considerable concerns that treatment for one or more teeth (i.e., periodontal pockets) in one treatment group could affect the other treatment sites in the same patient or that all treatment groups could be affected by host factors equally or differentially. The parallel-group design is preferable because the statistical unit is the patient, ensuring that sites in a treatment group are completely independent and not subject to confounding by the other treatment groups.

Minimizing Bias for Patients, Investigators, and Data Analysts

Pivotal trials are typically double blinded or triple blinded to prevent patients, investigators, and statistical analysts from being aware of treatment assignments. In this fashion, no patients, investigators, study staff, or those who analyze the data can consciously or inadvertently influence the study outcome.

Well-Defined Endpoints That Address the Primary Hypothesis

The study protocol should clearly describe all endpoints that will be assessed and the methods of assessment. Pivotal trials can include many dozens of study sites, and there is considerable risk of systematic differences among different investigators. Protocols must standardize study methods as much as possible among study sites so that all treatments and study procedures are performed and

all endpoints are assessed in the same manner at all study centers. The endpoints chosen should be relevant to the study objectives.

Current designs of clinical trials to assess periodontal outcomes usually are limited to the evaluation of surrogate endpoints (e.g., probing depth, attachment level) rather than direct and more clinically relevant endpoints such as tooth survival. An endpoint of tooth survival, although arguably better, is not practical for a clinical trial conducted within a reasonable period or with a reasonable number of patients. Surrogate variables are considered acceptable endpoints in periodontal clinical trials and relevant to tooth retention,[63,79] although surrogate outcomes have inherent weaknesses.[78] Discordance among surrogate periodontal endpoints[116] further highlights the need for long-term data from clinical trials with tooth survival as the primary objective.

Analysis of the Study Drug's Effects

Statistical analysis of the results allows differentiation of the effects of the study drug or treatment from those caused by systematic differences between treatment groups or biases of the participants in any aspect of the trial. The objective of a clinical trial is to answer a particular research question. The worst result possible is trial completion without being able to interpret the outcome of the trial with confidence, a nonresult that would require repeating the trial. The many elements of study design contribute to the degree of confidence with which investigators can consider the outcome of the trial and the interpretation of results.

The pivotal trials for the chlorhexidine chip[82] and the minocycline microspheres[207] are examples of phase III designs for the study of adjunctive, locally delivered, controlled-release antimicrobials for the treatment of periodontitis. Representative populations of patients with chronic adult periodontitis were enrolled in multicenter, double-blind clinical trials and were randomly assigned to treatment groups. Target pocket sites received SRP at baseline with or without adjunctive drug according to the randomization protocol. At 3 and 6 months, sites randomized to drug received additional drug only if probing depth remained 5 mm or more. Final results showed a reduction of probing depth from baseline at 9 months as expected in all groups, but the

treatment group (i.e., SRP plus adjunctive therapy) showed a significantly greater reduction from baseline compared with the control group (i.e., SRP alone or SRP plus placebo).

If the adjunctive therapy had no effect, probing depth at these sites would have trended toward baseline as in the SRP alone (or SRP plus placebo) sites. The observation that probing depth remained reduced demonstrated that the drug was efficacious. For the chlorhexidine chip trials,[82] baseline measurements were obtained after supragingival scaling. Because a supragingival scaling can result in a mean probing depth reduction of approximately 0.3 to 0.4 mm,[46] interpretation of the absolute changes in probing depth as a result of treatment should consider this potential prebaseline change.

It has been hypothesized that these trial results might have been different had control groups also received repeated treatment (i.e., repeated SRP).[8] However, if the control group had received repeated SRP, the adjunctively treated group also would have had to receive repeated instrumentation to maintain design balance. It cannot be assumed that results might have been different only for the control group. Locally delivered, controlled-release antimicrobials also can be effective in the setting of calculus[85] or with reduced amounts of instrumentation.[206] Additional instrumentation would have made data interpretation more difficult, and multiple treatments at multiple times make it more difficult to separate treatment effects meaningfully. In further support of the lack of an impact of additional instrumentation on the outcome, a similarly significant difference was reported when both treatment arms received SRP at baseline and a supragingival prophylaxis at 3 months.[136]

When considering locally delivered, controlled-release antimicrobials as adjunctive therapy or monotherapy, the general consensus of the professional community seems to be that the best use for these products is in the adjunctive setting. Considerable data, however, support efficacy in the monotherapy setting,[52] and Garrett and colleagues[51] suggested that monotherapy was equally as effective as mechanical instrumentation for supportive periodontal maintenance. The investigators cautioned, however, that further studies are needed to validate this treatment regimen,

and they emphasized the importance of compliance, including frequent visits for professional supportive maintenance.

Evaluating Safety and Efficacy

To approve a drug for market in the United States, the FDA requires conclusive evidence that it is safe and effective for its intended use. Data from at least two pivotal phase III trials usually are required for regulatory decisions, although in some circumstances (e.g., life-threatening disease such as cancer), only one trial may be required, such as when it would be unethical to withhold an effective treatment from patients and conduct a second trial. The concern is that results of one trial may represent a chance occurrence and should be confirmed by a second trial. Earlier trials (i.e., phase I and II) cannot provide data on which to base regulatory or clinical decisions. The FDA states that each of these pivotal trials must be "adequate and well controlled" and describes common characteristics of designs that are considered adequate and well-controlled studies (see Table 53.6).[201] Comments about trial design, especially phase III trials, and these characteristics were provided earlier in this chapter.

Clinical Correlation

Drugs must be shown to be safe and effective before they can be marketed.

Informed Consent and Legal Considerations

Concerns about malpractice litigation and the legal aspects of dentistry are realities of dental practice. Often at the core of malpractice issues is the concept of informed consent, and adjunctive therapy may have a place in this legal framework.

Informed consent is the standard for dental practice. Clinicians must treat all patients under the principles of informed consent, and all patients must provide their consent for treatment. For clinical research, the FDA [adapted from 21CFR 50.25(a)[200]] describes eight elements of informed consent (Table 53.7). These

elements also apply to clinical practice. Appropriate treatment that satisfies the principles of informed consent includes treatment that is evidence based; it is supported by appropriate research data. Because locally delivered, controlled-release antimicrobials as adjuncts have been consistently shown in adequate and well-controlled clinical trials to enhance the efficacy of SRP and provide an additional incremental benefit,[71] performing SRP but not at least offering an adjunctive agent seems to violate the principles of informed consent.

TABLE 53.7

Elements of Informed Consent

1. Description of planned treatment
2. Description of reasonably foreseeable risks or discomforts
3. Description of any reasonably expected benefits
4. Disclosure of appropriate alternative treatment
5. Description of procedures to maintain confidentiality
6. Disclosure of associated costs or payments
7. Answering all patient questions
8. Disclosure that all treatment or study participation is voluntary

Modified from U.S. Food and Drug Administration: 21CFR50.25, revised April 1, 2017. https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm?=50.25.

Undiagnosed or undertreated periodontitis is a major source of dental malpractice litigation.[213] Because SRP procedures are commonly considered the standard of care for nonsurgical periodontal therapy[11,26] and available data confirm that adjunctive locally delivered, controlled-release antimicrobials enhance the efficacy of SRP,[71] SRP plus adjunctive therapy could potentially be considered a new standard. Other investigators have supported the clinical relevance of locally delivered, controlled-release antimicrobials,[a] and SRP without adjunctive therapy could be considered less than maximally effective. In a malpractice litigation of alleged improperly managed periodontitis, it could be claimed that the patient had not been offered maximally effective therapy (i.e., SRP with an adjunctive agent).

Clinical Use

Potential Indications

Additional dental indications for locally delivered, controlled-release antimicrobials have not been evaluated by the FDA. Examples include combination adjunctive therapy and adjuncts for surgical therapy or peri-implantitis. Preliminary data for these indications are available and discussed in the following sections.

Combination Adjunctive Therapy

Many local and systemic adjunctive therapies are available with supportive data on their use in patients. None is labeled for use in combination therapy. It seems likely, however, that some practitioners may already be providing off-label combination adjunctive therapy for their patients, even though appropriate data do not exist.

Locally delivered, controlled-release antimicrobials enhance the clinical efficacy of SRP. Similarly, adjunctive systemic therapy with low-dose (20 mg) doxycycline, given orally twice daily as a host-modulating agent (later reported as a once-daily, modified-release formulation[157]) also can enhance the clinical efficacy of SRP.[30,35,156] Reddy and colleague[163] and Ryan and Golub[172] have reviewed matrix metalloproteinase modulation as a treatment strategy. The question is whether a combination of local antimicrobial and host-modulating adjunctive therapies can provide greater clinical benefit than either adjunctive agent used alone.

In a 6-month clinical trial, combination adjunctive therapies resulted in significantly greater improvements in probing depth and clinical attachment compared with SRP alone.[127] More sites showed a probing depth reduction of 2.0 mm or more, and fewer sites had a residual probing depth 5.0 mm or more.[127] A single case report from this trial was published.[148] Because the appropriate control groups (i.e., SRP plus single adjunctive therapy) were not included in the trial, definitive conclusions regarding increased benefit from combination versus single adjunctive therapy cannot be made. The potential for combined adjunctive therapy to enhance clinical benefit is promising and warrants additional research.

The focus of this chapter is locally delivered, controlled-release antimicrobials. Data support the efficacy of locally delivered,

controlled-release antimicrobials,[71] supporting the conclusion that SRP plus adjunctive therapy could be considered a new standard for nonsurgical periodontal therapy. Available data also support the adjunctive efficacy of systemic, low-dose oral doxycycline[30,35,84,157] to an extent that is numerically similar to that reported for locally delivered, controlled-release antimicrobials. Because appropriate comparative data are not available, comparisons of these therapies is not appropriate, and no conclusion can be reached regarding the most efficacious approach for adjunctive therapy, local or systemic adjunctive therapy or with single or combined agents.

In addition to the possibility of combination adjunctive therapy with a locally delivered agent and host modulatory therapy with low-dose oral doxycycline, Goodson and coworkers[60] reported outcomes from a randomized trial enrolling 231 patients that considered SRP alone and various combinations of SRP, systemic antimicrobials, and surgery using a 2 × 2 × 2 factorial design. Patients were followed for 24 months. Maximal reductions in probing depth and gains in attachment level were observed at 6 months, which were maintained at 24 months in all treatment groups. At 24 months, gains in attachment were increased by systemic antimicrobials (0.50 mm), and probing depth reductions were further augmented by systemic antimicrobials (0.51 mm) and surgical treatment (0.36 mm). Both types of improvements were reduced by smoking.

Surgical Therapy

Pocket sites that do not seem to respond adequately to nonsurgical therapy and evidence residual probing depth with inflammation are often treated with follow-up surgical therapy. A question is whether locally delivered, controlled-release antimicrobials could augment surgical results. This hypothesis was tested in a pilot study by Hellström and coworkers[76] with minocycline microspheres at all pocket sites of 5 mm or more. Sixty patients with at least one nonmolar pocket site with a probing depth of 6 mm or more in each of two quadrants were treated with (1) microspheres at baseline and immediately after each of two surgical

procedures at weeks 2 and 3 and again at week 5 or (2) standard surgical therapy. The mean probing depth was reduced in both treatment groups, but the reduction was significantly greater in the test group than in controls at 25 weeks (2.51 ± 0.10 mm vs. 2.18 ± 0.10 mm, $P = .027$). In contrast, the probing depth reduction after SRP with a limited surgical approach using adjunctive minocycline microspheres was not significantly different compared with SRP in a smaller pilot trial.[212]

A specialized periodontal surgical procedure, regenerative surgery, has become a standard procedure in periodontal practice. It had been suggested verbally as early as 1993 (Killoy WJ, personal communication, 2002) and in print in 1998[94,99] that adjunctive locally delivered, controlled-release antimicrobials might improve outcomes after regenerative periodontal surgery. In a pilot trial, the adjunctive use of the chlorhexidine chip with regenerative surgery resulted in more than a 100% greater mean improvement from baseline in bone height and mass 9 months after surgical treatment compared with SRP alone and surgery.[164] Both groups had also received prophylactic systemic antimicrobial treatment before surgery, but the addition of a locally administered antimicrobial resulted in a significant benefit compared with the control arm.

Other reports support the lack of efficacy of systemic antimicrobials[117] and the benefit of locally delivered antimicrobials[211] as adjunctive treatments in the regenerative setting. A microbiologic rationale for the use of locally delivered antimicrobials (i.e., tetracycline fiber) in the regenerative setting was also supported by Sbordone and colleagues.[177] Aichelmann-Reidy and coworkers[5] suggested that regenerative surgical procedures should include an adjunctive, locally delivered, controlled-release antimicrobial agent to provide a more consistent clinical benefit.

These preliminary reports suggested that the adjunctive use of locally delivered, controlled-release antimicrobials can improve clinical outcomes after periodontal surgery in regenerative and nonregenerative settings. These hypotheses require testing in prospective, adequate, and well-controlled trials. None of the three available agents is approved as an adjunct to surgery.

Peri-implantitis

Similar to periodontitis, peri-implantitis is an inflammatory disease process that is initiated by local microorganisms and that affects the tissues surrounding an implant. An opportunity exists to treat diseased implant sites chemically by targeting the local microflora. There is a potential rationale for the use of locally delivered, controlled-release antimicrobials for the treatment of peri-implantitis. Although the treatment of peri-implantitis is an off-label use, it seems likely that some clinicians have tried local delivery in this setting.

Renvert and coworkers[165] studied 32 patients with at least one implant site with a probing depth of 4 mm or more plus bleeding or exudate on probing. Patients were treated with debridement followed by minocycline microspheres (17 patients, 57 implants) or a chlorhexidine gel formulation (15 patients, 38 implants). Treatments were repeated at 30 and 90 days. Follow-up examinations were performed at 10 days and 1, 3, 6, 9, and 12 months. There were significant reductions in probing depth compared with chlorhexidine at 1, 3, and 6 months and marked reductions in indicator microorganisms in both treatment groups. The study authors concluded that adjunctive minocycline microspheres could be of value in treating peri-implant lesions.

Buchter and colleagues[28] studied 28 patients with a total of 48 peri-implant defects. Two to 18 weeks before baseline measurements, patients had been treated for peri-implantitis (including scaling with a plastic instrument). Patients then continued to receive this treatment alone or with the additional adjunctive use of the doxycycline gel. At 18 weeks, the test group evidenced a significant reduction in mean probing depth and a significant gain in mean attachment levels compared with controls.

Schar and associates[178] and Bassetti coworkers[21] studied 40 patients with peri-implantitis who had probing depths of 4 to 6 mm and less than 2 mm of radiographic bone loss that was treated with mechanical debridement and air polishing and adjunctively with local minocycline microspheres or photodynamic therapy for 12 months. A significant decrease in probing depth from baseline values was observed in photodynamic sites up 9 months and in minocycline sites up to 12 months. Decreases in *Porphyromonas*

gingivalis and *Tannerella forsythia* concentrations and in GCF levels of IL-1β were seen in both groups. There were no significant differences between groups, and no conclusions can be drawn about either therapy compared with mechanical therapy alone because an appropriate control group was not included.

Labels for the available locally delivered, controlled-release antimicrobials do not include an indication for peri-implantitis. Their potential treating peri-implantitis, however, is an exciting possibility, and one that warrants additional research. Phase III trials are needed to test the hypothesis that locally delivered, controlled-release antimicrobials offer clinical benefit as part of a treatment regimen to manage peri-implantitis.

Tobacco Smoking

Smoking is a well-known risk factor for the development or progression of periodontitis, and it can limit the effectiveness of periodontal therapy.[23,81,87,155] The adjunctive use of locally delivered, controlled-release antimicrobials can enhance the efficacy of SRP in smokers. In a 3-month trial, SRP plus adjunctive doxycycline gel resulted in significantly greater probing depth reduction and clinical attachment gain compared with SRP alone about equally in smokers and nonsmokers.[196] This result was consistent with subset analyses of current smokers, former smokers, and nonsmokers from two 9-month, multicenter trials of doxycycline gel[173] and of microspheres smokers versus nonsmokers in studies of minocycline microsphers.[207] Subset analyses of therapy with minocycline microspheres showed that results for smokers were consistent with overall trial results.[130,138]

Consistent results also were seen in a later clinical trial of minocycline microspheres.[67] Beneficial periodontal microbiologic alterations in adjunctively treated sites compared with SRP alone were reported for doxycycline gel and minocycline microspheres (Fig. 53.11).[67,109,179] A 2-year trial of doxycycline gel with a small number of patients provided further evidence of clinical efficacy.[108]

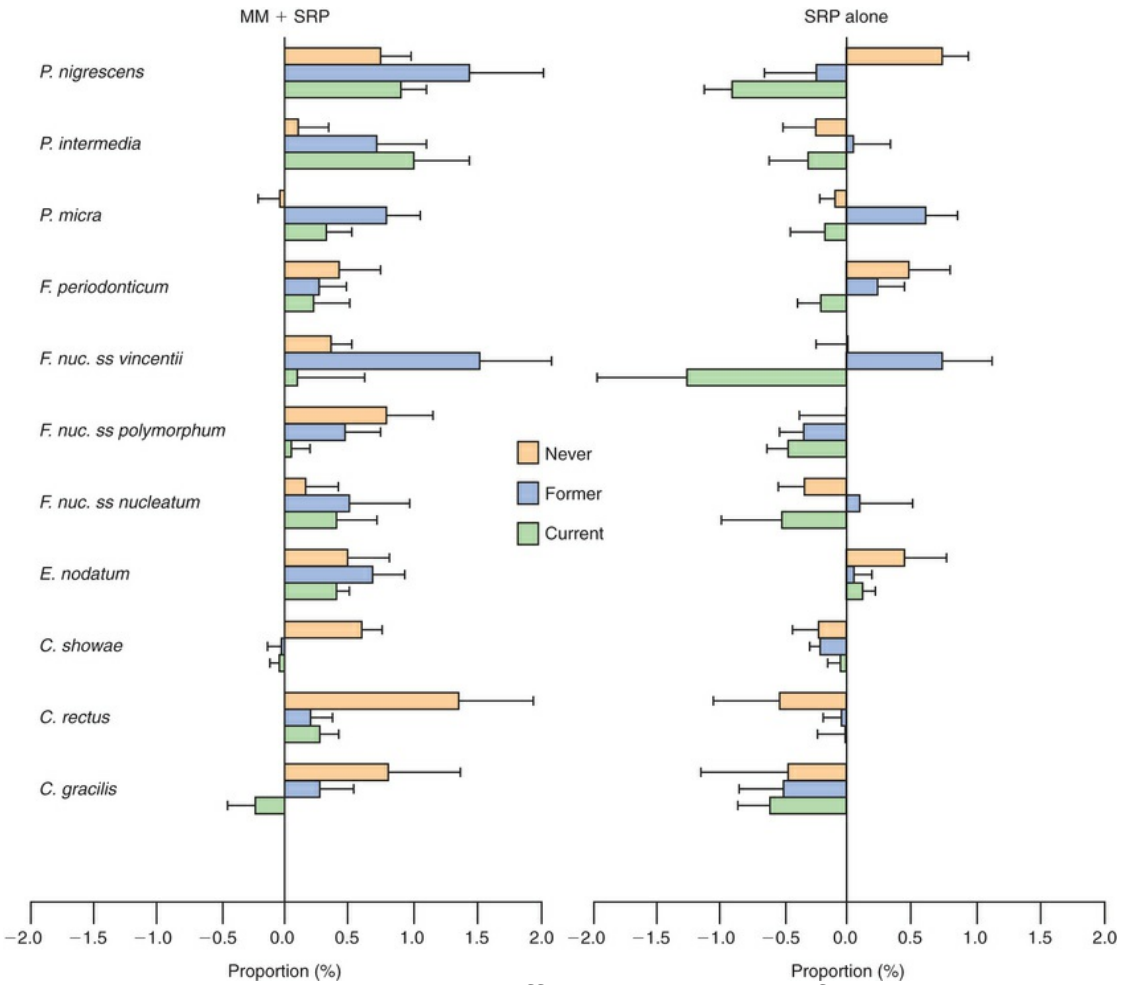

FIG. 53.11 Microbiologic effects are shown after the adjunctive administration of minocycline microspheres *(MM)* in smokers and nonsmokers. Therapy causes changes in the proportion of orange complex bacteria. Positive changes represent antibacterial effects as reductions in proportions. Negative changes represent proportional increases or proliferation of bacterial groups. *F. nuc.*, *Fusobacterium nucleatum; SRP,* scaling and root planing. (Reprinted from Grossi SG, Goodson JM, Gunsolley JC, et al: Mechanical therapy with adjunctive minocycline microspheres reduces red-complex bacteria in smokers. *J Periodontol* 78:1741, 2007, with permission from the American Academy of Periodontology.)

In a pilot trial to test the use of adjunctive minocycline microspheres in a surgical setting, clinical improvement was seen similarly in smokers and nonsmokers.[76] Adjunctive therapy may lessen the adverse impact of smoking on the periodontium and improve treatment outcomes for patients who smoke. A systematic review of the doxycycline gel and minocycline microspheres found

that available data are insufficient to conclude that adjunctive therapy significantly enhances SRP specifically in smokers, and it recommended additional clinical trials (i.e., adequate and well-controlled trials) to assess outcomes for smokers.[9]

Adverse Effects and Cautions for Use

A complete listing of cautions for use and possible adverse effects as listed on the FDA labels for these locally delivered, controlled-release antimicrobials is beyond the scope of this chapter, but complete details about the use of these products and their safety profiles are available in the full prescribing information.[16,17,145]

Clinicians are cautioned about adverse effects of this class of drugs:

- Potential for hypersensitivity reactions (i.e., not to be used in patients with a known sensitivity to any ingredient)
- Potential for the overgrowth of nonsusceptible microorganisms, including fungi
- Use in pregnancy
- Potential for discoloration during tooth development (i.e., tetracyclines only)
- Use in an acutely abscessed periodontal pocket or in extremely severe periodontal defects with little remaining periodontium
- Use of local mechanical oral hygiene procedures (e.g., toothbrushing, interdental cleaning devices) for approximately 7 to 10 days after administration

The most frequently reported adverse reactions reported in the clinical trials without mention of causality include headache, infection (including upper respiratory tract infection), flu syndrome, pain, tooth disorder and toothache, and various oral

signs or symptoms. Toothache was the only adverse reaction that was significantly higher (P = .042) in the chlorhexidine chip group compared with placebo.[145]

Costs and Outcomes

Locally delivered, controlled-release antimicrobials entail costs. Adjunctive therapy with these products adds cost for the patient in addition to that of SRP, depending on fees charged by the practice. Concerns about the costs and the cost-effectiveness of these agents have proved to be a deterrent to routine clinical use. Although a thorough cost-effectiveness analysis is beyond the scope of this chapter, incorporation of adjunctive therapy into clinical practice warrants some assessment of costs and outcomes.

In an economic evaluation of adjunctive therapy, the relevant issues are the additional costs associated with treatment compared with the additional benefits obtained. Because all therapies entail costs, and very few result in a cost savings, the issue is the value of the incremental benefit obtained. An analysis of the additional benefit obtained by adjunctive periodontal therapy in relation to the additional costs is challenging.

In a clinical trial enrolling more than 450 patients to study the costs associated with the chlorhexidine chip, adjunctive therapy increased total treatment costs by approximately 50% but reduced the likelihood for surgical treatment by about 50% compared with patients treated with standard care.[77] There was a sufficient reduction in other dental treatment to offset about one-half of the acquisition costs of the chip. The result was consistent with a previously published modeled assessment.[39] After 12 months, the examining periodontists recommended similar further degrees of surgery for both groups.[77] No information was available, however, regarding any further disease progression or tooth mortality or whether patients received further surgical care. No information was available for these patients about differential outcomes with follow-up surgical care or continued nonsurgical maintenance with SRP and adjunctive therapy.

A cost-effectiveness comparison of three locally delivered, controlled-release antimicrobial agents was performed by

Niederman and colleagues[126] based on a review of published data. The measures used in the analysis included the number needed to treat (i.e., number of teeth or sites treated to produce one site with a probing depth reduction of ≥2 mm) and the total cost of treatment. The analysis concluded with a cost-effectiveness ranking of tetracycline fibers > chlorhexidine chips > minocycline microspheres. Use of the number needed to treat analysis has been reviewed[114]; the key message is the inappropriateness of this method for a comparison of different therapies assessed in dissimilar populations at different times and perhaps with different baselines of disease or with different comparators.

What might be the outcomes if locally delivered, controlled-release antimicrobials were included in a long-term periodontal maintenance program? Phase III pivotal trials have provided evidence for the safety and efficacy of these agents to improve clinical signs of periodontitis (e.g., probing depth, attachment level) over the length of the trials (i.e., 6 to 9 months). Longer-term clinical trials, including studies of minocycline microspheres, doxycycline gel, and the chlorhexidine chip, have provided evidence for the safety and efficacy of locally delivered, controlled-release antimicrobials for periodontal maintenance.[b] The data suggest a benefit in improving tooth retention, but long-term adequate and well-controlled clinical trials are needed to provide conclusive data that adjunctive therapy reduces tooth mortality. Other potential outcomes may include an increase in nonsurgical periodontal therapy, with a corresponding reduction in surgical therapy.

In a meta-analysis of the effects of adjunctive therapy of chlorhexidine, metronidazole, minocycline, and tetracycline with SRP, Bonito and coworkers[26] concluded that the benefit in favor of adjunctive therapy with respect to changes in clinical attachment was significant for all antimicrobials assessed. Examples of clinical outcomes are shown in Figs. 53.12 and 53.13, including data as examples of additional microbiologic effects of adjunctive, locally delivered, controlled-release antimicrobials compared with SRP alone.[59] Chapter 8 provides details on the microbiology of periodontal diseases.[194]

FIG. 53.12 Clinical use of locally delivered, controlled-

release antimicrobials. The patient was a 75-year-old, black woman who had chronic adult periodontitis. A pocket site with a 5-mm probing depth was associated with the mesiobuccal of tooth #21; the site had signs of inflammation, including bleeding on probing and discomfort. Scaling and root planing (SRP) was performed at the site with the placement of minocycline microspheres as an adjunctive therapy. Clinical and radiographic conditions are shown for the patient before treatment, and clinical photographs show conditions during and after administration. (A) Clinical baseline. (B) Radiographic baseline. (C) Syringe next to the site and ready for administration. (D) Syringe is in the pocket site for administration. (E) Immediately after application, postoperative instructions were given. (F) One week after application, substantial clinical improvement was seen. (G) Clinical status 2 weeks after application. (H) Four weeks after application, improved clinical status is maintained. The patient reported a lack of bleeding during oral home care compared with the pretreatment condition. Probing to determine probing depth was not performed to allow continued postoperative healing. Although posttreatment site changes can be monitored clinically (e.g., resolution of inflammation; changes in probing depth), there is no way to clinically determine additional adjunctive treatment benefit, which can be assessed only with adequate and well-controlled clinical trials.

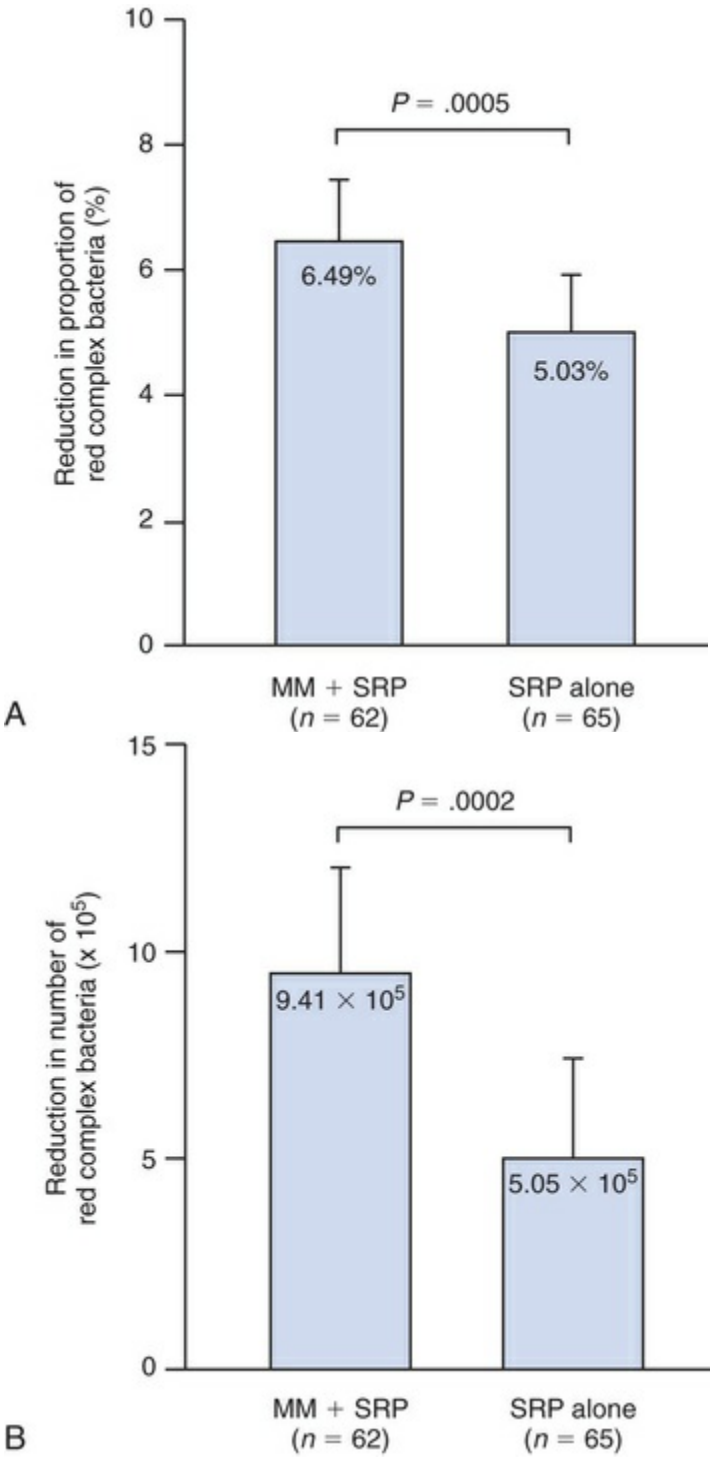

FIG. 53.13 The graphs show the microbiologic effects after adjunctive administration of minocycline microspheres *(MM)*.[59] (A) Mean percent reduction in the proportion of red complex bacteria (RCB) (i.e., sum of *Porphyromonas gingivalis*, *Tannerella forsythia*, and *Treponema denticola*) from baseline to day 30. Brackets represent the standard error (SE) (0.88% and 1.00% for the MM + scaling and root planing [SRP] and SRP-alone groups, respectively). (B) Mean reduction

in the number of RCB (i.e., sum of *P. gingivalis*, *T. forsythia*, and *T. denticola*) from baseline to day 30. Brackets represent the SE (both 2.43×10^5). (Reprinted from Goodson JM, Gunsolley JC, Grossi SG, et al: Minocycline HCl microspheres reduce red-complex bacteria in periodontal disease therapy. *J Periodontol* 78:1568, 2007, with permission from the American Academy of Periodontology.)

Little information is available regarding the effect of adjunctive therapy on alveolar bone levels. In a subset of patients from the chlorhexidine chip phase III clinical trials,[82] some patients receiving SRP alone had reduced alveolar bone over 9 months as measured by subtraction radiography, but no patient treated adjunctively showed radiographic evidence of bone loss.[83] In another small study of periodontitis patients treated adjunctively with another formulation of a chlorhexidine chip (i.e., PerioCol-CG), Grover and associates[68] reported that although most sites showed no changes in alveolar bone height, 5% of SRP-alone sites showed bone loss, and 21% of sites showed a bone gain. In contrast, 47% of SRP plus chlorhexidine chip sites showed bone gain, and no site lost alveolar bone.

Treatment with SRP plus adjunctive minocycline microspheres resulted in a significant reduction of markers associated with bone resorption (i.e., pyridinoline cross-linked carboxy terminal telopeptide of type I collagen [ICTP] and interleukin 1-beta [IL-1β]) in the GCF of sites with probing depths of 5 mm or more compared with SRP alone at 1 month.[129] GCF levels of ICTP and IL-1β were significantly increased in periodontitis patients compared with healthy controls.[129] SRP plus chlorhexidine chip reduced levels of matrix metalloproteinase-8 activity[18] and prostaglandin E_2 (PGE_2)[118] in GCF compared with SRP alone. Adequate and well-controlled clinical trials are needed to test the hypothesis that adjunctive, locally delivered controlled-release antimicrobials can reduce alveolar bone loss.

Consideration of the incremental costs of adjunctive therapy requires estimation of the cost-effectiveness of SRP alone compared with no treatment. The data reported by Antczak-Bouckoms and Weinstein,[13] perhaps the first cost-effectiveness analysis of periodontal therapy, support the idea that all treatment entails cost but that addition of antimicrobials can provide an incremental

benefit with an additional incremental cost. Just as the benefit of SRP is derived from continued maintenance treatment and repeated instrumentation for life, it seems likely that the benefits of locally delivered, controlled-release antimicrobials are derived from their routine incorporation as adjuncts to SRP procedures and as part of a periodontal maintenance program as indicated.

A detailed review of the cost-effectiveness of locally delivered, controlled-release antimicrobials in periodontal therapy has been provided by Heasman and coworkers.[73] The authors also emphasized the need for long-term studies to assess effects on tooth mortality and other patient-reported outcomes.

Clinical Studies of Non-U.S. Agents

Published clinical trials of non-U.S. agents accessible online and in English are tabulated in Table 53.8. These studies were not included in the literature review presented earlier of controlled-release, locally delivered antimicrobials available in the United States. Studies are listed in descending order based on the number of enrolled patients. A wide range of designs is evident. Table 53.5 includes studies that reported effects on probing depth or attachment levels. In general, the data reported for these products may be considered less robust compared with the data reported for the agents available in the United States. A meta-analysis of the effect of local drug delivery for chronic periodontitis, which included four agents (i.e., chlorhexidine chip [PerioChip]), doxycycline gel [Atridox], minocycline microspheres [Arestin], and tetracycline fibers [Periodontal Plus AB]), concluded that adjunctive local drug delivery provided additional probing depth reduction compared with SRP alone.[88] Additional microbiologic effects of these non-U.S. products with adjunctive therapy, which potentially provide additional clinical benefit compared with SRP alone, have been reported.[1,2]

TABLE 53.8

Clinical Trials of Locally Delivered, Controlled-Release Antimicrobials (Non-U.S. Products)

Drug	Study Design	Inclusion Criteria	Treatment Groups	Treatment	Study Durati
DOX (Ligosan Slow Release)[198]	Randomized, single-blind, multi-center, 2-stage sequential adaptive design	Regular maintenance pts; recurrent or persistent periodontitis, ≥6 mo supportive care; ≥4 teeth w PD ≥5 mm + BOP	(1) Mech. tx (sonic/ultrasonic) alone (2) Mech. Tx + DOX	12 mo	3 m (1) 0.48 1.73 (2) 0.53 2.30 6 m (1) 0.55 2.40 (2) 0.55 2.11 12 mo: (1) 0.57 2.23 (2) 0.58 2.09
CHL[137]	Randomized, multicenter, split-mouth, adjunctive	Moderate to advanced periodontitis, ≥10 teeth. 2 teeth w PD 5 mm & BOP in 2 opposite & contralateral quad; difference in PD ≤2 mm. No antimicrobial or antiinflammatory tx within 3 mo; no perio tx within 6 mo	(1) SRP alone (2) SRP + CHL *N* = 98	Full-mouth supragingival scaling 2 wk before baseline, at which full-mouth SRP w local anesthesia (2 visits 48 hr apart, 2 hr session each). SRP w Gracey curette 5 min per experimental site. CHL at test sites. At 3 mo a second supragingival prophylaxis per need	6 mo
CHL[43]	Randomized, split-mouth, adjunctive	Periodontitis, PD 5 mm, opposing quads in same arch	(1) SRP + chlorhexidine gel (PlakOut) (2) SRP + CHL *N* = 51	Full-mouth one-stage disinfection. Chlorhexidine gel or CHL administration. 0.2% chlorhexidine mouthwash for 4 wk	4 wk
CHL[205]	Randomized, single-center,	Moderate to advanced	(1) SRP alone (2) SRP + CHL	Supra- & subgingival SRP.	3 mo

	split-mouth, adjunctive	chronic periodontitis, 30–65 yr, ≥2 nonadjacent interproximal sites w 5–8 mm PD. No definitive perio tx or antibiotics in 6 mo. NSm	*N* = 46	At 1 mo, CHL in selected sites, no floss or interdental aids for 10 d	
PCOL-C[68]	Randomized, single-center, parallel-group, adjunctive	PD 5–8 mm in one or both sides of mouth	(1) SRP alone *N* = 20 (2) SRP + PCOL-C *N* = 20	Full-mouth supragingival scaling 1 wk before baseline. At baseline, subgingival SRP with hand instruments, then chip placement for group 2. No flossing for 10 days at selected sites or any chemotherapeutic mouthrinses or oral irrigation devices	3 mo
PCOL-C[14]	Randomized, single-center, parallel-group, adjunctive	Mild to moderate adult periodontitis, PD 5–8 mm	(1) SRP alone *N* = 20 (2) SRP + PCOL-C *N* = 20	1 wk before baseline, full mouth supragingival scaling. SRP w hand instruments; chip placed for group (2). No flossing for 10 d at selected & adjacent sites	3 mo
PPAB[174]	Randomized, single-center, split-mouth, adjunctive	2 nonadjacent teeth ≥1 tooth apart w PD ≥5 mm w BOP. No perio tx within 6 mo; no furcation involvement	(1) SRP + PPAB (2) SRP alone *N* = 35	SRP then adjunctive tx per randomization, cyanoacrylate adhesive at PPAB sites	3 mo
PPAB[135]	Single-center, split-mouth, adjunctive	Chronic periodontitis w PD of 5 mm in 2 quads	(1) SRP alone (2) SRP + PPAB *N* = 30	SRP then PPAB fibers. No brushing or flossing at treated areas, w chlorhexidine rinses twice daily	3 mo
DOX; CHL[69]	Randomized, single-center,	Moderately advanced	(1) SRP + DOX (2) SRP + CHL	Full-mouth supra- &	3 mo

	split-mouth, adjunctive	chronic periodontitis. No perio sx within 24 mo. ≥3 teeth ≥1 tooth apart, PD 5–8 mm w BOP.	(3) SRP alone *N* = 30	subgingival SRP w ultrasonic & curettes. No OH at treated sites for 7 d	
PPAB; CHL[54]	Randomized, single-center, split-mouth, adjunctive	Generalized chronic moderate periodontitis. 2 sites w PD >5 mm in symmetric quads. No perio tx within 6 mo	(1) SRP + PPAB (2) SRP + CHL *N* = 30	SRP then adjunctive tx per randomization, perio dressing at PPAB sites for 10 d	3 mo
PCOL-C[102]	Single-center, split-mouth, adjunctive	Chronic periodontitis, 2 posterior sites w PD ≥5 mm. No antibiotics or perio tx within 6 mo	(1) SRP alone (2) SRP + PCOL-C *N* = 20	Full-mouth supragingival scaling. Baseline: SRP, then PCOL-C at test sites. No interdental cleaning for 10 d. At 3 mo, supragingival scaling, then PCOL-C for group (2)	6 mo
PPAB[119]	Single-center, split-mouth, adjunctive, randomized	Chronic generalized periodontitis w PD ≤5 mm, ≥2 sites w PD ≥5 mm in 1 quad	(1) SRP alone (2) SRP + PPAB *N* = 20	SRP, PPAB in test sites, perio pack, removed after 10 d	3 mo
CHL[7]	Single-center, split-mouth, ± randomization NR	Moderate to severe chronic adult periodontitis. No antimicrobial tx for 6 mo; no perio tx before study	(1) SRP (2) SRP + CHL 1 : 2 ratio, respectively *N* = 15	SRP, then 1 side received CHL application at baseline & at 3, 6, 9, & 12 mo	12 mo
COL, PPAB[189]	Single-center, split-mouth (all 3 tx per patient), adjunctive	Chronic generalized periodontitis, pocket sites w PD 5–8 mm + BOP in diff quads, no perio tx or antibiotics in 6 mo or antimicrobial rinses in 2 mo	(1) SRP + PCOL-C (15 sites) (2) SRP + PPAB (15 sites (3) SRP alone *N* = 14 (45 sites w PD 5–8 mm + BOP)	SRP, adjunctive agents placed, perio pack placed (removed after 7 d). No brushing or flossing on treated site or hard, sticky food for 7 d	3 mo
CHL[103]	Single-center, split-mouth,	≥4 teeth w PD 5-8 mm, no perio tx	*N* = 10 patients (30 teeth each,	Supragingival prophylaxis	6 mo

	randomized, triple-blind, adjunctive	or antibiotics for 6 mo	control & experimental) (1) SRP + CHL (2) SRP + placebo gel	before baseline. SRP at baseline, then CHL or placebo gel placed subgingivally	
CHL[169]	Split-mouth, randomized, adjunctive	Chronic periodontitis w PD >5 mm, light or NSm; 188 teeth in opposing quads in same arch	(1) SRP + chlorhexidine gel (PlakOut) (2) SRP + CHL *N* = 8	Full-mouth one-stage disinfection. Chlorhexidine gel or CHL administration. 0.2% chlorhexidine mouthwash for 4 wk	4 wk
CHL[32]	Single-center, split-mouth, randomized, adjunctive	Chronic generalized periodontitis. Pockets with PD 5–7 mm in different quads and signs of bone loss	*N* = 6 patients [3 NSm, 3 Sm] Groups randomized by pocket site (141 sites) (1) SRP alone (46 sites; 21 NSm, 25 Sm) (2) SRP + CHL (49 sites; 25 NSm, 24 Sm) (3) CHL alone (46 sites; 21 NSm, 25 Sm)	SRP details NR. Sites washed with distilled water & dried w paper points before CHL application	3 mo

AL, Attachment level; *BOP*, bleeding on probing; *CHL*, (Chlo-Site) xanthan chlorhexidine gel; *d*, day; *DOX*, doxycycline gel (Atridox); *est.,* estimated; *h*, hour; *hs*, highly significant; *Mech.*, mechanical; *mo*, month; *min,* minutes; *N*, number of patients; *NR*, not reported; *ns*, not significant; *NSm,* nonsmokers; *OH,* oral hygiene; *PCOL-C*, (PerioCol-CG) chlorhexidine chip; *PD*, probing depth; *perio*, periodontal; *PPAB*, (Periodontal Plus AB) tetracycline fiber; *quad*, quadrant(s); *s*, significant; *Sm,* smokers; *SRP*, scaling and root planing; sx, surgery; *tx*, treatment; *vs*, versus; *w*, with; *wk*, week(s); *yr*, year.

Considerations for Future Research

Additional research is warranted for locally delivered, controlled-release antimicrobials for periodontal therapy. For example, research could include large, open-label extension trials or registries to assess outcomes with long-term maintenance therapy. Research is needed to explore new indications or cost-effectiveness issues, along with the suggestions made throughout this chapter for current agents. Other research regarding locally delivered

treatment strategies for periodontitis (e.g., targeting the periodontal pocket) could include different treatment regimens using currently available agents. For example, a phase III clinical trial (ClinicalTrials.gov NCT01249846) to study more frequent administration of a chlorhexidine chip has been completed.

Other classes of agents such as growth factors or antiinflammatory agents could be developed for local delivery into periodontal pockets. A multicenter, randomized clinical trial provided evidence that the delivery of recombinant human platelet-derived growth factor BB in combination with a beta-tricalcium phosphate (β-TCP) resulted in greater bone fill and attachment gain after treatment of advanced periodontal osseous defects compared with β-TCP as an active control[121]; gains were continued in a 36-month extension study.[122] This combination product has been approved for marketed use.[53]

A phase II trial of fibroblast growth factor 2 (FGF2) in a hydroxypropylcellulose vehicle has been published.[101] Phase II and III trials (NCT00199290, NCT00734708, NCT00514657, NCT01015404) of recombinant human basic FGF (i.e., trafermin) have been completed. Another growth factor, granulocyte-macrophage colony-stimulating factor (sargramostim), has been studied in a phase I trial (NCT00689143).

An example of the local delivery of antiinflammatory agents is the nonsteroidal antiinflammatory drug (NSAID) flurbiprofen. A phase II trial (NCT00425451) of a combination chip of chlorhexidine and flurbiprofen was completed, and a flurbiprofen chip was compared with a chlorhexidine chip in another completed phase II trial (NCT01040286).[110] Other NSAIDs (e.g., ketoprofin,[193] meloxicam[90]) have been studied.

A controlled-release system for the steady delivery of a chemoattractant for regulatory lymphocytes offers an exciting alternative. Local administration in preclinical canine and murine models led to reduced alveolar bone resorption and a reduction in clinical measures of inflammation.[55] Gamal and Kumper[50] reported the use of a doxycycline-loaded, biodegradable membrane in a randomized trial of regenerative surgical procedures with or without EDTA root surface etching.

Many other agents have been studied as possible local treatments

for periodontitis. Agents with potential value as locally delivered treatments for periodontitis include nitric oxide,[19] pentoxifylline films,[106] green tea catechin gel,[33] simvastatin,[151,152,159] metformin,[153,160] alendronate,[150,154,180] and antimicrobials such as azithromycin,[90,149] minocycline gels,[90] clindamycin in chitosan-based microparticles,[93] clarithromycin,[3,20,91] and metronidazole and doxycycline films and microspheres.[106,161,193] All of these agents require clinical development in appropriate controlled-release delivery systems.

There is considerable on-going research regarding local delivery, which may make available new locally delivered treatment strategies for the treatment of periodontitis. Adequate and well-controlled clinical trials are necessary to establish safety and efficacy for all new agents or treatment regimens.

Case Reports

The indications for the use of locally delivered, controlled-release antimicrobials in clinical practice are detailed in the full prescribing information for each product. Indications include potential use as part of nonsurgical periodontal treatment as adjunctive therapy or monotherapy. Examples of the clinical use of these products as part of nonsurgical periodontal therapy are shown in Figs. 53.14 and 53.15.

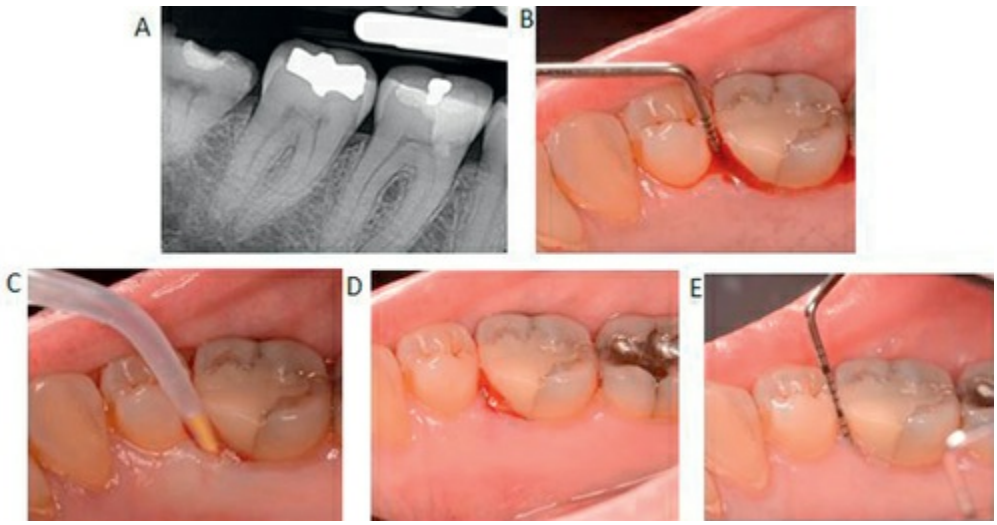

FIG. 53.14 Locally delivered, controlled-release antimicrobials can be used as part of nonsurgical

periodontal therapy. Evaluation of the patient revealed a pocket depth (PD) of 5+ mm and bleeding on probing (BOP) at tooth #30, mesiolingual (ML) surface. A combination of localized scaling and root planing (SRP) with local delivery of minocycline microspheres was performed for tooth #30. (A) Initial radiograph. (B) PD of 5+ mm with BOP. The patient received localized SRP because this was the only site showing a PD of more than 5 mm. (C) Local delivery is achieved by inserting the syringe before dispensing microspheres into the periodontal pocket. (D) Minocycline microspheres are inserted into the periodontal pocket. (E) At 10 weeks after the procedure, the patient has a 3-mm PD and no BOP at the #30 ML surface. There are no signs of clinical inflammation.

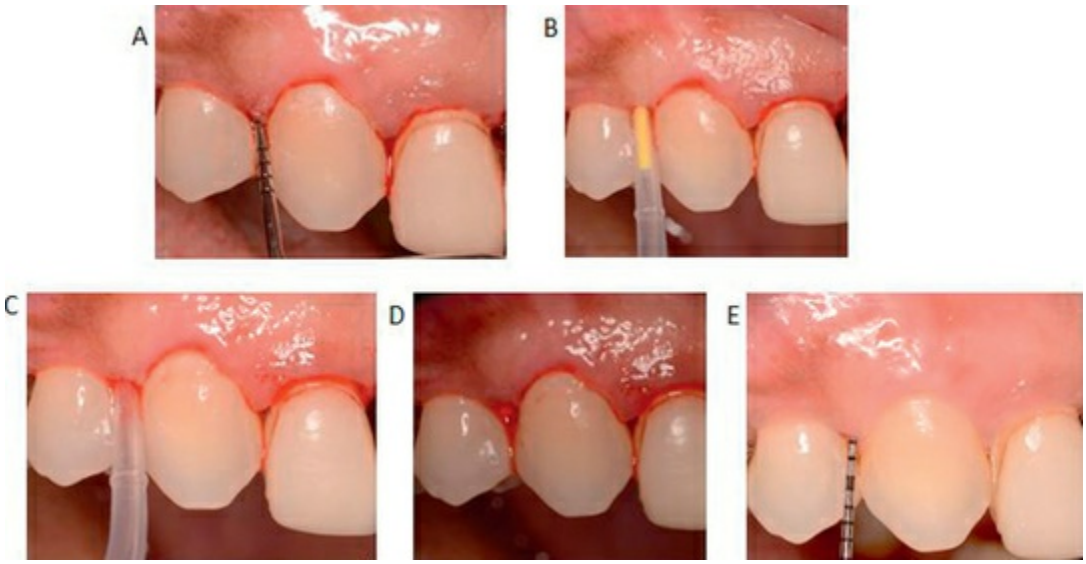

FIG. 53.15 The patient had a pocket depth (PD) of 6 mm on the tooth #4 mesiobuccal (MB) surface. Therapy included a combination of scaling and root planing (SRP) and local delivery of minocycline microspheres. Follow-up at 12 weeks showed an absence of bleeding on probing (BOP) or other signs of clinical inflammation and a reduced PD. (A) The MB surface of tooth #4 was treated with quadrant SRP in combination with minocycline microspheres. The initial PD at #4 MB was 6 mm. (B) Minocycline microspheres were inserted at tooth #4 MB. (C) Minocycline microspheres were deposited completely at the base

of the periodontal pocket. (D) Immediately after application, remnants of the minocycline microspheres can be seen at the level of the free gingival margin. (E) The 12-week postoperative examination revealed a 3-mm PD and no BOP.

Conclusions

The evidence is strong that adjunctive, locally delivered, controlled-release antimicrobials make SRP significantly more effective and have a known safety profile. SRP without adjunctive treatment in appropriately eligible sites (i.e., probing depth ≥5.0 mm) may be less than maximally effective. It is not appropriate to determine therapy based solely on clinical judgment. The practitioner should evaluate the evidence and suggest a treatment that has the greatest probability for success based on current data.

Spielman and Wolff[188] commented on the unfortunate tendency for many dentists to base treatment on personal experience rather than reported evidence. They stated that optimal care is evidence based. As an example of the suboptimal care that can result from the lack of incorporation of the best available evidence into clinical practice, O'Donnell and colleagues[128] reported on the underutilization of pit-and-fissure sealants in dental practice despite published American Dental Association (ADA) recommendations.[22] Available data support the adjunctive use of locally delivered, controlled-release antimicrobials, which provides significant additional clinical benefit.

SRP procedures have been considered the nonsurgical standard of care.[26] The evidence supports the idea that adjunctive locally delivered, controlled-release antimicrobials make SRP more effective[71] and have a known safety profile. Based on available data, when these agents are used routinely as adjuncts to SRP as indicated as part of initial periodontal treatment or maintenance therapy, clinicians can expect a significantly greater mean reduction in probing depth compared with SRP alone. SRP plus adjunctive therapy, used in a manner that is consistent with the approved full prescribing information, could be considered a new standard for nonsurgical periodontal therapy for the management of chronic

adult periodontitis.[49]

Clinical Correlation

SRP plus adjunctive therapy could potentially be considered a new standard for nonsurgical periodontal therapy.

A number of pilot trials have suggested additional indications for adjunctive locally delivered, controlled-release antimicrobials. More research is necessary to test these hypotheses before further clinical comments can be made.

Case Scenario 53.1

Patient:

47-year-old male

Chief Complaint:

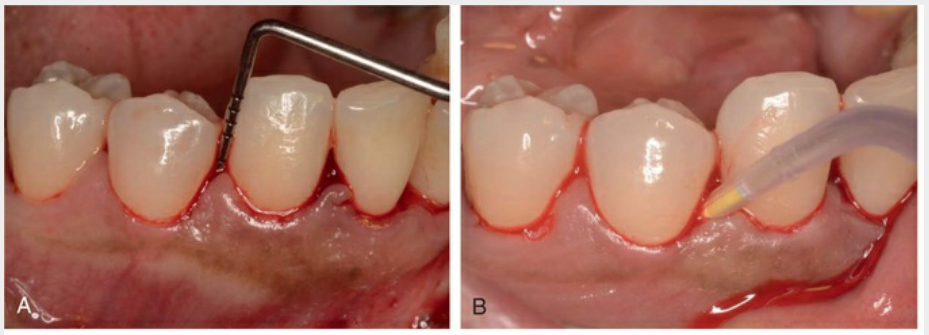
"My gums on the lower right side still bleed when I floss."

Background Information:

Patient is a current smoker (5 to 6 cigarettes/day). He has no systemic medical conditions and no known drug allergies. He underwent scaling and root planing (SRP) 6 months earlier and is now on a 4-month periodontal recall program. Today, he has a periodontal recall visit.

Current Findings:

Probing depths were in the range of 1 to 6 mm. (A) The 6-mm probing depth is localized to distal side of #27, and it bled on probing. All other probing depths were in the range of 1 to 4 mm. His oral hygiene improved significantly after SRP. Radiographically, a vertical bony defect was seen between #27 and #28. (B) The clinician decided to perform localized SRP as part of the recall appointment and used minocycline microspheres as an adjunct.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. In this patient with a vertical defect between #27 and #28 that is amenable to periodontal regeneration, do the data suggest that adding a locally delivered, controlled-release antimicrobial as part of the surgical protocol would be beneficial? A. Yes B. No	**Answer: A** **Explanation:** Clinical studies have suggested additional clinical benefits by adding controlled-release antimicrobials to regenerative procedures, but the data need to be confirmed in further clinical trials.[164,177,211]
2. Minocycline acts by inhibiting which of the following? A. 50S ribosomes B. 30S ribosomes C. Cell wall synthesis D. DNA synthesis	**Answer: B** **Explanation:** Minocycline inhibits protein synthesis in microbes by binding to 30S ribosomes.
3. The following locally delivered, controlled-release antimicrobials are available in the United States *except* A. Chlorhexidine-containing chip (PerioChip) B. Doxycycline gel (Atridox) C. Tetracycline fiber (Actisite) D. Minocycline microspheres (Arestin)	**Answer: C** **Explanation:** Tetracycline fiber was first introduced into the U.S. market in the early 1990s, and it was the prototypic system. The tetracycline fiber is no longer commercially available in the United States.

CHAPTER 54

Host Modulation

Maria Emanuel Ryan, Ying Gu

CHAPTER OUTLINE

Introduction
Systemically Administered Agents
Locally Administered Agents
Host Modulation and Comprehensive Periodontal Management
Sub-antimicrobial–Dose Doxycycline
Emerging Host Modulatory Therapies *(e-only)*
Host Modulation Factors In Systemic Disorders *(e-only)*
Summary

Introduction

The term *host modulation* has been incorporated in dental jargon, but it has not been well defined. *Host* can be defined as the organism from which a parasite obtains its nourishment or, in the transplantation of tissue, the individual who receives the graft. *Modulation* is the alteration of function or status of something in

response to a stimulus or an altered chemical or physical environment.

In diseases of the periodontium that are initiated by bacteria, the host is the individual who harbors the pathogens, but it was not clear for many years whether it was possible to modulate the host response to the pathogens and other stimuli that led to breakdown of the attachment apparatus. Host modulation with chemotherapeutic agents or drugs is the latest adjunctive therapeutic option for the management of periodontal diseases.

The concept of host modulation is fairly new to the field of dentistry but is universally understood by most physicians who routinely apply the principles of host modulation to the management of chronic progressive disorders such as arthritis and osteoporosis. The concept of host modulation was introduced to dentistry by Williams[113] and Golub and colleagues[42] and then expanded on by many other scholars in the dental profession. In 1990, Williams concluded that "there are compelling data from studies in animals and human trials indicating that pharmacologic agents that modulate the host responses believed to be involved in the pathogenesis of periodontal destruction may be efficacious in slowing the progression of periodontitis."[113] In 1992, Golub and colleagues discussed host modulation with tetracyclines and their chemically modified analogues.[42] The future that these investigators described has arrived, and to better understand this new era in disease management, we first consider the pathogenesis of periodontitis.

Many clinicians previously thought that periodontal disease was an inevitable consequence of aging and was uniformly distributed in the population. They thought that disease severity was directly correlated with plaque levels (i.e., the worse the oral hygiene, the worse the periodontal disease) and that disease progression occurred in a continuous, linear manner throughout life. As a result of better epidemiologic data, there has been a paradigm shift in how clinicians and scientists view the prevalence and progression of this common disease. It has been established that periodontal disease is not a natural consequence of aging and disease severity is not necessarily correlated with plaque levels. Theories about the pathogenesis of periodontitis have evolved from a purely plaque-

associated disease to the hypotheses that place considerable emphasis on the host's response to the bacteria.[13]

The Surgeon General's report on *Oral Health in America*, published in 2000, recognized the importance of dental health in the overall general health and well-being of a patient.[104] Research findings indicate possible associations between chronic oral infections, such as periodontitis, and systemic disorders, such as diabetes, cardiovascular and lung diseases, stroke, osteoporosis, and rheumatoid arthritis. The Surgeon General's report assesses these emerging associations and explores factors that may underlie oral-systemic disease connections. Along with these findings and the emergence of the discipline of periodontal medicine, there have been many developments in therapeutic approaches to the management of periodontitis. Development of the chemotherapeutic approach known as *host modulation* required a thorough understanding of the host response and the impact of a variety of risk factors.

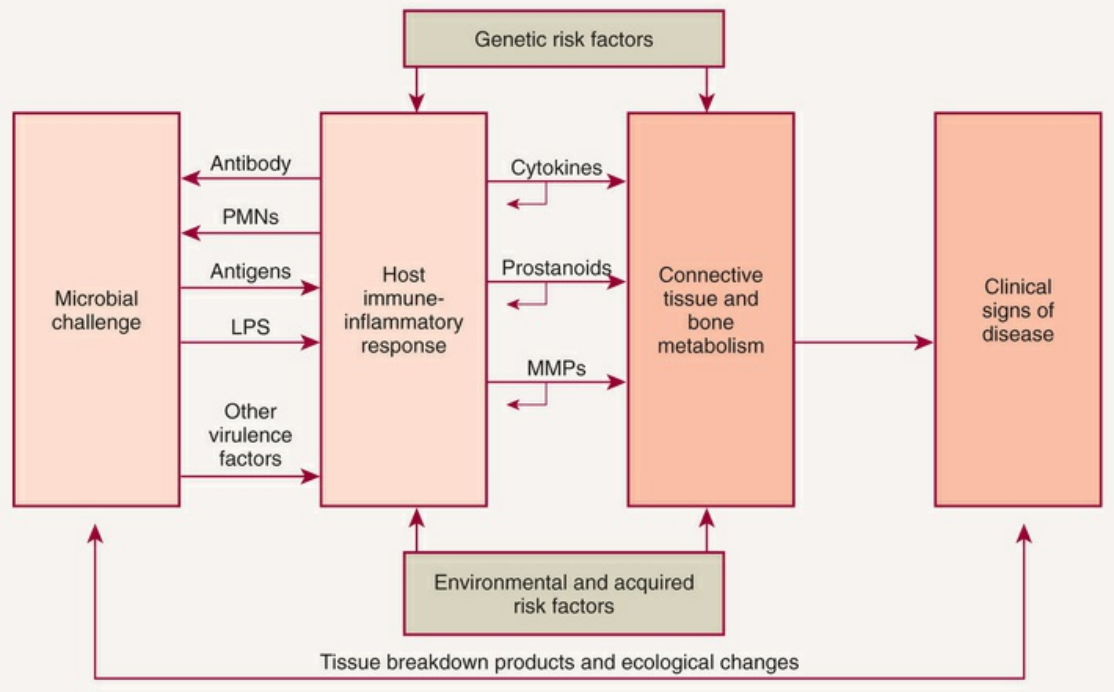
Anecdotally, many dentists have identified patients with abundant plaque and calculus deposits that manifest as gingivitis with shallow pocketing. In contrast, other patients, despite maintaining a high standard of plaque control, succumb to aggressive forms of periodontitis, with deep pocketing, tooth mobility, and early tooth loss. The former group of patients is *periodontal disease resistant,* whereas the latter group is *periodontal disease susceptible.* The response of the periodontal tissues to plaque is different in these two types of patients, and certain patients undergo advanced periodontal breakdown even though they achieve a high standard of oral hygiene.

These observations led researchers to realize that the *host response* to the bacterial challenge of subgingival plaque is the most important determinant of disease severity, progression, and response to therapy. Although plaque bacteria are capable of causing direct damage to the periodontal tissues (e.g., by release of hydrogen sulfide, butyric acid, and other enzymes and mediators), most destructive events occurring in the periodontal tissues result from activation of destructive processes that occur as part of the host immune-inflammatory response to plaque bacteria. The host response is essentially protective but paradoxically can also result

in significant tissue damage, including breakdown of connective tissue fibers in the periodontal ligament and resorption of alveolar bone.

In 1985, research began to focus on bacteria–host interactions.[68] It had been recognized that although bacterial pathogens initiate the periodontal inflammation, the host response to these pathogens is equally or more important in mediating connective tissue breakdown, including bone loss. The host-derived enzymes known as the *matrix metalloproteinases* (MMPs) and changes in osteoclast activity driven by cytokines and prostanoids cause most of the tissue destruction in the periodontium.[78] This shift in paradigms, with a focus on the host response, led to the development of host modulatory therapies to improve treatment outcomes, slow the progression of disease, and ensure more predictable management of patients with periodontitis. This therapeutic strategy may be relevant to individuals at greater risk for periodontal disease and may be important in the management of those at risk for several related systemic conditions.

To better understand the host factors that clinicians are attempting to modulate, a more detailed assessment of the role of the host response in periodontal pathogenesis is needed (eFig. 54.1). After the accumulation of subgingival plaque bacteria, a variety of microbial substances, including chemotactic factors such as lipopolysaccharide (LPS), microbial peptides, and other bacterial antigens, diffuse across the junctional epithelium into the gingival connective tissues. The periodontium is anatomically unique in that the junctional epithelium ends on the tooth surface, which is nonliving tissue; there is no other such discontinuous lining over the entire surface of the body. The dentogingival junction indicates a priori vulnerability to bacterial attack.



EFIG. 54.1 Pathogenesis of periodontitis. The microbial challenge presented by subgingival plaque bacteria up-regulates the host immune-inflammatory response in the periodontal tissues, which is characterized by the excessive production of inflammatory cytokines (e.g., interleukins, tumor necrosis factor), prostanoids (e.g., prostaglandin E_2), and enzymes, including the matrix metalloproteinases *(MMPs).* These proinflammatory mediators are responsible for most periodontal breakdown that occurs, leading to the clinical signs and symptoms of periodontitis. The process is modified by environmental (e.g., tobacco use) and acquired (e.g., systemic diseases) risk factors and by genetic susceptibility. *LPS*, lipopolysaccharide; *PMNs,* Polymorphonuclear leukocytes. (Modified from Kornman KS: Host modulation as a therapeutic strategy in the treatment of periodontal disease. *Clin Infect Dis* 28:520, 1999.)

Epithelial and connective tissue cells are stimulated to produce inflammatory mediators, resulting in an inflammatory response in the tissues. The gingival vasculature dilates (i.e., vasodilation) and becomes increasingly permeable to fluid and cells. Fluid accumulates in the tissues, and defense cells migrate from the circulation toward the source of the chemotactic stimulus (i.e., bacteria and their products) in the gingival crevice. Neutrophils, a type of polymorphonuclear leukocyte (PMN), predominate in the early stages of gingival inflammation to phagocytose and kill plaque bacteria. Bacterial killing by PMNs involves intracellular mechanisms (i.e., after phagocytosis of bacteria in membrane-bound structures inside the cell) and extracellular mechanisms (i.e., release of PMN enzymes and oxygen radicals outside the cell). As

bacterial products enter the circulation, committed lymphocytes return to the site of infection, and B lymphocytes are transformed to plasma cells, which produce antibodies against specific bacterial antigens. Antibodies are released in the gingival tissues and, in the presence of complement, facilitate and enhance PMN phagocytosis and bacterial killing.

A host immune-inflammatory response is established in the gingival tissues, and the clinical signs of gingivitis develop as the tissues become more edematous and erythematous. This response is essentially protective, designed to combat the bacterial infection and prevent ingress of bacteria into the tissues. In people who are not susceptible to periodontitis (i.e., disease resistant), these primary defense mechanisms control the infection, and chronic inflammation (i.e., chronic gingivitis) may persist indefinitely. In disease-susceptible individuals, inflammatory events extend apically and laterally to involve deeper connective tissues and alveolar bone. There is proliferation of the junctional epithelium, which becomes increasingly permeable and ulcerated, accelerating the ingress of bacterial products, and the inflammation worsens.

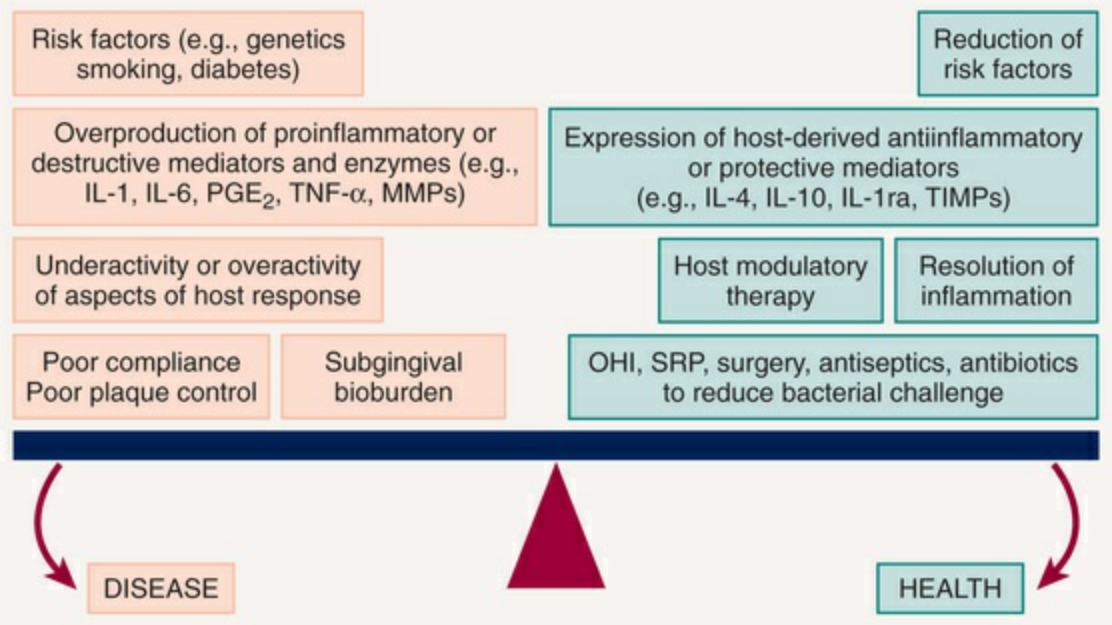
Other defense cells are recruited to the area, including macrophages and lymphocytes. Large numbers of PMNs migrate into the tissues, secreting excessive quantities of destructive enzymes and inflammatory mediators indiscriminately into the tissues. These enzymes include the MMPs, such as collagenase and gelatinase, which break down collagen fibers in the gingival and periodontal tissues. The infiltrating inflammatory and immune cells are accommodated by the breakdown of structural components of the periodontium. MMPs are a primary target for host modulation. Pharmacologic agents or chemotherapeutics can be administered to suppress excessive levels of MMPs.

Macrophages are recruited to the area and are activated (by binding to LPS) to produce prostaglandins (e.g., prostaglandin E_2 [PGE_2]), interleukins (e.g., IL-1α, IL-1β, IL-6), tumor necrosis factor alpha (TNF-α), and MMPs. The cytokines (i.e., interleukins and TNF-α) and prostanoids are additional targets for host modulatory therapeutics. Interleukins and TNF-α bind to fibroblasts, which are stimulated to produce additional quantities of PGE_2, interleukins, TNF-α, and MMPs in positive-feedback cycles. The concentration of

these enzymes and inflammatory mediators becomes pathologically high in periodontal tissues.

Host modulatory therapy (HMT) can be used to interrupt the positive-feedback loops and ultimately reduce the excessive levels of cytokines, prostanoids, and enzymes that result in tissue destruction. MMPs break down collagen fibers, disrupting the normal anatomy of the gingival tissues, ultimately resulting in destruction of the periodontal ligament. The inflammation extends apically, and osteoclasts are stimulated to resorb alveolar bone by the high levels of prostaglandins, interleukins, and TNF-α in the tissues. The osteoclasts are targets for host modulation. Drugs can be administered to down-regulate osteoclastic activity and ultimately to inhibit bone resorption by these cells.

Elevations in the proinflammatory or destructive mediators in response to bacterial challenge are counterbalanced by elevations in antiinflammatory or protective mediators such as the cytokines IL-4 and IL-10, other mediators such as IL-1ra (receptor antagonist), and tissue inhibitors of metalloproteinases (TIMPs) (eFig. 54.2). Under conditions of health, the antiinflammatory or protective mediators control tissue destruction. If there are adequate levels of these antiinflammatory or protective mediators to keep the host response to the bacterial challenge in check, the individual will be disease resistant. If an imbalance occurs, with excessive levels of the proinflammatory or destructive mediators present in the host tissues, tissue destruction will ensue in the susceptible host. Another potential target for host modulation could entail the use of pharmacologic agents, which mimic or result in elevations of endogenous antiinflammatory or protective mediators.



EFIG. 54.2 The balance between periodontal breakdown (i.e., disease) and periodontal stability (i.e., health) is tipped toward disease by risk factors, underactivity or overactivity of the immune-inflammatory host response, poor compliance, pathogenic microflora, and excessive production of inflammatory cytokines and enzymes, such as interleukin-1 and -6 (*IL-1* and *IL-6*), prostaglandin E_2 *(PGE_2)*; tumor necrosis factor alpha *(TNF-α,)*, and matrix metalloproteinases *(MMPs)*. The balance can be tipped toward health by risk factor modification, up-regulation of protective mediators, and restoration of the balance between naturally occurring inhibitors of inflammation such as *IL-4* and *IL-10,* interleukin-1 receptor antagonist *(IL-1ra)*, tissue inhibitors of metalloproteinases *(TIMPs)*, and host modulatory therapy and antibacterial treatments such as oral hygiene instruction *(OHI)*, scaling and root planing *(SRP)*, surgery, antiseptics, and antibiotics.

Plaque bacteria initiate the disease, and bacterial antigens that cross the junctional epithelium drive the inflammatory process. Bacteria are essential for periodontitis to occur, but they are insufficient by themselves to cause disease. For periodontitis to develop, a susceptible host is also required. Most periodontal breakdown (e.g., bone loss, attachment loss) is caused by host-derived destructive enzymes (e.g., MMPs) and inflammatory

mediators (e.g., prostaglandins, interleukins) that are released during the cascade of destructive events that occur as part of the inflammatory response[81] (see eFig. 54.1). Paradoxically, the inflammatory response, which is essentially protective in design, is responsible for much of the breakdown of the soft and hard periodontal tissues. Periodontal disease is characterized by high concentrations of MMPs, cytokines, and prostanoids in the periodontal tissues, whereas periodontal health is characterized by the opposite.[80]

The purpose of HMT is to restore the balance of proinflammatory or destructive mediators and antiinflammatory or protective mediators to that seen in healthy individuals. Pocket formation occurs as coronal junctional epithelium is broken down and restored at a more apical location. Plaque bacteria then migrate apically along the root surface deeper into the pocket, where the physical conditions favor the proliferation of gram-negative anaerobic species. Bacterial products continue to challenge the host, which continues his or her frustrated response against the bacteria and their products. Inflammation extends further and further apically, more bone is resorbed, and periodontal ligament (PDL) is broken down. The pocket deepens, and the associated attachment and bone loss result in clinical and radiographic signs of periodontitis. Intervention is required to prevent eventual tooth loss and other sequelae of the disease.

The nature of the host response to plaque is modified by genetic factors (helping to explain why aggressive periodontitis tends to have a familial aggregation) and systemic and environmental factors (e.g., smoking, diabetes, stress). These risk factors can lead to the imbalance between the proinflammatory and antiinflammatory mediators seen in susceptible individuals (see eFig. 54.2). Risk factors can affect onset, rate of progression, and severity of periodontal disease and the response to therapy[30,48,96] (eBox 54.1). Risk assessment is extremely important because some risk factors can be modified to reduce the patient's susceptibility to periodontitis. Risk reduction strategies include smoking cessation, improved control of diabetes, nutritional supplementation, improved oral hygiene, changes in medication, stress management, weight loss, and more frequent dental visits (eBox 54.2).

eBox 54.1

Risk Factors for Periodontal Disease

- Heredity: family history, PST Genetic Test
- Smoking: frequency, current status, history
- Diabetes: duration, control
- Obesity
- Stress: reported by patient
- Medications: calcium channel blockers, Dilantin, cyclosporine, drugs known to cause dry mouth
- Nutrition
- Poor oral hygiene: plaque and calculus
- Faulty dentistry: overhangs, subgingival margins
- Hormonal variations: pregnancy (i.e., increased estradiol and progesterone), menopause (i.e., decreased estrogen and osteoporosis)
- Immunocompromise: HIV infection, neutropenia
- Connective tissue diseases
- History of periodontitis

HIV, Human immunodeficiency virus; *PST,* periodontal screening test..

eBox 54.2

Risk Reduction Strategies

- Heredity: HMT chemotherapeutics
- Smoking: cessation, HMT chemotherapeutics
- Diabetes: improved control, work with physician, HMT chemotherapeutics
- Obesity: weight loss

- Stress: management, HMT chemotherapeutics
- Medications: change medications, work with physician; HMT chemotherapeutics
- Nutrition: supplements
- Poor oral hygiene: improved oral hygiene, HMT chemotherapeutics
- Faulty dentistry: corrective dentistry
- Hormonal variations: consultation with a physician, HMT chemotherapeutics
- Immunocompromise: consultation with a physician, HMT chemotherapeutics
- Connective tissue diseases: consultation with a physician, HMT chemotherapeutics

HMT, Host modulatory therapy.

The use of chemotherapeutic agents or drugs specifically designed to treat periodontal diseases is emerging to aid as a risk reduction strategy. Intervention in periodontal disease can include HMT as an adjunctive treatment options. The term *adjunctive* means *in addition to conventional therapies* or *in addition to other established therapies*. For the management of periodontal diseases, conventional approaches were initially mechanical in nature: surgery and scaling and root planing (SRP). Initially, adjunctive therapies were solely antimicrobial such as the use of local and systemic antiseptics and antibiotics.

Newer adjunctive approaches involve modulation of the host response. Researchers are investigating HMTs that modify or reduce destructive aspects of the host response so that the immune-inflammatory response to plaque is less damaging to periodontal tissues. Removal of plaque by SRP targets one aspect of the pathogenic process by reducing the bacterial burden and therefore the antigenic challenge that drives the inflammatory response in the host tissues. However, the bacterial challenge is never completely eliminated after SRP because recolonization by bacterial species occurs. HMTs offer the potential for down-regulating destructive aspects and up-regulating protective aspects of the host response so

that, in combination with conventional treatments to reduce the bacterial burden, the balance between health (i.e., resolution of inflammation and wound healing) and disease progression (i.e., continued proinflammatory events) is tipped in the direction of a healing response.

HMT is a *means of treating the host side of the host–bacteria interaction*. The host response is responsible for most of the tissue breakdown that occurs and leads to the clinical signs of periodontitis (i.e., loss of connective tissue attachment and bone). HMTs offer the opportunity for modulating or reducing this destruction by treating aspects of the chronic inflammatory response. HMTs do not block normal defense mechanisms or inflammation; instead, they ameliorate excessive or pathologically elevated inflammatory processes to enhance the opportunities for wound healing and periodontal stability.

HMT can be used to reduce excessive levels of enzymes, cytokines, and prostanoids and should not reduce levels below constitutive levels. HMTs can also modulate osteoclast and osteoblast function (Fig. 54.1) but should not affect normal tissue turnover. HMT is key to addressing many of the risk factors that have adverse effects on the host response that are not easily managed (e.g., smoking, diabetes) or cannot be changed (e.g., genetic susceptibility). Host modulatory agents can be used to increase the levels of a person's protective or antiinflammatory mediators. Use of systemic HMTs for treatment of a patient's periodontal condition may also provide benefits for other inflammatory disorders, such as arthritis, cardiovascular disease, dermatologic conditions, diabetes, rheumatoid arthritis, and osteoporosis. Patients who are currently taking host modulatory agents, such as nonsteroidal antiinflammatory drugs (NSAIDs), bisphosphonates, or tetracyclines, and newer agents targeting specific cytokines for the management of medical conditions, may experience periodontal benefits from the systemic medications prescribed for the management of other chronic inflammatory conditions.

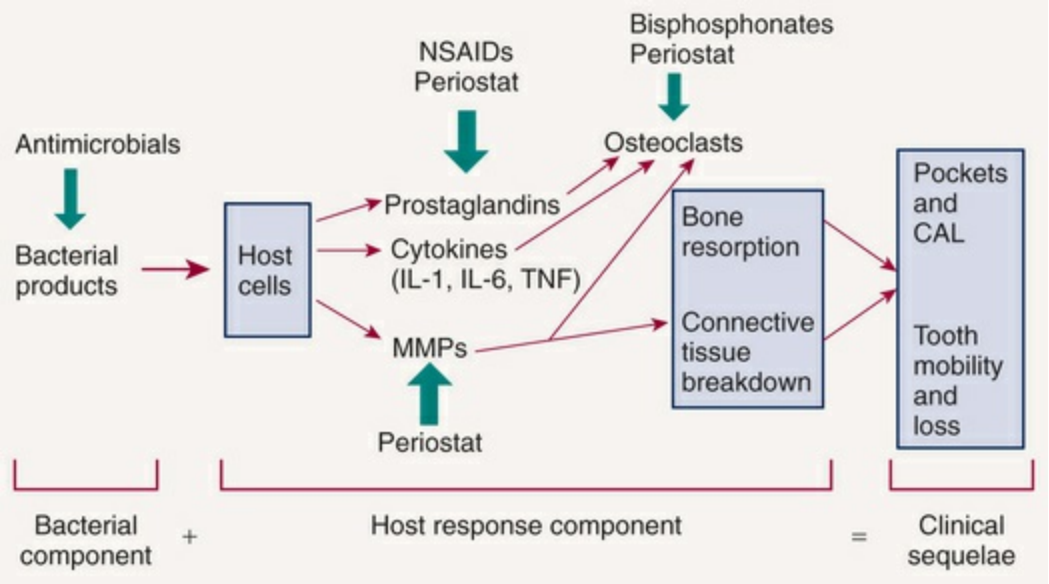


FIG. 54.1 Potential adjunctive therapeutic approaches and points of intervention in the treatment of periodontitis are shown in the context of the pathologic cascade of events. *CAL,* clinical attachment loss; *IL*, interleukin; *MMPs*, matrix metalloproteinases; *NSAIDs*, nonsteroidal antiinflammatory drugs; *TNF*, tumor necrosis factor.

Systemically Administered Agents

A variety of drug classes have been evaluated as host modulation agents, including NSAIDs, bisphosphonates, tetracyclines, enamel matrix proteins, growth factors, and bone morphogenetic proteins. Chemotherapeutic agents have been researched as adjunct treatments for periodontitis in clinical practice, and HMTs are still evolving.

Nonsteroidal Antiinflammatory Drugs

NSAIDs inhibit the formation of prostaglandins, including PGE_2, which is produced by neutrophils, macrophages, fibroblasts, and gingival epithelial cells in response to LPS, a component of the cell wall of gram-negative bacteria. PGE_2 has been extensively studied in periodontal disease because it up-regulates bone resorption by osteoclasts.[44,55,79] Levels of PGE_2 are elevated in patients with

periodontal disease compared with healthy patients.[45,79] PGE_2 also inhibits fibroblast function and has inhibitory and modulatory effects on the immune response.[46]

NSAIDs inhibit prostaglandin synthesis and therefore reduce tissue inflammation. They are used to treat pain, acute inflammation, and a variety of chronic inflammatory conditions. NSAIDs include the salicylates (e.g., aspirin), indomethacin, and propionic acid derivatives (e.g., ibuprofen, flurbiprofen, naproxen). The ability of NSAIDs to block PGE_2 production, thereby reducing inflammation and inhibiting osteoclast activity in the periodontal tissues, has been investigated in patients with periodontitis. Short-term administration of NSAIDs reduced gingival crevicular fluid (GCF) MMP-8 levels, but no statistically significant differences were observed in clinical attachment levels (CALs).[11] Studies also suggested that low-dose aspirin as an adjunct periodontal therapy was beneficial in reducing periodontal attachment loss.[27,29]

Studies have shown that systemic NSAIDs, such as indomethacin,[114] flurbiprofen,[115] and naproxen,[54] administered daily for up to 3 years significantly slowed the rate of alveolar bone loss compared with placebo. However, NSAIDs have some serious disadvantages when considered as an HMT for periodontitis. Daily administration for extended periods is necessary for periodontal benefits to become apparent, and NSAIDs are associated with significant side effects, including gastrointestinal problems, hemorrhage (from decreased platelet aggregation), and renal and hepatic impairment. Research shows that the periodontal benefits of taking long-term NSAIDs are lost when patients stop taking the drugs, with a return to or an acceleration of the rate of bone loss seen before NSAID therapy, often referred to as a *rebound effect*.[116] For these reasons, the long-term use of NSAIDs as an adjunctive treatment for periodontitis has never developed beyond research studies.

Selective cyclooxygenase-2 (COX-2) inhibitors may offer promise as adjunctive treatments for periodontitis. The enzyme cyclooxygenase, which converts arachidonic acid to prostaglandins, exists in two functionally distinct isoforms: COX-1 and COX-2. COX-1 is constitutively expressed and has antithrombogenic and cytoprotective functions. Inhibition of COX-1 by nonselective

NSAIDs therefore causes side effects such as gastrointestinal ulceration and impaired hemostasis.

COX-2 is induced after stimulation by various cytokines, growth factors, and LPS, resulting in the production of elevated quantities of prostaglandins. Inhibition of COX-2 by selective COX-2 inhibitors reduces inflammation. Researchers thought that the use of selective COX-2 inhibitors could reduce periodontal inflammation without the side effects typically observed after long-term (nonselective) NSAID therapy, and preliminary studies found that selective COX-2 inhibitors slowed alveolar bone loss in animal models[5,53] and modified prostaglandin production in human periodontal tissues.[107] However, the selective COX-2 inhibitors were later associated with significant and life-threatening adverse effects (e.g., myocardial infarction), resulting in some drugs being withdrawn from the market. NSAIDs, including selective COX-2 inhibitors, are not indicated as adjunctive HMTs for the treatment of periodontal disease.

Bisphosphonates

Bisphosphonates are bone-seeking agents that inhibit bone resorption by disrupting osteoclast activity. Their precise mechanism of action is unclear, but research has shown that bisphosphonates interfere with osteoblast metabolism and secretion of lysosomal enzymes.[112] Evidence suggests that bisphosphonates also possess anticollagenase properties.[74]

The ability of bisphosphonates to modulate osteoclast activity may be useful in the treatment of periodontitis. Research has demonstrated that in naturally occurring periodontitis in beagle dogs, treatment with the bisphosphonate alendronate significantly increased bone density compared with placebo.[90] In animal models of experimentally induced periodontitis, bisphosphonates reduced alveolar bone resorption.[98,112] In human studies, these agents resulted in enhanced alveolar bone status and density.[7,21,92]

Some bisphosphonates have the unwanted effects of inhibiting bone calcification and altering white blood cell counts. Reports of avascular necrosis of the jaws after bisphosphonate therapy highlight the risk of bone necrosis after dental extractions.[14] Reports

of bisphosphonate-related osteonecrosis of the jaw (BRON/ONJ), although primarily associated with intravenous administration of bisphosphonates rather than oral administration, has impeded the development of bisphosphonates as an HMT to manage periodontitis. As with NSAIDs, no bisphosphonate drugs are approved and indicated for the treatment of periodontal disease.

« Flash Back

Down-regulation of the destructive elements of the host immune response can add to treatment choices in the future. However, agents such as systemic nonsteroidal antiinflammatory drugs (e.g., ibuprofen) can cause significant side effects with long-term use and are not advised. Antiosteoporotic agents (e.g., bisphosphonates) have a minimal effect on periodontal bone loss but carry risks such as localized bone necrosis.

Sub-antimicrobial–Dose Doxycycline

Sub-antimicrobial–dose doxycycline (SDD) is a 20-mg dose of doxycycline (Periostat) that is approved and indicated as an adjunct to SRP in the treatment of chronic periodontitis (see Fig. 54.4). It is taken twice daily for 3 months, up to a maximum of 9 months of continuous dosing. The 20-mg dose exerts its therapeutic effect by enzyme, cytokine, and osteoclast inhibition rather than by any antibiotic effect. Research studies have found no detectable antimicrobial effect on the oral flora or the bacterial flora in other regions of the body and have identified clinical benefit when used as an adjunct to SRP.

SDD (Periostat) is the only systemically administered HMT specifically indicated for the treatment of chronic periodontitis that is approved by the U.S. Food and Drug Administration (FDA) and accepted by the American Dental Association (ADA). Studies conducted by Preshaw and colleagues[89] comparing this same modified-release SDD with placebo in 266 subjects with periodontitis as an adjunct to SRP resulted in significantly greater clinical benefits than SRP alone. A review paper on the nonsurgical treatment of chronic periodontitis by means of SRP with or without

adjuncts showed that clinical improvements with SRP alone resulted in a mean gain of 0.5 mm in CALs, whereas adjunctive therapy with SDD resulted in an additional 0.35 mm gain in CALs beyond that seen with mechanical therapy alone, representing a 70% improvement in CALs.[99]

A modified-release SDD (i.e., Oracea) was approved by the FDA for the treatment of the common skin disorder rosacea, and it is routinely prescribed within the dermatology community. It will be interesting to see what the long-term benefits to oral health will be in rosacea patients prescribed the time-release formulation of SDD. There has been considerable off-label use of this drug for the treatment of periodontal disease based on the understanding that once-daily administration can increase the level of compliance compared with twice-daily oral administration. Preshaw and coworkers demonstrated that this modified-release SDD resulted in significantly improved clinical benefits in the treatment of periodontitis.[89]

Clinical Correlation

- Host modulatory therapy (HMT) is an emerging option for the management of periodontitis.
- A promising form of HMT is the use of chemically modified tetracyclines.
- An FDA-approved agent for host modulation treatment of periodontal disease is sub-antimicrobial–dose doxycycline (SDD) at 20 mg, taken twice daily.
- SDD is the only systemically administered HMT approved, and it is indicated as an adjunct to scaling and root planing (SRP) for treating periodontitis.
- Clinical trials have demonstrated a clear benefit for SDD compared with SRP alone.

Locally Administered Agents

Nonsteroidal Antiinflammatory Drugs

Topical NSAIDs have shown benefit in the treatment of periodontitis. One study of 55 patients with chronic periodontitis who received topical ketorolac mouthrinse reported that GCF levels of PGE_2 were reduced by approximately one-half over 6 months and that bone loss was halted.[57] Locally administered ketoprofen also has been investigated. Topically administered NSAIDs have not been approved as local HMTs for the management of periodontitis.

Enamel Matrix Proteins, Growth Factors, and Bone Morphogenetic Proteins

Several local HMTs have been investigated for use as adjuncts to surgical procedures to improve wound healing and stimulate regeneration of lost bone, periodontal ligament, and cementum, restoring the complete periodontal attachment apparatus. They include enamel matrix proteins, bone morphogenetic proteins (e.g., BMP-2, BMP-7), growth factors (e.g., platelet-derived growth factor, insulin-like growth factor), and tetracyclines. The locally applied HMTs approved by the FDA for adjunctive use during surgery are enamel matrix proteins (Emdogain), recombinant human platelet-derived growth factor-BB (GEM 21S), and BMP-2 (rhBMP-2 [Infuse]), which are covered more extensively in Chapter 63.

The initial local host modulatory agent approved by the FDA for adjunctive use during surgery to assist with clinical attachment gain and wound healing was Emdogain. It was followed by platelet-derived growth factor combined with a resorbable synthetic bone matrix (GEM 21S) to assist in regenerative procedures approved by the FDA and by rhBMP-2 (Infuse) soaked onto an absorbable collagen sponge to assist with ridge and sinus augmentation. The technology behind GEM 21 also has been approved and marketed for use in wound healing, particularly in patients with diabetes, and Infuse has been used for some time for healing fractures by the orthopedic community. However, adverse events associated with the administration of BMPs have been reported, including osteolysis, seroma or hematoma, infection,

arachnoiditis, dysphagia, increased neurologic deficits, and cancer.[26] The remainder of this chapter focuses on the clinical utility of host modulation for nonsurgical procedures in clinical practice and the use of SDD (Periostat) in clinical practice.

Host Modulation and Comprehensive Periodontal Management

The term *periodontal management* suggests a much broader concept of periodontal care than the term *periodontal treatment.* This concept is extremely important considering the chronic nature of the disease. Management includes thorough medical and dental history and examination (i.e., clinical charting and radiographs), assessment of risk factors, diagnosis, development of a treatment strategy, initial and definitive treatment planning, review of treatment outcomes and reevaluation, long-term supportive periodontal therapy (i.e., maintenance care), and assessment of prognosis.

As new data continue to emerge regarding biochemical assessments of disease activity (i.e., measuring levels of proinflammatory mediators, bone and connective tissue breakdown products in the GCF, saliva, and tissues of the oral cavity), new diagnostic and prognostic tests may become part of established protocols for comprehensive periodontal disease management in the future. However, controlling the bacteria that cause periodontal infections remains a central focus of effective periodontal treatment. Understanding the importance of the host response and the impact of risk factors allows clinicians to provide complementary treatment strategies simultaneously for their patients (Fig. 54.2).

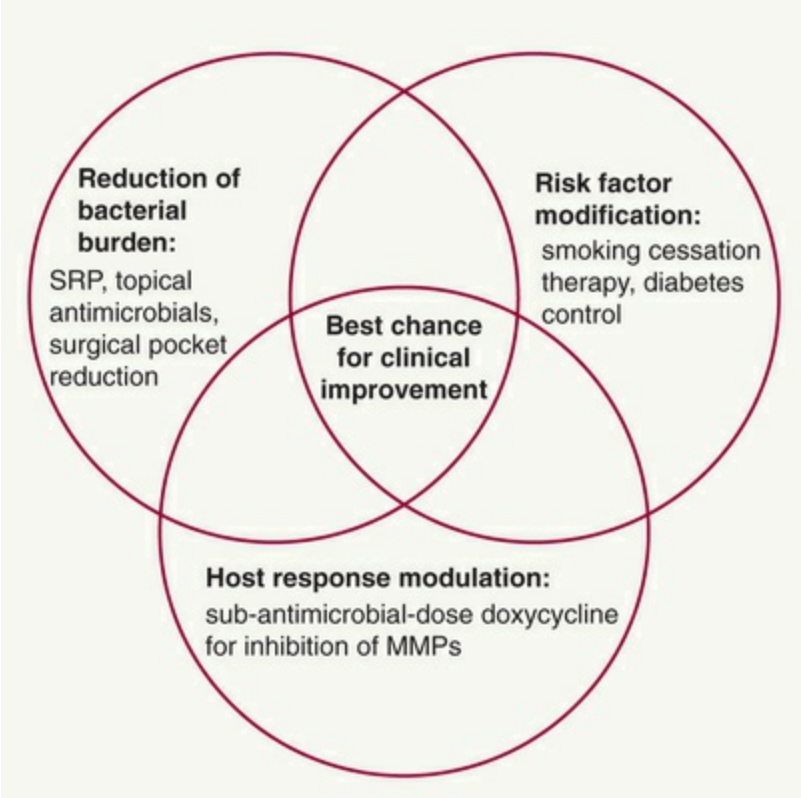

FIG. 54.2 The best chance for clinical improvement may come from implementing complementary treatment strategies for periodontitis that target different aspects of the periodontal balance. Reduction of the bacterial burden by scaling and root planing *(SRP)* is the cornerstone of treatment, and it can be augmented by the use of topical antimicrobials and surgical pocket therapy. In addition to antibacterial treatment, the host response can be treated with host modulatory therapy, such as sub-antimicrobial–dose doxycycline, for the inhibition of matrix metalloproteinases *(MMPs).* Risk factor assessment and modification, including smoking cessation counseling, must form a key part of the periodontal treatment strategy. These different treatment strategies can be used together as part of a comprehensive management approach.

Patients most likely to require the use of HMT include those with risk factors that are nonmodifiable or not easily modified. If the decision is made to use HMT, it must be discussed with the patient and the rationale for treatment thoroughly explained. This takes time at chairside, but it is time well spent; patients become increasingly interested in their periodontal status and are more

likely to develop ownership of their management, enhancing compliance with all aspects of care, including plaque control, risk reduction, and treatment protocols. Compliance with HMT is greatly facilitated if the rationale for prescribing is clearly explained.

The need for compliance with the prescribed drug regimen is important because with SDD, for example, a tablet must be taken twice daily (i.e., once in the morning and once in the evening) and should not be taken with calcium supplements. Compliance may be improved by administration of a modified-release SDD capsule taken only once daily. It should be emphasized to the patient that the use of HMT is not a substitute for excellent plaque control (just as it is not a substitute for excellent debridement and root surface instrumentation by the treating clinician). To achieve the best results, patients must be interested and well informed about their condition so that compliance is maximized. Patients must also be convinced that comprehensive and frequent recall appointments are necessary in the maintenance phase of this chronic and often progressive disease, which can be very well controlled with adequate follow-up.

In addition to patient motivation, oral hygiene instruction, and SRP to reduce the bacterial challenge, a key treatment strategy when managing periodontitis is *risk factor modification.* The harmful effects of smoking on the periodontal tissues are well documented,[60] and successful smoking cessation therapy can be a major benefit to patients with periodontitis. Smoking cessation counseling can be undertaken in the dental office (if staff are appropriately trained) or through collaboration with the patient's physician or specialized clinics. Given the evidence that smokers have worse periodontal disease than nonsmokers[100,117] and that the magnitude and predictability of clinical improvements after treatment are significantly reduced in smokers,[1,85] smoking cessation counseling should form a major part of treatment for smokers with periodontitis.

Patients with poorly controlled diabetes are also at increased risk for periodontitis,[69] and periodontal therapy can have an impact on diabetic control.[46] Collaboration with medical colleagues when treating patients with diabetes and periodontitis is warranted to

ascertain the degree of diabetic control.[31]

Other possible risks for periodontitis include nonmodifiable factors such as genetics, gender, and race. As the relevance of different risk factors is established through epidemiologic research, clinicians must remain aware of their responsibilities for informing and attempting to change patients' behaviors in relation to modifiable risks. The management of patients with periodontitis can involve the following complementary treatment strategies:

- Patient education and motivation, including oral hygiene instruction; use of powered toothbrushes, antiseptics in rinses, toothpastes, and irrigation; and explanation of the rationale for any adjunctive treatments
- Reduction of the bacterial burden by high-quality SRP
- Site-specific antibacterial treatment with local delivery systems or systemic antimicrobial therapy in selected cases
- Host response modulation by HMT
- Risk factor modification and risk reduction strategies
- Periodontal surgery with or without HMT

It is the responsibility of the dentist to customize the treatment plan for each patient by selecting and providing appropriate treatments after discussion and informed decision making by the patient. Good communication and showing an interest in the patient's condition are essential to maximize compliance and modify risk factors. The best chance for clinical improvement may come from a combination of targeted treatment approaches for each patient (see Fig. 54.2). Novak and colleagues published striking improvements in probing depth reductions and CAL gains in a 6-month, randomized, multicenter, examiner-blinded, placebo-controlled study, which showed that combination therapy of HMT

(i.e., SDD) plus a locally delivered antimicrobial (i.e., doxycycline hyclate gel) and SRP provided optimal improvements in clinical parameters compared with SRP alone in the treatment of moderate to severe periodontitis.[76]

Sub-antimicrobial–Dose Doxycycline

SDD is the only FDA-approved, systemically administered HMT indicated specifically for the treatment of periodontitis. SDD is used as an adjunct to SRP and must not be used as a stand-alone therapy (i.e., monotherapy). Because SDD, previously called low-dose doxycycline (LDD) and currently marketed as Periostat, is based on a sub-antimicrobial dosage of doxycycline, a member of the tetracycline family of compounds, the use of tetracyclines for the management of periodontal diseases must be put in perspective.

No class of drugs has made more of an impact on periodontal therapy than the tetracyclines. They have been used in conjunction with SRP, the gold standard of nonsurgical therapy, and with resective and regenerative surgical procedures. The tetracyclines have been used locally and systemically as antimicrobial agents and as host modulation agents (i.e., SDD). Tetracyclines have been prescribed to address chronic periodontitis and to manage specific and often more aggressive types of periodontitis.

Tetracyclines have been advocated for treatment of patients with systemic diseases such as diabetes, rheumatoid arthritis, and rosacea (i.e., treated with Oracea). Doxycycline has led to improvements in the periodontal health of compromised diabetic patients and long-term markers of glycemic control (i.e., glycated hemoglobin).[47] As an adjunct to mechanical therapies, the goal of tetracycline therapy has been to enhance reattachment or stimulate new attachment of the supporting apparatus and osseous formation. The following sections concentrate on the use of pleiotropic compounds for modulation of the host response in the treatment of periodontitis.

Mechanisms of Action

In addition to its antibiotic properties, doxycycline (and other

members of the tetracycline family) has the ability to down-regulate MMPs, a family of zinc-dependent enzymes that can degrade extracellular matrix molecules, including collagen.[8,95] MMPs are secreted by the major cell types in the periodontal tissues (e.g., fibroblasts, keratinocytes, macrophages, PMNs, endothelial cells) and play a key role in periodontitis. Excessive quantities of MMPs are released in inflamed periodontal tissues, resulting in breakdown of the connective tissue matrix. The predominant MMPs in periodontitis, particularly MMP-8 and MMP-9, are derived from PMNs[41] and are extremely effective in degrading type I collagen, the most abundant collagen type in gingiva and periodontal ligament.[67] Levels of PMN-type MMPs increase with the severity of periodontal disease and decrease after therapy.[34,41] The release of large quantities of MMPs in the periodontium leads to significant anatomic disruption and breakdown of the connective tissues, contributing to the clinical signs of periodontitis.

The rationale for using SDD as an HMT in the treatment of periodontitis is that doxycycline down-regulates the activity of MMPs by a variety of synergistic mechanisms, including reductions in cytokine levels, and stimulates osteoblastic activity and new bone formation by up-regulating collagen production (Fig. 54.3).

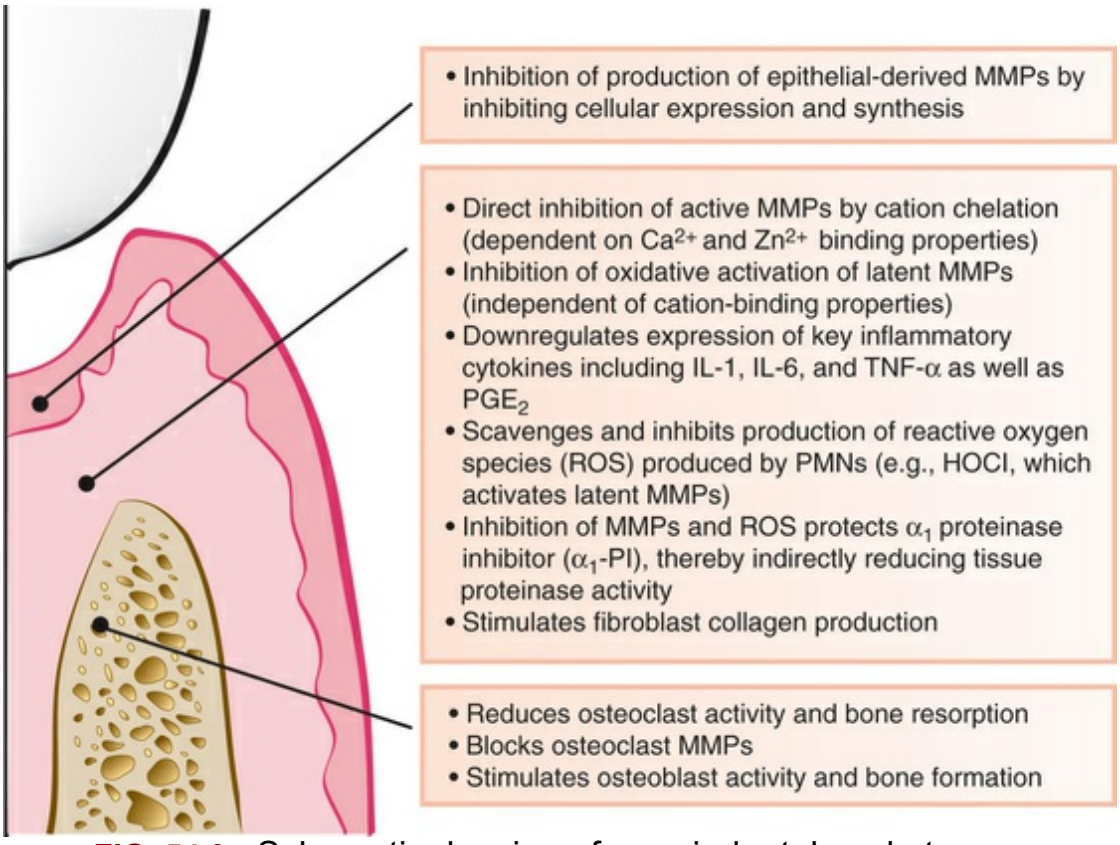

FIG. 54.3 Schematic drawing of a periodontal pocket shows the pleiotropic mechanisms by which doxycycline inhibits connective tissue breakdown. Down-regulation of destructive events in periodontal tissues by doxycycline results from modulation of a variety of proinflammatory pathways. *IL*, Interleukin; *MMPs*, matrix metalloproteinases; PGE_2, prostaglandin E_2; PMNs, polymorphonuclear leukocytes; *TNF*, tumor necrosis factor. (From Golub LM, Lee HM, Ryan ME, et al: Tetracyclines inhibit connective tissue breakdown by multiple non-antimicrobial mechanisms. *Adv Dent Res* 12:12, 1998.)

Clinical Research Data on Distinct Patient Populations

Tetracyclines work well as host modulation agents because of their pleiotropic effects on multiple components of the host response (see Fig. 54.1). The only enzyme (MMP) inhibitors that have been approved for clinical use and tested for the treatment of periodontitis are members of the tetracycline family of compounds. In early studies investigating the use of commercially available

tetracyclines, Golub and colleagues[43] reported that the semisynthetic compound doxycycline was more effective than the parent compound tetracycline in reducing excessive collagenase activity in the GCF of chronic periodontitis patients. Because doxycycline was a more effective inhibitor of collagenase than minocycline or tetracycline[11,35] and because of its safety profile, pharmacokinetic properties, and ready systemic absorption, clinical trials have focused on this compound.

In an effort to eliminate the side effects of long-term tetracycline therapy, especially the emergence of tetracycline-resistant organisms, SDD capsules were prepared and tested.[41] Each capsule contained 20 mg of doxycycline, compared with the commercially available 50-mg and 100-mg, antimicrobially effective capsules or tablets. Multiple clinical studies using sub-antimicrobial doses of doxycycline have shown no difference in the composition or resistance level of the oral flora.[102,111] Later studies demonstrated no appreciable differences in fecal or vaginal microflora samples.[109] These studies have shown no overgrowth of opportunistic pathogens, such as *Candida,* in the oral cavity, gastrointestinal system, or genitourinary system.

In a study of MMP inhibition, Golub and coworkers[34] reported that a 2-week regimen of SDD reduced collagenase in GCF and in the adjacent gingival tissues surgically excised for therapeutic purposes. Subsequent studies using SDD therapy adjunctive to routine scaling and prophylaxis indicated continued reductions in the excessive levels of collagenase in the GCF after 1 month of treatment. After cessation of SDD administration, however, there was a rapid rebound of collagenase activity to placebo levels, suggesting that a 1-month treatment regimen with this host modulation agent was insufficient to produce a long-term benefit.[3] During the same study, a 3-month regimen produced a prolonged drug effect without a rebound in collagenase levels to baseline during the no-treatment phase of the study. The mean levels of GCF collagenase were significantly reduced (i.e., 47.3% from baseline levels) in the SDD group compared with the placebo group of patients, who received scaling and prophylaxis alone (i.e., 29.1% reduction from baseline levels). Accompanying the reductions in collagenase levels were gains in the relative attachment levels in the

SDD group.[3,40]

A review paper reported that adjunctive therapy with SRP and SDD resulted in a 70% improvement in CAL.[99] Continuous drug therapy over several months appears to be necessary for maintaining collagenase levels near normal over prolonged periods. It is reasonable to speculate that levels of MMPs will eventually increase again in more susceptible patients after drug cessation and that individuals having the most risk factors and the greatest microbial challenge will require more frequent HMT than other patients.

General Patient Populations

Data from clinical trials of SDD are summarized in Table 54.1. A series of double-blind, placebo-controlled studies of 3, 6, and 9 months' duration showed clinical efficacy based on reductions in probing depth, gains in clinical attachment, and biochemical efficacy based on the inhibition of collagenase activity and protection of serum α_1-antitrypsin (a naturally occurring protective mediator) from collagenase attack in the periodontal pocket.[18,35,62] Golub and associates[37] showed that a 2-month regimen of SDD significantly decreased the level of bone-type collagen breakdown products (i.e., carboxy-terminal telopeptide of type I collagen [ICTP], a pyridinoline-containing, cross-linked peptide of type I collagen) and MMP-8 and MMP-13 enzyme levels (i.e., neutrophil and bone-type collagenase) in chronic periodontitis subjects (Fig. 54.4).

Summary data from Preshaw PM: Host response modulation in periodontics, *Periodontol 2000* 48:92, 2008.

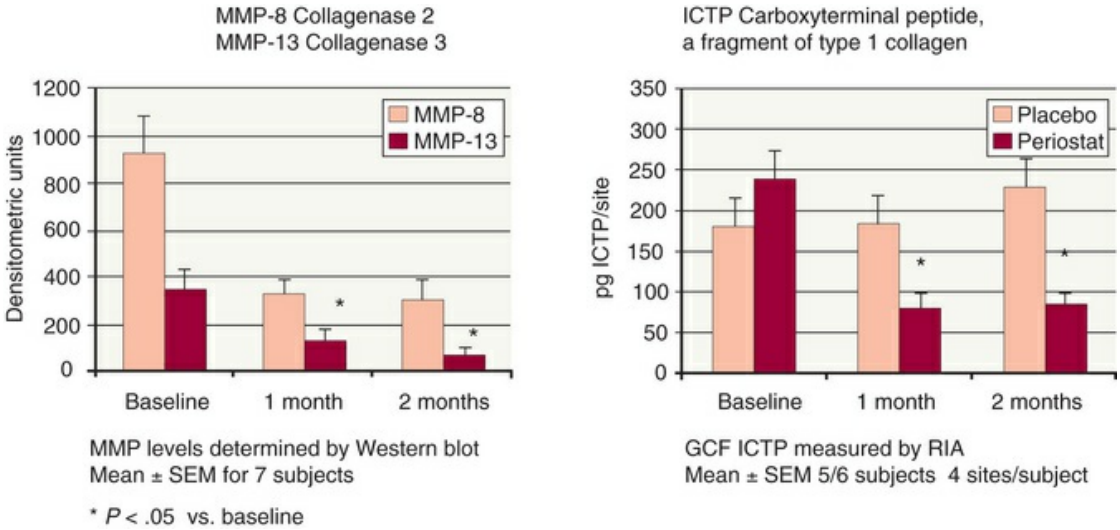

FIG. 54.4 Effects are shown for sub-antimicrobial–dose doxycycline (SDD) on gingival crevicular fluid *(GCF),* collagenase (e.g., MMP-8, MMP-13), and carboxy-terminal telopeptide of type I collagen *(ICTP).* A 2-month regimen of SDD significantly decreased levels of matrix metalloproteinases (i.e., neutrophil type [*MMP-8*] and bone-type [*MMP-13*]) and ICTP compared with placebo in GCF samples from adult periodontitis patients. Decreased levels of GCF bone-type collagen breakdown products (i.e., ICTP, a

pyridinoline-containing cross-linked peptide of type I collagen) in the SDD group versus placebo provides biochemical evidence of a reduction in bone resorption. *MMPs*, Matrix metalloproteinases; *RIA*, radioimmunoassay. (From Golub LM, Lee HM, Greenwald RA, et al: A matrix metalloproteinase inhibitor reduces bone-type collagen degradation fragments and specific collagenases in gingival crevicular fluid during adult periodontitis. *Inflamm Res* 46:310, 1997.)

The phase III, 9-month, randomized, double-blind, placebo-controlled trial conducted at five dental centers demonstrated clinical efficacy and safety of SDD versus placebo as an adjunct to SRP. The benefits of HMT as an adjunct to mechanical therapy were statistically significant reductions in probing depths, gains in clinical attachment levels, and prevention of disease progression.[15] When SDD administration was discontinued after 9 months of continuous therapy, the incremental improvements demonstrated in the SDD group were maintained for at least 3 months. There was no rebound effect in pocket depth reductions or clinical attachment level gains, and there appeared to be slight continued improvement in both clinical parameters, presumably because of the enhanced clinical status of the patients who had benefited from adjunctive SDD and possibly because of the known persistence or substantivity of doxycycline in the bone and soft tissue of the periodontium. The clinical relevance of these findings confirms the utility of an MMP inhibitor in the management of chronic periodontitis.

High-Risk Patients: Smokers

The harmful effects of cigarette smoking and the reduced response to periodontal treatment in smokers compared with nonsmokers are well established.[60] A meta-analysis of randomized clinical trials of SDD used as an adjunct to SRP revealed a benefit when using SDD in smokers with periodontitis[75,87] (see Table 54.1). A hierarchical treatment response was observed; nonsmokers who received SDD demonstrated the best clinical improvements and smokers who received placebo had the poorest treatment response. The responses of the smokers who received SDD and the nonsmokers who received placebo were intermediate to the two

extremes and were broadly identical. This suggests that even patients traditionally considered resistant to periodontal treatment (i.e., smokers) can benefit from SDD, with a treatment response similar to that expected when treating a nonsmoker by SRP alone.

Special Patient Populations

More recent phase IV (i.e., after licensing) clinical studies have revealed success using SDD in particular populations of susceptible individuals. Much interest has focused on genetic susceptibility to periodontal disease, particularly whether a specific variation in the genes that regulate the cytokine IL-1 confers increased susceptibility to disease. This polymorphism is known as the *periodontitis-associated genotype* (PAG), which can be characterized using the PST Genetic Test (Interleukin Genetics, Waltham, MA). Investigation of patients who possess these polymorphisms (i.e., two single nucleotide polymorphisms in the *IL-1A* promoter region and *IL-1B* gene) has been driven by the assumption that local phenotypic differences exist in chronic periodontitis associated with this genotype (e.g., that PAG-positive patients produce more IL-1 cytokines for a given bacterial challenge, resulting in increased tissue damage and more extensive periodontal disease). IL-1β levels in shallow periodontal pockets are higher in patients with this genotype than those without.[25]

Studies that have investigated associations between PAG and periodontal disease status have generated conflicting data.[101] A reasonable assumption is that there are genetic associations between polymorphisms in the *IL-1* gene cluster and periodontal disease but that unambiguous results are not apparent because of the heterogeneity of the disease or the various study designs. Cullinan and colleagues concluded that the IL-1 genotype is a contributory but nonessential risk factor for periodontal disease progression.[19] Despite the controversy surrounding the acceptance of this genotype as a risk factor, insurance companies are using testing as a determinant of covered treatment.[9]

A 5-month preliminary investigation by Ryan and coworkers[94] was designed to evaluate the impact of treatment on IL-1β and MMP levels in PST-positive (i.e., PAG) patients who had elevated levels of these biochemical markers in the GCF. They were initially

treated with SRP, resulting in no change in the levels of these biochemical markers after 1 month. Al-Shammari and colleagues[2] reported similar findings, with no changes in GCF levels of IL-1β and ICTP before and after SRP in patients who had not been genotyped. When the genotype-positive patients received SDD and the biochemical markers were monitored at 2 and 4 months, a significant decrease (50% to 61%) in the IL-1β and MMP-9 levels was found after treatment with SDD. Gains in clinical attachment and reduced probing depths were also observed. The study concluded that a sub-antimicrobial dose of doxycycline could provide PST-positive patients with a therapeutic strategy that specifically addresses their exaggerated host response.

Another study enrolling susceptible patients with severe generalized periodontitis looked at host modulation (i.e., SDD) as an adjunct to repeated subgingival debridement.[77] Seventy percent of the patients who completed the 9-month, double-blind, placebo-controlled study were smokers. SDD as an adjunct to mechanical therapy compared with mechanical therapy alone resulted in significantly greater mean probing depth reductions in pockets of 7 mm or greater at baseline as early as 1 month after therapy (2.52 mm vs. 1.25 mm). Improvements in the SDD group compared with those in the group receiving mechanical therapy were maintained during the 5.25 months of therapy (2.85 mm vs. 1.48 mm) and even at 3 months after stopping drug therapy (3.02 mm vs. 1.41 mm), demonstrating that no rebound effect occurred. Because of the beneficial effects of HMT in susceptible patients, multicenter studies are using SDD in other susceptible populations, including diabetic, osteoporotic, and institutionalized geriatric patients and smokers.

Because periodontitis is associated with many systemic diseases (e.g., osteoporosis, diabetes, cardiovascular disease [CVD]), researchers have investigated the effect of SDD on systemic conditions. Payne and associates[82] conducted a 2-year, randomized, double-blind, placebo-controlled trial enrolling osteopenic women at two dental centers and demonstrated that SDD could effectively reduce the levels of localized and systemic inflammatory mediators in osteopenic patients in addition to improving the clinical measurements of periodontitis.[38] SDD significantly reduced the

progression of periodontal attachment loss[91] and the severity of gingival inflammation and alveolar bone loss in postmenopausal osteopenic women.[83] Golub and coworkers[38] reported that collagenase activity in the GCF of osteopenic women was significantly reduced by SDD treatment. ICTP showed a similar pattern of change during SDD treatment, with GCF collagenase activity and ICTP levels positively correlated at all time periods ($P < .001$). MMP-8 accounted for approximately 80% of total collagenase in the GCF, with much lower levels of MMP-1 and -13. SDD reduced the elevated MMP-8 levels by 60%.

The 2-year study also demonstrated that long-term, continuous use of SDD did not produce antibiotic side effects,[110] confirming what had been reported in previous studies of continuous use of up to 12 months. Previously reported studies had demonstrated a relationship between serum high-sensitivity C-reactive protein (hsCRP) concentration and biochemical bone turnover markers in healthy premenopausal and postmenopausal women.[58] The findings suggested that low-grade systemic inflammation might be a common linking factor between the development of atherosclerosis and an increased bone turnover rate.

Payne and colleagues[79] demonstrated that the 2-year SDD regimen previously described in postmenopausal women significantly reduced serum inflammatory biomarkers (i.e., hsCRP and MMP-9) and, among women more than 5 years into menopause, increased the high-density lipoprotein (HDL) cholesterol level. These preliminary findings suggest that SDD can play a role in managing the care of patients at risk for coronary artery disease. Other studies have shown that SDD reduces systemic inflammatory biomarkers in CVD patients[10] and that SDD decreases glycated hemoglobin assay (HbA1c) in patients who are taking normally prescribed hypoglycemic agents.[24]

The impact of SDD therapy on periodontitis can be amplified by the concurrent use of other HMTs used to manage other inflammatory diseases. Additional studies are being conducted to investigate the impact of combined HMT use on periodontal disease and other chronic inflammatory conditions.

Suggested Uses and Other Considerations

Until recently, treatment options for periodontal disease have focused solely on reducing the bacterial challenge by nonsurgical therapy, surgery, and systemic or local antimicrobial therapy. Development of SDD as an HMT, driven by research into the pathogenesis of periodontal disease, is a great example of how translational research can lead to new treatments. By better understanding the biochemical processes that are important in periodontal disease, a pharmacologic principle (i.e., doxycycline down-regulates MMP activity) has been used in the development of a new drug treatment. Data from research studies show the clinical benefits of adjunctive SDD, and the science behind SDD has been transferred into clinical practice. Dentists have the opportunity to use SDD for patient care, with the aim of enhancing the treatment response to conventional therapy.

Candidate Patients

When deciding whether to use SDD as an adjunct to SRP, the dentist should first consider the patient's motivation for periodontal care, the medical history, and the patient's willingness to take a systemic drug treatment. SDD is contraindicated in any patient with a history of allergy or hypersensitivity to tetracyclines. It should not be given to pregnant or lactating women or to children younger than 12 years of age because of the potential for discoloration of the developing dentition. Because doxycycline can reduce the efficacy of oral contraceptives, alternative forms of birth control should be discussed if necessary. There is a risk of increased sensitivity to sunlight (manifested by an exaggerated sunburn) seen with higher doses of doxycycline, although this has not been reported in the clinical trials using the sub-antimicrobial dose.

The rationale for using SDD must be clearly explained to the patient. By discussing the cause of periodontal disease, the available treatment options, and the anticipated outcomes, patients become more interested in periodontal management, are more likely to comply with treatment, and take more responsibility for managing their disease. The anticipated compliance and likely commitment to treatment must also be gauged when considering SDD therapy. Patients who show little enthusiasm for complying with the treatment plan or with oral hygiene practices are less likely

to be good candidates for systemic drug therapy.

Treatable Periodontal Conditions

SDD is indicated in the management of chronic periodontitis, and studies have focused on chronic and aggressive forms of periodontitis.[15,23,77,88] SDD should not be used in conditions such as gingivitis and periodontal abscess or when an antibiotic is indicated. SDD can be used in patients with aggressive periodontitis who are being treated nonsurgically. Studies have supported efficacy of SDD as an adjunct to periodontal surgery.[28] SDD may also be of benefit in cases that are refractory to treatment and in patients with risk factors such as smoking, diabetes, osteoporosis or osteopenia, and genetic susceptibility and those in whom the treatment response is limited.

Side Effects

Doxycycline at antibiotic doses (≥100 mg) is associated with adverse effects, including photosensitivity, hypersensitivity reactions, nausea, vomiting, and esophageal irritation. However, in the clinical trials of SDD using a 20-mg dose, the drug was well tolerated, and the profile of unwanted effects was virtually identical in the SDD and placebo groups.[15,23,77,88] The types of adverse events were not significantly different between treatment groups, and the typical side effects of the tetracycline class of drugs were not observed, indicating that adverse events are dose related.[15,88] There was no evidence of adverse events that could be attributed to antimicrobial effects of treatment and no evidence of developing antibiotic resistance of the microflora after 2 years of continuous use.[15,102,103,110,111] The drug appears to be well tolerated, with a very low incidence of adverse effects.

Sequencing Prescription With Periodontal Treatment

SDD is indicated as an adjunct to mechanical periodontal therapy and should not be used as a stand-alone treatment or monotherapy. SDD should be prescribed to coincide with the first round of SRP and is prescribed for 3 months, up to a maximum of 9 to 24 months of continuous dosing depending on the patient's risk. Modification

of any risk factors, such as smoking, nutrition, stress, contributing medications, faulty restorations, poor oral hygiene, and poor diabetic control, should also be addressed at this time. A patient's refusal or inability to modify contributing risk factors is an important consideration for treatment planning and evaluation of therapeutic responses.

After initial periodontal treatment, the patient is enrolled in an intensive periodontal maintenance program. It involves regular monitoring of probing depths, reinforcement of oral hygiene, and repeat motivation of the patient, with further SRP to disrupt the plaque biofilm and remove reforming calculus deposits. The 3-month prescription of SDD fits well with the typical SDD therapy that is commenced at the start of initial periodontal therapy and continues for 3 months until the first reevaluation or maintenance appointment. At maintenance appointments, the need for another prescription of SDD can be assessed. For patients demonstrating a good treatment response with significant reductions in probing depths, more SDD may not be necessary. Periodontal maintenance care must continue, with an emphasis on plaque control, monitoring, and prophylaxis.

In other patients, the treatment response after completion of initial therapy may be less favorable. Sites with persisting or progressing pockets may require additional instrumentation, and the prescription of SDD can be extended for an additional 3 months. SDD can be combined with the use of locally applied antimicrobials and surgical procedures. Periodontitis is a chronic disease, and the treatment (with or without SDD) is long term. The patient must be regularly reevaluated to determine disease stability or progression and the need for additional active therapy.

Patients may cycle between phases of active treatment (i.e., SRP and SDD) and long-term periodontal maintenance. The success of the maintenance phase of treatment is affected by many factors, including the following:

- Compliance with the maintenance regimen
- Compliance with oral hygiene instruction
- Risk factors, such as smoking, poorly controlled

diabetes, or stress
- Extent (i.e., number) and severity (i.e., depth) of residual deep pockets

Maintenance therapy is more likely to be successful in patients with good compliance, good oral hygiene, minimal or no systemic risk factors, and minimal residual deep pocketing. The patient who enters the maintenance program may have periodontal stability for months or years. However, plaque control may deteriorate, the patient may develop or acquire new risk factors, and disease progression (i.e., further loss of attachment) may become apparent, indicating that a further course of treatment is required. Another course of SRP is then undertaken together with adjunctive SDD to restore periodontal stability.

Combining With Periodontal Surgery or Local Delivery Systems

Most clinical research has focused on using SDD as an adjunct to nonsurgical periodontal treatment. However, data from studies in which SDD was used as an adjunct to access flap surgery in 24 patients revealed better probing depth reductions in surgically treated sites greater than 6 mm compared with surgically treated sites in patients given placebo.[28] The SDD group demonstrated greater reductions in ICTP, a breakdown product of collagen, than the placebo group, indicating that collagenolytic activity was reduced in the patients taking SDD.

SDD treatment can also be combined with the local delivery of antibiotics into the periodontal pocket through sustained-delivery systems. The two treatment approaches target different aspects of the pathogenic process. Local delivery systems deliver antimicrobial concentrations of an antibacterial agent directly into the site of the pocket, whereas SDD is a systemic host response modulator. Combining these two complementary treatment strategies is another example of how antibacterial therapy (i.e., SRP plus local antibiotics) can be combined with HMT (i.e., SDD) to maximize the clinical benefit for patients. Preliminary results from a 6-month, 180-patient clinical trial designed to evaluate the safety

and efficacy of SDD combined with a locally applied antimicrobial (Atridox) and SRP compared with SRP alone demonstrated that patients receiving the combined treatments had more than a 2-mm improvement in mean attachment gains and probing depth reductions ($P < .0001$) compared with SRP alone.[76]

Monitoring Benefits of Therapy

To improve the ability of dentists to make appropriate treatment decisions for patients undergoing periodontal therapy, they need access to the types of diagnostic tests available to their medical colleagues. The tests could be used, for example, to distinguish between active and inactive lesions. Studies have shown that SRP alone, although effective for improving clinical parameters such as probing depths, may not be sufficient to reduce excessive levels of many underlying destructive mediators, particularly in more susceptible patients.

It would be valuable to monitor the levels of inflammatory mediators as treatment progresses. SDD results in down-regulation of MMP activity in inflamed periodontal tissues.[34,37] In theory, MMP levels could be monitored before, during, and after SRP plus SDD treatment. Published data support a concomitant reduction in MMP levels in GCF[16,23] and improvements in clinical parameters when combining SDD and SRP.[23] Although chairside tests for MMPs have been developed,[66] they are not in widespread use because of concerns about their specificity and sensitivity.

In the absence of new chairside tests or a centralized diagnostic facility for monitoring the inflammatory status of the tissues, dentists must rely on clinical periodontal monitoring to assess the outcomes of treatment. In addition to the reductions in probing depths and gains in attachment that may be observed after SRP plus SDD, the quality of the periodontal tissues tends to improve after treatment with SDD with significant reductions in gingival indices and bleeding on probing. More sensitive radiographic techniques, assessments of bone density, and bone height changes used solely in clinical trials in the past may be possible in clinical practice in the future. Until such diagnostic techniques are made widely available, clinicians must rely on clinical judgment to determine the most appropriate course of therapy.

Emerging Host Modulatory Therapies

In the future, a variety of HMTs will likely be developed as adjunctive treatments for periodontitis. Promising HMTs include *chemically modified tetracyclines* (CMTs). These tetracycline analogues are tetracycline molecules that have been modified to remove all antibiotic properties, but they retain host modulatory, anticollagenolytic effects. The CMTs are also designed to be more potent inhibitors of proinflammatory mediators and can increase levels of antiinflammatory mediators such as IL-10. Because they have no antimicrobial properties, the clinician can increase the dose for more susceptible patients with more risk factors and who may be more difficult to manage without experiencing the side effects seen with antibiotics.

CMTs, such as CMT-3 and CMT-8 (both of which lack antibiotic activity but retain anti-MMP activity), inhibit osteoclastic bone resorption and promote bone formation,[97] enhance wound healing,[84] and inhibit proteinases produced by periodontal pathogens.[45] CMTs also are being studied for other effects, such as inhibition of tumor cell invasion[64] and attenuation of intimal thickening after arterial injury.[56] CMTs will likely emerge as drugs that have beneficial effects in a variety of disease states because of their host modulation capabilities.

Other potential HMTs include the novel *anticytokine drugs* developed for the management of rheumatoid arthritis, a disease with a pathobiology similar to that of periodontitis.[72] Cytokines such as TNF-α have been targeted by TNF-α antagonists (e.g., infliximab, etanercept), which have been shown to be effective in treating rheumatoid arthritis.[108] These drugs have not been evaluated in the treatment of periodontal disease, but they could offer benefits given the importance of inflammatory cytokines such as TNF-α in periodontal disease pathogenesis. Drugs designed to increase the levels of antiinflammatory or protective mediators (e.g., IL-1ra) can perform similar functions. Evidence is emerging to support the benefits of combining HMTs that target different aspects of disease processes. For example, the combination of SDD with bisphosphonates has demonstrated synergy in animal models of bone loss.[61]

Research has found there is an active biochemical resolution phase involved in inflammation. Failure of this resolution pathway may play a role in the pathogenesis of periodontal diseases.[105] Restoration of the resolution pathway by the introduction of resolving molecules may provide new therapeutic methods for the management of inflammatory periodontitis.[6] In rabbit models of periodontitis, topical application of resolvin E1 protected against bone loss mediated by osteoclasts.[52] In a rat model of periodontitis resolvin E1 reversed periodontal bone loss and inflammatory gene expression, with reductions in osteoclast density also reported.[106]

As the concept of host modulation has become more widely accepted, much research has focused on developing additional HMTs. Some investigations have focused on the efficacy of available nutritional supplements such as fish oils. Studies have indicated that n-3 polyunsaturated fatty acids (n-3 PUFAs) (i.e., fish oil) as an adjunct to oral hygiene instructions can significantly lower gingival crevicular fluid (GCF) IL-8, IL-6, and PGE_2 levels compared with placebo controls.[20] Other studies have found that combination therapy with n-3 PUFA and low-dose aspirin as an adjunct to regenerative procedures using decalcified, freeze-dried bone allografts result in greater mean probing depth reductions ($P < .001$) and gains in clinical attachment ($P < .05$), accompanied by a trend for modulation of the cytokine profile of IL-1β and IL-10 in GCF compared with placebo-controlled regenerative therapy.[22]

Collagenase (i.e., MMP) inhibitors known as *polyenolic zinc-binding compounds* (PEZBINs) for periodontitis have been investigated. These new inhibitors are based on the natural product curcumin, which contains a calcium- and zinc-binding β-diketone moiety that is similar to that found in tetracyclines. The antiinflammatory properties of curcumin have been demonstrated in periodontal disease, cardiovascular diseases, cancer, arthritis, and diabetes.[118] A novel group of chemically modified curcumins (CMCs) with increased bioavailability and improved antiinflammatory activity have been tested. In vitro and in vivo findings demonstrate that these potential host modulatory agents can decrease pathologically elevated MMP levels in the plasma and gingiva of animal models of periodontitis.[39] One of the lead compounds demonstrated a significant effect on reducing alveolar

bone loss in experimental periodontitis models.

More research is being conducted to evaluate this new group of compounds as an HMT in periodontal diseases and in other systemic chronic inflammatory conditions such as arthritis and diabetes. Reports indicate the therapeutic potential of a novel semisynthetic glycosaminoglycan ether (SAGE) or sulfated polysaccharide to suppress inflammatory mediators in high-risk individuals, such as smokers and those with diabetes, based on the ability to reduce the impact of advanced glycation end products (AGEs) reducing the proinflammatory mediators of disease.[50] In vitro and in vivo studies found that systemic administration of SAGE significantly reduced local and systemic inflammation by modulating the production of cytokines and MMPs. Periodontal bone loss was significantly attenuated in the diabetic rats with infection.[49,50]

Research may enable the application of stem cells in HMT, offering interesting alternatives to existing therapies. Human periodontal stem cells can modulate neutrophil function and reduce excessive inflammation.[17] Bone marrow–derived mesenchymal stem cells have shown great potential for periodontal regeneration in animal models.[59] Additional studies are needed to characterize dental stem cells and evaluate the therapeutic efficacy of stem cell–based periodontal therapy. Enhanced stem cell approaches may result in innovative HMT strategies to achieve desired periodontal outcomes.

Host Modulation Factors in Systemic Disorders

In susceptible patients demonstrating an excessive local inflammatory response to the bacterial stimuli leading to periodontal disease, another consideration is the loss of epithelial integrity in the periodontal pocket. This tissue response allows bacterial penetration into the inflamed tissues and eventual entry of the bacteria into the systemic circulation. Patients with untreated periodontitis have an increased risk of transient bacteremias. Bacteremia and associated endotoxemia can incite the

overproduction of destructive proinflammatory mediators at distant sites in the periodontitis patient. Patients with periodontitis may be at greater risk for systemic conditions associated with a similar overactive host response to external stimuli, such as cardiovascular disease and diabetic complications. Elevated levels of cytokines, prostanoids, and enzymes are evident in all of these conditions.

In the era of periodontal medicine, systemic host modulatory approaches need to be considered. Host modulators used to manage periodontal disease, such as MMP, cytokine, and prostanoid inhibitors, can have additional beneficial effects on systemic diseases linked to periodontal disease, such as CVD and diabetes. Preliminary studies have indicated that individuals with periodontal disease and CVD are almost twice as likely to have a fatal heart attack and three times as likely to have a stroke.[4] MMPs and cytokines play a major role in weakening the plaques formed with CVD, leading to rupture and eventual thrombosis and infarction.[32] Golub and coworkers[36] suggested that tetracyclines could reduce the incidence of acute myocardial infarction[71] by blocking collagenase and stabilizing the collagen cap on the atherosclerematous arterial plaques.

In diabetes, the MMPs and cytokines involved in the development of periodontitis as the sixth long-term complication of diabetes[70] also play a role in the development of other well-known complications of diabetes such as nephropathy, angiopathy, retinopathy, and wound-healing problems.[93] Modulation of proinflammatory mediators in patients with diabetes can impede development of multiple long-term complications.

An inhibitor of MMPs, cytokines, and prostanoids used in the treatment of periodontitis can have an indirect effect on these diseases if a patient's risk of developing them is increased by untreated periodontitis. HMT can also directly aid in the treatment and prevention of CVD and diabetic complications.

Summary

Periodontal pathogens and destructive host responses are involved in the initiation and progression of periodontitis. Successful long-

term management can require an integrated treatment strategy that addresses both etiologic components. Evidence for the role of MMPs, cytokines, and other mediators in the pathogenesis of periodontal disease distinguishes them as targets for a chemotherapeutic approach. The introduction of novel, adjunctive therapies such as host modulation to enhance the efficacy of mechanical procedures can contribute favorably to an integrated approach for the long-term clinical management of periodontitis.

HMTs are an emerging treatment concept in the management of periodontitis. The use of HMT as an adjunct can be particularly useful in susceptible, high-risk patients in whom a prolonged and excessive host response to bacteria promotes the activity of MMPs and osteoclasts.

SDD is the only systemically administered HMT currently approved and indicated as an adjunct to SRP for treating periodontitis. Clinical trials have demonstrated a clear benefit for using SDD compared with SRP alone. SDD should be used as part of a comprehensive treatment strategy that includes antibacterial treatments (i.e., SRP, plaque control, oral hygiene instruction, local antimicrobials, and periodontal surgery), host response modulation (i.e., SDD), and assessment and management of periodontal risk factors.

In the future, a range of HMTs targeting different aspects of the destructive cascade of breakdown events in periodontal tissues are likely to be developed as adjunctive treatments for periodontitis. Development of these agents will permit dentists to treat specific aspects of the underlying biochemistry of periodontal disease. The goal is to maximize and make more predictable the treatment response by reducing inflammation and inhibiting destructive processes in the tissues, resulting in enhanced periodontal stability after conventional periodontal treatments such as SRP and surgery. The dentist is now in the exciting position of being able to combine established treatment strategies with new systemic and local drug treatments for this common, chronic disease.

The use of HMT to better manage chronic periodontal disease may have applications to other chronic systemic diseases such as arthritis, diabetes, osteoporosis, and CVD. Studies using locally applied antimicrobials as part of an intensive periodontal therapy

(IPT) regimen have shown promising results. Future studies may demonstrate that in addition to current standard therapies, IPT with adjunctive antibiotics and host modulation for the management of periodontal disease can have profound positive effects on the overall health status of high-risk patients. The proper management of local infection and inflammation (i.e., periodontitis) will have a significant impact on the general overall health of the population.

Key Fact

Host modulatory therapies directed at various aspects of the destructive cascade of breakdown events in periodontal tissues are being developed as adjunctive treatments for periodontitis. These agents target specific aspects of the underlying biochemistry of periodontal disease. The goal is to enhance response to therapy and achieve periodontal stability.

CHAPTER 55

Occlusal Evaluation and Therapy

Michael J. McDevitt

CHAPTER OUTLINE

Pathogenesis
Evidence-Based Decision Making
Terminology
Occlusal Function and Dysfunction
Parafunction
Clinical Examination
Occlusal Therapy
Conclusions

Among the numerous local and systemic factors with the potential to influence the progression of periodontitis, the patient's occlusion remains a variable that requires an exact diagnosis. All of the disciplines of dentistry include the comprehensive analysis of occlusal relationships for determination of appropriate care.

The functional demands of the occlusion may fall within or substantially exceed the tolerances and the adaptability of the patient's periodontium and masticatory system. The full range of knowledge and skill needed to analyze all aspects of occlusal anatomy and function is beyond the scope of this chapter, which does present practical guidelines for the assessment and management of the occlusion specific to a patient's unique susceptibility to periodontitis.

Pathogenesis

The host-driven inflammatory response of each patient to a pathogenic bacterial biofilm[39] is so specific that the patient is his or her only reference for the interpretation of possible contributing factors to the progressive loss of supporting bone. Destructive events can be episodic and are site specific.

A dentist's diagnostic responsibility includes careful measurement of periodontal structures in the entire circumference of each tooth, accurate documentation, and timely reassessment. Periodontal deterioration that occurs rapidly or that is excessive for a person's age should prompt the clinician to investigate all variables that can amplify his or her periodontitis. If a local factor such as an occlusal relationship can influence the course of the disease, its analysis must be as precise as any other aspect of the periodontal examination.

Evidence-Based Decision Making

In a perfect world, all diagnostic and therapeutic decisions would reflect evidence from multiple prospective clinical trials that have been subject to systematic review. Prospective human investigations of occlusal trauma are considered unethical, and periodontics has conscientiously struggled to reach discipline-wide consensus regarding the interaction of a patient's occlusion with his or her periodontal status.[15] To be clinically applicable, the investigation's methodology must parallel the clinical diagnosis and treatment of an individual with periodontitis.[17]

Historically, data management and statistical credibility and

methodology within retrospective studies limited the ability of dedicated researchers to interpret the role of occlusion in an individual's periodontitis experience.[19,38,44] The grouping of data points, especially for large study populations, departs from the site specificity that periodontal diagnosis requires. If occlusal trauma is affecting a tooth, the effect on the periodontium is site specific for only that tooth. Treatment for a patient with periodontitis would never be based on an average of diagnostic references, but rather on his or her unique susceptibility, anatomy, occlusion, and history.

Learning Box 55.1

The role of occlusal trauma and its possible influence on the progression of periodontitis is tooth specific.

In 2001, Nunn and Harrell[34] reported the retrospective findings for a group of patients with periodontitis. The analysis was based on measurement of the loss of attachment of each tooth and the presence or absence of occlusal interferences. This study and a similar investigation[4] confirmed that trauma from occlusion amplified the loss of attachment. Harrell and Nunn[18] also reported that eliminating occlusal interferences had a positive influence on the outcome of treatment when trauma from occlusion was found to be a contributing local factor. The positive influence of occlusal adjustment on the outcome of surgical and nonsurgical periodontal therapies was also reported by Burgett.[6] Evidence supports the possibility that trauma from occlusion can amplify damage to an inflamed periodontium.

Learning Box 55.2

Occlusal trauma can amplify (not cause) localized loss of attachment from inflammatory bone damage.

Although animal studies do not carry the evidence-based hierarchic weight of ideally structured clinical trials, several newer studies seem to support the potential for excessive occlusal forces to

amplify damage from inflammatory periodontitis. In two studies using a periodontitis-induced rat model, occlusal trauma resulted in readily identifiable changes in the periodontal ligament of the experimental group compared with the controls. Greater numbers of osteoclasts, perhaps related to increased receptor activator of nuclear factor kappa-B ligand (RANKL) expression, supported the observation of greater alveolar bone loss in the inflammation plus trauma group. That group also demonstrated increased numbers of immune complexes, which may be a product of the damaged periodontal ligament collagen fibers' greater permeability.[31,49] An in vitro study of human periodontal ligament fibroblasts from healthy individuals and chronic periodontitis patients also supported the observation of significant differences in healthy and diseased periodontal ligament fibroblasts when subjected to compression. Several matrix metalloproteins, interleukin-l6 and -21, and other inflammation-associated proteins were expressed by the diseased, compressed fibroblasts compared with healthy fibroblasts, suggesting the diseased fibroblasts could produce additional damage to the periodontium of patients with chronic periodontitis.[12]

Interest in occlusion in the discipline of periodontics appears to be increasing, especially with the rapid growth of the replacement of missing teeth with implants. Despite some conflicting reports in the literature, common ground for consensus exists, as shown in Fig. 55.1.

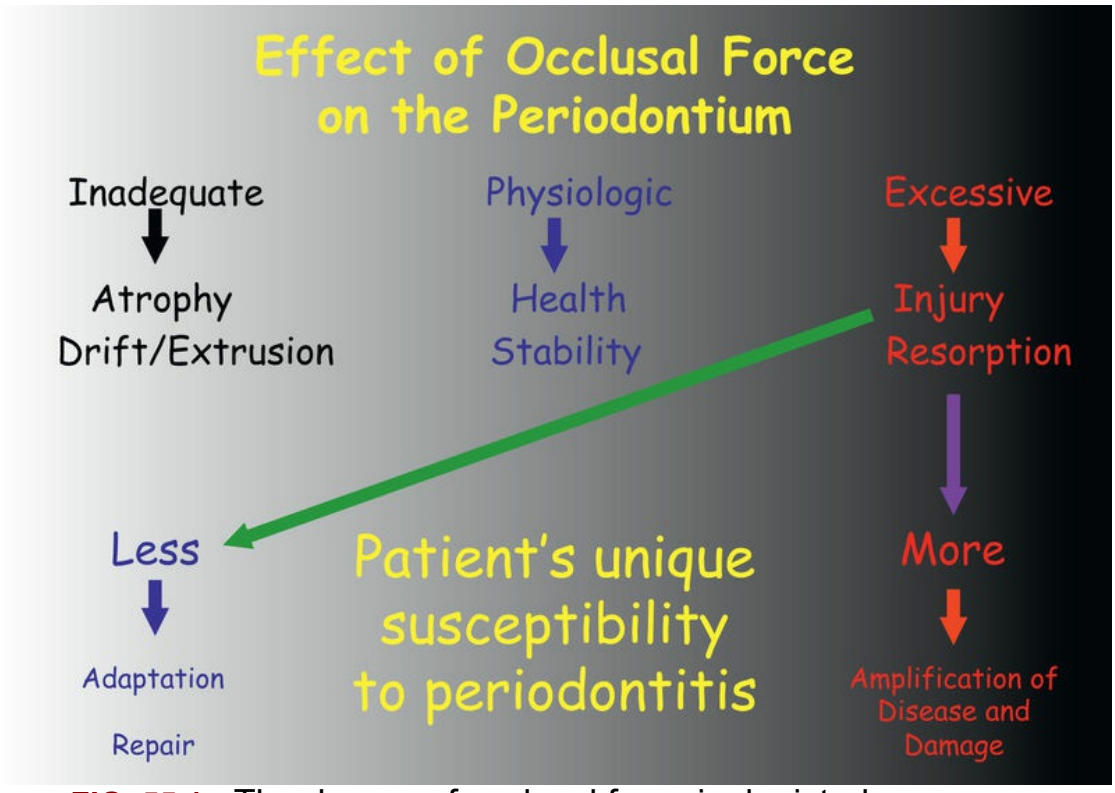

FIG. 55.1 The degree of occlusal force is depicted as a spectrum of white to black, representing none to excessive force.

Occlusal force has an effect on the periodontium (see Chapters 24 and 25) and that susceptibility to periodontitis is unique to each patient. Occlusal forces occur across a broad spectrum. No or minimal occlusal contact on a tooth results in disuse atrophy of the periodontium, which can result in instability of that tooth. Harmonious occlusal force on a tooth stimulates the physiologic arrangement of the periodontal attachment fibers and osseous architecture and encourages stability. Forces that exceed the tolerance of the periodontium result in resorption of the bone and disruption of the attachment.[21,30,33] In the healthy person, the periodontium around teeth that are subject to excessive occlusal force experiences adaptation and repair or remodeling with no loss of attachment, which often occurs with orthodontics.

For the patient who is losing bone as a result of periodontitis, coupling the ongoing inflammatory disease with excessive occlusal force can amplify destruction and damage to the periodontium of affected teeth.[34] If this conclusion is valid, the clinician has the responsibility to correlate the periodontal status of each tooth with

its occlusal responsibilities and possible occlusal excesses.

Terminology

The following is a list of key descriptive terms, as used in this chapter, and their common synonyms:

Centric relation: Position of the mandible when both condyle–disc assemblies are in their most superior positions in their respective glenoid fossae and against the slope of the articular eminences of each respective temporal bone.

Disclusion: Separation of certain teeth caused by the guidance provided by other teeth during an excursion. When anterior guidance provides separation of posterior teeth during an excursion, posterior disclusion is achieved.

Excursive movement: Any movement of the mandible away from maximum intercuspation.

Guidance: The pattern of opposing tooth contact during excursive movements of the mandible.

Initial contact in centric relation: The first occlusal contact in the centric relation closure arc.

Interference: Any occlusal contact in the centric relation closure arc or in any excursion that prevents the remaining occlusal surfaces from achieving stable contact or functioning harmoniously or that encourages masticatory system disharmony; also called an *occlusal discrepancy.*

Lateral excursion: Movement of the mandible laterally to the right or to left from maximal intercuspation.

Maximal intercuspation: Position of the mandible when there is maximal interdigitation and occlusal contact between the maxillary and mandibular teeth; also called *centric occlusion* and *intercuspal position.*

Nonworking side: The side of either arch that corresponds with the side of the mandible moving toward the midline during a lateral excursion; also called the *balancing side.*

Protrusion: Movement of the mandible anteriorly from maximal intercuspation.

Retrusion: Movement of the mandible posteriorly relative to a

more anterior position.

Working side: The side of either dental arch that corresponds with the side of the mandible moving away from the midline during a lateral excursion.

Occlusal Function and Dysfunction

Excellent sources for a comprehensive understanding of dental anatomy and function include textbooks by Ash and Nelson,[3] McNeill,[28] and Dawson.[9,10] Trauma from occlusion is determined by whether the composite of all occlusal forces on a specific tooth exceeds the tolerance or adaptability of its periodontium. Identification of masticatory system disharmonies begins with an appreciation of physiologic norms; this allows the clinician to recognize dysfunctional relationships, which can influence the accuracy of the diagnosis.[10,33,35]

Centric relation is a term used to describe the position of both condyles when they are fully seated in the fossae of their respective temporomandibular joints (TMJs). Rotation of the mandible around an axis through both condyles is called the *centric relation closure arc* (see Chapter 26). This is strictly a skeletal relationship until tooth contact occurs. Maximal intercuspation occurs when opposing teeth make contact, with optimal interdigitation, at the most stable endpoint of mandibular closure. Stability is enhanced by the simultaneous bilateral contact of multiple posterior teeth with occlusal forces in the long axis of most posterior teeth. If the initial tooth contact in the centric relation arc of closure occurs simultaneously with maximal intercuspation, the teeth do not displace the condyles. Conversely, if the teeth are firm and any contact occurs before maximal intercuspation, incline relationships of opposing occlusal surfaces guide the mandible into intercuspal position, thereby requiring one or both condyles to become dislocated from their fossa.[10,34] If the teeth are mobile and contact first in the centric relation closure arc, then *they may move away from opposing teeth rather than cause condylar displacement.*

Cusp–fossa or cusp–marginal ridge relationships of the posterior teeth provide resistance to vertical loading and functional stability for the patient's dentition. When occlusal forces load teeth in their

long axis, the periodontium is the most resistant and supportive.[9,10] The anterior teeth can be stable with little occlusal loading in centric occlusion if they are favorably influenced by the oral musculature. If the anterior teeth are in contact in maximal intercuspation, they are coupled.

Movement of the mandible from centric occlusion is called an *excursion.* Movement forward is called a *protrusive excursion,* and movement to either side is called a *lateral excursion.* If the mandible can move posteriorly, it is called *retrusion.* There is evidence that the contact of posterior teeth in excursions can overload those teeth, which results in negative dental, periodontal, muscular, and TMJ consequences.[1,7,10,35,50–52] The ideal relationship may be a light coupling of the anterior teeth in centric occlusion with immediate separation (i.e., disclusion) of all posterior teeth in all excursions.[51]

During a lateral excursion, posterior teeth that make contact on the same side as the direction of mandibular movement are described as having a working contact. Posterior teeth that make contact on the side opposite the direction of the lateral excursion are described as having a nonworking contact. Although nonworking contacts are classically associated with negative consequences,[52] the analysis of working contacts and the function of anterior teeth are critically important. Contacts that are disruptive to mandibular movement or stressful to individual teeth are called *occlusal interferences* or *discrepancies.* Dentists' ability to analyze the occlusion to identify contacts that can amplify a patient's periodontitis, thereby affecting certain teeth, is strategic to making the correct diagnosis.

Inflammation disrupts the integrity of the attachment apparatus, which results in less resistance to force from opposing teeth. When bone loss has occurred, less root surface area is supported,[2,20] and there are fewer sensory fibers in the periodontal ligament, which limits the protective muscle modulation of the occlusal forces.[41] The clinician must differentiate among inflammation-caused intolerance to occlusal forces, normal forces on teeth with reduced periodontal support, excessive occlusal forces, and well-tolerated forces on teeth affected by periodontitis.

Parafunction

Bruxism can cause occlusal forces on teeth that are susceptible to periodontitis to be increased in intensity or frequency, thereby magnifying the potential amplification of damage.[8,23,24,47] Daytime or awake occlusal parafunction is commonly limited to clenching the teeth during incidents that require a person's focused effort or mental concentration. Patients can be engaged in identification of daytime teeth clenching, as was the case in a study of sleep bruxism and myofascial pain. Awake clenching was reported by 58 of the 60 participants.[42] Selection criteria for a study must be very exacting because self-reports of sleep bruxism by patients is usually unreliable.[40] Patients' identification of their parafunction can help them to understand its importance, and it supports the clinical experience that daytime clenching can be a frequent contributor to a patient's increased susceptibility to bone loss in sites of inflammatory periodontitis.

Nighttime or sleep bruxing of the teeth can take the form of grinding the teeth during various excursions or clenching the teeth. Sleep bruxism is probably an extension of the rhythmic masticatory muscle activity that is also observed in nonbruxers. Why nuclei in the brain stem allow bruxing to occur in some individuals while others are spared is unclear.[8,23,24]

Bruxing is associated with the greater frequency and persistence of TMJ dysfunction, orofacial pain, and possibly periodontal attachment loss.[47] The sensory input of teeth that are subject to bruxism is probably dampened, which may interfere with the diagnosis and treatment.[37] There seems to be limited influence on bruxing tendencies from occlusal interferences.[25] An exception was discovered in a clinical study of 30 bruxers and 30 nonbruxers; there was a significant difference in nonworking interferences in the bruxing population compared with their absence in the nonbruxing group.[43] When these findings are viewed along with those reported by Youdelis and Mann decades ago, the correlation of bruxing and site-specific inflammatory bone damage appears meaningful.[52]

Gerber and Lynd studied selective serotonin reuptake inhibitor–induced movement disorders.[14] They found that selective serotonin reuptake inhibitors such as Prozac encouraged bruxism.

Evidence is emerging that sleep-disordered breathing can influence or be associated with inflammatory diseases such as periodontitis.[5,11,16] Although a causal relationship between obstructive sleep apnea and sleep bruxism has not been firmly established, the reported data and observations support a definite association.[36,45,46] A patient with periodontitis with clinical evidence of occlusal trauma may be experiencing the consequences of sleep-disordered breathing. Chapter 40 provides an overview of sleep-disordered breathing, offering a reference for the dentist who is seeking to develop skill in the recognition of oral signs of sleep-disordered breathing to complement his or her diagnostic skills in evaluation of a patient's occlusion. If an occlusal appliance is being considered to address the periodontal implications of excessive occlusal force experienced by a periodontitis-susceptible patient, compliance may be problematic for a person with sleep-disordered breathing because the appliance can contribute to airway obstruction.[13]

Clinical Examination

Before clinical evaluation, a conversation with the patient can help to provide a more complete diagnosis. With minimal symptoms, a patient may not associate loose teeth or significant dental wear with TMJ dysfunction or orofacial pain with occlusal function or parafunction. The list of questions in Chapter 26 and inquiries specific to the condition of the patient's teeth can help the clinician to open the lines of communication and set the tone for patient education during the clinical examination. Comprehensive evaluation of occlusal anatomy and relationships is accomplished by the analysis of many factors in the clinical setting and by mounted diagnostic casts.

Clinical evaluation of the occlusion is sequenced to support the patient's learning. It should always include a clinical assessment of masticatory system function and identification of disharmonies.

Temporomandibular Disorders Screening and Evaluation

Complete assessment of the masticatory system and identification of temporomandibular disorders are described in Chapter 26 and should be part of a patient's initial comprehensive examination. The temporomandibular disorder screening and clinical evaluation then become part of subsequent examinations.

The patient's range of motion is observed, maximal opening and the lateral and protrusive excursions are measured, and any deviation from the midline during opening and closing is defined. Light finger pressure applied over each TMJ can detect deflection of the tissue while the patient opens and closes the mouth; deflection suggests condyle–disc discoordination. Tenderness on palpation can indicate TMJ capsulitis. Listening to the joint with a stethoscope or a Doppler instrument during opening and closing can detect sounds that are consistent with uncoordinated condyle–disc relationships, arthritic changes, and other diagnostic sounds.[10]

Palpation of the muscles of mastication and the related head and neck musculature can reveal muscle tension or spasm related to compensation for occlusal or TMJ disharmonies.[10,35] Load testing of the TMJ is described in Chapter 26. Significant discoveries revealed during the screening examination summarized in Box 55.1 should lead the clinician to complete the comprehensive evaluation.

Box 55.1

Temporomandibular Disorder Screening Evaluation

1. Maximal interincisal opening (range, 40 to 50 mm)
2. Opening or closing pathway
3. Range of lateral and protrusive excursions (7 to 9 mm)
4. Auscultation for temporomandibular joint sounds
5. Palpation for temporomandibular joint tenderness or tissue displacement
6. Palpation for muscle tenderness
7. Load testing of the patient's temporomandibular joints

Testing for the Mobility of Teeth

Two basic methods are used to assess the firmness or looseness of a tooth. Classically, a dental instrument is used to exert pressure in the facial or lingual direction, and the dentist places his or her finger on the opposite side of the tooth to feel and see movement if it occurs (see Chapter 32). Recording a numeric value (range, 0 to 3) for the degree of mobility allows the clinician to track changes that may occur in response to therapy.

The other method is to test for the movement of teeth that are subject to pressure generated by the patient. Fremitus, vibration, or micromovement of a tooth can be felt when patients tap their teeth together. When the patient mimics clenching the teeth and then attempts to move the mandible in excursions, tooth movement can be observed. The patient placing a finger where the clinician felt tooth movement helps the patient to appreciate the looseness of his or her teeth (Fig. 55.2).

FIG. 55.2 (A) Tactile and visual testing for mobility is done with a dental instrument by the dentist. (B) Tactile and visual testing for mobility is done with the patient clenching and while beginning right lateral excursion by the dentist. (C) The patient feels movement of her tooth when lateral excursion is attempted while the teeth are clenched.

If the mobility of the teeth exceeds what is expected on the basis of the loss of support or the level of inflammation observed, trauma from occlusion is included in the diagnosis. The assimilation of all of the occlusal and periodontal diagnostic references can lead the clinician to conclude that even without mobility, there may be evidence of amplified periodontal damage as a result of unfavorable occlusal forces.

Learning Box 55.3

An inflamed periodontium often contributes to the mobility of a tooth.

Centric Relation Assessment

Bimanual manipulation of the mandible in the axis of rotation of the condyles in their respective glenoid fossae has become a standard method of assessing centric relation.[3,9,10,35] This method is illustrated in Fig. 55.3, and it involves gentle guidance rather than the forced positioning of the mandible. This technique is essential for load testing of the TMJs, and it is effective for generating centric relation records for mounting diagnostic casts. Telling the patient that he or she will feel modest lifting pressure on the inferior borders of the mandible and a light depressing force in the mental region often allows for relatively free and comfortable hinging of the mandible.[9,10] If hinging is uncomfortable or not repeatable, muscle deprogramming (see Chapter 26) may be beneficial. Other methods for guiding the condyles toward a seated position (e.g., leaf gauges, anterior bite stops) can be effective.[10]

FIG. 55.3 Bimanual manipulation is used to hinge the mandible in centric relation and to load test the temporomandibular joints.

Asking the patient to identify the first tooth to touch in the centric relation arc of closure may indicate that interferences to closure into

maximal intercuspation exist. Asking the patient to close further may demonstrate a slide from centric relation to centric occlusion because teeth are firm enough to dislocate one or both condyles.[35] Drying the occlusal surfaces, positioning marking paper, and then guiding the patient to the initial contact in centric relation allows marking of occlusal contact points, thereby identifying any interference. Asking the patient to then close into maximal intercuspation marks the points or surfaces that contact during the slide. An early occlusal contact in centric relation before closure to centric occlusion is obtained that does not cause a slide may indicate the early contact that occurs on teeth that are mobile enough to move, allowing maximal intercuspation to be gained without condylar accommodation (Fig. 55.4). Confirmation of permissive intercuspation is a product of marking the teeth clinically and comparing the marks with the ones on mounted diagnostic casts, which demonstrates that mobile teeth can move out of the way to allow others to contact.

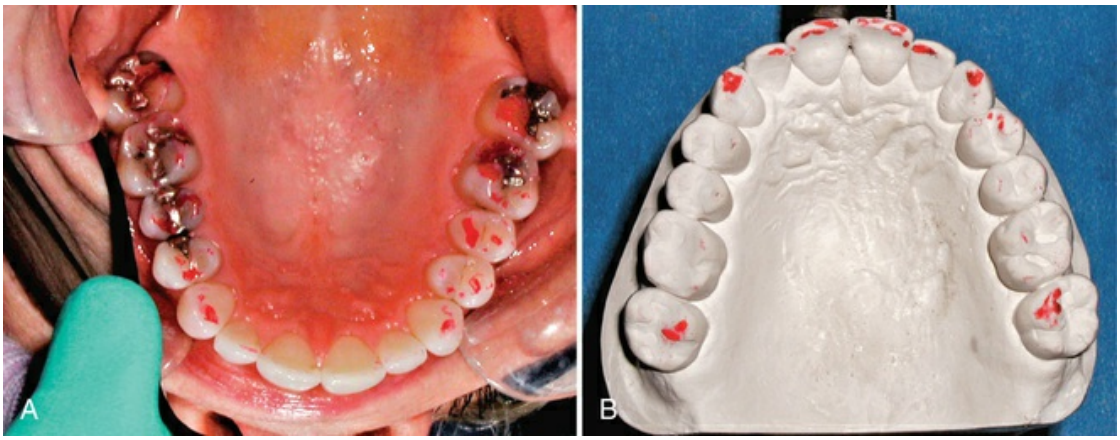

FIG. 55.4 (A) Teeth are marked clinically in maximal intercuspation and in excursions while clenching. (B) Teeth are marked in centric relation and maximal intercuspation on a diagnostic cast mounted in centric relation. Marks only on the second molars indicate that they were mobile and that they moved to permit the contact of other teeth.

Evaluation of Excursions

Marking the teeth in all excursions reveals the pathways of contact of opposing occlusal or incisal surfaces during function, and it may identify interferences to harmonious function.[3,10,28] Movement of any teeth during marking may lessen the intensity of the marks and the assessed severity of the forces experienced by the affected teeth.

Vectors of force and steepness of the opposing inclines are studied to determine whether the force is excessive. Interpreting contacts on a tooth-by-tooth basis can suggest or deny occlusal trauma as a contributing factor to the loss of attachment of each affected tooth. When patients are engaged in the evaluation of their occlusion, they can be given suggestions to observe certain habits, such as clenching their teeth during the day or sleeping with pressure on their mandible. As they contribute to their own diagnosis, patients become better prepared to make informed choices about treatment options.

Articulated Diagnostic Casts

When the maxillary diagnostic cast is mounted on an articulator with a facebow transfer technique, the occlusal surfaces become oriented to the axis of rotation of the patient's condyles. The centric relation transfer record orients the mandibular teeth to the maxillary teeth in centric relation.[9,10] Study of the accurately mounted diagnostic casts can reveal occlusal discrepancies between initial contact in the centric relation closure arc and maximal intercuspation and occlusal disharmonies in excursions. Mobile teeth may produce a mark on a solid model but little or no mark in that patient's mouth during clinical assessment. Accuracy of the observations made on the models should be confirmed clinically to whatever degree possible.

Occlusal Therapy

Effective nonsurgical therapy usually reduces inflammation within the periodontium and results in some healing of attachment,[32] which often results in mobile teeth becoming more stable. If the clinician concludes that inflammation has been optimally controlled and that occlusal forces on individual teeth still exceed the tolerance

of the periodontium, the basis for intervention is established.

The harmonious function of both TMJs and their associated muscles is required for occlusal stability. When there is sufficient evidence of excessive occlusal forces on the patient's teeth or when masticatory system disharmony exists and the patient desires a more stable occlusion, an occlusal appliance is prescribed.

Chapter 26 reviews TMJ anatomy, This can provide a better understanding of the therapy.

Learning Box 55.4

Optimal resolution of inflammation is necessary to accurately interpret tooth mobility.

Occlusal Appliance Therapy

A well-designed and accurately fitted appliance can benefit masticatory system function while encouraging loose teeth in both arches to tighten as the supporting periodontium heals. The bilateral simultaneous contact of all opposing posterior teeth in centric relation, shallow anterior guidance, and the immediate disclusion of all posterior teeth in every excursion are essential elements of maxillary and mandibular occlusal appliances (Figs. 55.5 and 55.6).

FIG. 55.5 (A) An occlusal appliance is fabricated on accurately mounted diagnostic casts. (B) The entire dental and palatal surface has been carefully relined to promote an optimal stabilizing influence on mobile teeth. (C) There is bilateral, simultaneous contact of the cuspids and all posterior teeth in centric relation, fabricated to enhance axial loading of opposing mandibular teeth. (D) There is smooth, relatively flat anterior guidance with immediate and sustained disclusion of all posterior teeth in protrusion. (E) There is smooth, relatively flat anterior guidance with immediate and sustained disclusion of all posterior teeth in right lateral excursions. (F) There is extreme left lateral excursion with smooth, harmonious transitions across the anterior teeth to maintain the disclusion of all posterior teeth. (G) Marks created by the opposing dentition demonstrate bilateral, simultaneous contact in centric relation and the immediate disclusion of the opposing posterior teeth in

all excursions.

FIG. 55.6 A mandibular occlusal appliance is fabricated after surgery to provide a stabilizing influence for the incisors in particular and to demonstrate occlusal attributes similar to those of the maxillary appliance.

Teeth that are opposing an appliance should be loaded as close as possible to their long axis. Maxillary appliances engage a portion of the hard palate, which provides substantial bracing of teeth and resistance to vertical and lateral forces. A horseshoe-shaped maxillary appliance relies on other, possibly compromised teeth to attempt to protect the most mobile teeth. Soft or partial coverage appliances are contraindicated for long-term protection and stabilization.[32] The protective role of occlusal appliances was addressed in the 8-year study by McGuire.[27] Occlusal appliances are not expected to cure bruxism,[26] but they are often prescribed for patients with habitual parafunction as a compensating or protective intervention to limit masticatory system disharmony, damage to the teeth, and overstressing of implants.[22]

Occlusal Adjustment

As teeth tighten from consistent use of the appliance, occlusal interferences may become more evident, and greater discrepancy between the initial dental contact and maximal intercuspation may be observed. Interferences with harmonious excursive movement of the mandible may also become more obvious. When the clinician confirms that the interferences correlate with a greater than expected loss of attachment, direct intervention in the patient's occlusion is considered. With the patient's full understanding and consent, occlusal adjustment or selective reshaping of the occluding surfaces of the teeth can reduce the magnitude of occlusal interferences or direct the forces to be more compatible with the long axes of the affected teeth.

Clinical analysis of the occlusion should be combined with a detailed analysis of diagnostic casts mounted in centric relation on an adjustable articulator. Accurately mounted duplicate models can be used to accomplish a trial occlusal adjustment to determine safety and efficacy for a patient.[10,28] Scheduling patients so that they leave their appliances on overnight and in place until they are seated in the dental chair allows assessment of their teeth at maximal firmness, when interferences are most readily identifiable. Teeth usually progressively tighten with continued compliance with the appliance and repeated careful occlusal adjustment.

Other methods that can be employed to alter occlusal relationships include orthodontics and restorative dentistry. Provisional restoration of teeth is another method of improving occlusal contacts and stability, and it often simplifies the process of occlusal adjustment and final restoration.

Occlusal Stability for Restorative Dentistry

A stable occlusion is considered a prerequisite for any restorative therapy (Box 55.2). Implants to replace the teeth of a partially dentate patient add to the occlusal considerations. Osseointegration of implants eliminates micromovement, which can allow teeth to accommodate occlusal forces. The extent and timing of occlusal loading and the guidance requirement for each tooth and for each implant must be carefully harmonized (see Chapter 74). This is

especially critical if any of the teeth are mobile or the patient bruxes to a significant degree.[48] If bruxism is suspected or the functional forces are considered to be excessive, the occlusal appliance as described may be a valuable application.[22,29]

Box 55.2

Requirements for Occlusal Stability

1. Forces on an individual tooth that do not exceed the support and resistance of the tooth's periodontium and that are vertically oriented to the long axis of each tooth as much as possible
2. Even and simultaneous contact of all posterior teeth in the centric relation closure or in maximal intercuspation, with minimal difference between the two
3. Little or no contact of the anterior teeth in centric occlusion, although such contact is readily available to provide guidance in excursion and to produce posterior disclusion
4. Harmonious excursive movement of the mandible within the patient's envelope of function and with complete absence of occlusal interference

Conclusions

Confirmation of the appropriateness of occlusal therapy is the product of a thorough evaluation of the patient's occlusion and his or her masticatory system. The sequence of occlusal treatment begins with antiinflammatory therapy and progresses through reversible appliance therapy before any irreversible options are considered. This provides the clinician with the most careful approach to assessing and treating the occlusion of a patient with periodontitis.

Case Scenario 55.1

Patient:
42-year-old female

Chief Complaint:
“My gums bleed and are tender whenever I try to floss my back teeth”

Background Information:
The patient had moderate, generalized periodontitis, which was primarily limited to the posterior teeth in all four quadrants.

Current Findings:
Mobility of individual teeth is observed and charted. With a comprehensive diagnosis, nonsurgical therapies are prescribed. After intervention and the patient's collaborative home therapies produced clear evidence of an ideal response, there appeared to be no persistent inflammation, but mobility of several teeth remained measurable. The premolar shown in the radiograph had class 1 mobility, although the 6-mm pocket on its mesial aspect measured only 4 mm after initial therapy.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What does the	**Answer: B**

radiographic image suggest to the dentist about the premolar? A. It is somewhat mobile. B. It is very stable. C. It is very mobile.	**Explanation:** The size and shape of the root and minimal loss of support strongly suggest the premolar should be very stable because of the success of antiinflammatory therapies.
2. What criteria suggested in the radiograph can the dentist use to determine expected stability or mobility? A. Dimension and shape of the root form of the premolar B. Evidence of significant previous bone damage and loss of support C. Evidence of other contributing pathology	**Answer: A** **Explanation:** Because there is no evidence of other pathology, and bone loss on the mesial aspect of the root of the premolar is minimal, assessment of the root form (i.e., not tapered) and size (i.e., significant root surface for attachment) should lead the dentist to conclude that another factor, occlusal trauma, is the likely source of persistent mobility.

Orthodontics

Interdisciplinary Periodontal and Implant Therapy

CHAPTER 56A

Adjunctive Role of Orthodontic Therapy

Vincent G. Kokich [†]

Abstract

Orthodontic tooth movement may be of substantial benefit to the adult periorestorative patient. Many adults who seek routine restorative dentistry have problems with tooth malposition, which compromises their ability to clean and maintain their dentition. If these individuals also are susceptible to periodontal disease, tooth malposition may be an exacerbating factor that could cause premature loss of specific teeth.

Orthodontic Treatment of Osseous Defects *(e-only)*
Orthodontic Treatment of Gingival Discrepancies *(e-only)*
Conclusion

Orthodontic tooth movement may be of substantial benefit to the adult periorestorative patient. Many adults who seek routine restorative dentistry have problems with tooth malposition, which compromises their ability to clean and maintain their dentition. If these individuals also are susceptible to periodontal disease, tooth malposition may be an exacerbating factor that could cause premature loss of specific teeth.

Orthodontic appliances have become smaller, less noticeable, and easier to maintain during orthodontic therapy. Many adults are taking advantage of the opportunity to have their teeth aligned to improve the aesthetics of their smile. Underlying gingival or osseous periodontal defects often can be improved during orthodontic therapy if the orthodontist is aware of the situation and designs the appropriate tooth movement. In addition, implants have become a major part of the treatment plan for many adults with missing teeth. If adjacent teeth have drifted into edentulous spaces, orthodontic therapy is often helpful to provide the ideal amount of space for implants and subsequent restorations. This

chapter shows the ways in which adjunctive orthodontic therapy can enhance the periodontal health and restorability of teeth and presents the role of implant dentistry in both periodontics and orthodontics.

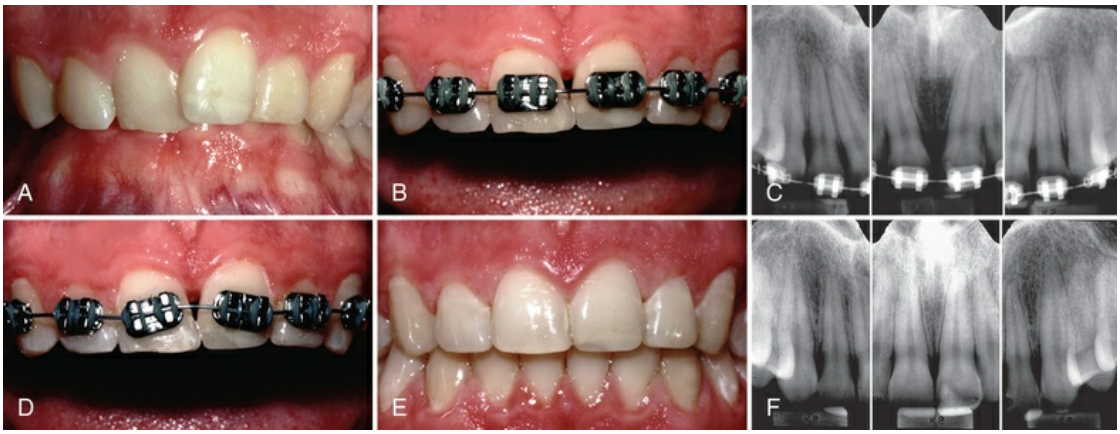
Benefits of Orthodontic Therapy

Orthodontic therapy can provide several benefits to adult periodontal patients. The following seven factors should be considered:

1. Aligning crowded or malpositioned maxillary or mandibular anterior teeth permits adult patients better access to clean all surfaces of their teeth. This could be a tremendous advantage for patients who are susceptible to periodontal disease or do not have the dexterity to maintain oral hygiene.
2. Vertical orthodontic tooth repositioning can improve certain types of osseous defects in periodontal patients. Often, moving the tooth eliminates the need for resective osseous surgery.
3. Orthodontic treatment can improve the aesthetic relationship of the maxillary gingival margins before restorative dentistry. Aligning the gingival margins orthodontically avoids gingival recontouring, which could also entail bone removal and exposure of the roots of the teeth (eFig. 56A.1).
4. Orthodontic therapy also benefits the patient with a severe fracture of a maxillary anterior tooth that requires forced eruption to permit adequate restoration of the root. Erupting the root allows the crown preparation to have sufficient resistance form and retention for the final restoration.
5. Orthodontic treatment allows open gingival embrasures to be corrected to regain lost papillae. If open gingival embrasures are located in the maxillary anterior region, this can present an aesthetic problem. In most patients, these areas can be corrected with a combination of orthodontic

root movement, tooth reshaping, and restoration.

6. Orthodontic treatment could improve adjacent tooth positioning before implant placement or tooth replacement. This is especially true for the patient who has been missing teeth for several years and has drifting and tipping of the adjacent dentition.
7. A common tooth malalignment problem that results in periodontal pockets is the mesially tipped molar. Orthodontic uprighting of tipped molars corrects the deep gingival contours and eliminates or reduces the mesial periodontal pocket (eFig. 56A.2).



EFIG. 56A.1 This patient initially had overlapped maxillary central incisors (A), and after initial orthodontic alignment of the teeth, an open gingival embrasure appeared between the centrals (B). Radiography showed that the open embrasure was caused by divergence of the central incisor roots (C). To correct the problem, the central incisor brackets were repositioned (D), and the roots were moved together. This required restoration of the incisal edges after orthodontic therapy (E) because these teeth had worn unevenly before therapy. As the roots were paralleled (F), the tooth contact moved gingivally and the papilla moved incisally, resulting in elimination of the open gingival embrasure.

EFIG. 56A.2 Before orthodontic treatment, this patient had significant mesial tipping of the maxillary right first and second molars, causing marginal ridge discrepancies and deep periodontal pockets (A). The tipping produced root proximity between the molars as well as a disruption of the normal gingival anatomy (B). To eliminate the root proximity, the brackets were placed perpendicular to the long axes of the teeth (C). This method of bracket placement facilitated root alignment and elimination of the root proximity, as well as leveling of the marginal ridge discrepancies (D through F).

Learning Box 56A.1

Orthodontic therapy can contribute in many ways to help patients

with periodontal problems. In selected cases, vertical orthodontic tooth repositioning can improve certain types of osseous defects to eliminate the need for resective periodontal surgery. Many patients have crowded, malaligned, and malpositioned maxillary or mandibular anterior teeth, presenting a difficult biofilm control problem. Aligning the crowded teeth orthodontically will help patients maintain improved biofilm control. The incorporation of orthodontic therapy in the treatment of these clinical periodontal problems is a great aid to the clinician and the patient.

Preorthodontic Osseous Surgery

The extent of periodontal osseous surgery depends on the type of defect (e.g., crater, hemiseptal defect, three-wall defect, or furcation lesion). The prudent clinician understands which defects can be improved with orthodontic treatment and which will require preorthodontic periodontal surgical intervention.

Osseous Craters

An osseous crater is an interproximal, two-wall defect that does not improve with orthodontic treatment. Some shallow craters (4 to 5 mm pocket) may be maintained nonsurgically during orthodontic treatment. However, if surgical correction is necessary, this type of osseous lesion can easily be eliminated by reshaping the defect[12,15] and reducing the pocket depth (eFig. 56A.3; see Chapter 62). This in turn enhances the ability to maintain these interproximal areas during orthodontic treatment. The need for surgery is based on the patient's response to initial root planing, the patient's periodontal resistance, the location of the defect, and the predictability of maintaining defects nonsurgically while the patient is wearing orthodontic appliances.

EFIG. 56A.3 This patient had a 6-mm probing defect distal to the maxillary right first molar (A). When this area was flapped (B), a cratering defect was apparent. Osseous surgery was performed to alter the bony architecture of the buccal and lingual surfaces to eliminate the defect (C and D). After 6 weeks, the probing pocket defect had been reduced to 3 mm and orthodontic appliances were placed on the teeth (E). Because the crater was eliminated before orthodontic therapy, the patient could maintain the area during and after orthodontic treatment (F).

Three-Wall Intrabony Defects

Three-wall osseous defects are amenable to pocket reduction with regenerative periodontal therapy.[1] Bone grafts using either autogenous bone from the surgical site or allografts, along with

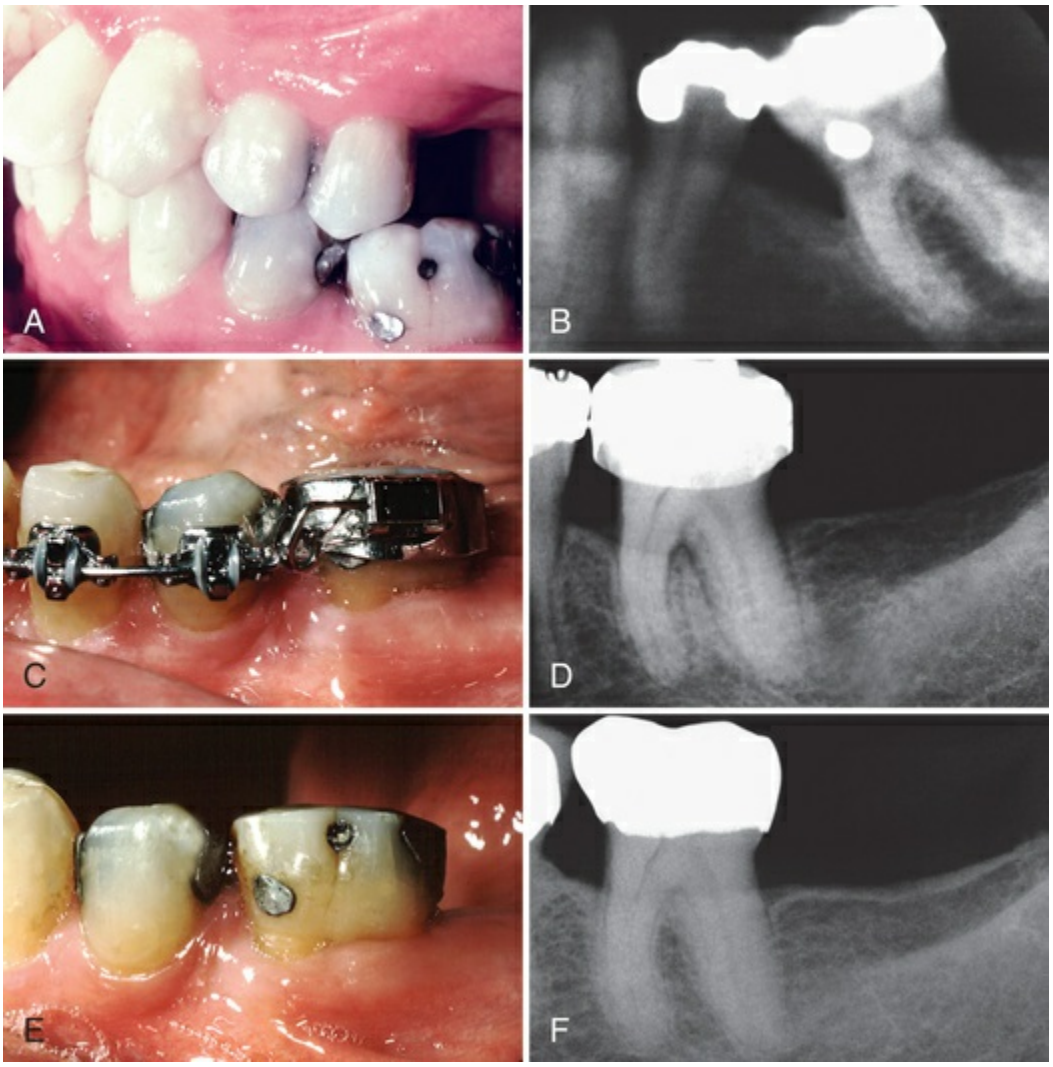
resorbable membranes, have been successful in regenerating three-wall defects.[14] If the result of periodontal therapy is stable 3 to 6 months after periodontal surgery (eFig. 56A.4), orthodontic treatment may be initiated.

EFIG. 56A.4 This patient had a significant periodontal pocket (A) distal to the mandibular right first molar. Periapical radiograph (B) confirmed the osseous defect. A flap was elevated (C), revealing a deep, three-wall osseous defect. Freeze-dried bone (D) was placed in the defect. Six months after the bone graft, orthodontic treatment was initiated (E). The final periapical radiograph shows that the preorthodontic bone graft helped regenerate bone and eliminate the defect distal to the molar (F).

Orthodontic Treatment of Osseous Defects

Hemiseptal Defects

Hemiseptal defects are one- or two-wall osseous defects that often are found around mesially tipped teeth (eFig. 56A.5) or teeth that have supererupted (eFig. 56A.6). Usually, these defects can be eliminated with the appropriate orthodontic treatment. In the case of the tipped tooth, uprighting[2,5] and eruption of the tooth levels the bony defect. If the tooth is supererupted, intrusion and leveling of the adjacent cementoenamel junctions (CEJs) can help level the osseous defect.



EFIG. 56A.5 This patient was missing the mandibular

left second premolar, and the first molar had tipped mesially (A). Pretreatment periapical radiograph (B) revealed a significant hemiseptal osseous defect on the mesial side of the molar. To eliminate the defect, the molar was erupted, and the occlusal surface was equilibrated (C). The eruption was stopped after the bone defect was leveled (D). The posttreatment intraoral photograph (E) and periapical radiograph (F) show that the periodontal health was improved by orthodontic correction of the hemiseptal defect.

EFIG. 56A.6 This patient showed overeruption of the maxillary right first molar and a marginal ridge defect between the second premolar and first molar (A). The pretreatment periapical radiograph (B) showed that the interproximal bone was flat. To avoid creating a

hemiseptal defect, the occlusal surface of the first molar was equilibrated (C and D), and the malocclusion was corrected orthodontically (E and F).

It is imperative that periodontal inflammation be controlled before orthodontic treatment. This usually can be achieved with patient education regarding biofilm control, initial debridement, and scaling and root planing. After the completion of orthodontic treatment, these teeth should be stabilized for at least 6 months and reassessed periodontally. Often, the pocket has been reduced or eliminated and no further periodontal treatment is needed. It would be injudicious to perform preorthodontic osseous corrective surgery on such lesions if orthodontics is part of the overall treatment plan.

Learning Box 56A.2

Excellent biofilm control before, during, and after orthodontic therapy is of utmost importance to prevent and control periodontal inflammation. This is especially important during orthodontic therapy because biofilm control is very difficult with the numerous appliances and brackets that are placed on the dentition.

In the periodontally healthy patient, orthodontic brackets are positioned on the posterior teeth relative to the marginal ridges and cusps. However, some adult patients may have marginal ridge discrepancies caused by uneven tooth eruption. When marginal ridge discrepancies are encountered, the decision as to where to place the bracket or band is not determined by the anatomy of the tooth. In these patients, it is important to assess these teeth radiographically to determine the interproximal bone level.

If the bone level is oriented in the same direction as the marginal ridge discrepancy, leveling of the marginal ridges will level the bone. However, if the bone level is flat between adjacent teeth (see eFig. 56A.6) and the marginal ridges are at significantly different levels, orthodontic correction of the marginal ridge discrepancy produces a hemiseptal defect in the bone. This could cause a periodontal pocket between the two teeth.

If the bone is flat and a marginal ridge discrepancy is present, the orthodontist should not level the marginal ridges orthodontically. In these situations, it may be necessary to equilibrate the crown of the tooth (see eFig. 56A.6). For some patients, the latter technique may require endodontic therapy and restoration of the tooth because of the required amount of reduction of the length of the crown. This approach is acceptable if the treatment results in a more favorable bone contour between the teeth.

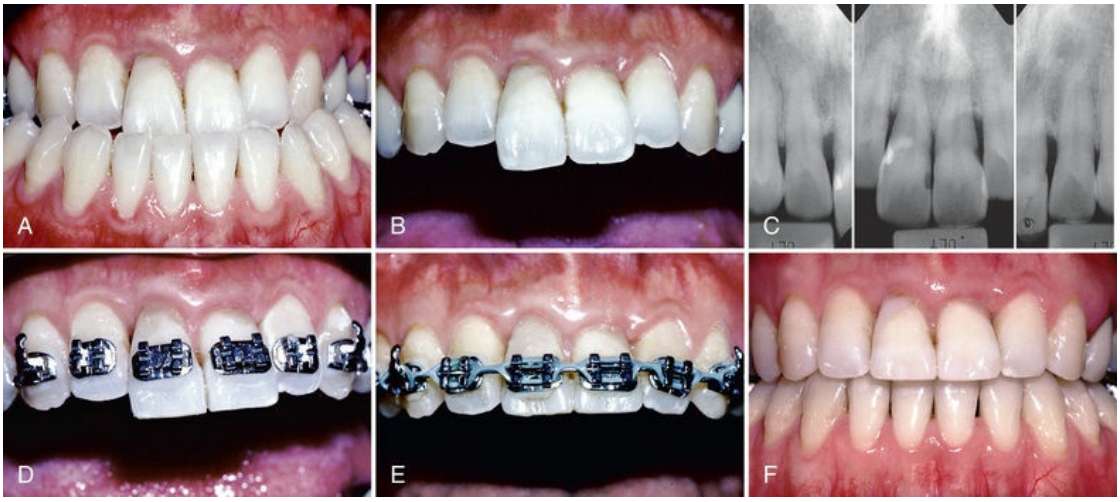
Some patients have discrepancies between both the marginal ridges and the bony levels between two teeth. However, these discrepancies may not be of equal magnitude; orthodontic leveling of the bone may still leave a discrepancy in the marginal ridges (see eFig. 56A.2). In these patients, the crowns of the teeth should not be used as a guide for completing orthodontic therapy. The bone should be leveled orthodontically, and any remaining discrepancy between the marginal ridges should be equilibrated. This method produces the best occlusal result and improves the patient's periodontal health.

During orthodontic treatment, when teeth are being extruded to level hemiseptal defects, the patient should be monitored regularly. Initially, the hemiseptal defect has a greater sulcular depth and is more difficult for the patient to clean. As the defect is ameliorated through tooth extrusion, interproximal cleaning becomes easier. The patient should be recalled every 2 to 3 months during the leveling process to control inflammation in the interproximal region.

Advanced Horizontal Bone Loss

After orthodontic treatment has been planned, one of the most important factors that determine the outcome of therapy is the location of the bands and brackets on the teeth. In a periodontally healthy individual, the position of the brackets is usually determined by the anatomy of the crowns of the teeth. Anterior brackets should be positioned relative to the incisal edges. Posterior bands or brackets are positioned relative to the marginal ridges. If the incisal edges and marginal ridges are at the correct level, the CEJ will be at the same level. This relationship creates a flat, bony

contour between the teeth. However, if a patient has underlying periodontal problems and significant alveolar bone loss around certain teeth, it is not appropriate to use the anatomy of the crown to determine bracket placement (eFig. 56A.7).



EFIG. 56A.7 Before orthodontic treatment, this patient had a significant class III malocclusion (A). The maxillary central incisors had overerupted (B) relative to the occlusal plane. Pretreatment periapical radiography (C) showed that significant horizontal bone loss had occurred. To avoid creating a vertical periodontal defect by intruding the central incisors, the brackets were placed to maintain bone height (D). The incisal edges of the centrals were equilibrated (E), and the orthodontic treatment was completed without intruding the incisors (F).

In a patient with advanced horizontal bone loss, the bone level may have receded several millimeters from the CEJ. As this occurs, the crown-to-root ratio becomes less favorable. By aligning the crowns of the teeth, the clinician may perpetuate tooth mobility by maintaining an unfavorable crown-to-root ratio. In addition, aligning the crowns of the teeth and disregarding the bone level leads to significant bone discrepancies between healthy and periodontally diseased roots. This could require periodontal surgery to ameliorate the discrepancies.

Many of these problems can be corrected by using the bone level as a guide to position the brackets on the teeth (see eFig. 56A.7). In

these situations, the crowns of the teeth may require considerable equilibration. If the tooth is vital, the equilibration should be performed gradually to allow the pulp to form secondary dentin and insulate the tooth during the equilibration process. The goal of equilibration and creative bracket placement is to provide a more favorable bony architecture and a more favorable crown-to-root ratio. In some of these patients, the periodontal defects that were apparent initially may not require periodontal surgery after orthodontic treatment.

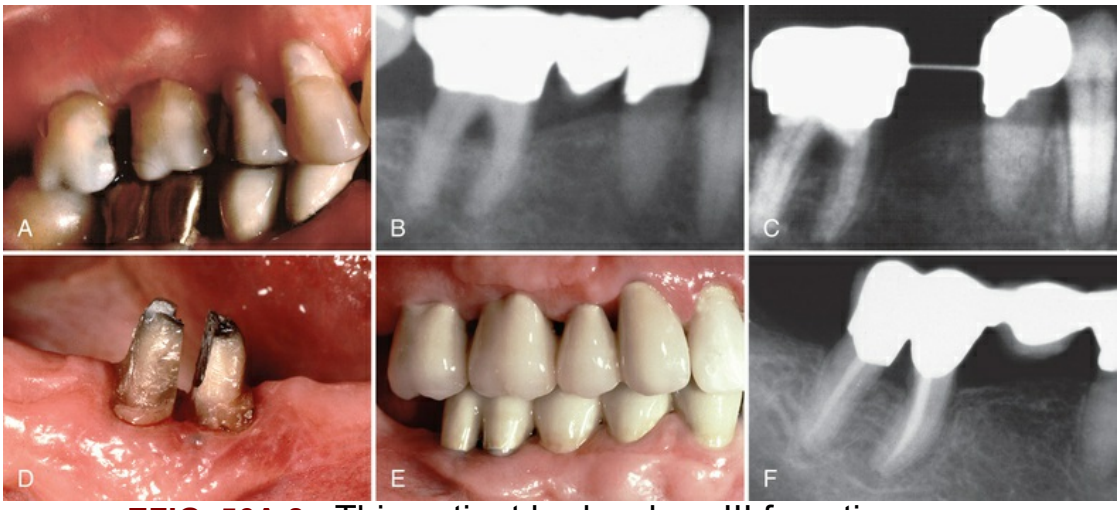
Furcation Defects

Furcation defects can be classified as *incipient* (class I), *moderate* (class II), or *advanced* (class III). Chapter 62 discusses furcation problems in detail.) These lesions require special attention in patients undergoing orthodontic treatment. Often, the molars require bands with tubes and other attachments that impede access to the buccal furcation for home care and instrumentation at the time of recall.

Furcation lesions require special consideration because they are the most difficult lesions to maintain and can worsen during orthodontic therapy. These patients should be maintained on a 2- to 3-month recall schedule. Detailed periodontal instrumentation and biofilm control of these furcation lesions will help to minimize further periodontal breakdown.

If a patient with a class III furcation defect will be undergoing orthodontic treatment, a possible method for treating the furcation is to eliminate it by hemisecting the crown and root of the tooth (eFig. 56A.8). However, this procedure requires endodontic, periodontal, and restorative treatment. If the patient will be undergoing orthodontic treatment, it is advisable to perform the orthodontic treatment first. This is especially true if the roots of the teeth will not be moved apart. In these patients, the molar to be hemisected remains intact during orthodontic therapy. These patients require recall visits every 2 or 3 months to ensure that the furcation defect does not lose bone during orthodontic treatment. Keeping the tooth intact during orthodontic therapy simplifies the concentration of tooth movement for the orthodontist. After

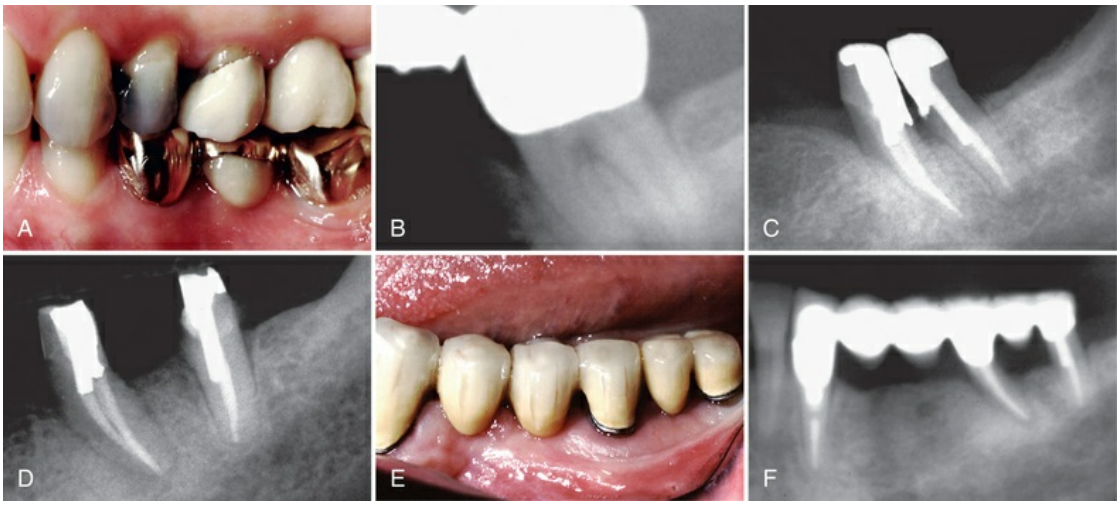
orthodontic treatment, endodontic therapy is required, followed by periodontal surgery to divide the tooth.



EFIG. 56A.8 This patient had a class III furcation defect before orthodontic treatment (A and B). Orthodontic treatment was performed (C), and the furcation defect was maintained by the periodontist with 2-month recalls until after orthodontic treatment. After appliance removal, the tooth was hemisected (D), and the roots were restored and splinted together (E). The final periapical radiograph (F) shows that the furcation defect was eliminated by hemisection and restoration of the two root fragments.

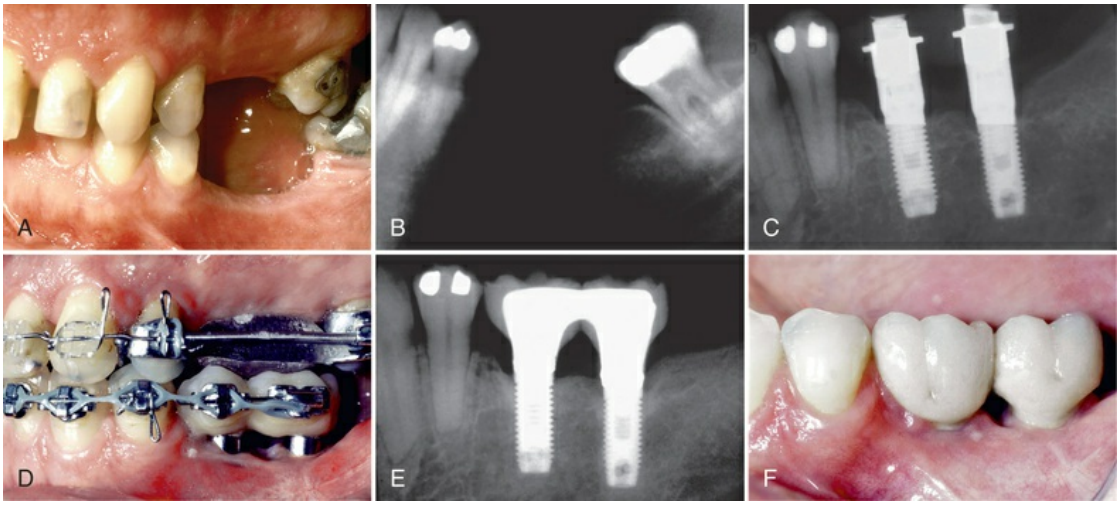
In some patients requiring hemisection of a mandibular molar with a class III furcation, moving the roots apart during orthodontic treatment may be advantageous (eFig. 56A.9). If the hemisected molar will be used as an abutment for a bridge after orthodontics, moving the roots apart orthodontically permits a favorable restoration and splinting across the adjacent edentulous spaces. In these patients, hemisection, endodontic therapy, and periodontal surgery must be completed before the start of orthodontic treatment. After completion of these procedures, bands or brackets can be placed on the root fragments, and coil springs can be used to separate the roots. The amount of separation is determined by the size of the adjacent edentulous space and the occlusion in the opposing arch. About 7 or 8 mm may be created between the roots of the hemisected molar. This process eliminates the original

furcation problem and allows the patient to clean the area with greater efficiency.



EFIG. 56A.9 Before orthodontic treatment, this patient had a class III furcation defect in the mandibular left second molar (A and B). Because the patient had an edentulous space mesial to the molar, the tooth was hemisected (C), and the root fragments were separated orthodontically (D). After orthodontic treatment, the root fragments were used as abutments to stabilize a multiunit posterior bridge (E and F).

In some molars with class III furcation defects, the tooth may have short roots, advanced bone loss, fused roots, or other problems that prevent hemisection and crowning of the remaining roots. In these patients, extracting the root with a furcation defect and placing an implant may be more advisable[11] (eFig. 56A.10). If this type of plan has been adopted, extraction and placement of the implant can occur at any time relative to the orthodontic treatment. In some patients, the implant can be used as an anchor to facilitate prerestorative orthodontic treatment.



EFIG. 56A.10 This patient was missing several teeth in the mandibular left posterior quadrant (A). The mandibular left third molar had a class III furcation defect and short roots (B). The third molar was extracted, and two implants were placed in the mandibular left posterior quadrant (C). The implants were used as anchors to facilitate orthodontic treatment (D) and help reestablish the left posterior occlusion (E and F).

Learning Box 56A.3

Furcation problems, especially class III and IV lesions, are challenging to treat and maintain because of the difficulty in attaining access for biofilm control and for scaling and root planing. Hemisection of a furcated molar after endodontic therapy followed by orthodontic separation of the remaining roots is expensive and time-consuming and may still have a questionable outcome. With the advent of predictable implant therapy, extraction of such a tooth should be considered.

The implant must remain embedded in bone for 4 to 6 months after placement before it can be loaded as an orthodontic anchor. It must be placed precisely so that it not only provides an anchor for tooth movement but also may be used as an eventual abutment for a crown or fixed bridge. If the implant will not be used as an anchor for orthodontic movement, it may be placed after the orthodontic

treatment has been completed. Considerations regarding timing are determined by the restorative treatment plan (see later discussion).

Root Proximity

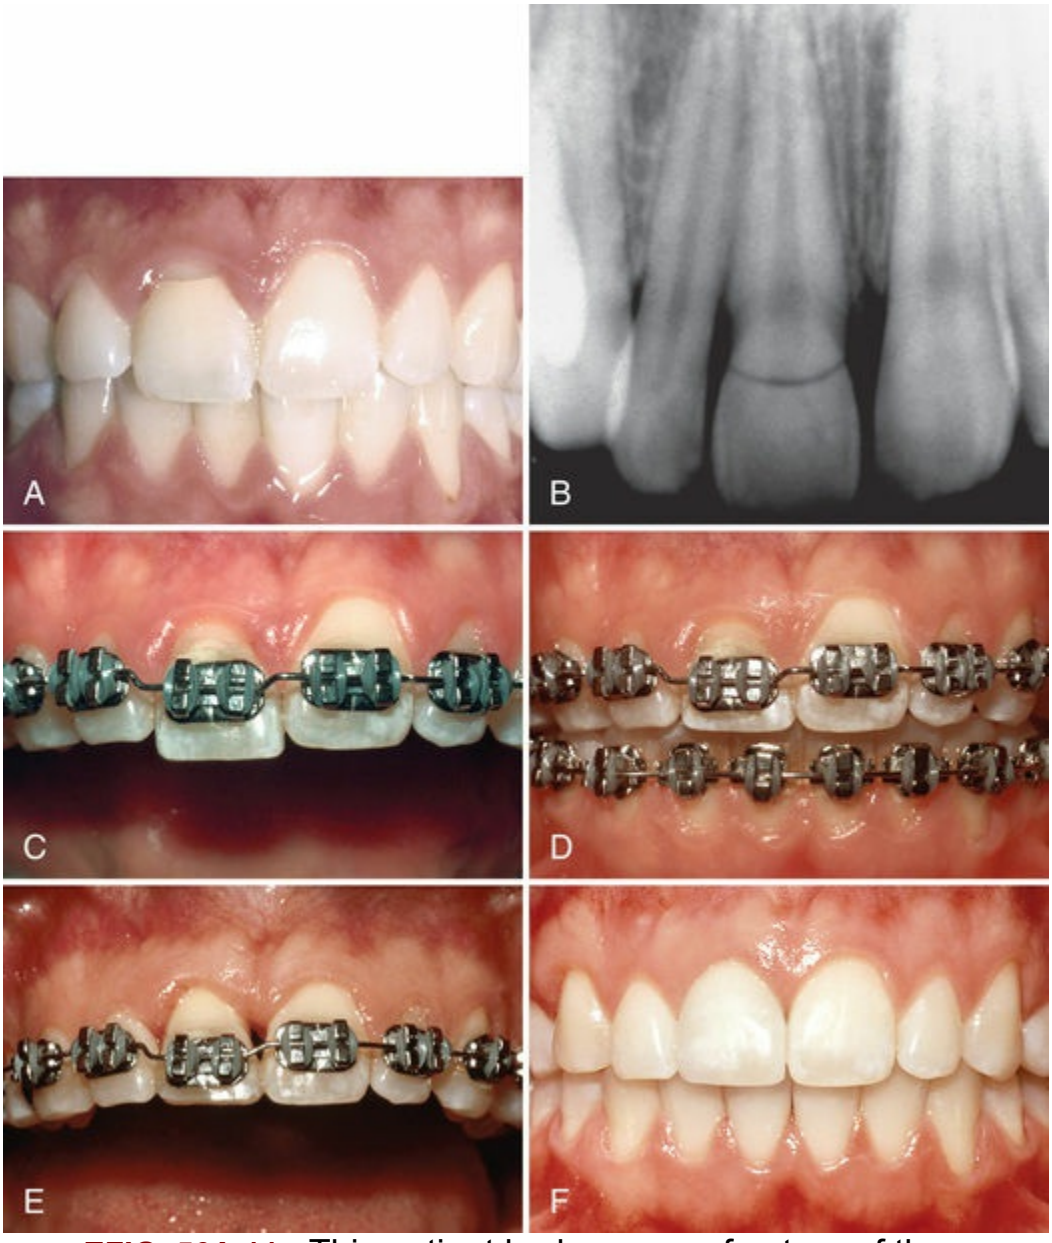
When roots of posterior teeth are close together, the ability to maintain periodontal health and accessibility for restoration of adjacent teeth may be compromised.[4] However, for the patient undergoing orthodontic therapy, the roots can be separated and bone will form between adjacent roots (see eFig. 56A.2). This opens the embrasure beneath the tooth contact, provides additional bone support, and enhances the patient's access to the interproximal region for hygiene. This approach generally improves the periodontal health of this area.

If orthodontic treatment will be used to separate the roots, this plan must be understood before bracket placement. It is advantageous to place the brackets so that the orthodontic movement to separate the roots will begin with the initial archwires (see eFig. 56A.2). Brackets must be placed obliquely to facilitate this process. Radiographs are needed to monitor the progress of orthodontic root separation. In general, 2 to 3 mm of root separation provides adequate bone and embrasure space to improve periodontal health. During this time, patients should be maintained on recall to ensure that a favorable bone response occurs as the roots are moved apart. In addition, these patients need occasional occlusal adjustment to recontour the crown because the roots are moving apart. As this occurs, the crown may develop an unusual occlusal contact with the opposing arch. This should be equilibrated to improve the occlusion.

Fractured Teeth and Forced Eruption

Occasionally, children and adolescents fall and injure their anterior teeth. If the injury is minor and results in a small fracture of enamel, this can be restored with light-cured composite or porcelain veneer. In some patients, however, the fracture extends beneath the level of the gingival margin and terminates at the level of the alveolar ridge (eFig. 56A.11). Restoration of the fractured crown is impossible because the tooth preparation would extend to the level of the bone.

This overextension of the crown margin could result in an invasion of the biologic width of the tooth and cause persistent inflammation of the marginal gingiva. It may be beneficial in such cases to erupt the fractured root out of the bone and move the fracture margin coronally so that it can be properly restored.[10] However, if the fracture extends too far apically, it may be better to extract the tooth and replace it with an implant or bridge. The following six criteria are used to determine whether the tooth should be forcibly erupted or extracted:



EFIG. 56A.11 This patient had a severe fracture of the maxillary right central incisor (A) that extended apical

to the level of the alveolar crest on the lingual side (B). To restore the tooth adequately and avoid impinging on the periodontium, the fractured root was extruded 4 mm (C). As the tooth erupted, the gingival margin followed the tooth (D). Gingival surgery was required to lengthen the crown of the central incisor (E), so that the final restoration had sufficient ferrule for resistance and retention as well as the appropriate gingival margin relationship with the adjacent central incisor (F).

1. *Root length.* Is the root long enough so that a one-to-one crown-to-root ratio can be preserved after the root has been erupted? To answer this question, the clinician must know how far to erupt the root. If a tooth fracture extends to the level of the bone, it must be erupted 4 mm. The first 2.5 mm moves the fracture margin far enough away from the bone to prevent a biologic width problem. The other 1.5 mm provides the proper amount of ferrule for adequate resistance form of the crown preparation. Therefore, if the root is fractured to the bone level and must be erupted 4 mm, the periapical radiograph must be evaluated (see eFig. 56A.10B) and 4 mm subtracted from the end of the fractured tooth root. The length of the residual root should be compared with the length of the eventual crown on this tooth. The root-to-crown ratio should be about 1:1. If the root-to-crown ratio is less than that, there may be too little root remaining in the bone for stability. In this situation, it may be prudent to extract the root and place a bridge or implant.
2. *Root form.* The shape of the root should be broad and nontapering rather than thin and tapered. A thin, tapered root provides a narrower cervical region after the tooth has been erupted 4 mm. This could compromise the aesthetic appearance of the final restoration. The internal root form is also important. If the root canal is wide, the distance between the external root surface and the root canal filling will be narrow. In these patients, the walls of the crown preparation are thin, which could result in early fracture of

the restored root. The root canal should not be more than one-third of the overall width of the root, so that the root can still provide adequate strength for the final restoration.

3. *Level of the fracture.* If the entire crown is fractured 2 to 3 mm apical to the level of the alveolar bone, it is difficult, if not impossible, to attach to the root to erupt it.
4. *Relative importance of the tooth.* If the patient is 70 years of age and both adjacent teeth have prosthetic crowns, it would be more prudent to construct a fixed bridge. However, if the patient is 15 years of age and the adjacent teeth are unrestored, forced eruption would be much more conservative and appropriate.
5. *Aesthetics.* If the patient has a high lip line and displays 2 to 3 mm of gingiva when smiling, any type of restoration in this area will be more obvious. Keeping the patient's own tooth would be much more aesthetic than any type of implant or prosthetic replacement.
6. *Endodontic/periodontal prognosis.* If the tooth has a significant periodontal defect, it may not be possible to retain the root. In addition, if the tooth root has a vertical fracture, the prognosis would be poor, and extraction of the tooth would be the proper course of therapy.

If all these factors are favorable, forced eruption of the fractured root is indicated. The orthodontic mechanics necessary to erupt the tooth can vary from elastic traction to orthodontic banding and bracketing. If a large portion of the tooth is still present, orthodontic bracketing is necessary. If the entire crown has fractured, leaving only the root, elastic traction from a bonded bar may be possible. The root may be erupted rapidly or slowly. If the movement is performed rapidly, the alveolar bone will be left behind temporarily, and a circumferential fiberotomy may be performed to prevent bone from following the erupted root. However, if the root is erupted slowly, the bone follows the tooth. In this situation, the erupted root requires crown lengthening to expose the correct amount of tooth to create the proper ferrule, resistance form, and retention for the final restoration.

After the tooth root has been erupted, it must be stabilized to

prevent it from intruding back into the alveolus. The reason for *reintrusion* is to orient the principal fibers of the periodontium. During forced eruption, the periodontal fibers become oriented obliquely and stretched as the root moves coronally. These fibers eventually reorient themselves after about 6 months. Before this occurs, the root can reintrude significantly. Therefore, if this type of treatment is performed, an adequate period of stabilization is necessary to avoid significant relapse and reintrusion of the root.

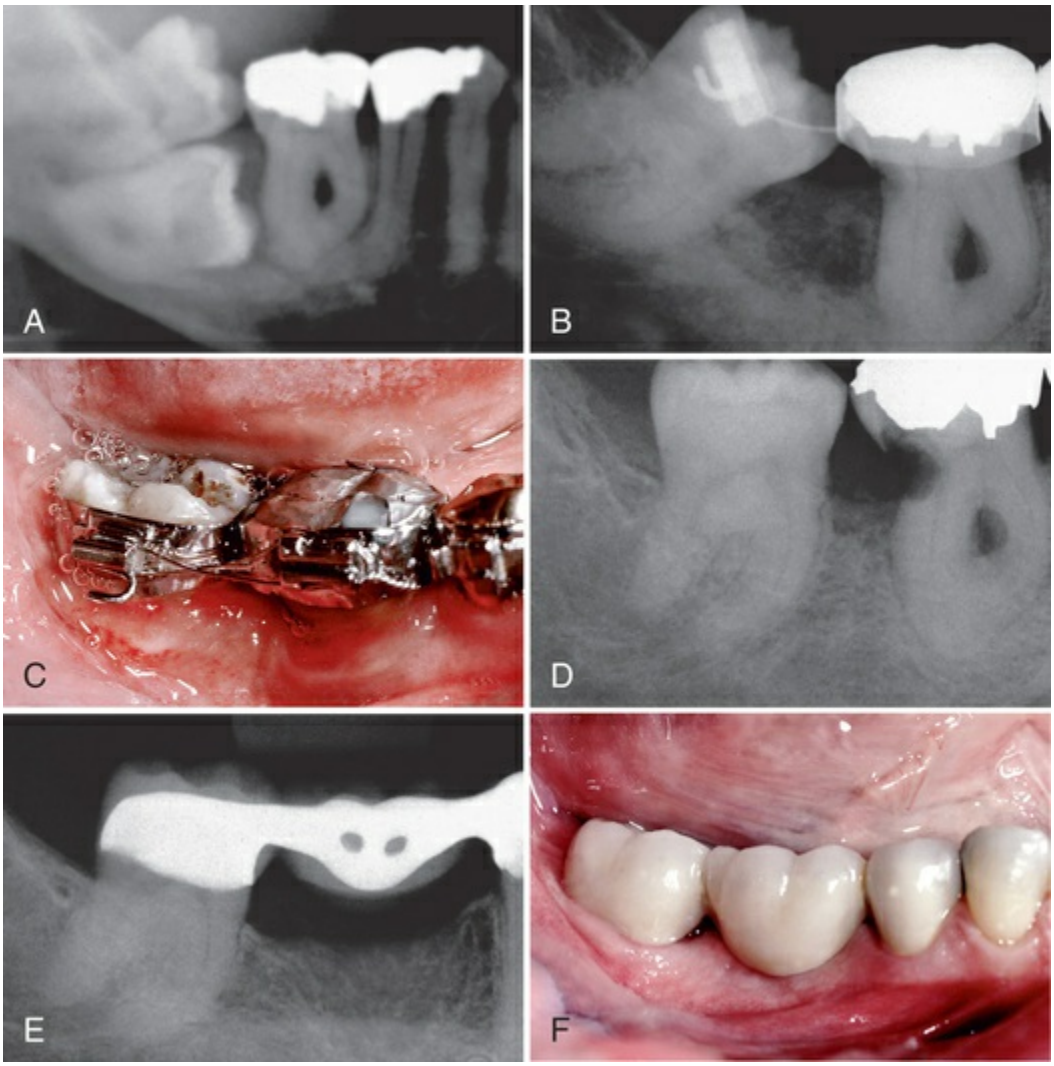
As the root erupts, the gingiva moves coronally with the tooth. As a result, the clinical crown length becomes shorter after extrusion (see eFig. 56A.10). In addition, the gingival margin may be positioned more incisally than the adjacent teeth. In these patients, gingival surgery is necessary to create ideal gingival margin height. The type of surgery varies, depending on whether bone removal is necessary. If the bone has followed the root during eruption, a flap is elevated and the appropriate amount of bone is removed to match the bone height of the adjacent teeth. If the bone level is flat between adjacent teeth, a simple excisional gingivectomy corrects the gingival margin discrepancy.

After gingival surgery, an open gingival embrasure may exist between the erupted root and adjacent teeth (see eFig. 56A.10). The space occurs because the narrower root portion of the erupted tooth has been moved into the oral cavity. This space may be closed in two ways: (1) overcontouring of the replacement restoration or (2) reshaping of the crown of the tooth and movement of the root to close the space. The second method often helps improve the overall shape of the final crown on the restored tooth.

Hopeless Teeth Maintained for Orthodontic Anchorage

Patients with advanced periodontal disease may have specific teeth that are diagnosed as hopeless and would be extracted before orthodontic therapy (eFig. 56A.12). However, these teeth may be useful for orthodontic anchorage if the periodontal inflammation can be controlled. In moderate to advanced cases, some periodontal surgery may be indicated around a hopeless tooth. Flaps are reflected for debridement of the roots to control inflammation

around the hopeless tooth during the orthodontic process. The important factor is to maintain the health of the bone around the adjacent teeth. Periodontal recall is imperative during this process.



EFIG. 56A.12 This patient had an impacted mandibular right second molar (A). The mandibular right first molar was periodontally hopeless because of an advanced class III furcation defect. The impacted second molar was extracted, but the first molar was maintained as an anchor to help upright the third molar orthodontically (B through D). After orthodontic uprighting of the third molar, the first molar was extracted and a bridge was placed to restore the edentulous space (E and F).

Treatment of orthodontic, periodontal, and restorative cases can be planned from many perspectives based on the choices made by

the patient after discussion with the clinician, financial and time commitment, complexity of the case, and other factors that must be considered before deciding on the therapy that will be instituted. The case presented in eFig. 56A.12 involved a difficult and complex therapy that was beautifully executed using a hopeless first molar as an anchor to upright and move a third molar mesially into the position of the impacted second molar, which was extracted. The third molar was eventually used as an abutment for a fixed bridge. Removal of all three molars would have been an alternative and possibly simpler treatment in this case. Bone grafting of the extraction site could be done if necessary, waiting for healing before placement of implants at the sites of the first and second molars.

After orthodontic treatment, there is a 6-month period of stabilization before reevaluation of the periodontal status. Occasionally, the hopeless tooth may be so improved after orthodontic treatment that it is retained. In most cases, however, the hopeless tooth requires extraction, especially if other restorations are planned in the segment. Again, these decisions require reevaluation by the clinician.

Learning Box 56A.4

Periodontal diagnosis, prognosis, and treatment planning are important in deciding when a tooth is hopeless because there are orthodontic cases where this knowledge is utilized to decide when a tooth can be used as a temporary anchor. When a tooth is used for this purpose, the patient is instructed on biofilm control and the tooth is scaled and root planed to eliminate the inflammation. When the tooth is no longer needed for orthodontic anchorage, it can be extracted.

Orthodontic Treatment of Gingival Discrepancies

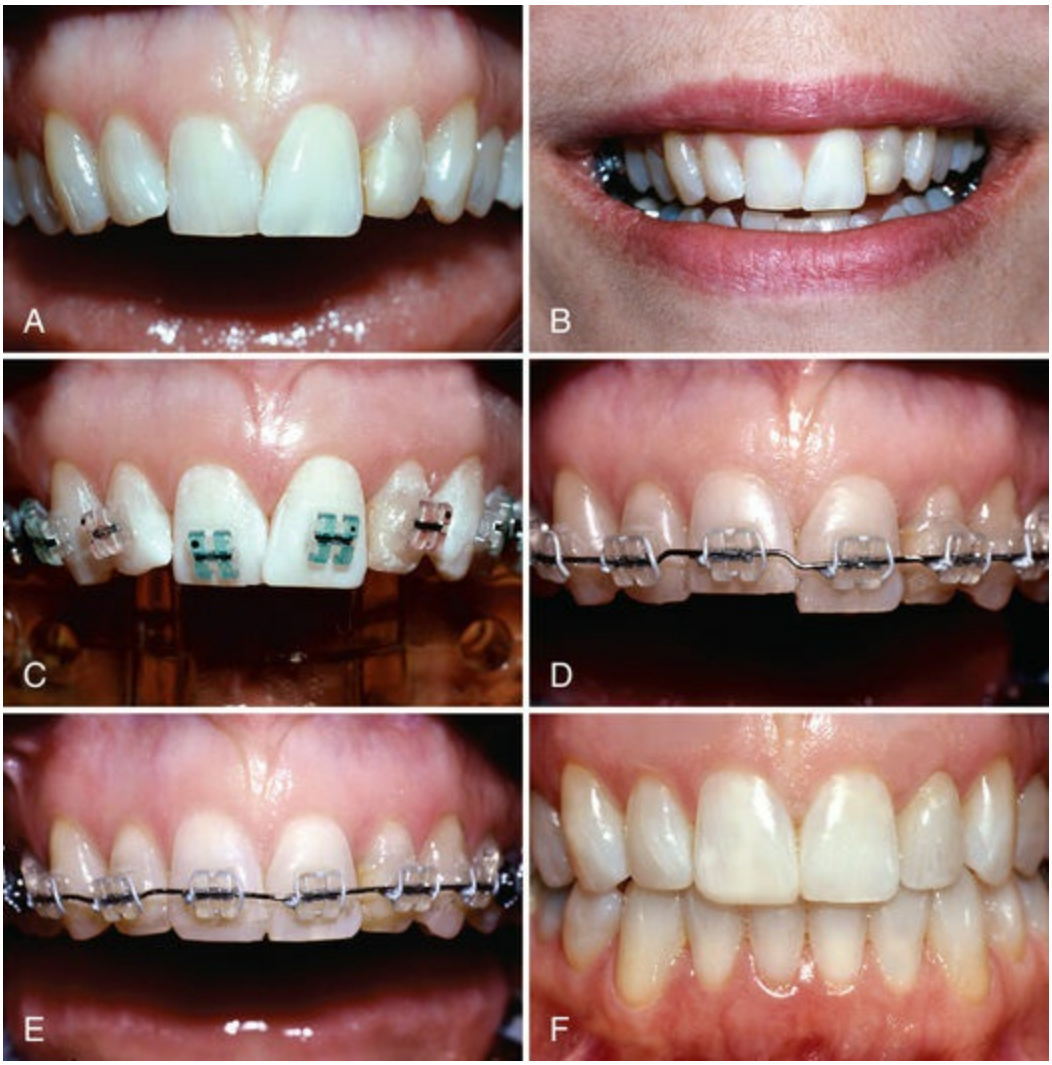
Uneven Gingival Margins

The relationship between the gingival margins of the six maxillary

anterior teeth plays an important role in the aesthetic appearance of the crowns. The following four factors contribute to ideal gingival form:

1. The gingival margins of the two central incisors should be at the same level.
2. The gingival margins of the central incisors should be positioned more apically than the lateral incisors and at the same level as the canines.[13]
3. The contour of the labial gingival margins should mimic the CEJs of the teeth.
4. A papilla should exist between each tooth, and the height of the tip of the papilla is usually halfway between the incisal edge and the labial gingival height of contour over the center of each anterior tooth. Therefore, the gingival papilla occupies half of the interproximal contact and the adjacent teeth form the other half.

However, some patients have gingival margin discrepancies between adjacent teeth (eFig. 56A.13). These discrepancies may be caused by abrasion of the incisal edges or by delayed migration of the gingival margins. When gingival margin discrepancies are present, the proper solution for the problem must be determined: orthodontic movement to reposition the gingival margins or surgical correction of the discrepancies.



EFIG. 56A.13 This patient had a protrusive bruxing habit that resulted in abrasion and overeruption of the maxillary right central incisor (A). The objective was to level the gingival margins during orthodontic therapy. Although gingival surgery was a possibility, the labial sulcular depth of the maxillary right central incisor was only 1 mm, and the cementoenamel junction was located at the bottom of the sulcus. Therefore, the best solution involved positioning the orthodontic brackets to facilitate intrusion of the right central incisor (B through D). This permitted the restorative dentist to restore the portion of the tooth that the patient had abraded (E), resulting in the correct gingival margin levels and crown lengths at the end of treatment (F).

To make the correct decision, it is necessary to evaluate four criteria. First, the relationship between the gingival margin of the maxillary central incisors and the lip line should be assessed when

the patient smiles. If a gingival margin discrepancy is present but is not exposed, it does not require correction.

If a gingival margin discrepancy is apparent, the second step is to evaluate the labial sulcular depth over the two central incisors. If the shorter tooth has a deeper sulcus, excisional gingivectomy may be appropriate to move the gingival margin of the shorter tooth apically. However, if the sulcular depths of the short and long incisors are equivalent, gingival surgery does not correct the problem.

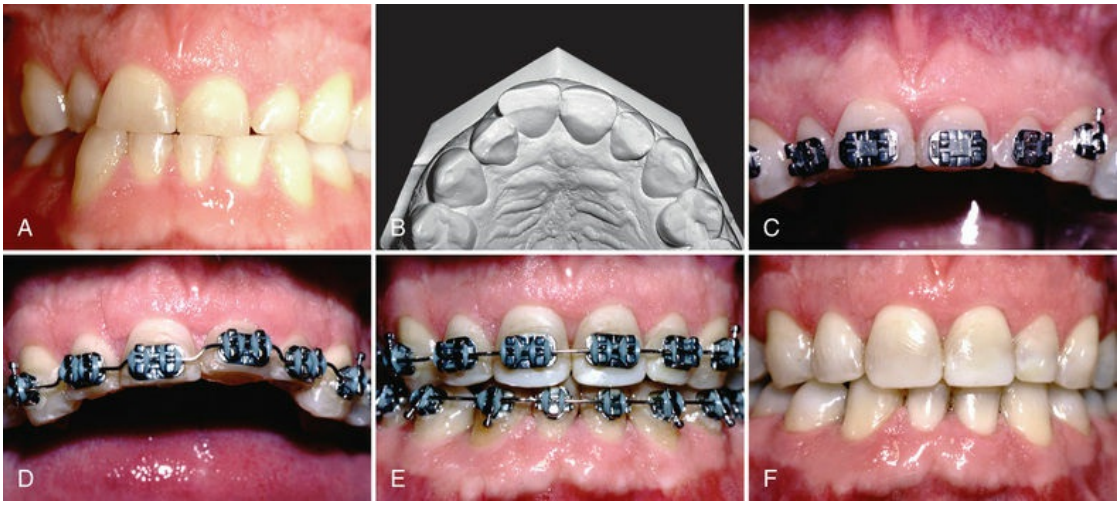
The third step is to evaluate the relationship between the shortest central incisor and the adjacent lateral incisors. If the shortest central incisor is still *longer* than the lateral incisors, the other possibility is to extrude the longer central incisor and equilibrate the incisal edge. This moves the gingival margin coronally and eliminates the gingival margin discrepancy. However, if the shortest central incisor is *shorter* than the lateral incisors, this technique would produce an unaesthetic relationship between the gingival margins of the central and lateral incisors.

The fourth step is to determine whether the incisal edges have been abraded. This is best accomplished by evaluating the teeth from an incisal perspective. If one incisal edge is thicker labiolingually than on the adjacent tooth, this may indicate that it has been abraded and the tooth has overerupted. In such cases, the best method of correcting the gingival margin discrepancy is to intrude the short central incisor (see eFig. 56A.13). This method moves the gingival margin apically and permits restoration of the incisal edges.[3,6-9] The intrusion should be accomplished at least 6 months before appliance removal. This allows reorientation of the principal fibers of the periodontium and avoids reextrusion of the central incisor or incisors after appliance removal.

Significant Abrasion and Overeruption

Occasionally, patients have destructive dental habits, such as protrusive bruxing, that can result in significant wear of the maxillary and mandibular incisors and compensatory overeruption of these teeth (eFig. 56A.14). The restoration of these abraded teeth is often impossible because of the lack of crown length to achieve

adequate retention and resistance form for the crown preparations. Two options are available. One option is extensive crown lengthening by elevating a flap, removing sufficient bone, and apically positioning the flap to expose adequate tooth length for crown preparation. However, this procedure is contraindicated in the patient with short, tapered roots because it could adversely affect the final root-to-crown ratio and potentially open gingival embrasures between the anterior teeth.



EFIG. 56A.14 This patient had a protrusive bruxing habit that caused severe abrasion of the maxillary anterior teeth, resulting in the loss of over half of the crown length of the incisors (A and B). Two possible options existed for gaining crown length to restore the incisors. One option was an apically positioned flap with osseous recontouring, which would expose the roots of the teeth. The less destructive option was to intrude the four incisors orthodontically, level the gingival margins (C and D), and allow the dentist to restore the abraded incisal edges (E and F). The orthodontic option was clearly successful and desirable in this patient.

The other option for improving the restorability of these short abraded teeth is to intrude the teeth orthodontically and move the gingival margins apically (see eFig. 56A.14). It is possible to intrude up to four maxillary incisors by using the posterior teeth as anchors during the intrusion process. This is accomplished by placing the

orthodontic brackets as close to the incisal edges of the maxillary incisors as possible. The brackets are placed in their normal position on the canines and remaining posterior teeth. The patient's posterior occlusion resists the eruption of the posterior teeth, and the incisors gradually intrude and move the gingival margins and the crowns apically. This creates the space necessary to restore the incisal edges of these teeth temporarily and eventually to place the final crowns.

When abraded teeth are significantly intruded, it is necessary to hold these teeth for at least 6 months in the intruded position with orthodontic brackets or archwires (or both) or some type of bonded retainer. The principal fibers of the periodontium must accommodate to the new intruded position, a process that takes a minimum of 6 months in most adult patients. Orthodontic intrusion of severely abraded and overerupted teeth usually carries a distinct advantage compared with periodontal crown lengthening, unless the patient has extremely long and broad roots or has had extensive horizontal periodontal bone loss.

Open Gingival Embrasures

The presence of a papilla between the maxillary central incisors is a key aesthetic factor in any individual. Occasionally, adults have open gingival embrasures or lack gingival papillae between their central incisors. These unaesthetic areas are often difficult to resolve with periodontal therapy. However, orthodontic treatment can correct many of these open gingival embrasures. This open space is usually caused by (1) tooth shape, (2) root angulation, or (3) periodontal bone loss.[9]

The interproximal contact between the maxillary central incisors consists of two parts: the tooth contact and the papilla. The papilla/contact ratio is 1:1. Half the space is occupied by papilla, and half is formed by the tooth contact. If the patient has an open embrasure, the first factor that must be evaluated is whether the problem is caused by the papilla or the tooth contact. If the papilla is the problem, the cause is usually a lack of bone support for the papilla due to an underlying periodontal problem.

In some situations, a deficient papilla can be improved with

orthodontic treatment. By closing open contacts, the interproximal gingiva can be squeezed and moved incisally. This type of movement may help create a more aesthetic papilla between two teeth despite alveolar bone loss. Another possibility is to erupt adjacent teeth when the interproximal bone level is positioned apically.

Most open embrasures between the central incisors are caused by problems with tooth contact. The first step in the diagnosis of this problem is to evaluate a periapical radiograph of the central incisors. If the root angulation is divergent, the brackets should be repositioned so that the root position can be corrected (see eFig. 56A.1). In these patients, the incisal edges may be uneven and require either composite or porcelain restoration. If the periapical radiograph shows that the roots are in their correct relationship, the open gingival embrasure is caused by a triangular tooth shape (eFig. 56A.15).

EFIG. 56A.15 This patient initially had triangular-shaped central incisors (A and B), which produced an open gingival embrasure after orthodontic alignment (C). Because the roots of the central incisors were parallel to one another, the appropriate solution for the open gingival embrasure was to recontour the mesial surfaces of the central incisors (D). As the diastema was closed (E), the tooth contact moved gingivally and the papilla moved incisally, resulting in the elimination of the open gingival embrasure (F).

If the shape of the tooth is the problem, two solutions are possible: (1) restore the open gingival embrasure or (2) reshape the tooth by flattening the incisal contact and closing the space (see eFig. 56A.15). This second option results in lengthening of the contact until it meets the papilla. In addition, if the embrasure space is large, closing the space squeezes the papilla between the central incisors. This helps create a 1:1 ratio between the contact and the

papilla and restores uniformity to the height between the midline and adjacent papillae.

Learning Box 56A.5

Orthodontic therapy to assist the periodontal patient with the aesthetic problem of missing interdental papilla is important because it is difficult, and in many cases impossible, to surgically create a missing papilla.

Conclusion

There are many benefits to integrating orthodontics and periodontics in the management of adult patients with underlying periodontal defects. The key to treating these patients is communication and proper diagnosis before orthodontic therapy, as well as continued dialog during treatment. Not all periodontal problems are treated in the same way. This chapter provides a framework for the integration of orthodontics to solve periodontal problems.

Case Scenario 56A.1

Orthodontic, periodontal, and restorative treatment can be approached in multiple ways, depending on choices made by the patient after discussion with the clinician, financial and time commitment, complexity of the case, and other factors that must be considered before deciding on therapy. The case presented in eFig. 56A.12 was a difficult and complex therapy that was beautifully executed using a hopeless first molar as an anchor to upright and move mesially a third molar into the position of the impacted second molar, which was extracted. The third molar was eventually used as an abutment for a fixed bridge.

Question

What would be another alternative and possibly a simpler way to treatment plan this case?

Answer

(Please refer to eFig. 56A.12) The removal of all three molars. Possibly bone graft the site, if necessary, where the three molars are extracted, wait for the healing of the extraction site, and then place implants at the site of the first and second molars.

CHAPTER 56B

Orthodontics, Implants, and Periodontal Interactions

Frank Celenza

Abstract

The interrelationships between the disciplines of orthodontics and implants are quite intimate. In addition, the integration of periodontics with orthodontics and implants presents an even more interesting and important combination. Although the conventional orthodontic patient might be quite different from the periodontal patient, many useful interactions between the disciplines can be harnessed for the best treatment outcomes. This is especially true in current treatment planning, where implants are used as anchors to move teeth.

The conventional orthodontic patient might be characterized as an adolescent or young adult, usually with a healthy dentition and

without significant medical or dental history. Conversely, the periodontal patient often presents with a significant medical history and a long list of dental dilemmas, which can include restorative considerations, a periodontium in need of treatment, and tooth replacement considerations to be sequenced into the therapy. In this situation, implant therapy becomes involved in treatment. But how should these two divergent patient types be managed when combining treatment modalities from these three disciplines?

This section will delineate interrelationships that can improve therapeutic outcomes. When the clinician fully appreciates the periodontal apparatus that supports a tooth and understands the physiology of tooth movement, the body's reparative and remodeling capacities can be used to effect periodontal alterations resulting from tooth movement. Further, as implant modalities are used, a greater demand for accurate tooth position arises. Moreover, as more adults seek orthodontic and implant treatment, understanding the need and methods to ensure periodontal health before and during orthodontic and implant care becomes paramount. Consequently, the relationship between these three distinct dental disciplines becomes apparent in the planning and execution of treatment.

Implant Interactions in Orthodontics *(e-only)*
Conclusion

Introduction

Whereas the interrelationships between the disciplines of orthodontics and implantology might not seem close to the casual observer, in fact they are quite intimate. In addition, the integration of periodontics with orthodontics and implants presents an even more interesting and important combination. Although the conventional orthodontic patient might be quite different in nature from the periodontal patient, there are many useful and interesting interactions between the disciplines that can and should be harnessed for the best treatment outcomes. This is especially true in current treatment planning in which implants are used as anchors to move teeth.

The conventional orthodontic patient might be characterized as an adolescent or young adult, usually with a healthy, although not always complete, dentition. This patient most often does not present with a significant medical or dental history. Conversely, the periodontal patient often does present with a significant and contributory medical history and a long list of dental problems, which often includes restorative considerations. Further, the periodontium will be compromised and in need of treatment, usually preparatory to orthodontic intervention. Also, there will often be tooth replacement considerations to be sequenced into the therapy. It is in this situation that implant therapy may be part of the treatment scenario. How, then, are these two divergent patient types to be managed by combining treatment modalities from these three disciplines?

This section delineates some of the interrelationships that can be utilized for better therapeutic outcomes. When the clinician gains an appreciation for the periodontal apparatus that supports a tooth and applies an understanding of the physiology of tooth movement, one can utilize the body's reparative and remodeling capacities to effect periodontal alterations as a result of tooth movement. Further, as implant modalities are called upon, a greater

demand for accurate tooth position arises. Moreover, as more adult patients are seeking orthodontic and implant treatment, an understanding of the need for and methods of ensuring periodontal health before and during orthodontic and implant care becomes paramount. Consequently, the intimate relationships among these three distinct dental disciplines become apparent in both the treatment planning and treatment execution phases of therapy. We can truly address this topic as *interdisciplinary dentistry*.

Implant Interactions in Orthodontics

Planning Phase

As implant dentistry has impacted virtually all realms of the profession and clinical practice, so too has implantology interacted with orthodontics. As with the other clinical disciplines of dentistry, these potential interactions must be considered prior to the onset of treatment, in the treatment planning stages, because the appropriate sequencing and timing of various steps is important for maximizing the benefits of their coordination.

More specifically, including implants in orthodontic therapy can have two fundamentally different goals, and the clinician needs to clarify the intent, which in turn will dictate the treatment sequence. There are two basic circumstances in which implants (of various configurations) should be considered.

First, are implants being included in the actual orthodontic mechanotherapy (e.g., used for anchorage purposes)? If so, these types of devices need to be sequenced early in treatment, so as to best utilize them in facilitating the orthodontic movement. Implants used solely for providing orthodontic anchorage will be subsequently explanted when their intended function is completed, and consequently they are referred to as temporary anchorage devices (TADs; eFig. 56B.8).

Second, are implants under consideration for the replacement of missing or lost teeth? In this more conventional role, implant placement is usually sequenced much later, if not at the conclusion of orthodontic movement. In fact, the orthodontic mechanotherapy treatment in this instance is preparatory to the implant therapy, and

it is now employed as a means of implant site development.

It is also feasible that an implant scheme can be devised in which the fixture serves both functions: to provide anchorage for orthodontic mechanotherapy and to be subsequently used as a means of dental replacement.

Learning Box 56B.1

Implants can be used to facilitate orthodontic mechanotherapy by providing anchorage, and orthodontic treatment can facilitate implant therapy by providing site development. The sequence of therapy is determined by which of these roles are being harnessed. When an implant is utilized to provide a source of orthodontic anchorage, it should be placed and loaded early in the orthodontic treatment. When orthodontics is being employed for site development, the implant placement will follow the orthodontic treatment.

Implant Anchorage in Orthodontics

Owing to the nature of their integration or stabilization in the alveolus, implants have been proven to be reliable and immobile sources of orthodontic anchorage; when properly planned and included, they can dramatically facilitate orthodontic therapy.[a] Traditionally, orthodontists classify case types according to the intended use of available dental sources of anchorage. Appliances are designed and treatment planning decisions are made based on the classification schemes known as minimal, moderate, and maximum anchorage demands. These schemes reflect the intended balance between desired movement and concomitant reciprocal movement. The inclusion of implants in orthodontic mechanotherapy has resulted in the advent of a new class of anchorage, termed *absolute anchorage*. Among other features, the implications of absolute anchorage are that the predictability of the outcome rises dramatically, mechanotherapy can be simplified and streamlined, and, perhaps most importantly, compliance dependency is eliminated.

With conventional orthodontic anchorage strategies, movement

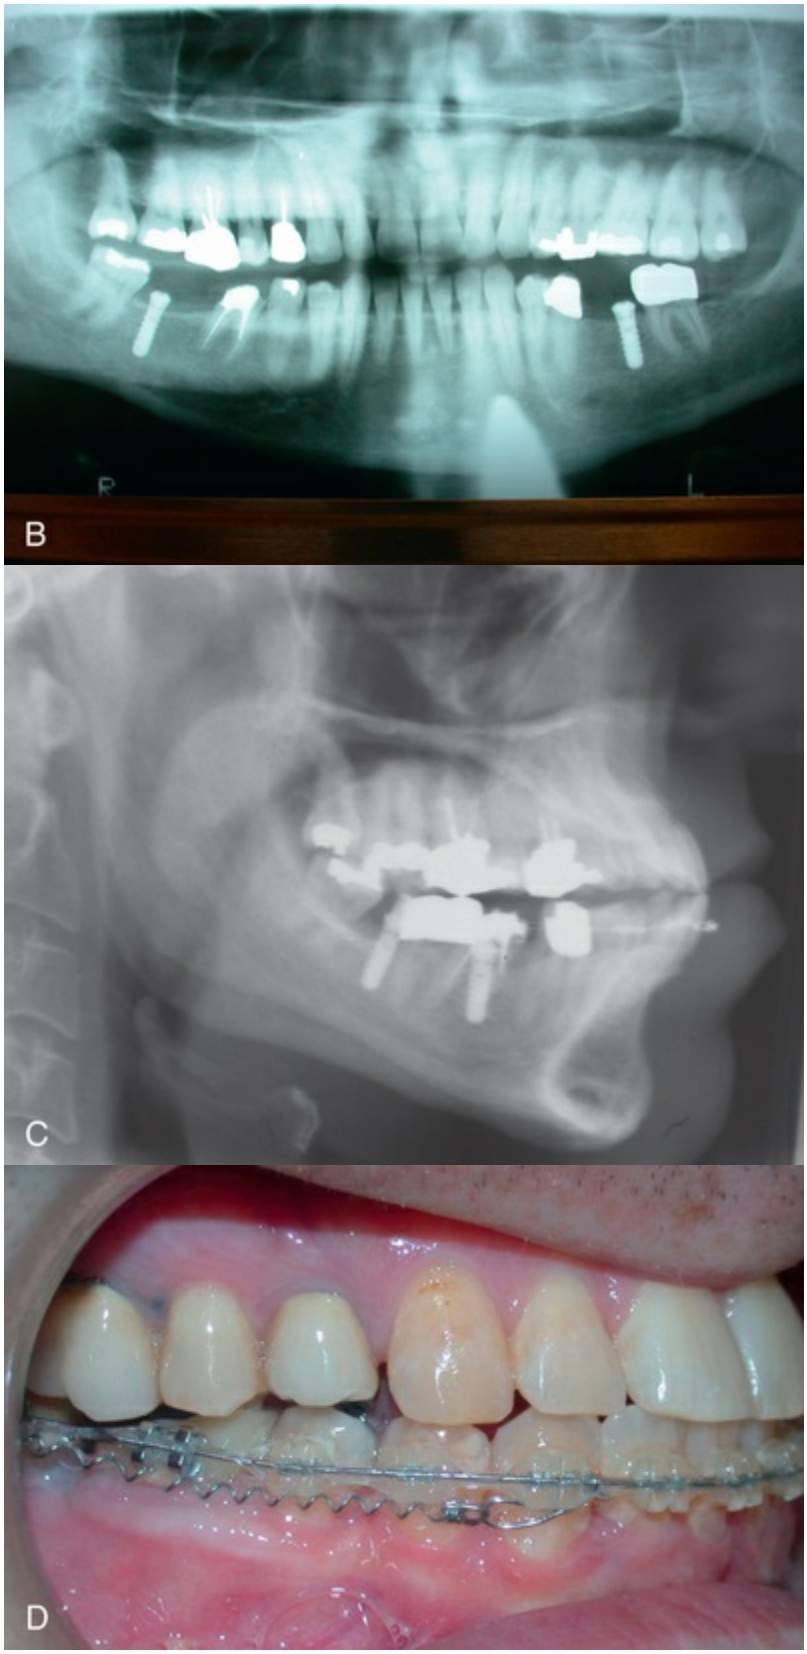
is generally controlled by embracing anchor segments of teeth that outnumber the active segments of the teeth. In this way, the combined root surface area of the anchor units is collectively greater than that of the active segments and consequently is less likely to lead to movement under orthodontic load. The desired movement is theoretically achieved with minimal or no reciprocal movement. However, when the anchor segment includes a nondental device, such as an implant or a miniscrew, this concept no longer applies. Owing to the nature of an implant's or miniscrew's direct attachment to bone, devoid of any ligamentous insertion, its feature is immovability. As a result, when the anchor segment includes an implant or miniscrew, the active units can actually outnumber the anchor units because anchorage preservation is no longer an issue. For this reason, *en masse* movement is quite easily achieved. The implication is that sequencing of orthodontic movement for the purpose of anchor preservation is no longer required, both saving time and significantly simplifying the orthodontic mechanotherapy (see eFig. 56B.1).

EFIG. 56B.1 In this example of direct anchorage, a miniscrew (or TAD) is placed between the roots of the mandibular bicuspid and cuspid teeth and is activated through by a nickel titanium coil spring from the TAD to the molar bracket. In this way, the posterior teeth are protracted by direct force application to the TAD.

Learning Box 56B.2

The nature of attachment of an implant or miniscrew is very different than that of a tooth to alveolar bone. Whereas a dento-alveolar attachment features a ligamentous insertion, implants or minicrews either osseointegrate or rely upon skeletal fixation. Consequently, Wolff's law of pressure and tension stimuli to remodel bone and allow tooth movement does not apply to fixtures. When properly fixated, implants and miniscrews can withstand orthodontic force application without incurring movement and thus can be used to overpower teeth, which respond very efficiently when proper mechanotherapy is designed.

It is important to consider the eventual long-term role of the implant in the treatment planning stage. If an implant is going to be placed in a dental position for eventual restoration after the completion of orthodontics, then proper positioning must be determined regarding both orthodontic utilization and restorative consideration.[64] In this scenario, implant anchorage will most likely be direct (meaning that orthodontic forces are applied directly to the implant). Further, the location of such a dualistically conceived implant needs to take into account the postorthodontic dental restoration (eFig. 56B.2).

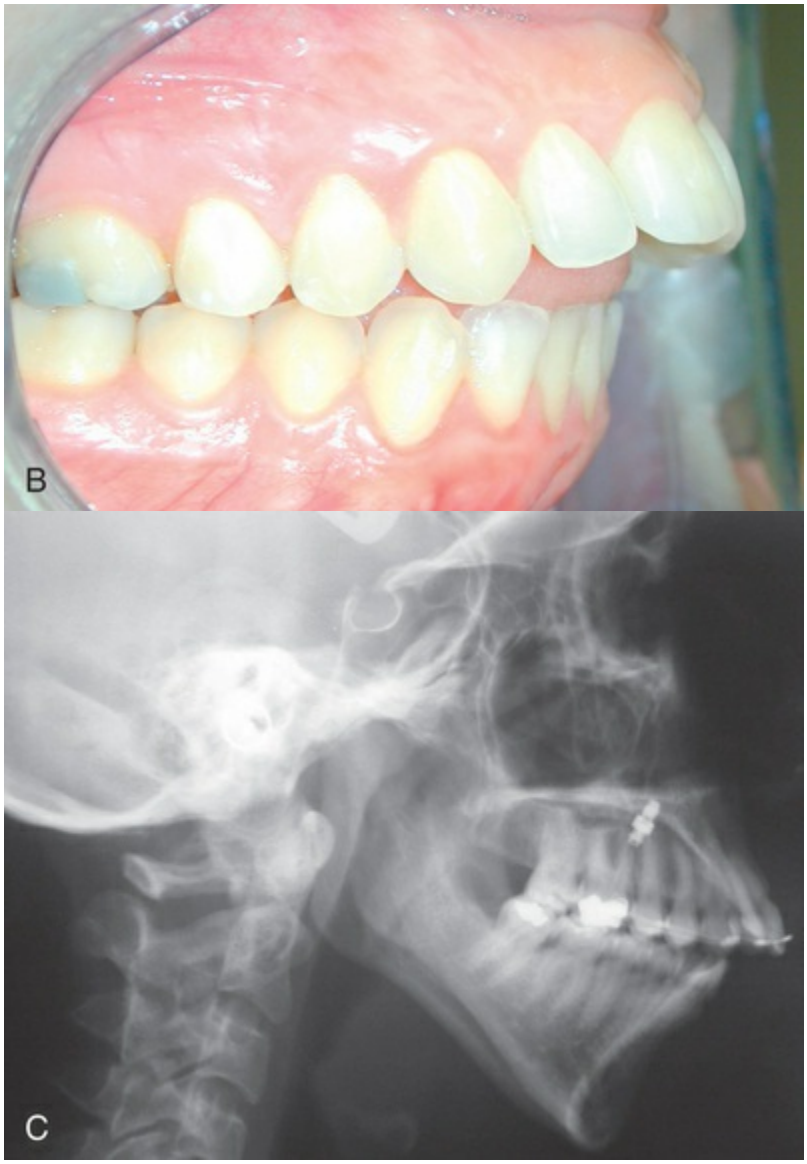


EFIG. 56B.2 In this example of direct anchorage, implants are placed in dental locations to provide both orthodontic anchorage and eventual tooth replacement. The patient presented with an anterior cross-bite and was missing mandibular molars

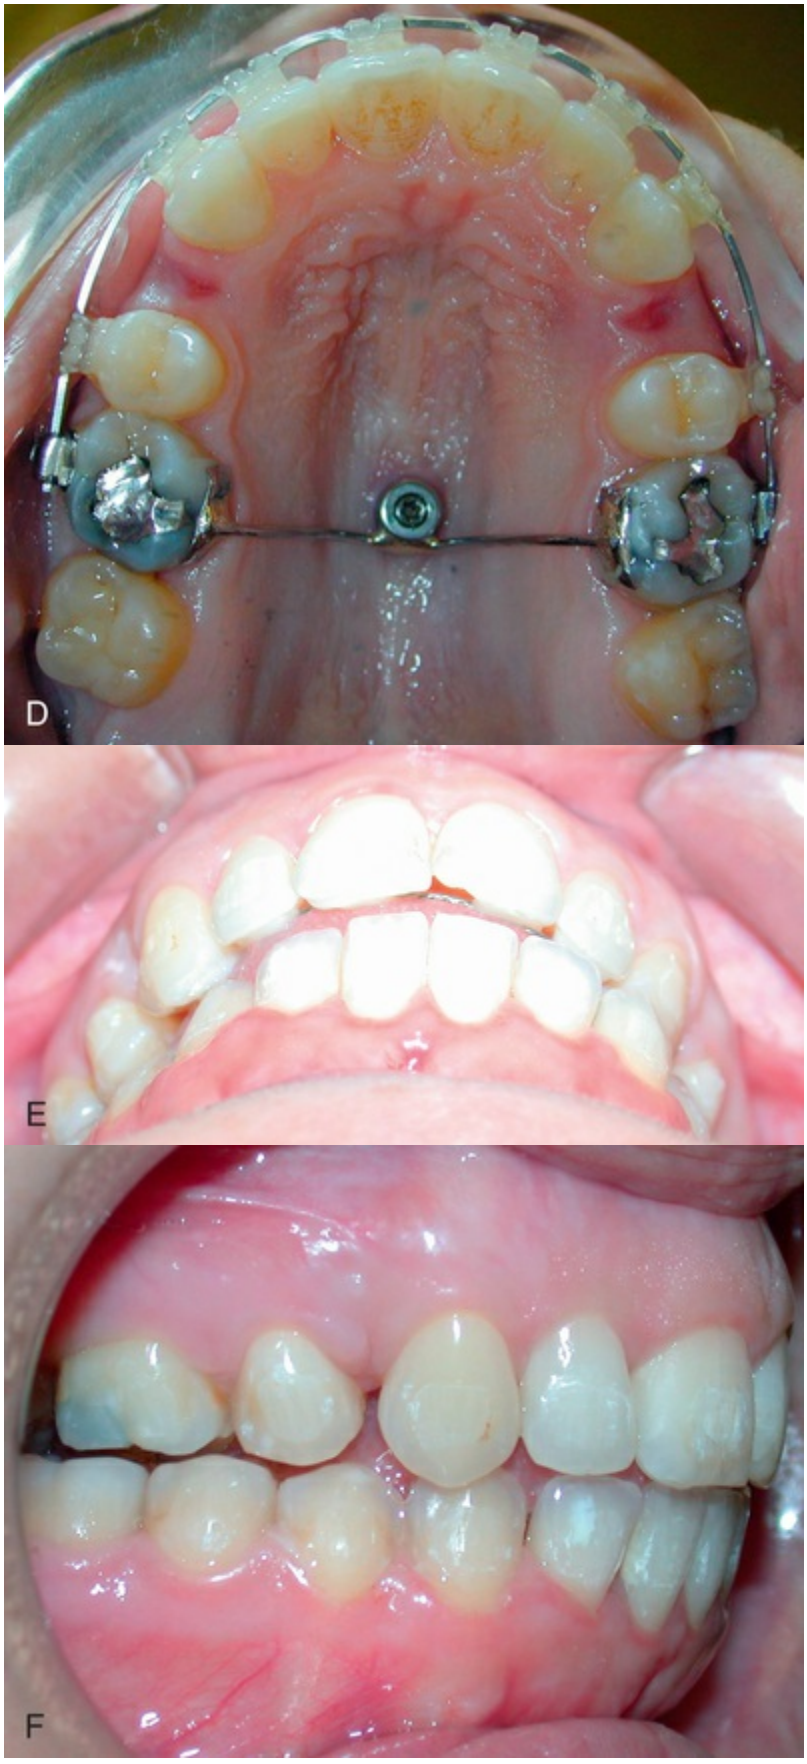
bilaterally (A). Implants were placed prior to the initiation of orthodontic treatment and allowed to integrate. They were placed slightly distal to the center of the edentulous spaces, in anticipation of distalization of the dentition (B). The implants were subsequently provisionally restored and then incorporated into the orthodontic appliance and loaded for retraction of the entire dentition anterior to the implants (C and D). At the conclusion of the orthodontic treatment, the implants are ready to be restored.

If an implant is being used solely for orthodontic facilitation and will be explanted instead of restored, then the implant is considered to be a TAD.[b] In this indication, the need for restorative consideration is obviously negated, and the position of the device is driven solely by orthodontic and anatomic considerations. Consequently, TADs can be employed for the creation of anchorage by either a direct or indirect strategy. With direct anchorage, a TAD is placed in a position that optimizes the orthodontic force vectors required for the specific movement. Elastomerics, nickel titanium springs, or any force module desired is attached directly to the TAD from the orthodontic appliance, thereby effecting the desired movement. With indirect anchorage, the TAD fixture is attached through some stabilization strategy to a tooth or teeth or archwire on which orthodontic force is secondarily applied. Both direct and indirect anchors can be placed in a wide variety of locations, such as buccal cortex (eFig. 56B.3), interradicular, palatal (eFig. 56B.4) retromolar, and other locations. Interesting and extremely efficient appliance designs result from all of these strategies.

EFIG. 56B.3 Indirect anchorage. Here an orthodontic miniscrew is placed in the buccal cortex between the maxillary left cuspid and first premolar. The temporary anchorage device is used to stabilize the orthodontic archwire and prevent unwanted mesial movement by employing a T-bar. This allows an open coil spring to be placed on the orthodontic archwire for distal driving of the upper left posterior teeth into a class I relation, thereby creating space to eliminate the crowding that the patient presented with. The upper left bicuspid tooth is considered as an indirect anchor because it is attached to the TAD, which serves to stabilize it.



B
C



D
E
F

EFIG. 56B.4 Indirect anchorage through the use of a palatal implant. (A and B) Initial presentation shows Class II molar and canine relation and significant anterior open bite. (C and D) A palatal implant is placed midpalatally and then anchored to the palatal surfaces of the maxillary molars by virtue of a bonded transpalatal arch. In this way, the molars were rendered as indirect absolute anchors. The first premolars were extracted, and retraction mechanics were employed to close a significant anterior open bite, with no regard for posterior anchor preservation (E and F). (G) The implant was subsequently explanted, and the osteotomy site healed.

In effect, the application of force and the guidance of movement are separated because the force is not necessarily being applied through the orthodontic appliance. Consequently, a greater variety of options for appliance design arise (e.g., sequential aligner therapy).

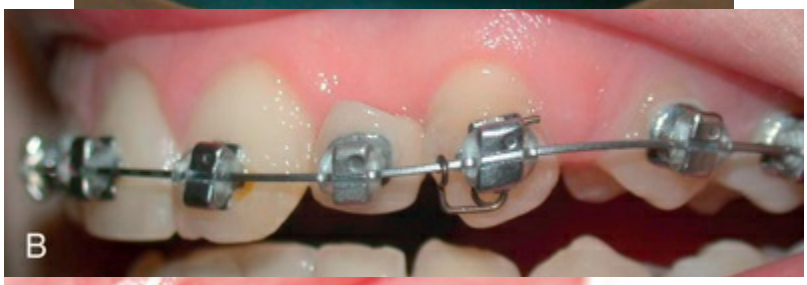
Orthodontic Site Preparation

Preimplant or preparatory orthodontics can have a vital role in the eventual success and restoration of an implant. Orthodontic movement can be very beneficial, and often it is essential for accurate implant placement. In fact, because implant tooth replacement is conservative in regard to the existing adjacent teeth (i.e., tooth preparation is obviated and cannot be relied on to

compensate for less than ideal tooth position), the importance of precise tooth position is greater.

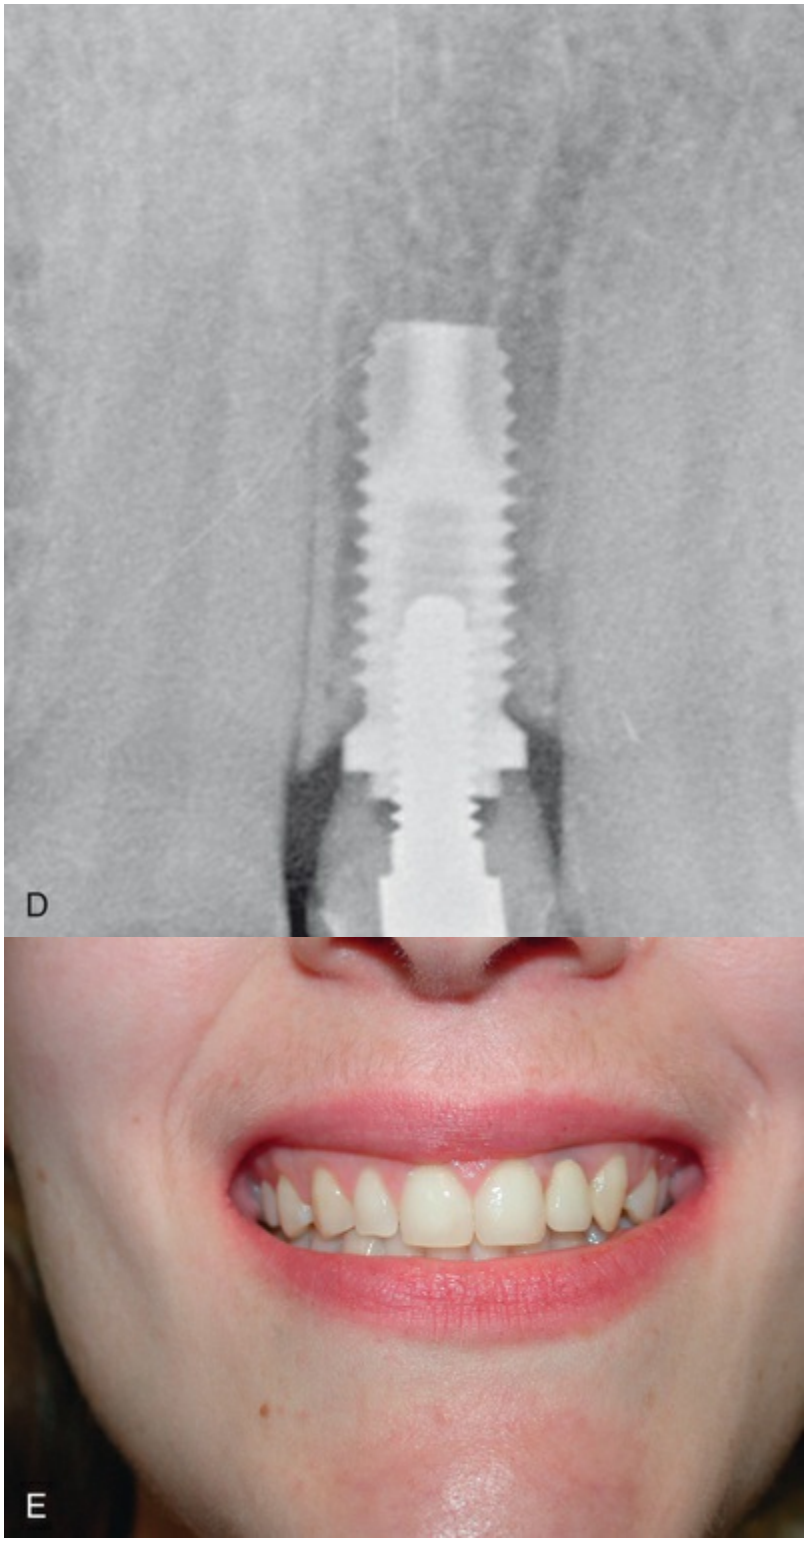
There are differences in regard to root angulation and parallelism between congenitally missing teeth and missing teeth that existed at one time and were subsequently lost. In the situation of a congenitally missing tooth, the neighboring teeth erupt into the space of the missing tooth and therefore can be parallel or even convergent to the other teeth. This situation requires important root control during the space opening phase of orthodontics and must be monitored radiographically (eFig. 56B.5). Conversely, the changes that accompany the loss of a tooth include tipping or drifting movements of the remaining teeth. The correction for this situation orthodontically usually entails a much simpler tipping or uprighting movement, which is much more easily accomplished than a translation or root torquing movement (eFig. 56B.6). The important distinction between these two situations must be made at the diagnostic stage because it will affect the mechanotherapy and treatment.

A



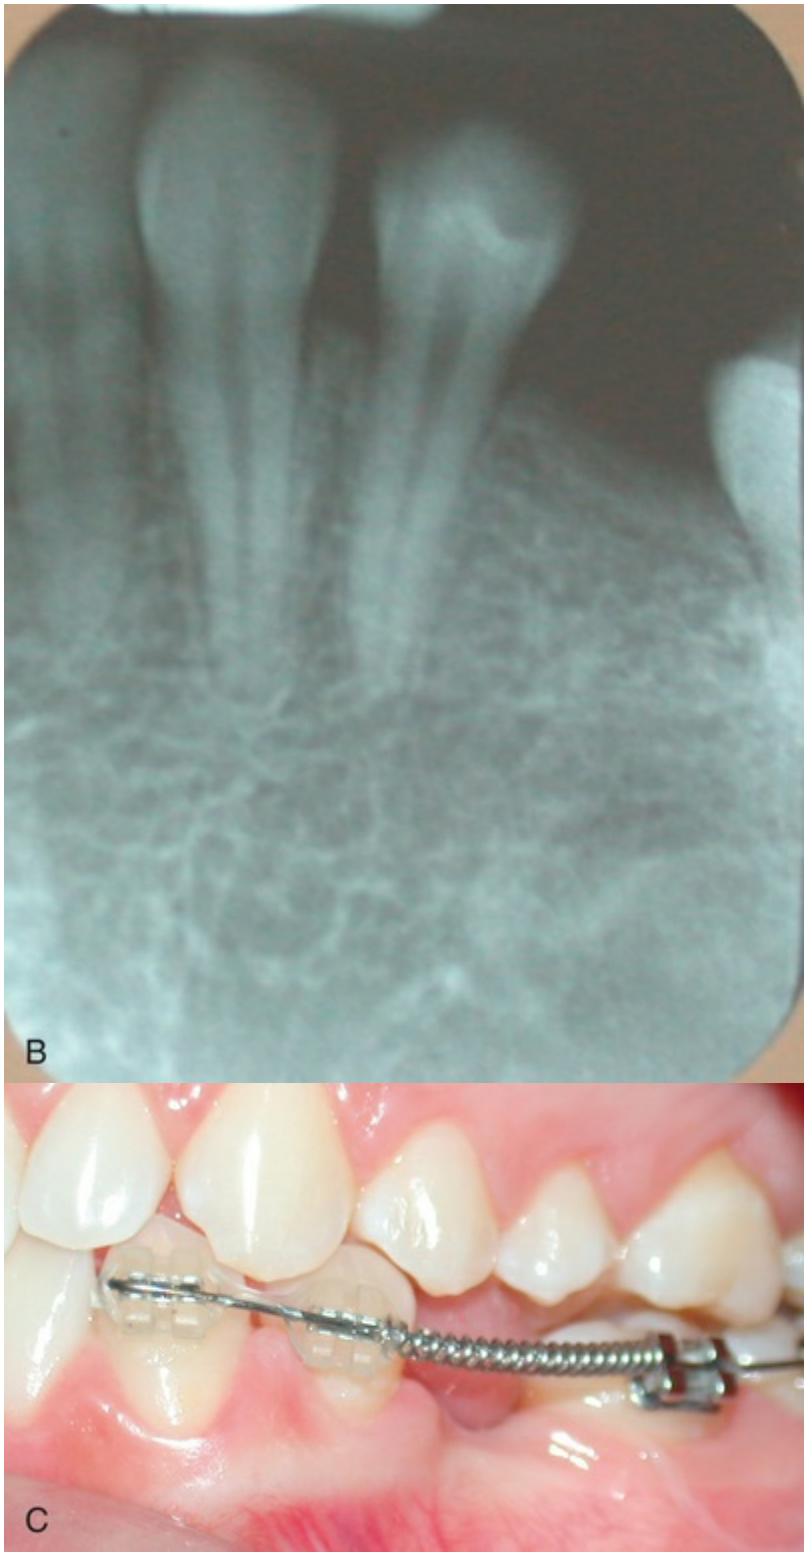
B

C

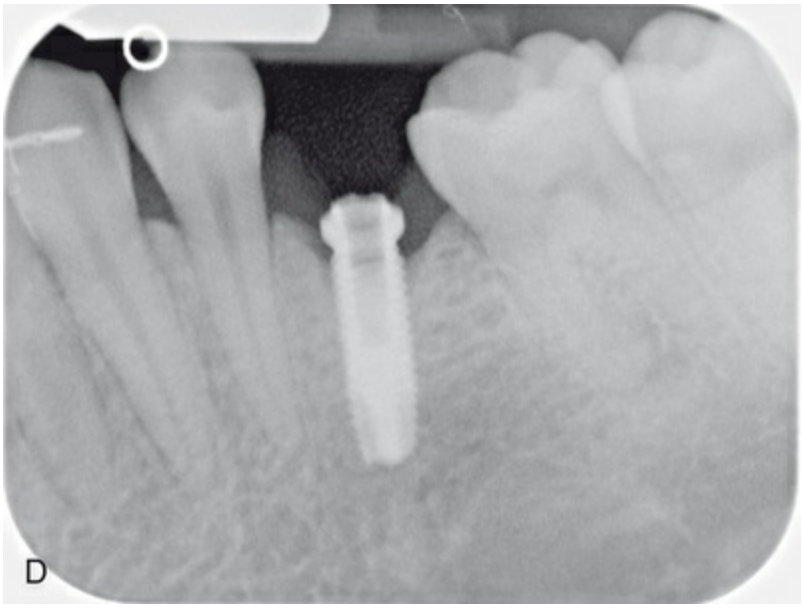


EFIG. 56B.5 In this case, an orthodontic fixed appliance was utilized to restore space for the implant replacement of a maxillary left lateral incisor. (A) Convergence of the central incisor and cuspid roots preclude implant placement. (B) Features of this fixed appliance to achieve root parallelism are bracket placement and orientation, vertical slotted brackets for

uprighting springs, nickel titanium archwire, and pontic placement at the lateral incisor. (C) Implant placement after correcting tooth position and root parallelism is achieved with the archwire in place to facilitate proper orientation. (D) Radiograph of restored implant shows proper interradicular management to permit ideal implant placement. (E) Clinical view of final restoration.



B
C



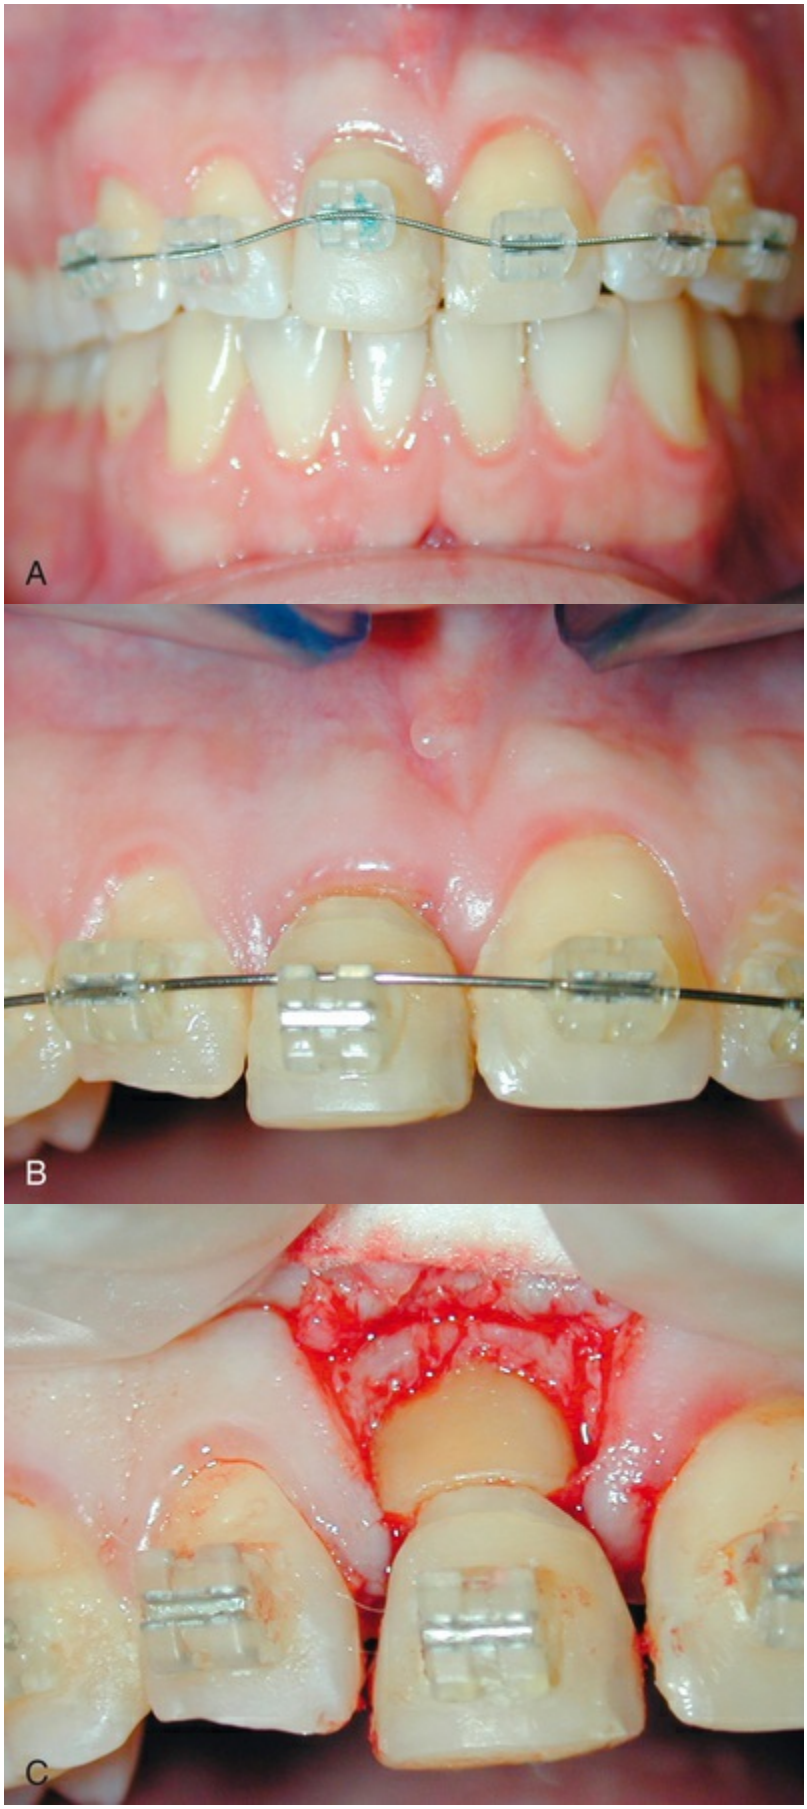
EFIG. 56B.6 Space management in a case of tooth relocation or drifting after earlier tooth loss. (A) The mandibular left premolar has drifted into the edentulous space over time. (B) The drifting of the tooth occurs by distal crown tip, not bodily movement. (C) Correction of the migration occurs by simple uprighting mechanics, much more easily achieved than when root parallelism is required (such as that seen in eFig. 56B.5). (D) Implant placement proceeds after tooth position is corrected.

Additionally, there are beneficial and physiologic aspects of tooth movement that can also be harnessed for site development. As shown in many examples of forced eruption, both hard and soft tissue augmentation can be achieved through this relatively simple form of tooth movement.[30,31,46-48,62] Further, as has also been shown, when the body's capacity to modify and form tissue in response to orthodontic stimuli is harnessed, vital tissue types result, which is often preferable to allografting and other forms of augmentation endeavors. Orthodontic eruption of teeth that are planned to be extracted can present a change in thought pattern and must be understood to be appreciated. Whereas it might seem odd to move a tooth that is slated for extraction, the physiologic benefits of doing so can be appreciable.[62] It is not unusual in this situation to maximize these augmentative steps by effectively extracting hopeless teeth orthodontically. Further, these alterations can be achieved quite effectively even on teeth that have significantly

diminished attachment levels.[20,68]

Soft tissue augmentation is achieved with orthodontic eruption by virtue of sulcular eversion during the movement. The hemidesmosomal adherence of the epithelial tissues to the tooth causes the soft tissue to elongate as the tooth is erupted. As the nonkeratinized sulcular epithelium everts outward in response to movement, it becomes exposed to the oral environment and undergoes the process of keratinization, eventually forming mature keratinized gingiva. The immature tissue undergoing this keratinization process is termed *Atherton tissue* in reference to the author who first documented the gingival changes associated with tooth movement.[21-23] The result is that the free gingival margin can be moved incisally with eruptive movements, and, depending on the mobility of the mucogingival junction, the zone of keratinized gingiva can be increased or augmented (eFig. 56B.7).

Hard tissue changes occur in the alveolar region in response to eruption by virtue of the ligamentous and connective tissue fiber attachments in the dentoalveolar complex.[59] These fibers exert tension on the alveolar bone in response to eruptive forces, which, according to Wolff's law, results in bone deposition. Although there is a time lapse between the tensile stimulus on bone and its actual calcification, the bone augmentation that results can eventually be visualized radiographically and is evidenced in both the angularity of the alveolar crest and the narrowing of ligament spaces that result from the tooth movement (see eFig. 56A.7C). Bone fill is observed as the apical group of periodontal ligament fibers exert tension on the socket alveolus in the apical area, and the operator is cautioned not to mistake the appearance of periapical radiolucency during tooth eruption as periapical pathology.



EFIG. 56B.7 This case illustrates the hard and soft

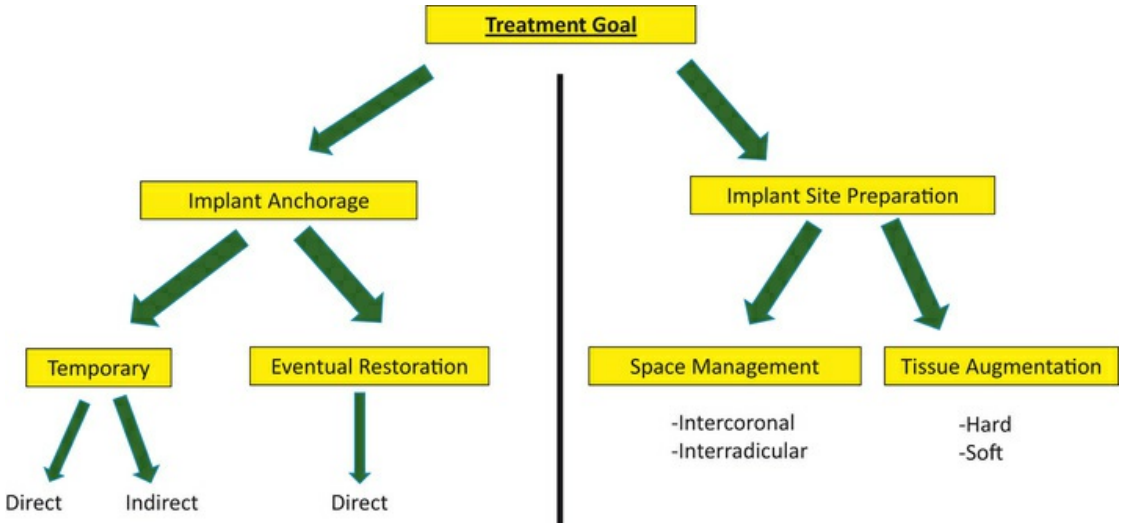
tissue changes that accompany an eruption movement. (A) Bracket placement is geared toward erupting the upper right central incisor. Notice the bracket placement on that tooth, which is gingival to the neighboring brackets. (B) After eruption, the free gingival margin of the erupted right central incisor is relocated, a result of sulcular eversion and keratinization of Atherton tissue. (C) The hard tissue changes are visualized when a full-thickness flap is elevated to expose the remodeled alveolar crestal tissue and the incisal orientation of bone spicules that result from the eruptive tension stimulus.

Learning Box 56B.3

Orthodontic movement is a useful modality for site development preparatory to implant placement. If a hopeless tooth is destined to be replaced by an implant, the remaining attachment apparatus of that tooth can be called upon to augment or remodel the hard and soft tissues of the eventual implant site before its extraction. Orthodontic movement is also frequently essential to the proper special preparation of the adjacent teeth preparatory to implant placement. Accurate tooth position and guidance is an essential prerequisite to effective implant planning and restoration.

Treatment Phase (eFig. 56B.8)

Direct Anchorage



EFIG. 56B.8 Flowchart for treatment plan.

In one form of direct anchorage, distalization is achieved through TAD placement and activation (see eFig. 56B.1). In other cases, implants are placed in dental locations to provide orthodontic anchorage and eventual tooth replacement (see eFig. 56B.2).

Indirect Anchorage

Indirect anchorage can utilize the buccal cortex (see eFig. 56B.3) or a palatal location (see eFig. 56B.4).

Space Management

An orthodontic fixed appliance may be utilized to restore space for implant replacement. Space is created not just at the coronal level but also at the interradicular level through proper root parallelism (see eFig. 56B.5).

Tooth loss and nonreplacement with subsequent drifting has a very different presentation than that of congenitally missing teeth, in that the teeth tend to tip into the edentulous space and are consequently much easier to correct. Tipping a crown to restore a previous tooth position is more easily achieved than torqueing a root (i.e., in the congenital case), which requires more movement in the apical region of the tooth (see eFig. 56B.6).

Hard and soft tissue changes accompany an eruption movement, as illustrated in eFig. 56B.7.

Orthodontic Acceleration

An interesting and promising new direction for the seemingly ubiquitous dilemma in orthodontics of reducing treatment duration has been receiving widespread attention; it deserves mention here because of the periodontal implications involved. Historically, orthodontists and their suppliers have sought to improve appliance efficiency and hence treatment time, and the attention has been on the actual appliance. Developments such as low-friction wires, exotic alloys, temperature-sensitive archwires, and self-ligating brackets are just a few examples. However, more recently, research has turned to the actual biology of tooth movement.[c] Consequently, procedures and even devices aimed at the biologic responses to tooth movement have evolved. In a sense, for the first time, the host's response to orthodontic stimuli is being affected by procedures such as piezocision and micro-osteoperforation and stimulatory devices such as AcceleDent (by OrthoAccel Technologies, Houston, Texas) and VPro5 (by Propel Orthodontics, Milpitas, California). Both devices are discussed later in this chapter.

Learning Box 56B.4

Orthodontic acceleration techniques have arisen that are proving to be effective at reducing treatment time for tooth movement. Historically, the focus for finding greater efficiencies in orthodontics has been upon the actual appliance mechanics and devices, but more recently stimulation of the body's remodeling capacity has become the focus. These new modalities offer stimulation that can be achieved through surgical intervention (e.g., decortication and microperforation), vibratory stimulation, or micropulsation. Other modalities being studied include heat and light applications.

Surgical Methods

The various surgical types of acceleration procedure seem to have in common the intent of decortication of the alveolar bone—locally, partially, or more extensively, depending on the procedure. In any

case, some form of injury to the periodontium is inflicted and triggers the cytokinetic and chemokinetic reactions that are known to recruit cytoblastic precursors. These precursors stimulate cytoblastic differentiation, which promotes the healing and remodeling of tissue that is also necessary for tooth movement. In this way, the body's response to the application of orthodontic force is accelerated.

PAOO (periodontally accelerated osteogenic orthodontics) was the first such surgical endeavor; it has also been termed "Wilckodontics" after its pioneers.[18,70] The technique involves elevation of full-thickness mucoperiosteal flaps and cortical cuts or perforations. This, in turn, recruits cellular responses that promote bone healing and remodeling, thereby accelerating bone turnover and tooth movement. PAOO is often combined with particulate bone grafting techniques that seemingly incorporate very effectively.

An apparently less intrusive surgical technique of piezocision was later developed that obviates the need for mucoperiosteal flaps by providing a similar decortication through gingival incisions. Healing and discomfort with this method are reportedly improved while it provides a similar effect. The ability to deliver bone grafting material is lost, however.

The next development was micro-osteoperforation.[54,55] In this technique, a surgical-grade screw device is used transmucosally to provide the cortical injury. This device, manufactured by Propel Orthodontics, is the least invasive of the surgical modalities. Propel's Alveocentesis procedure features the option of localized delivery, as might be indicated in the case of a recalcitrant tooth that needs to be stimulated. The depth of the micro-osteoperforation can be controlled to accommodate various locations through clever design of the device.

Stimulatory Devices

Electronic stimulatory devices have also been developed. These methods attempt to harness the same healing cascade that surgical endeavors attempt to initiate, but rather than accomplishing this through actual injury, they rely on micropulsation, or vibratory stimulus.[d] This technology has been explored and successfully

employed in orthopedic science.[51,53]

The first of these devices is the AcceleDent by Orthoaccel. It features a microprocessor that delivers a micropulsation stimulus to the dentition through a bite block. It is worn for 20 minutes every 24 hours and delivers its pulse at a frequency and amplitude that are reportedly most conducive to cytokine recruitment, which is necessary for accelerated bone turnover.

A similar device is the VPro5 by Propel, which functions in similar fashion but delivers its pulse at a higher frequency. It is reportedly equally effective as the AcceleDent device but requires just 5 minutes per day.

The exact effects of these devices and how they actually alter the dentoalveolar complex are not yet fully understood, but their results are promising, and further developments will likely be forthcoming.[19,50]

Conclusion

Significant and fascinating interplays exist between the practices of orthodontics and periodontics, which also includes implantology. Reciprocal relationships can be harnessed through proper sequencing of treatments to enhance outcomes. Utilization of various implants can facilitate orthodontic mechanotherapy, streamline treatment, eliminate compliance dependency, improve predictability and even introduce new treatment options. Conversely, orthodontic preparation prior to implant placement can yield a more favorable environment through orthodontically induced site development in which both hard and soft tissue can be augmented and remodeled. Further, spatial management of implant sites and neighboring tooth positions is often essential to ideal implant location.

Periodontal treatment preparatory to orthodontic treatment is often required to eliminate inflammation and bolster the investing tooth structures, thereby permitting successful tooth movement without further loss of attachment. Likewise, orthodontic modalities can be employed to remodel the hard and soft tissues of the periodontium to benefit various situations, such as defect eradication.

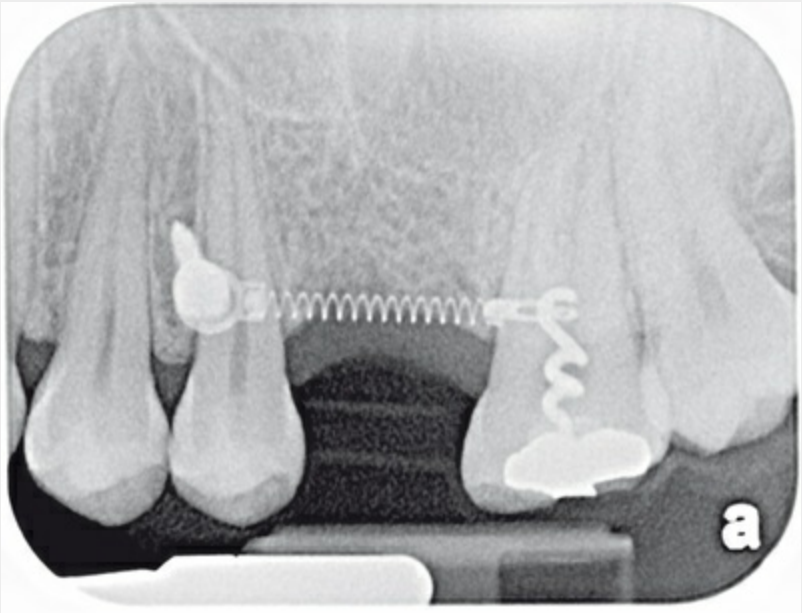
Consequently, there are many instances in which interdisciplinary interactions can facilitate treatment, and these interactions can be considered bidirectional. Thus implant utilization can sometimes enhance orthodontic outcomes, while other times orthodontic treatment should be employed to enhance implant outcomes. Just as applicable are the bidirectional possibilities between orthodontics and periodontics. This chapter has illustrated these concepts and has stressed the importance of proper sequencing of therapy to maximize these possibilities.

Case Scenario 56B.1

Patient:
26-year-old healthy male

Chief Complaint:
Nonrestorable upper left first molar

Background Information:
Patient is seeking orthodontic treatment for class I crowded dentition and is requesting an aligner appliance. A significant finding is that the upper left first molar is nonrestorable due to decay. The intact upper left second and third molars are deemed useful for transpositional replacement.



Current Findings:

The distoangular position of the upper left second and third molars is deemed favorable for their protraction into the first and second molar positions. Use of a TAD and power arm to apply force in conjunction with aligner sequencing will effect the movement.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. The appliance being utilized is an example of:	**Answer: D** **Explanation:** A miniscrew is placed buccally between the bicuspids and used solely for orthodontic facilitation; it will subsequently be

A. Indirect implant-assisted anchorage B. Indirect TAD-assisted anchorage C. Direct implant-assisted anchorage D. Direct TAD-assisted anchorage	explanted. Force is applied via a nickel-titanium coil spring directly applied to the head of the miniscrew.
2. The design of the appliance mechanotherapy is such that: A. The miniscrew and the spring provide the necessary force, and the aligners guide the movement. B. The aligners provide the necessary force, and the miniscrew and spring provide the guidance.	**Answer: A** **Explanation:** Force application is achieved by direct anchorage to the immovable miniscrew. A nickel-titanium coil spring between the screw and the power arm is secured by bonding to the buccal surface of the molar. A sequence of aligners is designed to guide the movement and contain the molars as they protract, preventing unwanted rotations.
3. Reciprocal movements are avoided because: A. The anchor system is independent of other teeth. B. The aligners embrace the entire dentition. C. Force is applied only to the teeth that are intended to move.	**Answer: D** **Explanation:** Extradental anchorage by virtue of miniscrew application applies force only to the teeth that are attached to it. The need to plan for reciprocal movement is obviated, and anchor control is not pertinent. The aligners are also programmed to control all teeth in the arch.

D. All of the above.	

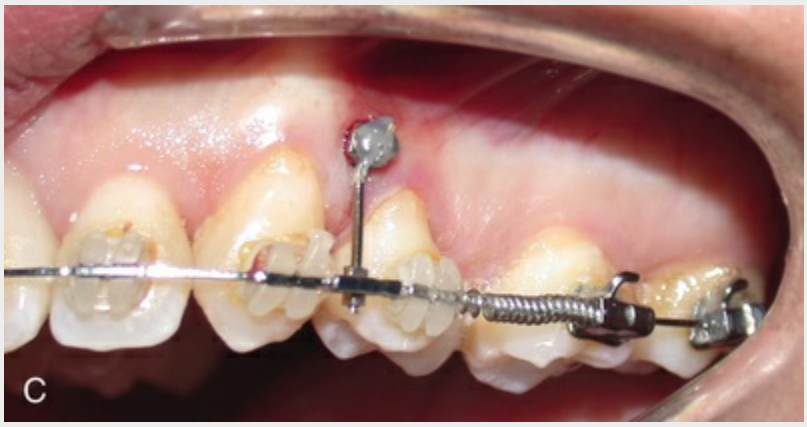
Case Scenario 56B.2

Patient:
32-year-old healthy female

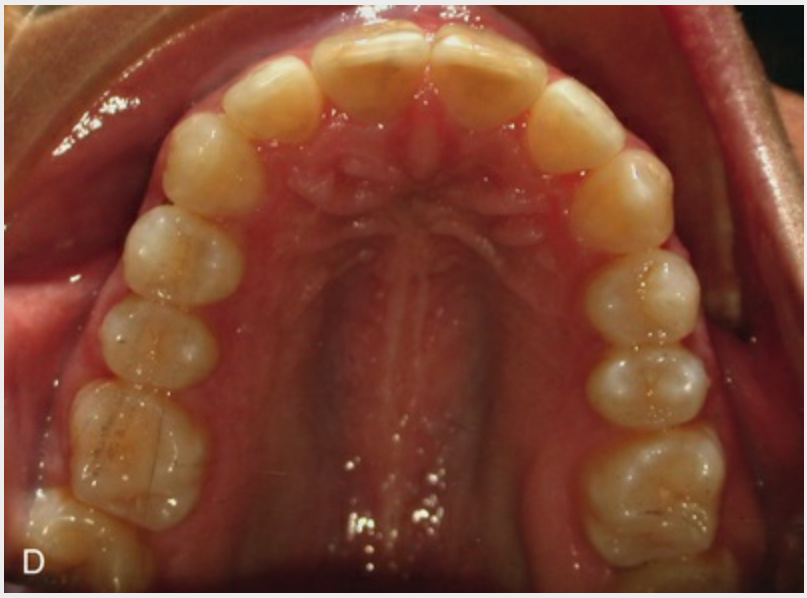
Chief Complaint:
Crowded dentition and overlapped incisors

Background Information:
Patient is seeking orthodontic treatment for cosmetic purposes and for long-term health of her dentition and periodontium. Patient reports difficulty in maintaining hygiene and is not happy with the appearance of her teeth.

B



C



Current Findings:

The bimaxillary dentition is crowded with retroclined maxillary incisors and class II molar relation on the left side. Distal driving of the upper left posterior teeth will provide for a class I molar relation and make space for buccal movement of the palatally displaced second bicuspid. Distal movement avoids the need for a bicuspid extraction to alleviate crowding. A TAD is placed between the bicuspids and used to stabilize the archwire and bicsupids so that force application is directed to the molars.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. The appliance being utilized is an example of: A. Indirect implant-assisted anchorage B. Indirect TAD-assisted anchorage C. Direct implant-assisted anchorage D. Direct TAD-assisted anchorage	**Answer: B** **Explanation:** A miniscrew is placed between the upper left bicuspids and utilized to prevent unwanted mesial movement of the first bicuspid by connecting it to the archwire with an auxiliary T-bar. A coil spring distal to the bicuspid applies a distal force to the molar. The indirect attachment of the TAD to the bicuspid prevents reciprocal movement.

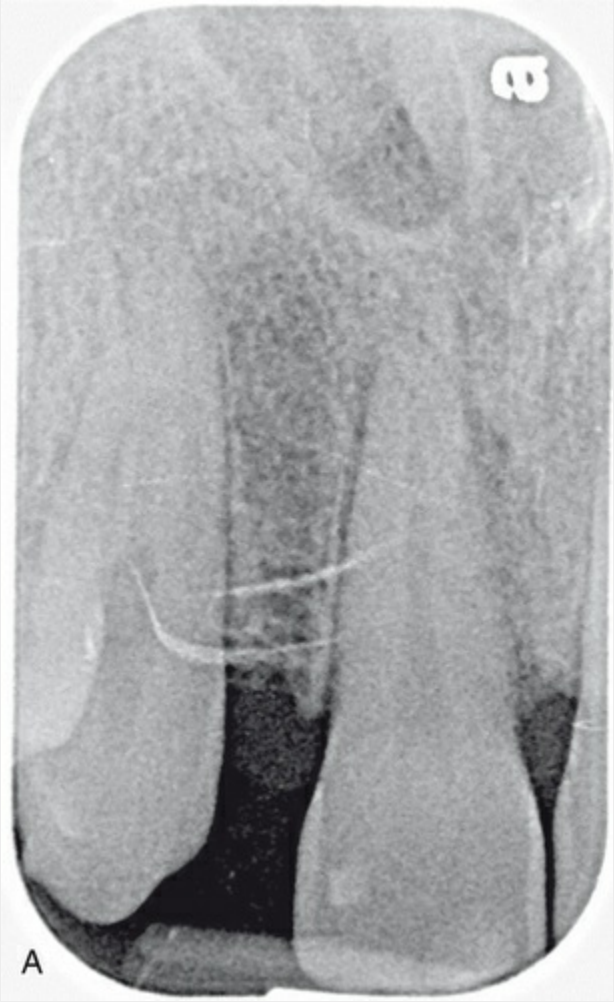
2. The design of the appliance mechanotherapy is such that: A. The miniscrew provides for indirect anchorage to the first bicuspid. B. The fixed appliance guides the movement. C. The open coil spring provides the force application. D. The TAD and T-bar prevent unwanted reciprocal movement. E. All of the above.	**Answer: E** **Explanation:** All of the above choices are true and describe the design of the mechanotherapy.
3. Distal driving of the posterior dentition in cases like this has which added feature(s)? A. It can restore a class I molar relation. B. It can prevent the need for an extraction. C. It can just as easily be achieved without TAD inclusion. D. A and B only	**Answer: D** **Explanation:** The use of indirect anchorage in this case allows the force application to drive the posterior dentition distally to restore a class I molar relation. This in turn increases arch length and provides the space necessary to incorporate the palatally displaced bicuspid into the arch. However, without the extradental source of indirect anchorage, unwanted reciprocal mesial movement would occur, increasing the anterior overjet.

Case Scenario 56B.3

Patient:
56-year-old healthy male with congenitally missing maxillary lateral incisor

Chief Complaint:
Unattractive upper dentition with spaces and missing teeth

Background Information:
Patient was referred to orthodontics by his restorative dentist. Patient is seeking a more aesthetic appearance for his upper dentition. Restoration of the missing lateral incisor requires space management, either for a fixed prosthesis to provide for a full-size lateral incisor or, if root alignment can be achieved, for implant replacement of the missing tooth.



Current Findings:

The patient is missing the upper right lateral incisor, and the adjacent central incisor and cuspid teeth encroach on the root space

necessary for implant placement. At the coronal level, there is insufficient space for a full-size lateral incisor. Orthodontic therapy was used for special site development to allow for implant placement and restoration. Total treatment time was 1.5 years and included orthodontic acceleration for expedition.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. This case is an example of: A. Implant-assisted direct orthodontic anchorage B. Implant-assisted indirect orthodontic anchorage C. Orthodontic special site development D. Orthodontic tissue augmentation	**Answer: C** **Explanation:** Orthodontic therapy was employed to develop an implant site by proper root paralleling of the central incisor and cuspid teeth to allow for implant placement. Concomitantly, space for restoration at the coronal level was provided to allow a full-size lateral incisor to be restored. Implant placement occurred at the completion of orthodontic treatment and the implant was not used for anchorage at any time; its sole purpose was tooth replacement.
2. The orthodontic mechanotherapy: A. Is immaterial to the outcome. B. Must provide for proper root alignment. C. Should be monitored periodically by radiography. D. Can be easily monitored by measuring the developing intercoronal distance. E. B and C only	**Answer: E** **Explanation:** The design and execution of the orthodontic appliance are critical to a successful outcome. Root alignment and parallelism are essential to allow for the eventual placement of an implant between the adjacent teeth. Measuring the developing coronal space as the cuspid and central incisor are separated does not ensure that the roots are parallel; radiographic monitoring is necessary to ensure that interradicular site development is occurring.
3. Which of the following is the proper sequencing of this case type? A. Early	**Answer: D** **Explanation:** Orthodontic therapy must precede implant placement because of special deficiency in the proposed site. The eventual implant is used solely for tooth replacement and plays no role in anchor provision.

implant placement to allow for implant anchorage B. Implant placement prior to orthodontic treatment to allow for integration C. Orthodontic site development after implant placement D. Orthodontic site development followed by implant placement

CHAPTER OUTLINE

Objectives of the Surgical Phase
Pocket Elimination Versus Pocket Maintenance
Reevealuation After Phase I Therapy
Critical Zones in Pocket Surgery
Indications for Periodontal Surgery
Methods of Pocket Therapy
Conclusions

Therapy for periodontal disease, which encompasses many techniques and procedures, depends on the disease status and objective of the final outcome. Early problems can be corrected with successful phase I therapy, consisting of biofilm removal by the patient on a daily basis, scaling, and root planing when necessary.

Many moderate to advanced cases cannot be resolved without surgically gaining access to the root surface for root planing and

reducing or eliminating pocket depth to allow the patient to remove biofilm. The surgical phase of therapy is also referred to as phase II therapy. This chapter describes the surgical techniques used for the following purposes:

- Controlling or eliminating periodontal disease
- Correcting anatomic conditions that favor periodontal disease, impair aesthetics, or impede placement of prosthetic appliances
- Placing implants to replace lost teeth and improving the environment for their placement and function

Many cases are successfully treated and maintained by phase I therapy. The chapters in Section V discuss the techniques and concepts used to treat periodontal diseases that require a surgical approach to reduce or eliminate pockets and obtain access to the root surface to remove accretions.

Objectives of the Surgical Phase

The surgical phase of periodontal therapy has the following objectives:

1. To improve the prognosis for teeth and their replacements
2. To improve aesthetics

Surgical techniques are used for pocket therapy and for correction of related morphologic problems (i.e., mucogingival defects). In many cases, therapies are combined to provide one surgical intervention that fulfills both objectives.

Surgical techniques (1) increase access to the root surface, allowing the clinician to remove all irritants; (2) reduce or eliminate pocket depth, making it possible for the patient to maintain the root surfaces free of biofilm; and (3) reshape soft and hard tissues to attain a harmonious topography. Resective or regenerative surgery,

or both, is used to reduce pocket depth (Box 57.1) (see Chapters 60 to 61).

Box 57.1

Periodontal Surgery

Pocket Reduction Surgery

- Resective (e.g., gingivectomy, apically displaced flap, undisplaced flap with or without osseous resection)
- Regenerative (e.g., flaps with grafts, membranes)

Correction of Anatomic or Morphologic Defects

- Plastic surgery techniques used to widen attached gingiva (e.g., free gingival grafts)
- Esthetic surgery (e.g., root coverage, recreation of gingival papillae)
- Pre-prosthetic techniques (e.g., crown lengthening, ridge augmentation, vestibular deepening)
- Placement of dental implants, including techniques for site development for implants (e.g., guided bone regeneration, sinus grafts)

The second objective of phase II therapy is to correct anatomic defects that favor plaque or biofilm accumulation and pocket recurrence or impair aesthetics. The aim of correcting anatomic problems is to alter defects of the gingival and mucosal tissues that predispose these areas to disease. Three types of techniques are performed on noninflamed tissues and in the absence of periodontal pockets (see Box 57.1):

- *Plastic surgery techniques* are used to create or widen the attached keratinized gingiva by placing grafts of various types.

- *Aesthetic surgery techniques* are used to cover denuded root surfaces resulting from recession and to recreate lost papillae.
- *Pre-prosthetic techniques* are used to modify the periodontal and neighboring tissues to receive prosthetic replacements. They include crown lengthening, ridge augmentation, and vestibular deepening.

Fig. 57.1 provides a three-tiered classification of the surgical procedures used in periodontics: pocket reduction surgery, periodontal plastic surgery, and pre-prosthetic surgery. Pocket reduction surgery consists of resective and regenerative procedures, and periodontal plastic surgery includes aesthetic and gingival augmentation (anatomic) procedures. Crown lengthening, ridge augmentation, and implant procedures are listed under pre-prosthetic surgery. Plastic and aesthetic surgery techniques are explored in Chapter 65, and pre-prosthetic techniques are discussed in Chapter 69.

FIG. 57.1 Classification of periodontal surgery. The surgical procedures accomplished in periodontics are organized as pocket reduction surgery, periodontal plastic surgery, and pre-prosthetic surgery.

Periodontal surgical procedures also are available for the placement of dental implants. They include implant placement techniques and a variety of surgical procedures to modify neighboring tissues for the placement of implants. Bone augmentation of the sinus floor or for a narrow edentulous ridge is an example (see Box 57.1). These topics are discussed in Chapters 79 and 80.

Surgical Pocket Therapy

Surgical pocket therapy can be used to gain access to the diseased root surface to ensure the removal of calculus located subgingivally before surgery and to eliminate or reduce the depth of the periodontal pocket.

Successful periodontal therapy completely eliminates calculus, plaque or biofilm, and diseased cementum from the tooth surface. Numerous investigations have shown that the difficulty of this task increases as the pocket becomes deeper.[2,5] The irregularities and concavities on the root surface also increase, which adds to the difficulty of instrumenting the root surfaces.[11,15] Furcations also create problems for scaling and root planing in these areas[4] (see Chapter 50). Most of these problems can be remedied by resecting or displacing the soft tissue wall of the pocket, which increases the visibility and accessibility of the root surface.[3] The surgical flap technique allows the clinician to overcome these problems of access to the root surface.

Pocket elimination is another important consideration. It consists of reducing the depth of the periodontal pocket to that of a physiologic sulcus to enable cleaning by the patient. By proper case selection, resective and regenerative techniques can be used to accomplish this goal. A pocket makes it impossible for the patient to remove biofilm, which is part of the vicious cycle depicted in Fig. 57.2.

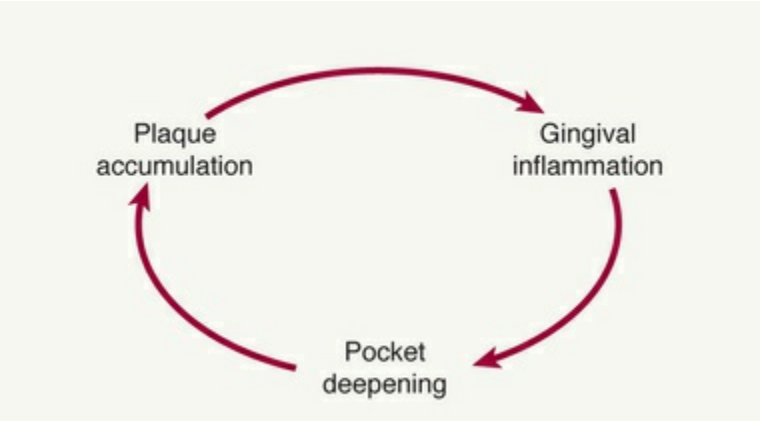

FIG. 57.2 Accumulation of plaque leads to gingival inflammation and pocket deepening, which increases the area of plaque accumulation.

Results of Pocket Therapy

A periodontal pocket can be in an active state or a period of inactivity or quiescence. In an active pocket, underlying bone is being lost (Fig. 57.3, *top left*). It often is diagnosed clinically by bleeding that occurs spontaneously or in response to probing. After phase I therapy, the inflammatory changes in the pocket wall subside, rendering the pocket inactive and reducing its depth (see Fig. 57.3, *top center*). The extent of this reduction depends on the depth before treatment and the degree to which the depth is the result of the edematous and inflammatory component of the pocket wall (i.e., pseudopocket).

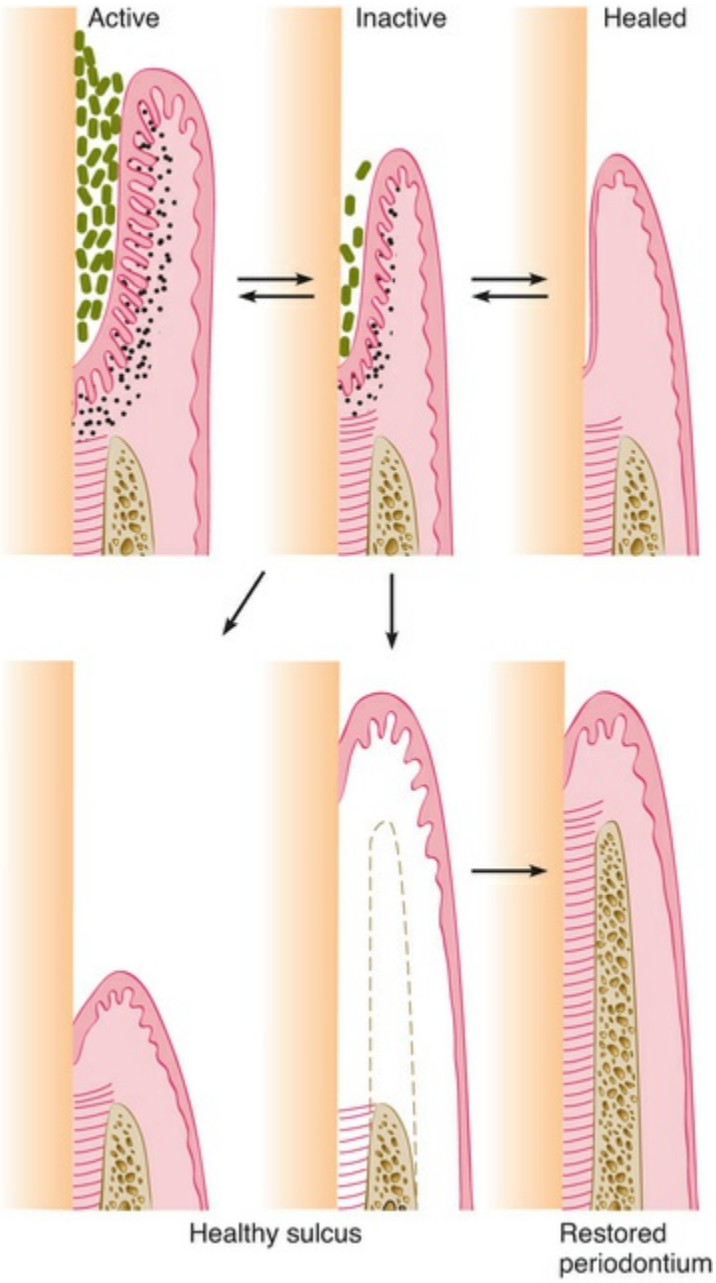

FIG. 57.3 Possible results of pocket therapy are shown. An active pocket can become inactive and heal by means of a long junctional epithelium. Surgical pocket therapy can result in a healthy sulcus, with or without gain of attachment. Improved gingival attachment promotes restoration of bone height, with re-formation of periodontal ligament fibers and layers of cementum.

Whether the pocket remains inactive depends on the depth, the individual characteristics of the plaque or biofilm components, and the host response. Recurrence of the initial activity is likely.

Inactive pockets sometimes heal with a long junctional epithelium (see Fig. 57.3, *top right*). This condition can be unstable, and the chance of recurrence and re-formation of the original pocket remains because the epithelial union with the tooth is weak. However, one study in monkeys showed that the long junctional epithelial union could be as resistant to biofilm infection as a true connective tissue attachment.[9]

Several studies reported that inactive pockets could be maintained for long periods with little loss of attachment by means of frequent therapy[6,10,12] and by excellent plaque or biofilm removal by the patient on a daily basis. A more reliable and stable result is obtained by transforming the pocket into a healthy sulcus. The bottom of the healthy sulcus can be located where the bottom of the pocket was localized or coronal to it. In the first case (see Fig. 57.3, *bottom left*), there is no gain of attachment, and the area of the root that was previously the tooth wall of the pocket becomes exposed. Rather than causing recession, periodontal treatment uncovers the recession previously caused by disease.

The healthy sulcus can be located coronal to the bottom of the preexisting pocket (see Fig. 57.3, *bottom center* and *right*). This is conducive to a restored marginal periodontium; the result is a sulcus of normal depth with a gain of attachment. The creation of a healthy sulcus and a restored periodontium entails total restoration of the status that existed before periodontal disease began, which is the ideal result of treatment. The bone regeneration diagram in Fig. 57.3 (*bottom center* and *right)* is for illustrative purpose only because bone regeneration without an osseous wall is seldom achieved (see Chapter 24).

Pocket Elimination Versus Pocket Maintenance

Pocket elimination (i.e., depth reduction to gingival sulcus levels) has traditionally been considered a type of periodontal therapy. It was considered vital because of the need to improve access to root surfaces for the therapist during treatment and for the patient after healing. Prevailing opinion considers deep pockets after therapy to

represent a greater risk of disease progression than shallow sites. Individual probing depths are not good predictors of future clinical attachment loss. Conversely, the absence of deep pockets in treated patients is an excellent predictor of a stable periodontium.[5]

Longitudinal studies of different therapeutic modalities over the past 30 years have produced conflicting results,[7,16] probably because of problems created by the split-mouth design. After surgical therapy, pockets that rebound to a shallow or moderate depth can be maintained in a healthy state and without radiographic evidence of advancing bone loss by maintenance visits consisting of scaling and root planing, with oral hygiene reinforcement performed at regular intervals of 3 months or less. In these patients, the residual pocket can be examined with a thin periodontal probe without pain, exudate, or bleeding. This indicates that biofilm has not formed on the subgingival root surfaces.

These findings do not alter the indications and need for periodontal surgery because the results are based on surgical exposure of the root surfaces for thorough elimination of irritants. However, the findings also emphasize the importance of the maintenance phase and close monitoring of the level of attachment and pocket depth along with the other clinical variables (e.g., bleeding, exudation, tooth mobility). *Transformation of the initial deep, active pocket into a shallower, inactive, maintainable pocket requires some form of definitive pocket therapy and constant supervision thereafter.*

Pocket depth is an extremely useful and widely employed clinical determination, but it must be evaluated together with the level of attachment and degree of bleeding, exudation, and pain. The most important variable for evaluating whether a pocket is progressing is the *level of attachment,* which is measured in millimeters from the cementum–enamel junction. Apical displacement of the level of attachment places the tooth in jeopardy, not the increase in pocket depth, which may be caused by coronal displacement of the gingival margin.

Pocket depth remains an important clinical variable in making decisions about treatment. Lindhe and colleagues[8] compared the effect of root planing alone or using a modified Widman flap with the resultant level of attachment and in relation to initial pocket depth. They reported that scaling and root planing procedures

induced loss of attachment if performed in pockets shallower than 2.9 mm, whereas gain of attachment occurred in deeper pockets. The modified Widman flap induced loss of attachment if performed in pockets shallower than 4.2 mm but resulted in a greater gain of attachment than root planing in pockets deeper than 4.2 mm. The loss is a true loss of connective tissue attachment, whereas the gain can be considered a false gain because of reduced penetrability of connective tissues apical to the bottom of the pocket after treatment.[9,17]

Probing depths established about 6 months after active therapy and healing can be maintained, remain unchanged, or be reduced even further during a maintenance period involving careful reevaluation, plaque or biofilm removal, and root therapy as necessary every 3 months.[8]

Ramfjord[12] and Rosling[13] and their colleagues reported that a certain pocket depth recurs regardless of the surgical technique used for pocket therapy. *Maintaining this depth without any further loss of attachment becomes the goal.*

Reevaluation After Phase I Therapy

Longitudinal studies found that all patients should be treated initially with scaling, root planing, and plaque or biofilm control and that a final decision on the need for periodontal surgery should be made only after a thorough evaluation of the effects of phase I therapy.[5] Assessment typically is made no less than 1 to 3 months and sometimes as much as 9 months after the completion of phase I therapy.[1] Reevaluation of the periodontal condition includes repeat probing of the entire mouth. Calculus, root caries, defective restorations, and signs of persistent inflammation should also be evaluated.

Critical Zones in Pocket Surgery

Criteria for the selection of a surgical technique for pocket therapy are based on clinical findings in the soft tissue pocket wall, tooth surface, underlying bone, and attached gingiva.

Zone 1: Soft Tissue Pocket Wall

The clinician should determine the morphologic features, thickness, and topography of the soft tissue pocket wall and persistence of inflammatory changes in the wall.

Zone 2: Tooth Surface

The clinician should identify the deposits on and alterations of the cementum surface and determine the accessibility of the root surface to instrumentation. Phase I therapy should have solved many or all of the problems on the tooth surface. Evaluation of the results of phase I therapy can determine the need for further therapy and the method to be used.

Zone 3: Underlying Bone

The clinician should establish the shape and height of the alveolar bone next to the pocket wall through careful probing and clinical and radiographic examinations. The number of osseous walls—one, two, or three—helps to determine whether resective or regenerative therapy can be used (see Chapter 24). Bony craters, horizontal or angular bone losses, and other bone deformities also are important criteria in selection of the treatment technique.

Zone 4: Attached Gingiva

The clinician should consider the presence or absence of an adequate band of keratinized, attached gingiva when selecting the pocket treatment method. Diagnostic techniques for mucogingival problems are described in Chapter 65. An inadequate attached gingiva can be caused by a high frenum attachment, marked gingival recession, or a deep pocket that reaches the level of the mucogingival junction. All of these conditions should be explored and their influence on pocket therapy considered.

Indications for Periodontal Surgery

The following findings can indicate the need for a surgical phase of

therapy:

1. Areas with irregular bony contours, deep craters, and other defects usually require a surgical approach.
2. Pockets around teeth where access to the root surface for complete removal of root irritants is not clinically possible are an indication for surgery. This occurs frequently around molars and premolars.
3. Furcation involvement of grade II or III may require a surgical approach to ensure the removal of irritants around root surfaces. If root resection or hemisection is necessary, surgical intervention will be needed.
4. Intrabony pockets distal to the last molars, which in many cases are complicated by mucogingival problems, often require surgery.
5. Persistent inflammation in areas after past procedures that have moderate to deep pockets may require a surgical approach. These are usually areas where all of the subgingival calculus could not be removed. Cases with shallow pockets and good hygiene but bleeding on probing can be caused by mucogingival problems in areas where there is no keratinized tissue. Trauma to these areas can cause bleeding.

Methods of Pocket Therapy

The methods for pocket therapy can be classified as follows:

1. *New attachment techniques* offer the ideal result because they eliminate pocket depth by reuniting the gingiva with the tooth at a position coronal to the bottom of the preexisting pocket. New attachment involves regeneration of bone, connective tissue, periodontal ligament, and cementum.
2. *Removal of the pocket wall* is the most common method. The wall of the pocket consists of soft tissue and can include bone in the case of intrabony pockets. It can be removed by the following methods:
    - Retraction or shrinkage, where plaque or biofilm

removal by the patient and scaling and root planing resolve the inflammatory process, can occur. The gingival tissue shrinks, reducing the pocket depth.
- Surgical removal of the pocket is done by gingivectomy or the undisplaced flap technique.
- Apical displacement of the flap is performed with an apically displaced flap.

3. *Removal of the tooth side of the pocket*, which is accomplished by tooth extraction or by partial tooth extraction in the case of furcation involvement (i.e., hemisection or root resection).

The techniques, what they accomplish, and the factors governing their selection are discussed in Chapters 60 through 63.

Criteria for Selection of the Method of Surgical Therapy

Scientific criteria to establish indications for the use of each technique are difficult to determine. Criteria are based on longitudinal studies that follow a significant number of cases over a number of years, standardization of multiple factors, and long-term clinical experience. Selection of a technique for treating a particular periodontal lesion is based on the following considerations:

1. Characteristics of the pocket: depth, relation to bone, and configuration
2. Accessibility to instrumentation, including furcation involvement
3. Existence of mucogingival problems
4. Response to phase I therapy
5. Patient cooperation, including the ability to perform effective oral hygiene and stop smoking
6. Age and general health of the patient
7. Overall diagnosis of the case: various types of gingival enlargement and types of periodontitis (e.g., chronic marginal periodontitis, localized aggressive periodontitis, generalized aggressive periodontitis)

8. Aesthetic considerations
9. Previous periodontal treatments

Each variable is analyzed in relation to the pocket therapy techniques available. A specific technique is then selected. The one most likely to successfully solve the problem with the fewest undesirable effects should be selected. Clinicians who adhere to one technique to solve all problems do not take advantage of the wide repertoire of techniques that are at their disposal.

Approaches to Specific Pocket Problems

Therapy for Gingival Pockets

Gingival pockets do not have an osseous component (i.e., no attachment loss) and usually have edematous or fibrotic gingival tissue. Two factors are taken into consideration: the character of the pocket wall and the accessibility of the pocket.

The pocket wall can be edematous or fibrotic. *Edematous tissue* shrinks after the elimination of local factors, reducing or totally eliminating pocket depth. Scaling and root planing is the technique of choice for these cases.

Pockets with a *fibrotic wall* are not appreciably reduced in depth after scaling and root planing. These pockets are eliminated or reduced by surgical therapy. In the past, gingivectomy was frequently used to reduce these pockets. This solved the problem, but in cases of marked gingival enlargement (e.g., severe phenytoin-related enlargement), treatment could leave a large, open wound, and the patient had to endure a painful and prolonged healing process. Currently, a modified flap technique is used, and fewer postoperative problems are associated with primary closure of the wound (see Chapter 61). Some clinicians have advocated the use of laser therapy to manage gingival enlargement (see Chapter 68),

Therapy for Incipient Periodontitis

In patients with slight or incipient periodontitis with minimal attachment and bone loss, the pocket depths are shallow or a moderate depth. In these patients, the conservative approach of

good oral hygiene, scaling, and root planing when necessary usually suffices to control the disease. Incipient periodontitis that recurs in previously treated sites with good hygiene may require a thorough analysis of the recurrence, which may be caused by remnants of calculus that were missed during previous treatment or other factors such as open margins of a restoration located subgingivally. Occasionally, a surgical approach may be required to correct these problems.

Therapy for Moderate to Severe Periodontitis in the Anterior Sector

Because the maxillary anterior teeth are important aesthetically, techniques that cause the least amount of visual root exposure should be considered. However, each patient has different expectations regarding the final result of therapy. The clinician must explain that the therapy may be a compromise between complete pocket elimination and achieving an aesthetic result that is acceptable to the patient. The patient must be educated before therapy that the result may be some degree of gingival recession and some loss of the interdental papilla (see Chapter 65).

The anterior dentition has two advantages for using a conservative (nonsurgical) approach: (1) the teeth are all single rooted and easily accessible for subgingival scaling and root planing, and (2) patient compliance and thoroughness in plaque or biofilm control may be easier to attain. *Nonsurgical therapy is therefore the technique of choice for the maxillary anterior dentition.*

In some situations, surgical therapy may be necessary to improve accessibility for root planing, or regenerative therapy may be possible. Chapters 59, 60, and 63 discuss the surgical aspects in detail. The papilla preservation flap or modified papilla preservation flap can be used for both purposes and offers a better postoperative result with less recession and reduced soft tissue crater formation interproximally.[14]

When the interdental space is minimal, papilla preservation techniques may not be feasible. Instead, a technique that splits the papilla and retains as much of the papilla as possible is the appropriate surgical technique.

When the aesthetic outcome is not the primary consideration and

a flap procedure is necessary for root surface access, the *modified Widman flap* can be selected. This technique uses an internal bevel incision about 1 to 2 mm from the gingival margin without thinning the flap. This procedure may result in minor recession of the surrounding gingival tissue.

In cases with advanced osseous involvement, bone contouring may be needed despite the resultant root exposure. The technique of choice is the *apically displaced flap with osseous bone contouring*. The clinician must educate the patient before therapy about the possibility of aesthetic difficulties due to the expected recession of gingival tissue.

Therapy for Moderate to Severe Periodontitis in Posterior Areas

Treatment for the maxillary and mandibular premolars and molars does not entail aesthetic problems but frequently involves difficult access for root therapy. Bone defects occur more often in the posterior area than the anterior, with many areas having deep infrabony lesions and anatomic root problems with concavities, such as the mesial surface of the maxillary first premolar. A difficult problem encountered in the posterior area is the furcation lesion. Because this area can pose insurmountable problems for instrumentation unless a flap is reflected, surgery is frequently indicated.

Surgery is used in the posterior area for enhanced access to the root surface or for definitive pocket reduction requiring osseous surgery. Access can be obtained by an undisplaced or apically displaced flap (see Chapter 60).

Most patients with moderate to severe periodontitis have developed osseous defects that require some degree of bone remodeling or reconstruction. For osseous defects amenable to reconstruction, the *papilla preservation flap* or *modified papilla preservation flap* is the technique of choice because it better protects the interproximal areas where defects frequently occur. Second and third choices are the *sulcular flap* and *modified Widman flap,* maintaining as much of the papilla as possible.

For osseous defects with no possibility of reconstructive therapy, such as interdental craters, the technique of choice is an

undisplaced or apically displaced flap with osseous contouring. All surgical flap procedures are discussed in Chapters 57, 59, and 60.

Surgical Techniques for Correction of Morphologic Defects

The rationales and objectives for techniques performed to correct morphologic defects (i.e., mucogingival, aesthetic, and pre-prosthetic) are described in Chapters 60 and 62.

Surgical Techniques for Implant Placement and Related Problems

The rationales and objectives for techniques performed for implant placement and related problems are described in Chapters 78 through 80.

Conclusions

Many steps are required to achieve and maintain a healthy periodontal status. After completion of phase I therapy, which consists of patient education, biofilm control, and thorough root therapy, the involved periodontal areas are reevaluated. The necessity of phase II therapy, which is the surgical phase of treatment, depends on the success of the initial phase and the severity of the periodontal condition. Periodontal surgery, which includes plastic, aesthetic, resective, and regenerative procedures, becomes necessary when access for root therapy is required or correction of anatomic or morphologic defects is necessary. Placement of dental implants can be part of this therapy.

CHAPTER 58

Periodontal and Peri-Implant Surgical Anatomy

Perry R. Klokkevold, Fermin A. Carranza

CHAPTER OUTLINE

Mandible
Maxilla
Exostoses
Muscles
Anatomic Spaces
Conclusion

A sound knowledge of the anatomy of the periodontium and the surrounding hard and soft tissue structures is essential to determine the scope and possibilities of periodontal and implant surgical procedures and to minimize their risks. The spatial relationship of bones, muscles, blood vessels, and nerves, as well as the anatomic

spaces located in the vicinity of the periodontal or implant surgical field, are particularly important. Only those features of periodontal and implant surgery relevance are mentioned in this chapter; the reader is referred to books about oral anatomy for a more comprehensive description of these structures.[4,6]

Mandible

The mandible is a horseshoe-shaped bone connected to the skull by the temporomandibular joints. It presents several landmarks of great surgical importance for both periodontal and implant surgical procedures.

The *mandibular canal,* which is occupied by the inferior alveolar nerve and vessels, begins at the mandibular foramen on the medial surface of the mandibular ramus and curves downward and forward until it becomes horizontal below the apices of the molars (Fig. 58.1). The distance from the canal to the apices of the teeth is shortest in the third molar area. A small percentage (1%) of mandibular canals bifurcates in the body of the mandible, thereby resulting in two canals and two mental foramina.[5,10] In the premolar area, the mandibular canal divides in two branches, with one exiting the mandible and the other continuing anteriorly: the *incisive canal,* which continues horizontally to the midline, and the *mental canal,* which turns upward and opens in the mental foramen.

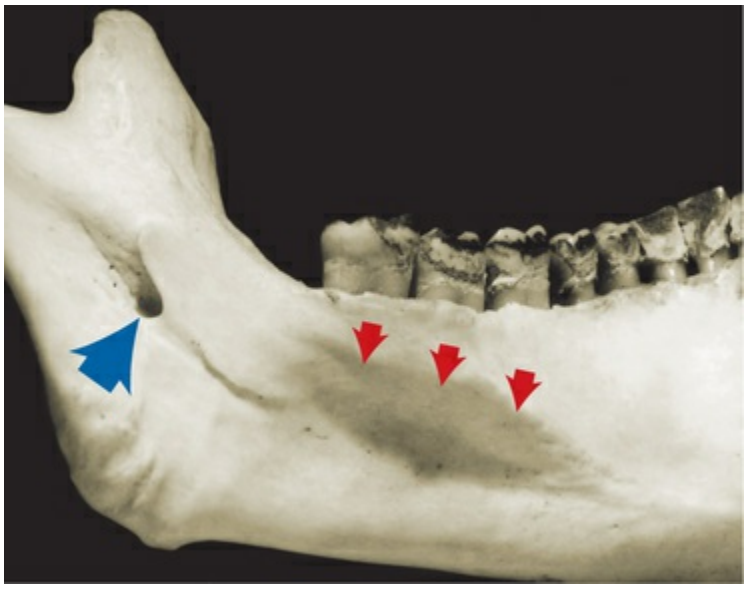

FIG. 58.1 Mandible, lingual surface view. Note the lingual or mandibular foramen *(blue arrow)*, where the inferior alveolar nerve enters the mandibular canal, and the mylohyoid ridge *(red arrows)*.

The *mental foramen,* from which the mental nerve and vessels emerge, is located on the buccal surface of the mandible below the apices of the premolars, sometimes closer to the second premolar and usually halfway between the lower border of the mandible and the alveolar margin (Fig. 58.2). It is often but not always visible on conventional radiographs. The opening of the mental foramen, which may be oval or round, typically faces upward and distally, with its posterior-superior border slanting gradually to the bone surface. An "anterior loop" of the mental foramen has been described, with the use of cadaver dissection, as a reverse turn and looping back of the mental nerve within the body of the mandible before its exit out of the mental foramen; the estimated length of the anterior loop ranges from 0.5 to 5.0 mm.[10] A more recent evaluation of the anterior loop of the mental nerve involving the use of cone beam scans and cadaveric dissection reported this loop extension to range from 0.0 to 9.0 mm.[22,23] The anterior loop of the mental nerve has a high prevalence (88%), symmetric occurrence, and a mean length of 4.13 ± 1.08 mm.[18] As it emerges, the *mental nerve* divides into three branches. One branch of the nerve turns forward and downward to supply the skin of the chin. The other two branches course anteriorly and upward to supply the skin and mucous membrane of the lower lip and the mucosa of the labial alveolar surface.

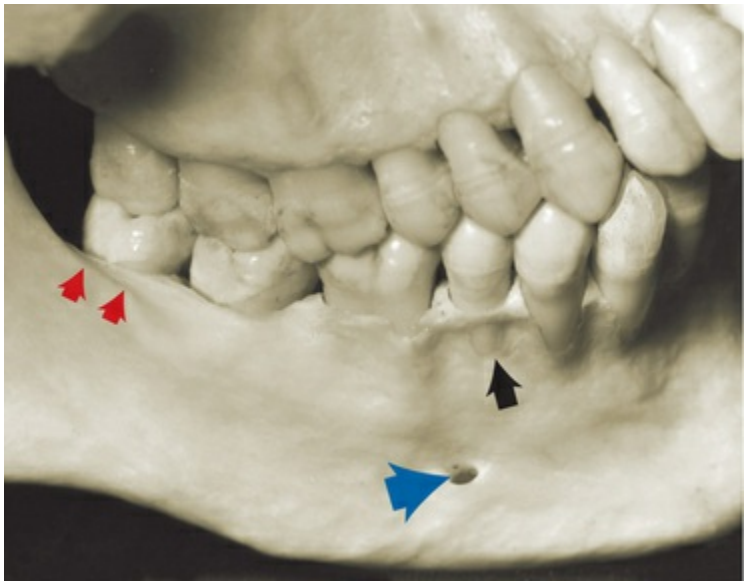

FIG. 58.2 **Mandible, facial surface view. Note the location of the mental foramen *(blue arrow)*, which is slightly distal and apical to the apex of the second premolar, and the shelflike area in the region of the molars *(red arrows)* that is created by the external oblique ridge. Note also the fenestration that is present in the second premolar *(black arrow).***

Surgical trauma (e.g., pressure, manipulation, postsurgical swelling) to the mental nerve can produce paresthesia of the lip, which recovers slowly. Partial or complete cutting of the nerve can result in permanent paresthesia, dysesthesia, or both. Familiarity with the location and appearance of the mental nerve reduces the likelihood of injury (Fig. 58.3).

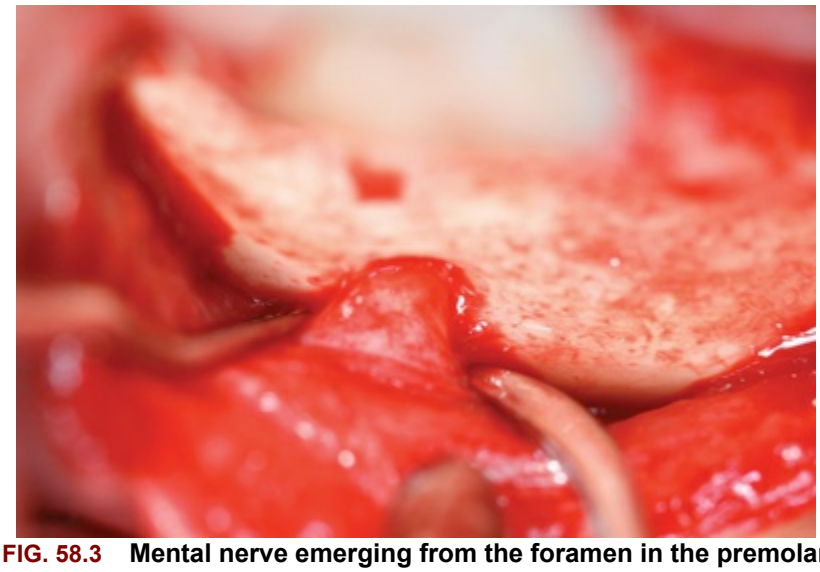

FIG. 58.3 **Mental nerve emerging from the foramen in the premolar area.**

Key Fact

Surgical trauma, including pressure, manipulation, or postsurgical swelling of the mental nerve tissues, may result in transient paresthesia of the lip. Partial or complete nerve cutting of the mental nerve may result in permanent paresthesia, dysesthesia, or both.

In partially or totally edentulous jaws, the disappearance of the alveolar portion of the mandible brings the mandibular canal and mental foramen closer to the superior border (Figs. 58.4 and 58.5). When these patients are evaluated for the placement of implants, the distance between the canal and the superior surface of the bone, as well as the location of the mental foramen, must be carefully determined to avoid surgical injury to the nerve (see Chapter 76).

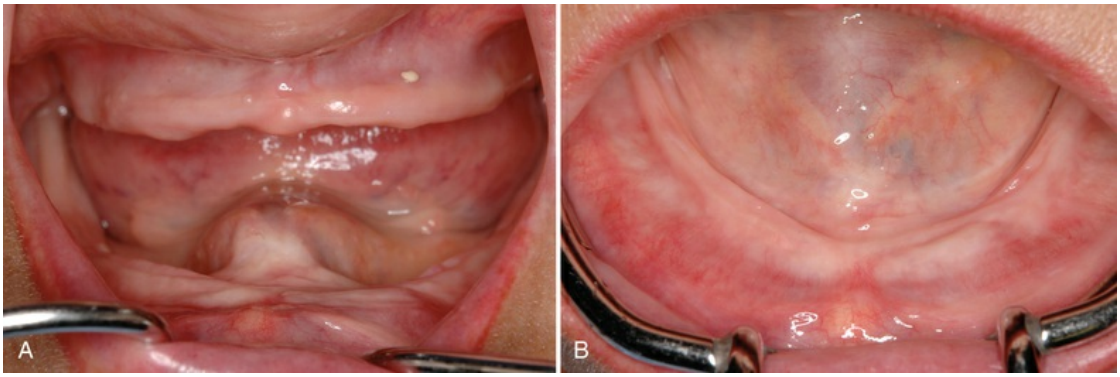

FIG. 58.4 Loss of the alveolar ridge in an edentulous patient brings the mental foramen and the inferior alveolar nerve canal closer to the surface, which may lead to discomfort for the patient. (A) Anterior view demonstrating a severe loss of vertical alveolar ridge height. (B) Occlusal view of the same patient demonstrating a loss of vestibular depth with alveolar bone loss.

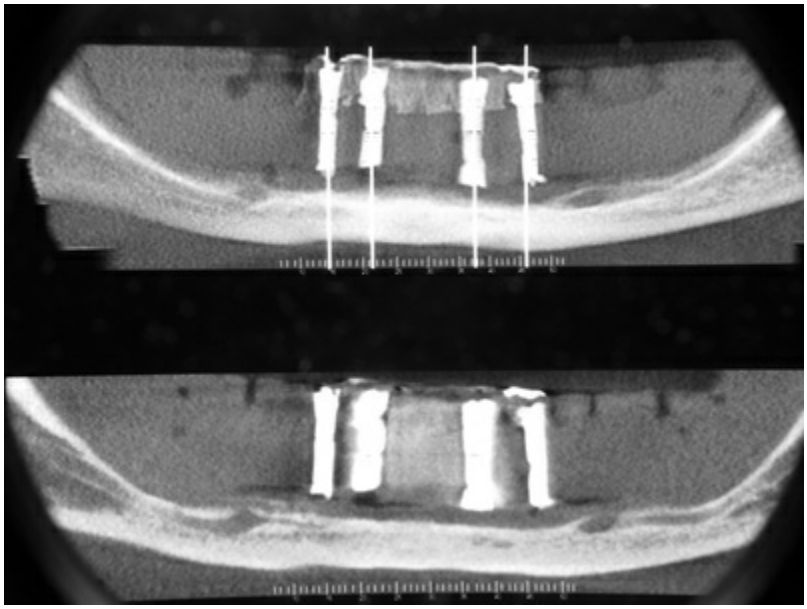

FIG. 58.5 **Panoramic radiograph of an edentulous patient with a loss of alveolar bone height. This results in the mental foramen exiting the jaw at the superior aspect of the remaining bone (ridge crest), which is the denture-bearing surface. Pressure from the complete removable denture over this area causes pain.**

The anterior extension of the inferior alveolar nerve or incisive nerve has been measured with the use of conventional radiographs, computed tomography (CT) scans, cadaver dissections, and cone beam scans.[3,10,22,23] This nerve, which is less evident on conventional radiographs and often unnoticed, extends beyond the anterior loop of the mental foramen in a horizontal direction toward the midline. The length of the incisive canal has been reported to be up to 21.45 mm from the mesial aspect of the mental foramen and to terminate just 4 mm from the midline.[3]

The *lingual nerve,* along with the inferior alveolar nerve, is a branch of the posterior division of the mandibular nerve. It descends along the mandibular ramus medial to and in front of the inferior alveolar nerve. The lingual nerve lies close to the surface of the oral mucosa in the third molar area and goes deeper as it travels forward (Fig. 58.6). It can be damaged during anesthetic injections and during oral surgery procedures (e.g., third molar extractions).[14] Less often, the lingual nerve may be injured when a periodontal partial-thickness flap is raised in the third molar region or when releasing incisions are made in the area.

FIG. 58.6 Lingual view of the mandible showing the pathway of the lingual nerve *(red)*, which goes near the gingiva in the third molar area and then continues forward, going deeper and medially.

The *alveolar process,* which provides the supporting bone to the teeth, has a narrower distal curvature than the body of the mandible (Fig. 58.7), thus creating a flat surface in the posterior area between the teeth and the anterior border of the ramus. This results in the formation of the *external oblique ridge,* which runs downward and forward to the region of the second or first molar (Fig. 58.8) to create a shelflike bony area. Resective osseous therapy may be difficult or impossible in this area because of the amount of bone that must be removed distally toward the ramus to achieve resection of a periodontal osseous defect on the distal aspect of the mandibular second or third molar.

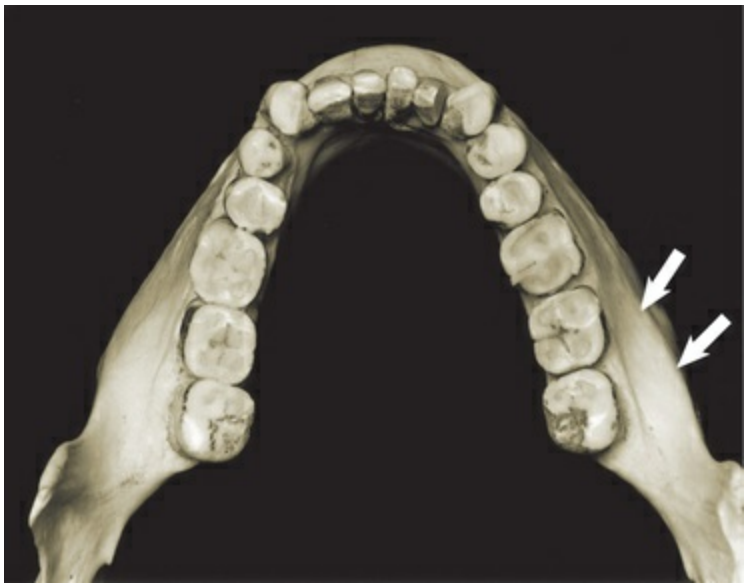

FIG. 58.7 **Occlusal view of the mandible. Note the shelf that is created in the facial molar areas by the external oblique ridge. *Arrows* show the attachment of the buccinator muscle.**

FIG. 58.8 Mandible; occlusal view of the ramus and molars. Note the retromolar triangle area distal to the third molar *(arrows).*

Distal to the third molar, the external oblique ridge circumscribes the *retromolar triangle* (see Fig. 58.8). This region is occupied by glandular and adipose tissue and covered by unattached, nonkeratinized mucosa. If sufficient space exists distal to the last

molar, a band of attached gingiva may be present; only in such a case can a distal flap procedure be performed effectively (see Chapter 60).

The medial side of the body of the mandible is traversed obliquely by the *mylohyoid ridge,* which starts close to the alveolar margin in the third molar area and continues anteriorly in an apical direction, thereby increasing its distance from the osseous margin as it travels forward (Fig. 58.9). The *mylohyoid muscle* inserts along this ridge and separates the *sublingual space,* which is located above or more anteriorly and superiorly, from the submandibular space, which is located below or more posteriorly and inferiorly.

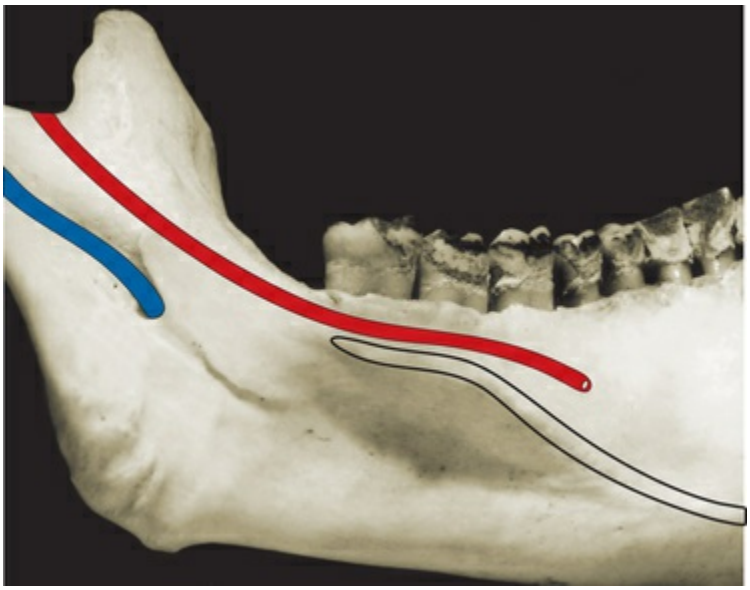

FIG. 58.9 Lingual view of the mandible showing, The inferior alveolar nerve entering the mandibular canal *(blue)*, the lingual nerve traversing near the lingual surface of the third molar *(red)*, and the attachment of the mylohyoid muscle inferiorly *(outline)*.

Maxilla

The maxilla is a paired bone that is hollowed out by the maxillary sinus and the nasal cavity. The maxilla has the following four processes:

- The *alveolar process* contains the sockets for and supports the maxillary teeth.
- The *palatine process* extends horizontally from the alveolar process to meet its counterpart from the opposite maxilla at the midline intermaxillary suture, and it extends posteriorly with the horizontal plate of the palatine bone to form the hard palate.
- The *zygomatic process* extends laterally from the area above the first molar and determines the depth of the vestibular fornix on the lateral aspect of the maxilla.
- The *frontal process* extends in an ascending direction and articulates with the frontal bone at the frontomaxillary suture.

The terminal branches of the nasopalatine nerve and vessels pass through the incisive canal, which opens in the midline anterior area of the palate (Fig. 58.10). The mucosa overlying the incisive canal presents a slight protuberance called the *incisive papilla.* Vessels that emerge through the incisive canal are of small caliber, and their surgical interference is of little consequence.

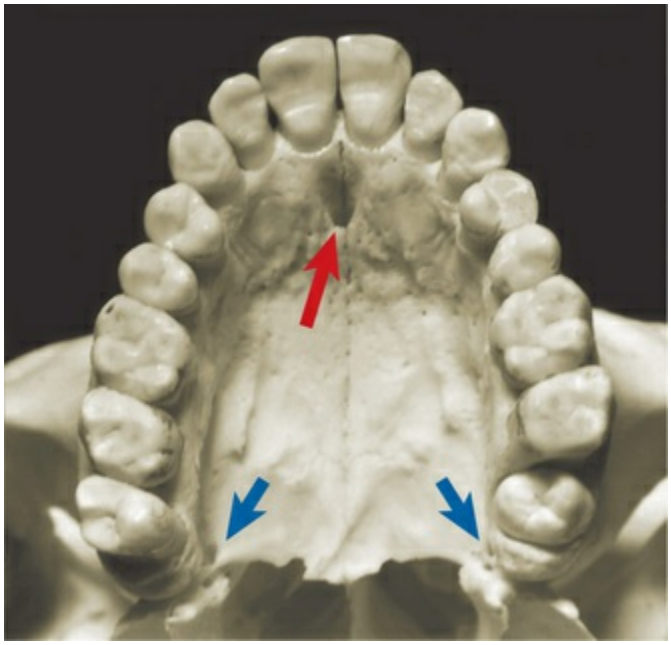

FIG. 58.10 **Occlusal view of the maxilla and the palatine bone. Note the opening of the incisive canal or the anterior palatine foramen *(red arrow)* and the greater palatine foramen *(blue arrows).***

The *greater palatine foramen* opens 3 to 4 mm anterior to the posterior border of the hard palate (Fig. 58.11). The greater palatine nerve and vessels emerge through this foramen and run anteriorly in the submucosa of the palate, between the palatal and alveolar processes (Fig. 58.12). Palatal flaps and donor sites for gingival and connective tissue grafts should be carefully performed and selected to avoid invading these areas because profuse hemorrhage may ensue, particularly if vessels are damaged at the greater palatine foramen. Vertical incisions in the molar region should be avoided.

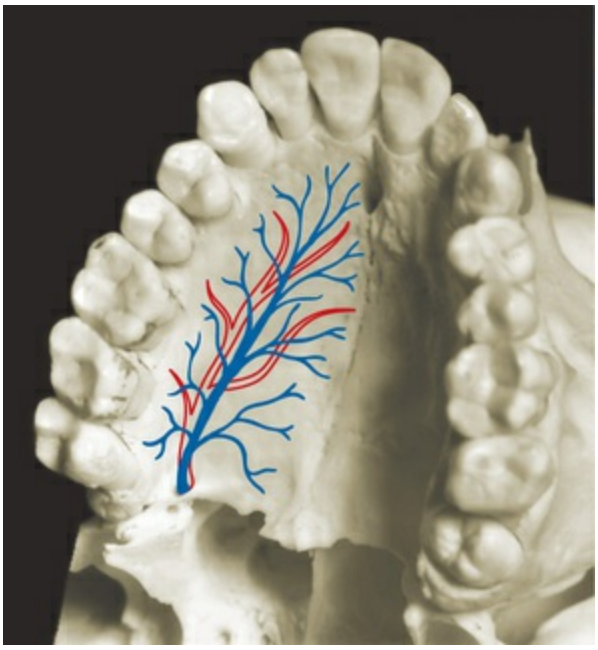

FIG. 58.11 Occlusolateral view of the palate showing nerves *(red)* and vessels *(blue)* emerging from the greater palatine foramen and continuing anteriorly on the palate.

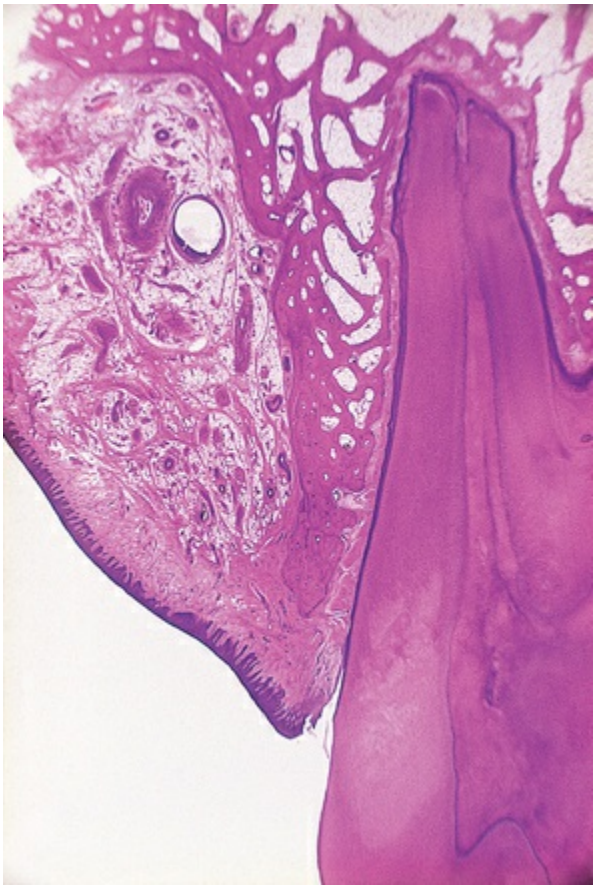

FIG. 58.12 Histologic frontal section of a human palate at the level of the first molar showing the location of the vessels and the nerve surrounded by adipose and glandular tissue.

The mucous membrane that covers the hard palate is firmly attached to the underlying bone. The submucous layer of the palate posterior to the first molars contains the *palatal glands,* which are more compact in the soft palate and extend anteriorly, thereby filling the gap between the mucosal connective tissue and the periosteum and protecting the underlying vessels and nerve (see Fig. 58.22, later).

The area distal to the last molar, called the *maxillary tuberosity,* consists of the posterior-inferior angle of the infratemporal surface of the maxilla. Medially it articulates with the pyramidal process of the palatine bone. It is covered by dense, fibrous connective tissue, and it contains the terminal branches of the middle and posterior palatine nerves. Excision of the area for distal flap surgery may reach medially to the tensor palati muscle. The tensor palati muscle comes from the greater wing of the sphenoid bone and ends in a tendon that forms the palatine aponeurosis, which expands, fanlike, to attach to the posterior border of the hard palate.

The body of the maxilla is occupied by the *maxillary sinus,* which is the largest of the paranasal sinuses. It is an air-filled cavity located in the posterior maxilla superior to the teeth. The lateral wall of the nasal cavity borders the sinus medially; it is bordered superiorly by the floor of the orbit and laterally by the lateral wall of the maxilla, the alveolar process, and the zygomatic arch (Fig. 58.13). It is pyramidal, with its apex in the zygomatic arch and its base at the lateral wall of the nasal cavity. The size of the maxillary sinus varies from one individual to another (depending on the individual and his or her age) and from very small and narrow to quite large and expansive.

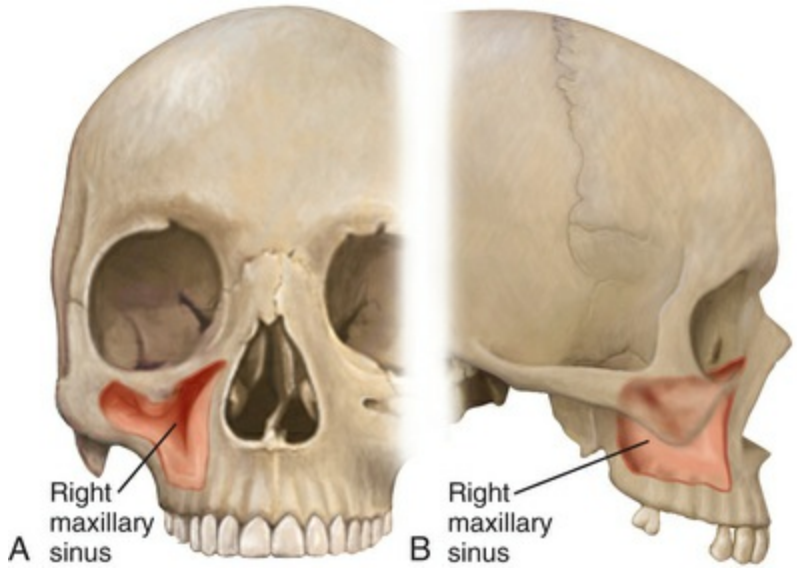

FIG. 58.13 **Location and anatomy of the maxillary sinus. (A) Frontal view. (B) Lateral view.**

The maxillary sinus is frequently subdivided (incompletely) into recesses by one or more septa. Maxillary sinus septa vary in size and location. Clinical and radiographic examinations suggest that septa are frequently present (≤39% of sinuses).[8,13,25] CT scanning is the preferred method for detecting septa because panoramic radiographs are not reliable (i.e., 26.5% false diagnosis of the presence or absence of septa).[13,15] Septa are found in the anterior (24%), middle (41%), and posterior (35%) aspects of the maxillary sinus, with the most common location being between the second premolar and the first molar.[12,25] The height of septa varies as well, ranging from 0 to 20.6 mm.[25] Only 0.5% of septa form a complete separation of the sinus spaces into separate chambers.[16]

The entire maxillary sinus is lined with a thin mucosal membrane called the *schneiderian membrane.* This specialized structure of the respiratory mucous membrane, with its motile cilia and rich blood supply, is well adapted to purifying, moistening, and warming air to protect the lungs. The entrance to the maxillary sinus, through the orifice or maxillary duct, is located at the superior medial aspect of the cavity. The orifice is relatively small, measuring only 3 to 6 mm in length and diameter. An accessory opening is occasionally found inferior and posterior to the main opening. The maxillary sinus drains into the middle meatus of the nasal cavity through the maxillary duct, which passes secretions medially to the semilunar hiatus. Normal amounts of secretion are moved from the sinus by

the spiral pattern of the beating cilia that surround the orifice. If the maxillary sinus becomes infected or chronically inflamed, swelling of the mucosa around the orifice impairs drainage. The floor of the maxillary sinus extends down below the level of the nasal cavity into the alveolar process.

The roots of the maxillary first and second molars are often close to the floor of the sinus. Less frequently, the roots of the premolars and third molars may protrude into the floor of the sinus. With increasing age, the maxillary sinus expands. It becomes more and more pneumatized down around the roots of the maxillary teeth, sometimes resulting in exposure of the roots through the bony floor into the sinus, with only the thin mucosal membrane covering the root surface. The ability to perform periodontal osseous surgery in the posterior maxilla may be limited when the sinuses are severely pneumatized. Extraction of teeth with roots exposed into the maxillary sinus (i.e., without bone to maintain integrity of the maxillary sinus floor) can result in an oroantral communication.

Blood supply to the maxillary sinus arises from the superior alveolar (anterior, middle, and posterior) branches of the maxillary artery (Fig. 58.14A).[24] The maxillary artery, which is a large terminal branch of the external carotid artery, gives off many branches to supply the maxillary sinus, including the infraorbital artery, which travels superiorly and anteriorly and gives off the anterior superior alveolar artery.[9] Branches of the greater palatine artery contribute to a lesser extent. Venous blood drains via the pterygoid plexus. Much of the vasculature travels through channels in the bony walls of the maxillary sinus, with many branches anastomosing with the highly vascularized schneiderian membrane. Innervation of the maxillary sinus is supplied by the superior alveolar (anterior, middle, and posterior) nerves and the branches of the maxillary nerve (Fig. 58.14B).

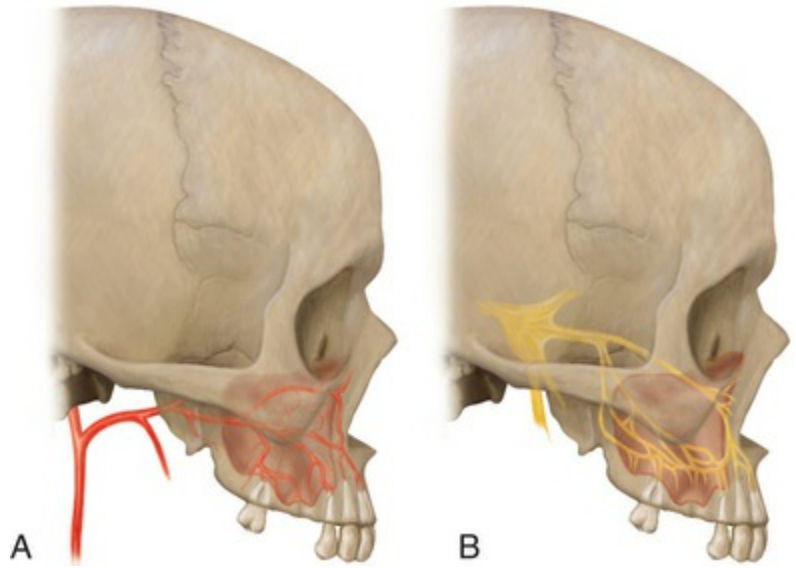

FIG. 58.14 **Blood supply and innervation of the maxillary sinus. (A) Arterial blood supply. (B) Innervation of the maxillary sinus.**

Knowledge of the arterial blood supply is particularly important when considering a lateral window approach to sinus floor elevation and bone augmentation. Solar and colleagues[19] found an intraosseous branch of the posterior superior alveolar artery anastomosing with the infraorbital artery in 100% of their human cadaver specimens (134 sinuses, all in male cadavers). On average, the vessel was located 18.9 mm from the alveolar crest. By studying 50 CT scans from 625 patients (both male and female) who were undergoing sinus bone augmentation, Elian and colleagues[7] found that the vessel was radiographically evident in 52.9% of sinuses. The vessel was located an average of 16.4 mm from the alveolar crest, a slightly shorter distance but consistent with the previous study. Human cadaver dissection and CT scan evaluations of the vessels running through the lateral wall of the maxillary sinus have revealed that intraosseous vessels are present in the lower two-thirds of the anterolateral wall in approximately 10.5% of cases (Fig. 58.15).[9] In 57.1% of those cases (about 6% of all sinuses), the vessel diameter ranged in size from 1 to 2.5 mm. The location of the artery in relation to the position of the lateral window for sinus augmentation presents a risk for bleeding complications in 10% to 20% of cases.[7,9]

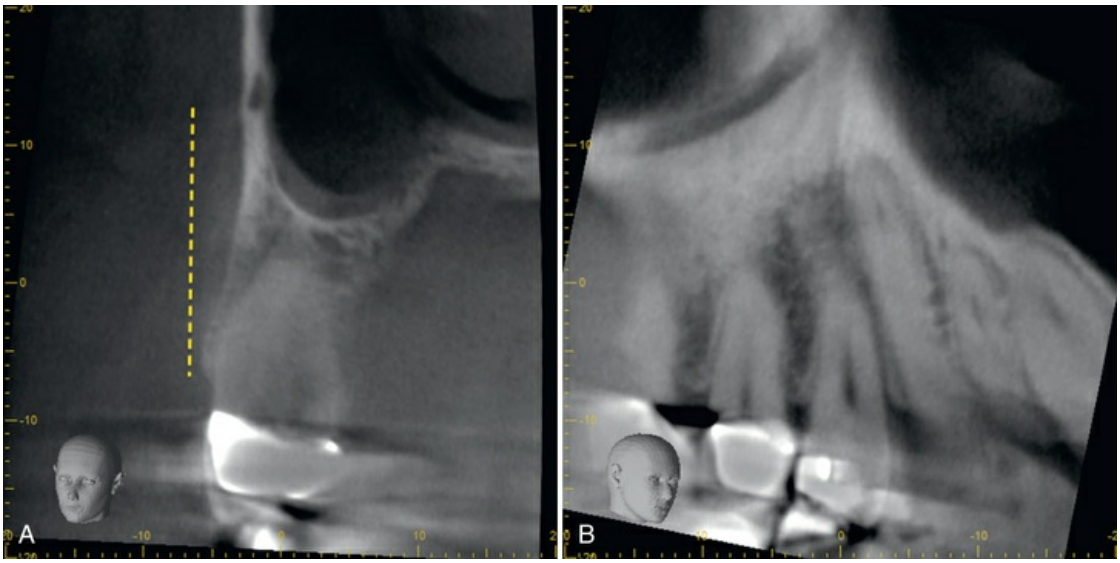

FIG. 58.15 (A) Cross-sectional image from a cone beam computed tomography scan of the maxillary sinus demonstrating the presence of an intraosseous vessel in the lateral wall approximately 20 mm from the alveolar crest. (B) Sagittal section through the maxillary sinus in the same patient demonstrating an intraosseous vessel extending along the maxillary sinus. The diameter of the intraosseous canal is 2 mm.

The inferior wall of the maxillary sinus is frequently separated from the apices and roots of the maxillary posterior teeth by a thin, bony plate (Fig. 58.16). In edentulous posterior areas, the maxillary sinus bony wall may be only a thin plate that is in intimate contact with the alveolar mucosa (Fig. 58.17). Adequate determination of the extension of the maxillary sinus into the surgical site is important to avoid creating an oroantral communication, particularly in relation to osseous reduction in periodontal surgery or surgical procedures for bone augmentation or the placement of implants in edentulous areas. Determining the amount of available bone in the anterior area, below the floor of the nasal cavity, is also critical for the placement of implants (see Chapter 76).

FIG. 58.16 Radiograph of the maxillary molars and premolars, with the maxillary sinus apparently near the apices.

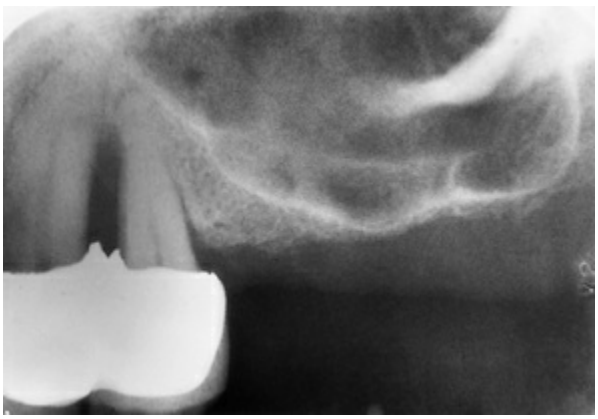

FIG. 58.17 Radiograph of an edentulous molar maxillary area demonstrating severe pneumatization of the maxillary sinus. Only a thin layer of cortical bone separates the sinus from the oral cavity.

Exostoses

Both the maxilla and the mandible may have exostoses or tori, which are considered to be within the normal range of anatomic variation. Sometimes these structures may hinder the removal of plaque by the patient and may have to be removed to improve the prognosis of neighboring teeth. Additional indications for the removal of exostoses include the inability to wear removable prostheses comfortably over these areas. The most common

location of a mandibular torus is in the lingual area of the canines and the premolars, above the mylohyoid muscle (Fig. 58.18). Mandibular tori can also be found on the buccal and labial surfaces of the mandibular teeth. Maxillary tori are usually located in the midline of the hard palate (Fig. 58.19). Smaller tori may be seen over the palatal roots of the maxillary molars, in the area above the greater palatine foramen (see Fig. 58.19), or on the buccal and labial surfaces of the maxillary teeth (Fig. 58.20).

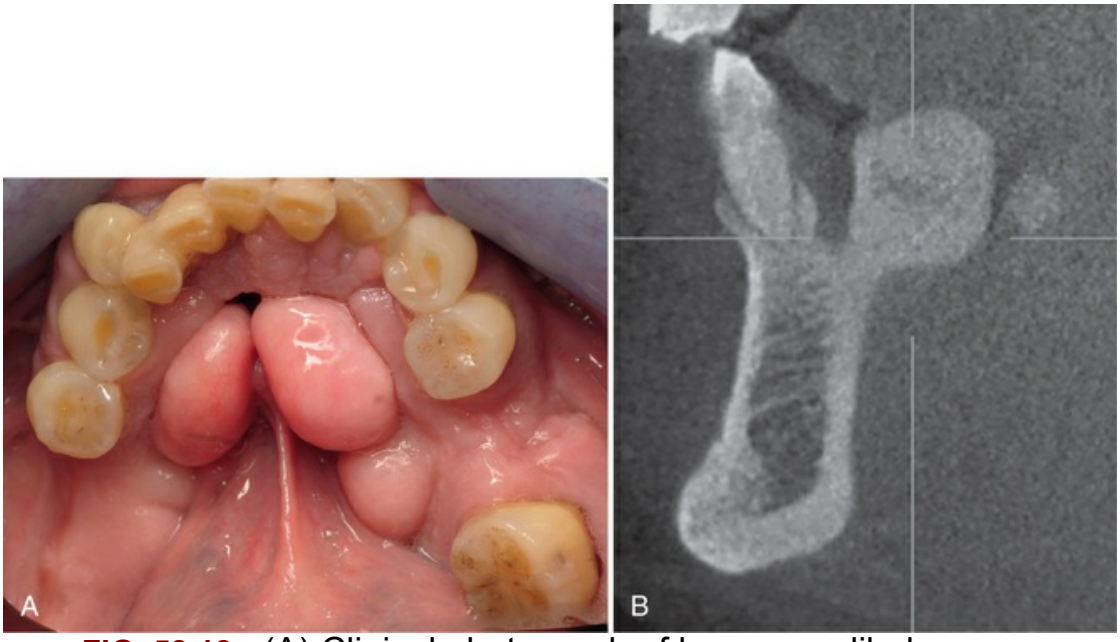

FIG. 58.18 (A) Clinical photograph of large mandibular tori on the lingual aspect of both the right and left mandible. (B) Cross-sectional image of a mandibular torus in the premolar area in the same patient.

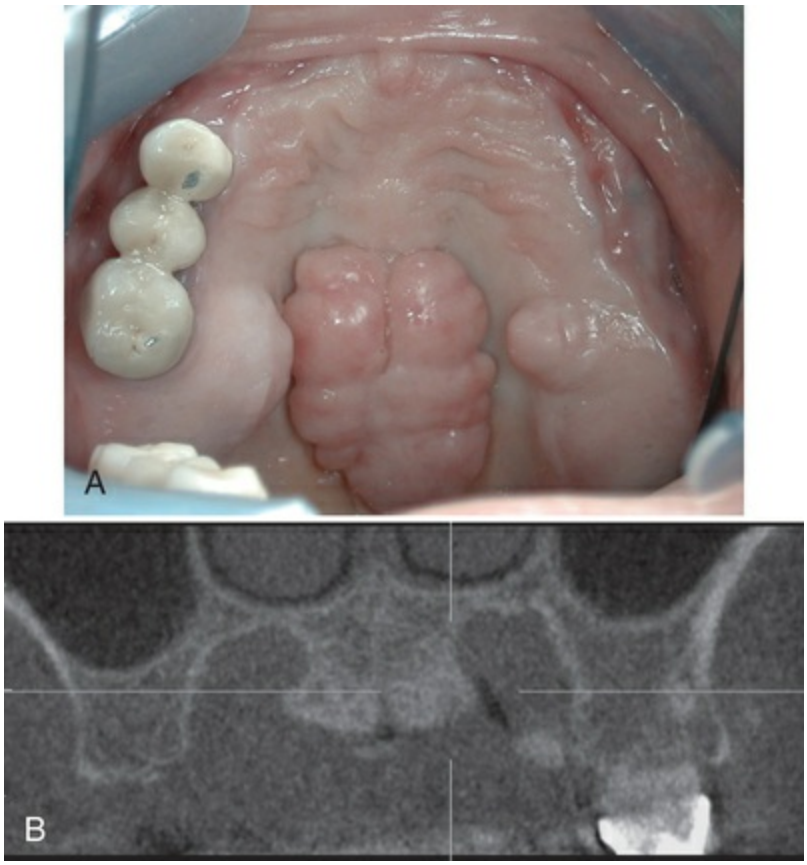

FIG. 58.19 (A) Clinical photograph of a large palatal torus located in the midline of the palate. Notice also the large tori on the palatal aspects of the maxillary alveolar ridge. (B) Cross-sectional image of the maxillary midline torus in the same patient. Notice also the torus located on the palatal aspect of the alveolar ridge.

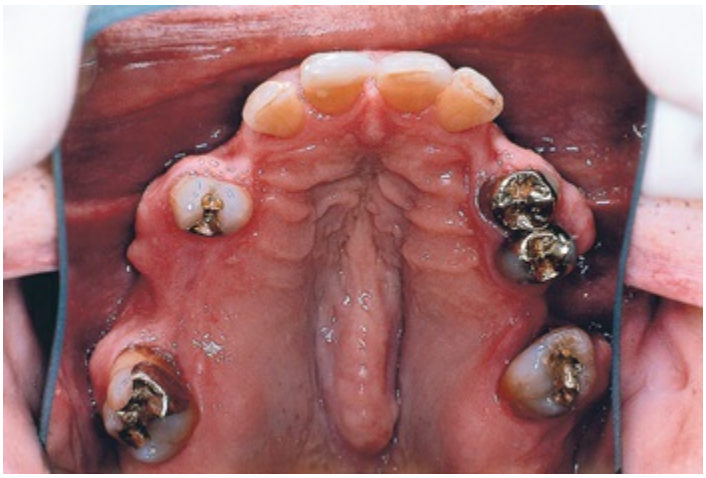

FIG. 58.20 Clinical photograph of large buccal exostosis in the maxillary arch. The patient also has a large midline palatal torus.

Muscles

Several muscles may be encountered when performing periodontal and implant flap surgery, particularly during mucogingival surgery and bone augmentation procedures. These are the mentalis, the incisivus labii inferioris, the depressor labii inferioris, the depressor anguli oris (triangularis), the incisivus labii superioris, and the buccinator muscles. Their bony attachments are shown in Fig. 58.21. These muscles provide mobility to the lips and cheeks.

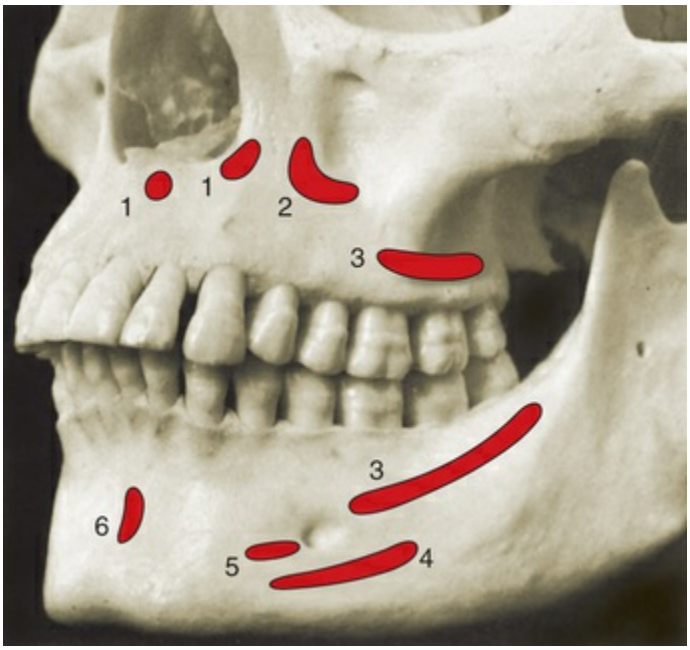

FIG. 58.21 Muscle attachments that may be encountered in mucogingival surgery. *1,* Nasalis; *2,* levator anguli oris; *3,* buccinator; *4,* depressor anguli oris; *5,* depressor labii inferioris; *6,* mentalis.

Anatomic Spaces

Several anatomic spaces or *compartments* are found close to the operative field of periodontal and implant surgery sites. These spaces contain loose connective tissue, but they can be easily distended by hemorrhage, inflammatory fluid, and infection.

Surgical invasion of these areas may result in dangerous

hemorrhage (intraoperative) or infections (postoperative) and should be carefully avoided. Some of these spaces are briefly described in the following paragraphs. For more information, the reader is referred to other sources.[2,11,20,21]

The *canine fossa* contains varying amounts of connective tissue and fat. It is bounded superiorly by the quadratus labii superioris muscle, anteriorly by the orbicularis oris, and posteriorly by the buccinator. Infection of this area results in swelling of the upper lip, which obliterates the nasolabial fold, and of the upper and lower eyelids, which closes the eye.

The *buccal space* is located between the buccinator and the masseter muscles. Infection of this area results in swelling of the cheek that may extend to the temporal space or the submandibular space, with which the buccal space communicates.

The *mental* or *mentalis space* is located in the region of the mental symphysis, where the mental muscle, the depressor muscle of the lower lip, and the depressor muscle of the corner of the mouth are attached. Infection of this area results in large swelling of the chin that extends downward.

The *masticator space* contains the masseter muscle, the pterygoid muscles, the tendon of insertion of the temporalis muscle, the mandibular ramus, and the posterior part of the body of the mandible. Infection of this area results in swelling of the face and severe trismus and pain. If the abscess occupies the deepest part of this compartment, facial swelling may not be obvious, but the patient may complain of pain and trismus. Patients may also have difficulty and discomfort when moving the tongue and swallowing.

The *sublingual space* is located below the oral mucosa in the anterior part of the floor of the mouth. It contains the sublingual gland and its excretory duct, the submandibular or Wharton duct; it is traversed by the lingual nerve and vessels and by the hypoglossal nerve (Fig. 58.22). Its boundaries are the geniohyoid and genioglossus muscles medially, the lingual surface of the mandible below, and the mylohyoid muscle laterally and anteriorly (Fig. 58.23). Infection of this area raises the floor of the mouth and displaces the tongue, which results in pain and difficulty swallowing but little facial swelling.

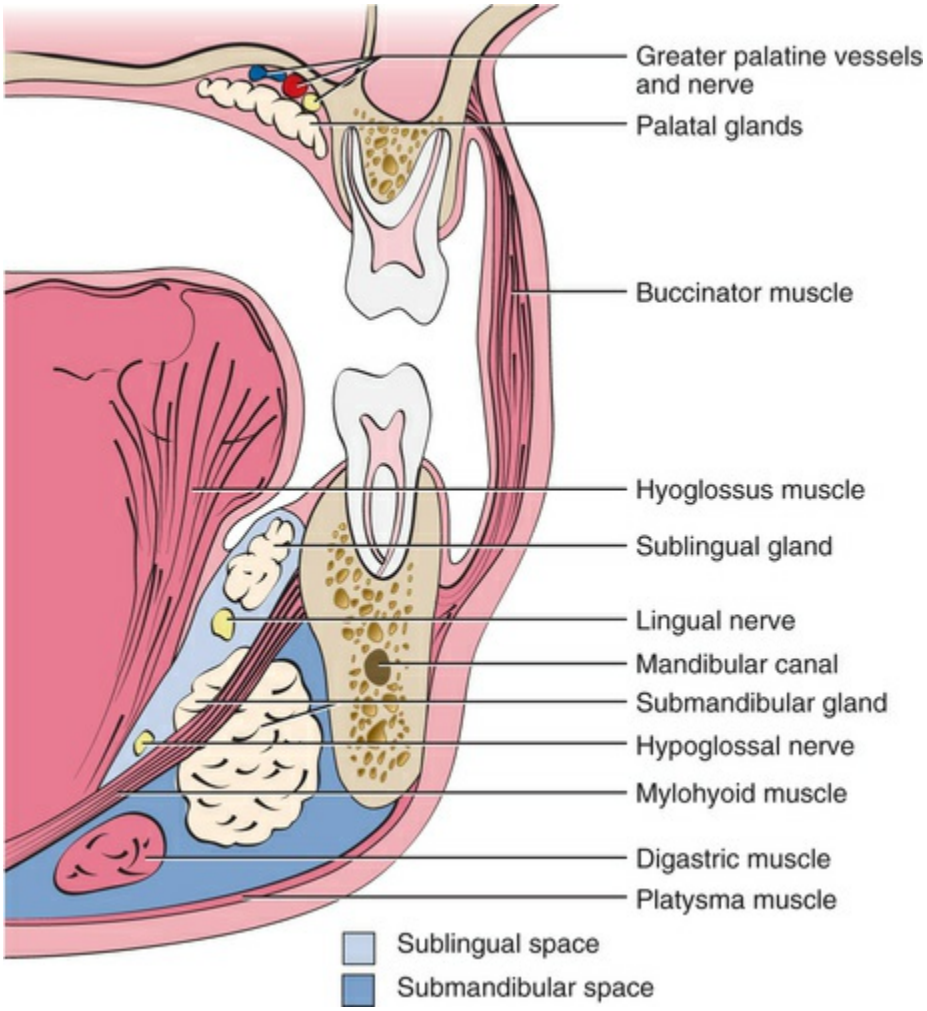

FIG. 58.22 Diagram of a frontal section of the human head at the level of the first molars depicting the most important structures in relation to periodontal surgery. Note the location of the sublingual space, the submandibular space, and the greater palatine nerve and vessels.

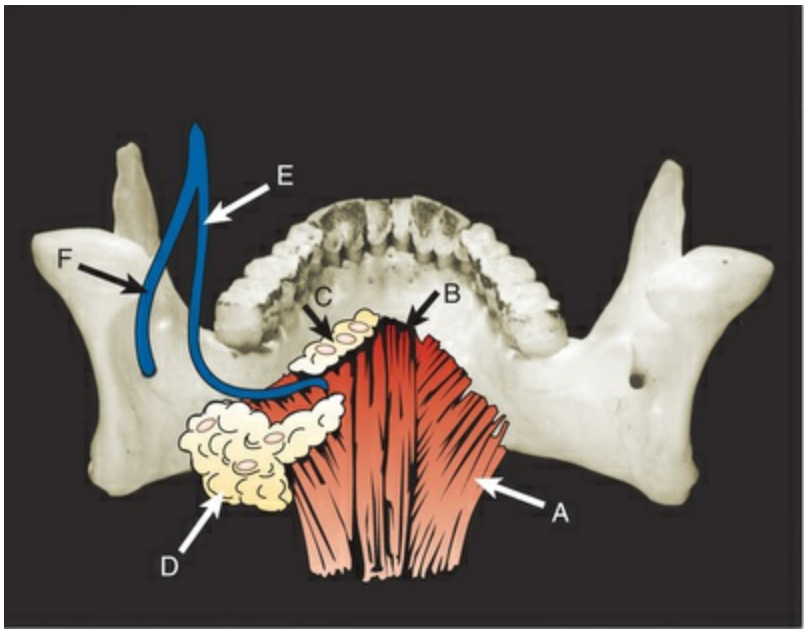

FIG. 58.23 Posterior view of the mandible showing, *A,* the attachment of the mylohyoid muscles; *B,* the geniohyoid muscles; *C,* the sublingual gland; *D,* the submandibular gland, which extends below and also to some extent above the mylohyoid muscle; *E,* the sublingual nerve; and *F,* the inferior alveolar nerve.

The *submental space* is found between the mylohyoid muscle superiorly and the platysma inferiorly. It is bounded laterally by the mandible and posteriorly by the hyoid bone. It is traversed by the anterior belly of the digastric muscle. Infections of this area arise from the region of the mandibular anterior teeth and result in swelling of the submental region; infections become more dangerous as they proceed posteriorly.

The *submandibular space* is found external to the sublingual space, below the mylohyoid and hyoglossus muscles (see Figs. 58.22 and 58.23). This space contains the submandibular gland, which extends partially above the mylohyoid muscle, thereby communicating with the sublingual space and numerous lymph nodes. Infections of this area originate in the molar or premolar area and result in swelling that obliterates the submandibular line and in pain with swallowing. Ludwig angina is a severe form of infection of the submandibular space that may extend to the sublingual and submental spaces. It results in the hardening of the floor of the mouth, and it may lead to asphyxiation from edema of the neck and glottis. Although the bacteriology of these infections has not been

completely determined, they are presumed to be mixed infections with an important anaerobic component.[1,17]

« Flash Back

Ludwig angina is a life-threatening fascial space infection involving the submandibular, sublingual, and submental spaces. It is characterized by extraoral swelling and edema of the lower face and neck with intraoral swelling that raises the floor of the mouth and tongue. If not treated urgently, it can lead to airway obstruction requiring tracheostomy. Infection can spread to other fascial spaces of the head and neck including the retrosternal space.

Conclusion

Having a thorough understanding of the anatomic structures of the periodontium and the surrounding hard and soft tissues is essential for periodontal and implant surgical procedures. Knowledge of anatomy and function is important for proper execution of surgical procedures, as well as to minimize the risk of injury and complications. The spatial relationship of bones, muscles, blood vessels, and nerves, as well as the anatomic spaces located in the vicinity of the periodontal or implant surgical field, are particularly important. This chapter describes anatomic features that are significant to clinicians performing periodontal and implant surgical therapy.

Case Scenario 58.1

Patient:

A 73-year-old female patient

Chief Complaint:

"I want to replace my missing back teeth with implants."

Background Information:

Patient is a nonsmoker. She denies any serious illnesses and takes

no medications. She brushes two to three times per day and uses interproximal brushes. She maintains regular dental visits, including professional cleanings with the hygienist.

Current Findings:

Examination reveals moderate to severe gingival recession around all remaining teeth. Tissues are pink, firm, well adapted, and healthy. Probing depths are generally in the range of 1 to 3 mm. No bleeding on probing is observed, and oral hygiene is excellent. All remaining teeth are stable.

CASE-BASED QUESTIONS	SOLUTIONS AND EXPLANATIONS
1. There are important anatomic structures to evaluate as part of the assessment for dental implants in the posterior mandible. A. Yes B. No	**Answer: A** **Explanation:** The mandibular canal and mental foramen need to be located to identify the position of the inferior alveolar nerve and mental nerve relative to potential implant positions.
2. The submandibular space is not a concern when placing implants in the posterior mandible. A. Yes B. No	**Answer: B** **Explanation:** The submandibular space is found below the mylohyoid and hyoglossus muscles. It forms an undercut space that could be violated by inadvertent drilling. Infections in this area can extend to sublingual and submental spaces.

Case Scenario 58.2

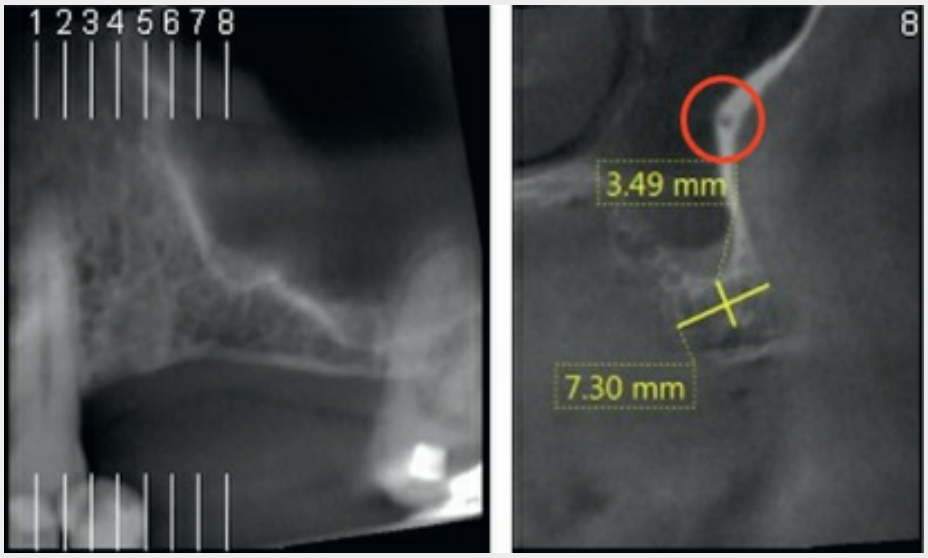
Patient:
A 62-year-old Asian male patient

Chief Complaint:
"I would like implants to replace my missing upper left back teeth."

Background Information:

- No major systemic illnesses
- No known drug allergies
- Nonsmoker
- Patient is currently wearing maxillary treatment partial prostheses to replace missing upper left posterior teeth #12 to #14.

Clinical Findings:
Clinical examination reveals missing teeth #12, #13, and #14. Tooth #15 is present. All remaining teeth appear to be stable. The edentulous ridge has good position and shape. Adequate keratinized attached tissue is present. Cone beam computed tomography scan reveals a pneumatized maxillary sinus with limited remaining alveolar bone. A lateral sinus bone augmentation procedure is indicated.



CASE-BASED QUESTIONS	SOLUTIONS AND EXPLANATIONS
1. What artery travels through the neurovascular bundle structure (circled in red)? A. Descending palatine artery B. Posterior superior alveolar artery C. Maxillary artery D. Infraorbital artery E. Sphenopalatine artery	**Answer: B** **Explanation:** The posterior superior alveolar artery is often found on the lateral wall of the maxillary alveolus.
2. What anatomic structure is the medial wall of the maxillary sinus? A. Alveolar process B. Lateral wall of the maxilla C. Lateral wall of the nasal cavity D. Floor of the orbit	**Answer: C** **Explanation:** The maxillary sinus is an air-filled cavity located in the posterior maxilla superior to the teeth. The lateral wall of the nasal cavity borders the medial wall of the maxillary sinus; it is bordered superiorly by the floor of the orbit and laterally by the lateral wall of the maxilla, the alveolar process, and the zygomatic arch.
3. Augmentin is an antibiotic with a good spectrum of antibacterial coverage (often prescribed) for sinus bone augmentation procedures. What is it? A. Penicillin B. Amoxicillin + clavulanic acid C. Clindamycin + clavulanic acid D. Amoxicillin + metronidazole	**Answer: B** **Explanation:** Augmentin is a combination antibiotic useful for a number of bacterial infections. It consists of amoxicillin, a beta-lactam antibiotic, and clavulanic acid, a beta-lactamase inhibitor.

CHAPTER 59

General Principles of Periodontal Surgery

Perry R. Klokkevold, Henry H. Takei, Fermin A. Carranza

CHAPTER OUTLINE

Outpatient Surgery
Hospital Periodontal Surgery
Surgical Instruments
Conclusion

All surgical procedures must be carefully planned. The patient should be adequately prepared medically, psychologically, and practically for all aspects of the intervention. This chapter covers the preparation of the patient and the general considerations that are common to all periodontal surgical techniques. Complications that may occur during or after surgery are also discussed.

Although periodontal surgical procedures are usually performed in the dental office, an online section of this chapter briefly discusses situations that may require hospitalization and treatment using general anesthesia in the operating room. This chapter is

concluded with a review of common surgical instruments.

Outpatient Surgery

Patient Preparation

Reevaluation After Phase I Therapy

Almost every patient undergoes the so-called initial or preparatory phase of therapy, which basically consists of thorough scaling and root planing and the removing of all irritants responsible for the periodontal inflammation. When these procedures are executed well and are combined with patient education, the results will: (1) eliminate some lesions entirely; (2) render the tissues firm and consistent, thereby allowing for accurate and minimally invasive surgery; and (3) acquaint the patient with the office, the clinician, and the assistants, thereby reducing the patient's apprehension and fear.

Learning Box 59.1

Phase I therapy and reevaluation are important to minimize the necessity for periodontal surgery. When excellent biofilm removal by the patient and scaling and root planing are accomplished, numerous cases may not require surgical therapy, or if it is necessary, the surgical therapy may be minimal.

The reevaluation phase consists of reprobing and reexamining all of the pertinent findings that previously indicated the need for the surgical procedure. The persistence of these findings confirms the indication for surgery. The number of surgical procedures, the expected outcome, and the postoperative care necessary are all determined before therapy and are explained to the patient. After all of the important information regarding the surgery is discussed, a final decision is made that incorporates any necessary adjustments to the original plan.

Premedication

For patients who are not medically compromised, the value of administering antibiotics routinely for periodontal surgery has not been clearly demonstrated.[29] However, some studies have reported reduced postoperative complications, including reduced pain and swelling, when antibiotics are given before periodontal surgery and continued for 4 to 7 days after surgery.[4,12,21,32]

The prophylactic use of antibiotics in patients who are otherwise healthy has been advocated for bone-grafting procedures and purported to enhance the chances of new attachment. Although the rationale for such use appears logical, no research evidence is available to support it. In any case, the risks inherent in the administration of antibiotics should be evaluated together with the potential benefits. Additional presurgical medications that may be administered include a nonsteroidal antiinflammatory drug such as ibuprofen (e.g., Motrin) 1 hour before the procedure and an antimicrobial mouthrinse such as 0.12% chlorhexidine gluconate (e.g., Peridex or PerioGard).[38]

Precautions to be taken with medically compromised patients are discussed in Chapter 39.

Smoking

The deleterious effect of smoking on the healing of periodontal wounds has been amply documented[20,33,43] (see Chapter 12). Patients should be clearly informed of this fact and asked to quit smoking completely or to stop smoking for a minimum of 3 to 4 weeks after the procedure. For patients who are unwilling to follow this advice, an alternate treatment plan that does not include complicated techniques (e.g., regenerative, mucogingival, aesthetic) should be considered.

Informed Consent

The patient should be informed at the initial visit regarding the diagnosis, prognosis, and recommended treatment options including explanations about expected outcomes. The pros and cons of each approach should be discussed, and the patient should be encouraged to ask questions. At the time of surgery, the patient should again be informed both verbally and in writing of the procedure to be performed, including the risks and expected

outcomes. Patients should be given the opportunity to ask any additional questions, and, once their questions are answered, they should indicate their agreement to undergo the procedure by signing the informed consent form.

Emergency Equipment

The clinician, all assistants, and office personnel should be trained to handle all possible emergencies that may arise. Drugs and equipment for emergency use should be readily available at all times.

The most common emergency is syncope, which is a transient loss of consciousness caused by a reduction in cerebral blood flow. The most common causes of syncope are fear and anxiety. Syncope is usually preceded by a feeling of weakness, and then the patient experiences pallor, sweating, coldness of the extremities, dizziness, and a slowing of the pulse. The patient should be placed in a supine position with the legs elevated; tight clothes should be loosened, and a wide-open airway should be ensured. The administration of oxygen should be started. Unconsciousness may persist for a few minutes. A previous history of syncope during dental appointments should be explored before the treatment is started. If the patient has had other experiences with syncope, every effort should be made to minimize the patient's fear and anxiety, as well as considering the use of oral sedatives. The reader is referred to Chapter 38 and other texts for a complete analysis of this important topic.[3]

Measures to Prevent Transmission of Infection

The danger of transmitting infections to the dental team or to other patients is an important precaution that must be a part of every appointment in the dental office, especially with the threat of acquired immunodeficiency syndrome and hepatitis B virus infection. Universal precautions (e.g., protective attire) and barrier techniques must be incorporated into the surgical protocol of every procedure. These include the use of disposable sterile gloves, surgical masks, and protective eyewear. All surfaces that may be

contaminated with blood or saliva and cannot be sterilized (e.g., light handles, unit syringes) must be covered with sterile aluminum foil or plastic wrap. Aerosol-producing devices (e.g., ultrasonic scalers) should not be used on patients with suspected infections, and their use should be kept to a minimum in all other patients. Special care should be taken when using and disposing of sharp items such as needles and scalpel blades.

Sedation and Anesthesia

Pain control in periodontal surgery is important. Most procedures should either be painless or minimally painful. The patient should be assured of this at the beginning and throughout the procedure. The most reliable means of providing painless surgery is the effective administration of local anesthesia. The area to be treated should be thoroughly anesthetized by means of regional block and local infiltration. Injections directly into the interdental papillae may also be helpful.

Apprehensive and neurotic patients may require special management with antianxiety or sedative–hypnotic agents. Modalities for the administration of these agents include inhalation, oral, intramuscular, and intravenous routes. The specific agents and the modality of administration are based on the desired level of sedation, the anticipated length of the procedure, and the overall condition of the patient. Specifically, the patient's medical history and physical and emotional status should be considered when determining the need for sedation, as well as the specific agents and techniques to be used. The reader is referred to Chapter 38 for a detailed description of conscious sedation methods.

Hospital Periodontal Surgery

For most patients, periodontal surgical procedures are managed well in the dental office with local anesthesia only or with some form of sedation and are performed in quadrants or sextants, usually at biweekly or longer intervals. However, certain patients and procedures warrant treatment in the hospital operating room with general anesthesia. These include patients who are not well

enough to undergo treatment in a dental office and procedures that are more extensive and difficult for patients to endure. Readers are referred to the online material for a discussion of indications and procedures in a hospital setting.

Indications

Indications for hospital periodontal surgery include (1) optimal control and management of patients with severe anxiety and apprehension, (2) optimal safety for individuals who cannot endure multiple or extensive visits to complete surgical treatment, and perhaps most importantly, (3) optimal medical management of older and severely debilitated or medically compromised patients.

Patient Anxiety and Apprehension

Gentleness, understanding, and preoperative sedation usually suffice to calm the fears of most patients. For some patients, however, the prospect of a series of surgical procedures is stressful enough to trigger disturbances that jeopardize their well-being and hamper treatment. Explaining that the treatment at the hospital will be performed painlessly and that it will be accomplished by a level of anesthesia that is neither practical nor safe for patients in a dental office is an important step in allaying patients' fears. The thought of completing the necessary surgical procedures in one session rather than in repeated visits is an added comfort to many patients because it eliminates the prospect of repeated anxiety episodes in anticipation of each treatment.

Patient Safety and Protection

Some patients have systemic conditions that are not severe enough to contraindicate elective surgery but that may require special precautions and are best managed in a hospital setting. This group includes (but is not limited to) patients with severe cardiovascular disease, abnormal bleeding tendencies, hyperthyroidism, or uncontrolled hypertension. Treating such a patient in a hospital operating room or an equivalent procedure room with an anesthesiologist present to monitor and manage vital signs and patient comfort throughout the surgical procedure is the safest way

to manage the patient.

The purpose of hospitalization is to protect patients by anticipating their special needs, not to perform periodontal surgery when it is contraindicated by the patient's general condition. For some patients, elective surgery is contraindicated, regardless of whether it is performed in the dental office or in the hospital. When consultation with the patient's physician leads to this conclusion, palliative periodontal therapy in the form of scaling and root planing, if permissible, is the necessary compromise.

Patient Preparation

Premedication

Patients should be given a sedative the night before surgery. Benzodiazepines work well for most patients because they allow the patient to sleep well the night before surgery. If the patient is extremely nervous about the procedure, it is also helpful to advise him or her to take a benzodiazepine the morning of surgery. This ensures that the patient will be as rested and relaxed as possible before surgery.

Patients with systemic problems (e.g., history of rheumatic fever, cardiovascular problems) are premedicated as needed (see Chapter 39).

Anesthesia

When general anesthesia is indicated, it is administered by an anesthesiologist. It is important that the patient also receive local anesthesia, administered as for routine periodontal surgery, to ensure comfort for the patient and reduced bleeding during the procedure. The judicious use of local anesthetics to block regional nerves allows the level of sedation or general anesthesia to be lighter. Hence, the entire operation is performed with a wider margin of safety.

Positioning and Periodontal Dressing

Surgery in the operating room is typically performed on the operating table with the patient lying down and the table either

positioned flat or with the head inclined up to 30 degrees. Some operating rooms are equipped with dental chairs that can be used either flat or at up to 30 degrees of inclination.

When general anesthesia is used, it is advisable to delay placing the periodontal dressing until the patient has recovered sufficiently to have a demonstrable cough reflex. Periodontal dressings placed before the end of general anesthesia can be displaced during the recovery period and pose serious risks of blocking the airway.

Postoperative Instructions

After a full recovery from general anesthesia, most patients can be discharged home with a responsible adult. The effects of general anesthesia and sedative agents make the patient drowsy for hours, and adult supervision at home is recommended for up to 24 hours after surgery. The typical postoperative instructions should be given to the responsible adult, and the patient should be scheduled for a postoperative visit in 1 week.

Tissue Management

1. *Operate gently and carefully.* In addition to being most considerate to the patient, this is also the most effective way to operate. Tissue manipulation should be precise, deliberate, and gentle. It is essential to be thorough, but traumatic instrumentation must be avoided because it produces excessive tissue injury, causes postoperative discomfort, and delays healing.
2. *Observe the patient at all times.* It is essential to pay careful attention to the patient's reactions. Facial expressions, pallor, and perspiration are distinct signs that may indicate when a patient is experiencing pain, anxiety, or fear. The clinician's responsiveness to these signs can be the difference between success and failure.
3. *Be certain that the instruments are sharp.* Instruments must be sharp to be effective; successful treatment is not possible without sharp instruments. Dull instruments inflict unnecessary trauma as a result of poor cutting and excessive

force applied to compensate for their ineffectiveness. A sterile sharpening stone should be available on the operating table at all times.

Scaling and Root Planing

Although scaling and root planing have been performed previously as part of phase I therapy, all exposed root surfaces should be carefully explored and planed as needed during the surgical procedure. In particular, areas of difficult access (e.g., furcations, deep infrabony pockets) often have rough areas or even calculus that was undetected during the preparatory sessions. The assistant who is retracting the tissues and using the aspirator should also check for the presence of calculus and the smoothness of each surface from a different angle.

Learning Box 59.2

The most important objective of periodontal pocket reduction surgery is to gain access to the root surface for scaling and root planing. The exposure obtained to the subgingival root surfaces when the flap is reflected allows not only access for root therapy but also the opportunity to alter the osseous defects that may exist.

Hemostasis

Hemostasis is an important aspect of periodontal surgery because good intraoperative control of bleeding permits accurate visualization of the extent of disease, the pattern of bone destruction, and the anatomy and condition of the root surfaces. It provides the operator with a clear view of the surgical site, which is essential for wound debridement and scaling and root planing. In addition, good hemostasis also prevents excessive loss of blood into the mouth, oropharynx, and stomach.

Periodontal surgery can produce profuse bleeding, especially during the initial incisions and flap reflection. After flap reflection and the removal of granulation tissue, bleeding stops or is considerably reduced. Typically, the control of intraoperative

bleeding can be managed with aspiration. Continuous suctioning of the surgical site with an aspirator is indispensable when performing periodontal surgery. The application of pressure to the surgical wound with moist gauze can be a helpful adjunct to control site-specific bleeding. Intraoperative bleeding that is not controlled with these simple methods may indicate a more serious problem and require additional control measures.

Excessive hemorrhaging after initial incisions and flap reflection may be caused by the laceration of venules, arterioles, or larger vessels. Fortunately, the laceration of medium or large vessels is rare because incisions near highly vascular anatomic areas (e.g., the posterior mandible [the lingual and inferior alveolar arteries], the posterior midpalatal regions [the greater palatine arteries]) are avoided by incision and flap procedures. Proper design of the flaps that takes these areas into consideration will help avoid these accidents (see Chapter 58). However, even when all anatomic precautions are taken, it is possible to cause bleeding from medium or large vessels due to anatomic variations that occur and may result in inadvertent laceration. If a medium or large vessel is lacerated, a suture around the bleeding end may be necessary to control the hemorrhage. Pressure should be applied through the tissue to determine the location that will stop blood flow in the severed vessel. A suture can then be passed through the tissue and tied to restrict blood flow. Excessive bleeding from a surgical wound may also result from incisions across a capillary plexus. Minor areas of persistent bleeding from capillaries can be stopped by applying cold pressure to the site with moist gauze for several minutes.

The use of a local anesthetic with a vasoconstrictor (epinephrine) may also be useful for controlling minor bleeding from the periodontal flap. Both of these methods act through vasoconstriction, thereby reducing the flow of blood through incised small vessels and capillaries. This action is relatively short lived, and it should not be relied on for long-term hemostasis. It is important to avoid the use of vasoconstrictors to control bleeding before sending a patient home. If a more serious bleeding problem exists or if a firm blood clot is not established, bleeding is likely to recur when the vasoconstrictor has metabolized and the patient is

no longer in the office.

Learning Box 59.3

Along with the usual procedures to help control hemorrhage during surgery (pressure; irrigation with cold, sterile water; removal of granulation tissue) the use of local anesthesia with epinephrine is also helpful. It is important to remember that this action is effective for a short duration and should not be used toward the end of the surgical procedure. When the patient is dismissed from the appointment and the effect of the vasoconstriction is no longer present, bleeding can occur during the patient's trip home.

For a slow, constant blood flow and for oozing, hemostasis may be achieved with hemostatic agents. Absorbable gelatin sponge (Gelfoam), oxidized cellulose (Oxycel), oxidized regenerated cellulose (Surgicel Absorbable Hemostat), and microfibrillar collagen hemostat (Avitene, CollaCote, CollaTape, CollaPlug) are useful hemostatic agents for the control of bleeding in capillaries, small blood vessels, and deep wounds (Table 59.1).

TABLE 59.1
Absorbable Hemostatic Agents

Generic (Brand)	Directions	Adverse Effects	Precautions
Absorbable gelatin sponge (Gelfoam)	May be cut into various sizes and applied to bleeding surfaces	May form nidus for infection or abscess	Should not be overpacked into extraction site or wound—may interfere with healing
Oxidized cellulose (Oxycel)	Most effective when applied to wound dry as opposed to moistened	May cause foreign-body reaction	Extremely friable and difficult to place; should not be used adjacent to bone—impairs bone regeneration; should not be used as a surface dressing—inhibits epithelialization
Oxidized regenerated cellulose (Surgicel Absorbable Hemostat)	May be cut to various shapes and positioned over bleeding sites; thick or excessive amounts should not	Encapsulation, cyst formation, and foreign-body reaction possible	Should not be placed in deep wounds—may physically interfere with wound healing and bone formation

	be used		
Microfibrillar collagen hemostat (Avitene, CollaCote, CollaTape, CollaPlug)	May be cut to shape and applied to bleeding surface	May potentiate abscess formation, hematoma, and wound dehiscence; possible allergic reaction or foreign-body reaction	May interfere with wound healing; placement in extraction sockets has been associated with increased pain
Thrombin (Thrombostat)	May be applied topically to bleeding surface	Allergic reaction can occur in patients with known sensitivity to bovine materials	Must not be injected into tissues or vasculature—can cause severe (and possibly fatal) clotting

Absorbable gelatin sponge is a porous matrix prepared from pork skin that helps to stabilize a normal blood clot. The sponge can be cut to the desired dimensions and either sutured in place or positioned within the wound (e.g., an extraction socket). It is absorbed in 4 to 6 weeks.

Oxidized cellulose is a chemically modified form of surgical gauze that forms an artificial clot. The material is friable, and it can be difficult to keep it in place. It is absorbed in 1 to 6 weeks.

Oxidized regenerated cellulose is prepared from cellulose via a reaction with alkali to form a chemically pure and uniform structure than oxidized cellulose. The material is prepared in a cloth or thin gauze form that can be cut to the desired size and sutured or layered on the bleeding surface. It can be used as a surface dressing because it does not impair epithelialization, and it is bactericidal against many gram-negative and gram-positive microorganisms that are both aerobic and anaerobic. Caution should be used when wounds are infected or have an increased potential to becoming infected (e.g., immunocompromised patients) because the absorbable hemostatic agents can serve as a nidus for infection.

Microfibrillar collagen hemostat is type I collagen derived from bovine skin. It is commonly dispensed in a flour form but also comes in a nonwoven sponge form. It binds tightly to blood surfaces and causes the aggregation of platelets, thus working even when the field is not dry. In addition to its blood binding properties as a collagen product, it also activates platelets.

Thrombin is a drug that is capable of hastening the process of blood clotting. It is intended for topical use only, and it is applied as a liquid or powder. Thrombin should never be injected into tissues because it can cause serious or even fatal intravascular coagulation. In addition, because thrombin is a bovine-derived material, caution

should be used for any patient with a known allergic reaction to bovine products.

Finally, it is imperative to recognize that excessive bleeding may be caused by systemic disorders, including (but not limited to) platelet deficiencies, coagulation defects, medications, and hypertension. As a precaution, all surgical patients should be asked about any current medications that may contribute to bleeding, any family history of bleeding disorders, and hypertension. All patients, regardless of health history, should have their blood pressure evaluated before surgery, and anyone who is diagnosed with hypertension must be advised to see a physician before surgery. Patients with known or suspected bleeding deficiencies or disorders must be carefully evaluated before any surgical procedure. A consultation with the patient's physician is recommended, and laboratory tests should be performed to assess the risk of bleeding. It may be necessary to refer the patient to a hematologist for a comprehensive workup.

Learning Box 59.4

Thrombin is a very effective drug to help coagulate blood and is applied topically. This drug should never be injected into tissues because it can cause serious or even fatal intravascular coagulation. In addition, thrombin is a bovine-derived drug, so caution should be used for patients with a known allergy to bovine products.

Periodontal Dressings (Periodontal Packs)

At completion of the periodontal surgical procedure, clinicians may elect to cover the area with a surgical dressing. In general, dressings have no curative properties but assist healing by protecting the tissue rather than providing “healing factors.” The dressing minimizes the likelihood of postoperative infection, facilitates healing by preventing surface trauma during mastication, and protects the patient from pain induced by contact of the wound with food or with the tongue during mastication. (For a complete literature review on this subject, see the article by Sachs and colleagues.[37])

Zinc Oxide–Eugenol Dressing

Dressings that are based on the reaction of zinc oxide and eugenol include the Wonder Pak, which was developed by Ward[46] in 1923, and several other dressings that use modified forms of Ward's original formula. The addition of accelerators such as zinc acetate gives the dressing a better working time.

Zinc oxide–eugenol dressings are supplied as a liquid and a powder that are mixed before use. Eugenol in this type of dressing may induce an allergic reaction that produces reddening of the area and burning pain in some patients.

Noneugenol Dressing

The reaction between a metallic oxide and fatty acids is the basis for the Coe-Pak, which is the most widely used dressing in the United States. This is supplied in two tubes, the contents of which are mixed immediately before use until a uniform color is obtained. One tube contains zinc oxide, an oil (for plasticity), a gum (for cohesiveness), and lorothidol (a fungicide).

The other tube contains liquid coconut fatty acids that have been thickened with colophony resin (or rosin) and chlorothymol (a bacteriostatic agent).[37,40] This dressing does not contain asbestos or eugenol, thereby avoiding the problems associated with these substances.

Other noneugenol dressings include cyanoacrylates[6,19,24] and tissue conditioners (methacrylate gels).[2] However, these products are not in common use.

Retention of Dressing

Periodontal dressings are usually kept in place mechanically by interlocking the dressing in interdental spaces and joining the lingual and facial portions of the dressing. In isolated teeth or when several teeth in an arch are missing, retention of the dressing may be difficult. Numerous reinforcements and splints and stents for this purpose have been described.[17,18,47] The placement of dental floss tied loosely around the teeth enhances retention of the dressing.

Antibacterial Properties of Dressing

Improved healing and patient comfort with less odor and taste[6] have been obtained by incorporating antibiotics into the dressing. Bacitracin,[5] oxytetracycline (Terramycin),[13] neomycin, and nitrofurazone have been used. Care must be taken when any antibiotic products are used because they may produce hypersensitivity reactions. The emergence of resistant organisms and opportunistic infections has been reported.[35] The incorporation of tetracycline powder into the Coe-Pak is generally recommended, particularly when long and traumatic surgical procedures are performed.

Allergy

Contact allergies to eugenol and rosin have been reported.[34]

Preparation and Application of Dressing

Zinc oxide dressings are mixed with eugenol or noneugenol liquids on a wax paper pad with a spatula or a wooden tongue depressor. The powder is gradually incorporated with the liquid until a thick paste is formed.

The Coe-Pak is prepared by mixing equal lengths of paste from tubes that contain the accelerator and the base until the resulting paste is a uniform color (Fig. 59.1A to C). A capsule of tetracycline powder can be added at this time. The dressing is then placed in a cup of water at room temperature (Fig. 59.1D). After 2 to 3 minutes, the paste loses its tackiness, and it can be handled and molded. The mixed dressing remains workable for 15 to 20 minutes. The working time can be shortened by adding a small amount of zinc oxide to the accelerator (pink paste) before spatulating.

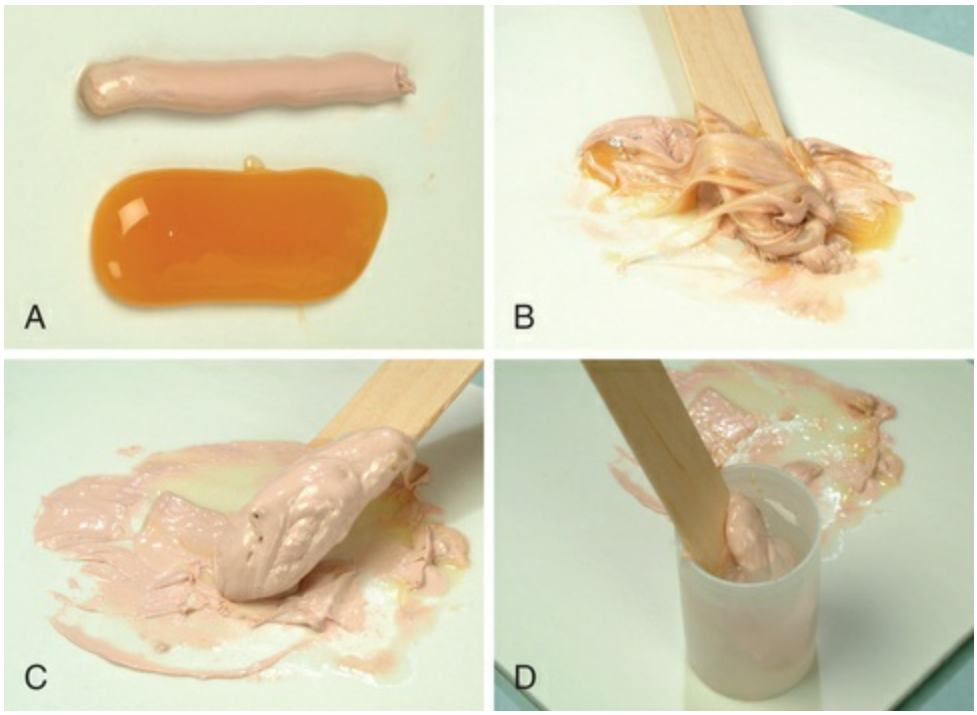

FIG. 59.1 **Preparing the surgical pack (Coe-Pak). (A) Equal lengths of the two pastes are placed on a paper pad. (B) The pastes are mixed with a wooden tongue depressor for 2 or 3 minutes until (C) the paste loses its tackiness. (D) The mixed paste is placed in a paper cup of water at room temperature. With lubricated fingers, it is then rolled into cylinders and placed on the surgical wound.**

The dressing is then rolled into two strips that are approximately the length of the treated area. The end of one strip is bent into a hook shape and fitted around the distal surface of the last tooth to approach that tooth from the distal surface (Fig. 59.2A). The remainder of the strip is brought forward along the facial surface to the midline and gently pressed into place along the gingival margin and interproximally. The second strip is applied from the lingual surface. It is joined to the dressing at the distal surface of the last tooth and then brought forward along the gingival margin to the midline (Fig. 59.2B). The strips are joined interproximally by applying gentle pressure on the facial and lingual surfaces of the dressing (Fig. 59.2C). For isolated teeth separated by edentulous spaces, the dressing should be made continuous from tooth to tooth to cover the edentulous areas (Fig. 59.3).

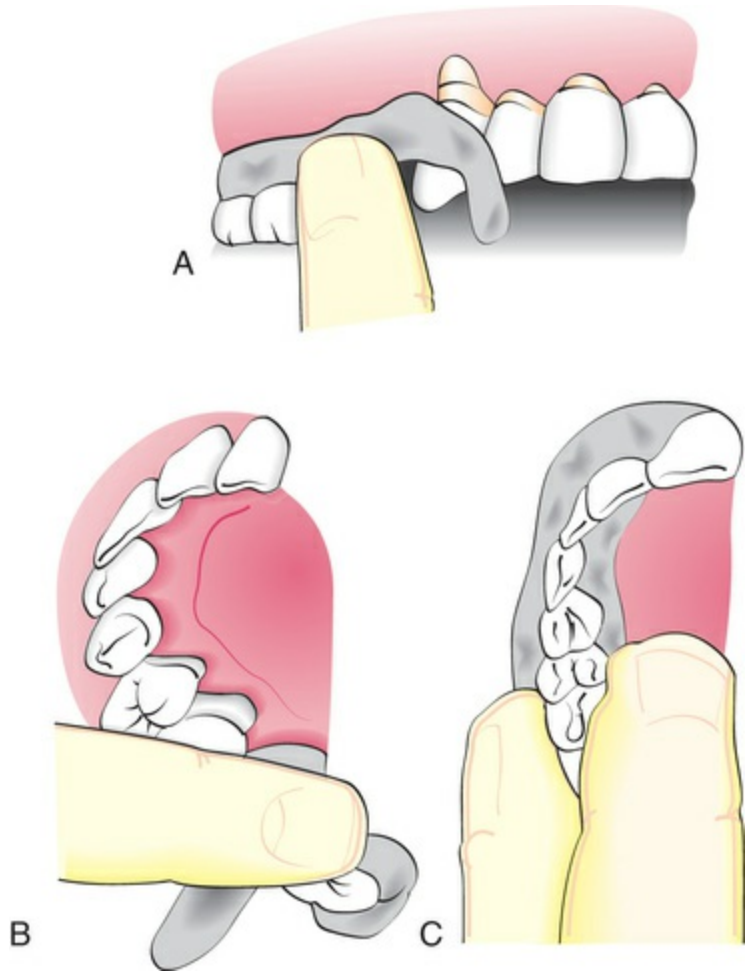

FIG. 59.2 **Inserting the periodontal pack. (A) A strip of pack is hooked around the last molar and pressed into place anteriorly. (B) The lingual pack is joined to the facial strip at the distal surface of the last molar and fitted into place anteriorly. (C) Gentle pressure on the facial and lingual surfaces joins the pack interproximally.**

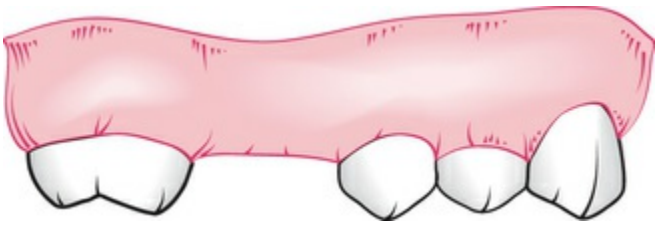

FIG. 59.3 Continuous pack covers the edentulous space.

When split-thickness flaps have been performed, the area should be covered with a sterile tinfoil to protect the sutures before the dressing is placed.

The dressing should cover the gingiva, but overextension onto

uninvolved mucosa should be avoided. *Excess dressing irritates the mucobuccal fold and the floor of the mouth, and it interferes with the tongue.* Overextension also jeopardizes the remainder of the dressing because the excess tends to break off and loosens the dressing from the operated area. *Dressing that interferes with the occlusion should be removed before the patient is dismissed* (Fig. 59.4). Failure to do this causes discomfort and jeopardizes the retention of the dressing.

FIG. 59.4 Periodontal pack should not interfere with the occlusion.

The operator should ask the patient to move the tongue forcibly out and to each side, and the cheek and lips should be displaced in all directions to mold the dressing while it is still soft. After the dressing has set, it should be trimmed to eliminate all excess.

As a general rule, the dressing is kept on for 1 week after surgery. This guideline is based on the usual timetable of healing and clinical experience. It is not a rigid requirement; the period may be extended, or the area may be redressed for an additional week.

Portions of the dressing may not remain during the week, but this should not present a problem. If the dressing is lost from the operated area and the patient is uncomfortable, it is usually best to redress the area. The clinician should remove the remaining dressing, irrigate the area with warm water, and apply a topical anesthetic before replacing the dressing, which is then retained for another week. The excess dressing should be trimmed away with care taken to ensure that the new margin is not rough before the

patient is dismissed.

Postoperative Instructions

After the dressing is placed, oral and printed postoperative instructions are given before the patient is dismissed from the chair (eBox 59.1, online).

eBox 59.1

Patient Instructions After Periodontal Surgery Instructions for _____ (Patient's Name)

The following information about your gum operation has been prepared to answer questions that you may have about how to take care of your mouth. Please read the instructions carefully; our other patients have found them to be very helpful.

Although there will be little or no discomfort when the anesthesia wears off, you should take two acetaminophen (Tylenol) tablets every 6 hours for the first 24 hours. After that, take the same medication if you have any discomfort. Do not take aspirin because this may increase bleeding.

We have placed a periodontal dressing over your gums to protect them from irritation. The dressing prevents pain, helps with healing, and enables you to carry on most of your usual activities in comfort. The dressing will harden in a few hours, after which it can withstand most of the forces of chewing without breaking off. It may take a little while to become accustomed to it.

The dressing should remain in place until it is removed in the office at your next appointment. If particles of the dressing chip off during the week, do not be concerned as long as you do not have pain. If a piece of the dressing breaks off and you are in pain or if a rough edge irritates your tongue or cheek, please call the office. The problem can be easily remedied by replacing the dressing.

For the first 3 hours after the operation, avoid hot foods to permit the dressing to harden. It is also convenient to avoid hot liquids during the first 24 hours. You can eat anything you can

manage, but try to chew on the nonoperated side of your mouth. Semisolid or finely minced foods are suggested. Avoid citrus fruits and fruit juices, highly spiced foods, and alcoholic beverages; these will cause pain. Food supplements or vitamins are generally not necessary.

Do not smoke. The heat and smoke will irritate your gums, and the immunologic effects of nicotine will delay healing and prevent a completely successful outcome of the procedure that was performed. If possible, use this opportunity to give up smoking. In addition to all other well-known health risks, smokers have more gum disease than nonsmokers.

Do not brush over the dressing. Brush and floss the areas of the mouth that are not covered by the dressing as you normally would do. Use chlorhexidine (Peridex, PerioGard) oral rinses after brushing; a prescription for this rinse has been given to you.

During the first day, apply ice intermittently to your face over the operated area. It is also beneficial to suck on ice chips intermittently during the first 24 hours. These methods will keep tissues cool and reduce inflammation and swelling.

You may experience a slight feeling of weakness or chills during the first 24 hours. This should not be a cause for alarm, but it should be reported at your next visit. Follow your regular daily activities, but avoid excessive exertion of any type. Golf, tennis, skiing, bowling, swimming, and sunbathing should be postponed for a few days after the operation.

Swelling is not unusual, particularly in areas that required extensive surgical procedures. The swelling generally begins 1 to 2 days after the operation and subsides gradually after 3 or 4 days. If this occurs, apply moist heat over the operated area. If the swelling is painful or appears to become worse, please call the office.

Occasionally, blood may be seen in the saliva for the first 4 or 5 hours after the operation. This is not unusual, and it will correct itself. If there is considerable bleeding beyond this, take a piece of gauze, form it into the shape of the letter U, hold it with your thumb and index finger, apply it to both sides of the dressing, and hold it there under pressure for 20 minutes. Do not remove it during this period to examine it. If the bleeding does not stop at the end of 20 minutes, please contact the office. Do not try to stop

bleeding by rinsing the area with water.

After the dressing is removed, the gums most likely will bleed more than they did before the operation. This is perfectly normal during the early stage of healing, and it will gradually subside. Do not stop cleaning because of it. If any other problems arise, please call the office.

First Postoperative Week

When the therapy is properly performed, periodontal surgery should present minimal postoperative problems. Patients should be instructed to rinse with 0.12% chlorhexidine gluconate (Peridex, PerioGard) immediately after the surgical procedure and twice daily thereafter until normal biofilm control can be resumed.[30,38,45] The following complications may arise during the first postoperative week, although they are the exception rather than the rule:

1. *Persistent bleeding after surgery.* The dressing is removed, and local anesthesia may be needed before the bleeding areas are located. The bleeding is stopped with pressure, or if necessary the area may have to be anesthetized and resutured. After the bleeding has been stopped, the area is again redressed.
2. *Sensitivity to percussion.* Extension of inflammation into the periodontal ligament may cause sensitivity to percussion. The patient should be questioned regarding the progress of the symptoms. Gradual diminishing discomfort is a favorable sign. The dressing should be removed and the surgical area checked for localized areas of infection or irritation. The area should be irrigated or incised to provide drainage if areas of localized exudate are present. Particles of calculus that may have been overlooked should be removed. Relieving the occlusion can be helpful. Sensitivity to percussion may also be caused by excess dressing, which interferes with the occlusion. Removal of the excess usually corrects the condition.
3. *Swelling.* During the first 2 postoperative days, some patients

may report a soft, painless swelling of the cheek in the surgical area. Lymph node enlargement may occur, and the temperature may be slightly elevated. The area of operation itself is usually symptom free. This type of involvement results from a localized inflammatory reaction to the surgical procedure. It generally subsides by the fourth postoperative day without necessitating the removal of the dressing. If swelling persists, enlarges, or is associated with increased pain, amoxicillin (500 mg) should be taken every 8 hours for 1 week. The patient should also be instructed to apply moist heat intermittently over the area.

4. *Feeling of weakness.* Occasionally, patients report having experienced a "washed-out," weakened feeling for about 24 hours after surgery. This represents a systemic reaction to transient bacteremia induced by the procedure. This reaction can be prevented by premedication with amoxicillin (500 mg) every 8 hours. This protocol should be started 24 hours before the next procedure and continued for 5 days postoperatively.

Removal of the Dressing and Return Visit

When the patient returns in 1 week, the periodontal dressing is removed by inserting a curette along the margin and exerting gentle lateral pressure. Pieces of the dressing retained interproximally and particles adhering to the tooth surfaces are also removed with curettes. Particles of dressing and debris may be enmeshed in the surgical surfaces and should be carefully removed with cotton pliers. The entire area is irrigated with peroxide to remove the superficial debris.

Findings at the Time of Dressing Removal

The following are usual findings when the dressing is removed:

- If g*ingivectomy* has been performed, the incised surface is covered with a friable meshwork of new epithelium. This tissue should not be disturbed. If

calculus has not been completely removed, red, beadlike protuberances of granulation tissue will persist. The granulation tissue must be removed with a curette to expose the calculus so the root can be planed. Granulation tissue will recur if the residual calculus is not completely removed.

- After a *flap operation*, the areas that correspond to the incisions are epithelialized, but they may bleed readily if irritated. These areas should not be disturbed nor probed.
- The facial and lingual mucosa may be covered with a grayish-yellow or white granular layer of debris that has entered under the dressing. This is easily removed with a moist cotton pellet. The root surfaces may be sensitive to touch or to thermal change. The patient should be assured that these changes will disappear with time (4 to 6 weeks). The dentition that was beneath the dressing may be stained in a brownish-yellow color that can be removed by polishing at a later date.
- *Fragments of calculus delay healing.* Each root surface should be carefully rechecked visually to be certain that no calculus was missed during surgery. The grooves on the proximal root surfaces and the furcations are areas where calculus is likely to be overlooked.

Redressing

After the dressing is removed, it is usually not necessary to replace it. However, redressing for an additional week is advised for the following types of patients: (1) those with a low pain threshold who

are particularly uncomfortable when the dressing is removed; (2) those with unusually sensitive root surfaces postsurgically; or (3) those with an open wound where the flap edges have necrosed. Clinical judgment helps when deciding whether to redress the area or to leave the initial dressing for a longer period.

Learning Box 59.5

Periodontal dressings have no curative properties but assist healing by protecting the tissue rather than providing "healing factors." The dressing facilitates healing by preventing surface trauma during mastication and protects the patient from pain induced by contact of the wound with food or with the tongue during mastication.

Tooth Mobility

Tooth mobility usually increases immediately after surgery.[8] This results from edema in the periodontal ligament space from the inflammation that occurs postsurgically. The mobility diminishes to the pretreatment level by the fourth week.[25] The patient should be reassured before surgery that the mobility is temporary.

Mouth Care Between Procedures

Care of the mouth by the patient between the treatments as well as after the surgery is completed is extremely important.[48] These measures should begin after the dressing is removed from the first surgical procedure. The patient has had instructions on oral hygiene before surgical therapy but must be instructed again after surgical therapy. Plaque or biofilm removal post surgery is different from that of presurgical hygiene because the areas are still healing and uncomfortable.

Vigorous brushing is not feasible during the first week after the dressing is removed. However, the patient is informed that biofilm and food accumulation impair healing and is advised to try to keep the area as clean as possible with the gentle use of a soft toothbrush and light water irrigation. Rinsing with a chlorhexidine mouthwash

or applying such a rinse topically with cotton-tipped applicators is indicated for the first few postoperative weeks. Brushing is introduced when the healing of the tissues permits, and the overall hygiene regimen is increased as healing progresses. Patients should be told that (1) some gingival bleeding will occur when the wounded areas are gently cleaned; (2) this bleeding is normal and will subside as healing progresses; and (3) the bleeding should not deter them from following their oral hygiene regimen.

Management of Postoperative Pain

Periodontal surgery that follows the basic principles outlined here should produce only minimal pain and discomfort.[41] A study of 304 consecutive periodontal surgical interventions revealed that 51.3% of the patients reported minimal or no postoperative pain, and only 4.6% reported severe pain. Of these, only 20.1% took five or more doses of analgesic.[11] The same study indicated that mucogingival procedures result in six times more discomfort and that osseous surgery is three and a half times more uncomfortable than plastic gingival surgery. For the few patients who may have severe pain, the control of pain becomes an important part of patient management.[29]

As indicated earlier, a common source of postoperative pain is overextension of the periodontal dressing onto the soft tissue apical to the mucogingival junction or onto the frena. Overextended dressings cause localized areas of edema that are usually noticed 1 to 2 days after surgery. The removal of excess dressing is followed by resolution in about 24 hours. Extensive and excessively prolonged exposure of bone with poor irrigation during surgery induces greater pain. For most healthy patients, a preoperative dose of ibuprofen (600 to 800 mg) followed by one tablet every 8 hours for 24 to 48 hours is very effective for reducing discomfort after periodontal surgery. Patients are advised to continue taking ibuprofen or acetaminophen thereafter, if needed. If pain persists, acetaminophen plus codeine (Tylenol #3) can be prescribed. Caution should be used when prescribing or dispensing ibuprofen to patients with hypertension that is controlled by medications because it can interfere with the effectiveness of the medication.

Patients experiencing severe postoperative pain should be seen on an emergency basis. The area should be anesthetized by infiltration, and the dressing should be removed to allow for the examination of the area in pain. Postoperative pain related to infection is accompanied by localized lymphadenopathy and a slight elevation in temperature.[31] This type of pain should be treated with systemic antibiotics and analgesics.

Dentin (Root) Hypersensitivity

Dentin or root hypersensitivity is a relatively common problem in periodontal practice. It may occur spontaneously when the root becomes exposed as a result of gingival recession or pocket formation, or it may appear after scaling and root planing and other periodontal surgical procedures. The reader is referred to the online discussion for a detailed discussion of root sensitivity and its management.

Treatment of Sensitive Roots

Root hypersensitivity is a relatively common problem in periodontal practice. It may occur spontaneously when the root becomes exposed as a result of gingival recession or pocket formation, or it may appear after scaling and root planing and other surgical procedures. (See the article by Curro[10] for a literature review of this subject.) This type of sensitivity is manifested as pain that is induced by thermal changes (cold or hot temperature), by citrus fruits or sweets, or by contact with a toothbrush or a dental instrument.

Root sensitivity occurs more frequently in the cervical area of the root, where the cementum is extremely thin. Scaling and root planing procedures remove this thin cementum, thereby inducing the hypersensitivity.

The transmission of stimuli from the surface of the dentin to the nerve endings located in the dental pulp or in the pulpal region of the dentin could result from the odontoblastic process or from a hydrodynamic mechanism (i.e., the displacement of dentinal fluid). The latter process seems more likely and would explain the importance of burnishing desensitizing agents to obturate the

dentinal tubule. An important factor for reducing or eliminating hypersensitivity is adequate biofilm control. However, hypersensitivity may prevent biofilm control, and therefore a vicious cycle of escalating hypersensitivity and biofilm accumulation may be created.

The patient should be informed about the possibility of root hypersensitivity before treatment is undertaken. A patient who is educated about any problematic issues before surgery will not complain because he or she is aware and expects the occurrence of the discomfort. The following information on how to cope with the problem should also be given to the patient:

1. Hypersensitivity appears as a result of the exposure of dentin, which is inevitable if calculus, biofilm, and their products, which are buried in the root, are to be removed.
2. Hypersensitivity slowly disappears in a few weeks.
3. An important factor in reducing hypersensitivity is biofilm control.
4. Desensitizing agents do not produce immediate relief and must be used for several days or even weeks to produce results.

Desensitizing Agents

Numerous agents have been proposed to control root hypersensitivity. The clinical evaluation of the many agents proposed is difficult for the following reasons: (1) measuring and comparing pain among patients with different thresholds are difficult, (2) the time table for hypersensitivity before it is completely alleviated is different for each patient, and (3) each desensitizing agent acts differently both in terms of time and the level of relief it offers.

Desensitizing agents can be applied by the patient at home or by the dentist or hygienist in the dental office. The most likely mechanism of action is the reduction of the diameter of the dentinal tubules to limit the displacement of fluid. According to Trowbridge and Silver,[44] this can be attained in the following ways: (1) by the formation of a smear layer produced by burnishing the exposed surface, (2) via the topical application of agents that form insoluble

precipitates within the tubules, (3) with the impregnation of tubules with plastic resins, or (4) by sealing the tubules with plastic resins.

Agents Used by the Patient

The most common agents used by the patient for oral hygiene are dentifrices. Although many dentifrice products contain fluoride, additional active ingredients for desensitization are strontium chloride, potassium nitrate, and sodium citrate. The American Dental Association has approved the following dentifrices for desensitizing purposes: Sensodyne and Thermodent, which contain strontium chloride[7,9,36]; Crest Sensitivity Protection, Denquel, and Promise, which contain potassium nitrate[1,9]; and Protect, which contains sodium citrate. Fluoride rinsing solutions and gels can also be used after the usual biofilm control procedures.[42]

Patients should be aware that several factors must be considered during the treatment of tooth hypersensitivity, including the history and severity of the problem, as well as the physical findings of the tooth or teeth involved. A proper diagnosis is required before any treatment can be initiated so that pathologic causes of pain such as caries, cracked tooth, and other pulpal problems should be ruled out before attempting to treat the hypersensitivity. Desensitizing agents act through the precipitation of crystalline salts on the dentin surface that block dentinal tubules. Patients must be aware that their use will not prove to be effective unless they are used continuously for at least 2 weeks.

Agents Used in the Dental Office

eBox 59.2 lists various office treatments for the desensitization of hypersensitive dentin. These products and treatments aim to decrease hypersensitivity by blocking dentinal tubules with either a crystalline salt precipitation or an applied coating (varnish or bonding agent) on the root surface.[44]

eBox 59.2

Office Treatments for Dentinal Hypersensitivity

Cavity varnishes
- Antiinflammatory agents
- Treatments that partially obturate dentinal tubules
- Burnishing of dentin
- Silver nitrate
- Zinc chloride–potassium ferrocyanide
- Formalin

Calcium compounds
- Calcium hydroxide
- Dibasic calcium phosphate

Fluoride compounds
- Sodium fluoride
- Stannous fluoride
- Iontophoresis
- Strontium chloride
- Potassium oxalate
- Restorative resins
- Dentin bonding agents

From Trowbridge HO, Silver DR: A review of current approaches to in-office management of tooth hypersensitivity. *Dent Clin North Am* 34:566, 1990.

Several agents have been used to precipitate crystalline salts on the dentin surface in an attempt to occlude the dentinal tubules. *Fluoride solutions* and *pastes* historically have been the agents of choice. In addition to their antisensitivity properties, fluoride agents have the advantage of anticaries activity, which is particularly important for patients with a tendency to develop root caries. Certain agents, such as chlorhexidine, decrease the ability of fluoride to bind with calcium on the root surfaces.[1] Thus it is important to advise patients not to rinse or eat for 1 hour after a desensitizing treatment. Currently, potassium oxalate (Protect) and ferric oxalate (Sensodyne Sealant) solutions are the preferred agents, and special applicators have been developed for their use. These agents form insoluble calcium oxalate crystals that occlude the dentinal tubules.[27,30]

The most current method of treatment for hypersensitive dentin is the use of varnishes or bonding agents to occlude dentinal tubules. Newer restorative materials, such as glass-ionomer

cements and the dentin bonding agents, are under investigation. These materials are considered for use when the tooth requires recontouring or when difficult cases do not respond to other treatments. Resin primers alone could be promising, but the effects are not permanent, and further investigations are ongoing.[14] Despite some success with decreasing dentin hypersensitivity, these "dental office" treatments have not been predictable in resolving hypersensitivity, and the success that is achieved is often short-lived. The crystalline salts, varnishes, and other sealants can be washed away over time, and the hypersensitivity may return. Repeated therapy will be necessary to help alleviate the hypersensitivity for these patients.

More recently, attempts have been made to improve the success and longevity of these treatments with the use of lasers. Low-level laser "melting" of the dentin surface appears to seal dentinal tubules without damage to the pulp.[15,22] In a combined treatment modality, the neodymium:yttrium-aluminum-garnet laser has been used to congeal fluoride varnish on root surfaces. This in vitro study demonstrated that the laser-treated fluoride varnish resisted removal by electric toothbrushing, with 90% of tubules remaining blocked. In the control subjects (i.e., those who did not undergo laser treatment), the fluoride varnish was almost completely brushed away.[23] Despite these convincing preliminary results, further research is needed before laser treatment can be considered an effective and predictable means of desensitization (see Chapter 68).

Learning Box e59.1

Root sensitivity occurs more frequently in the cervical area of the root, where the cementum is extremely thin. Scaling and root planing procedures can remove this thin cementum, thereby inducing the hypersensitivity.

Surgical Instruments

Periodontal surgery is accomplished with numerous instruments;

Fig. 59.5 shows a typical surgical cassette. Periodontal surgical instruments are classified as follows:

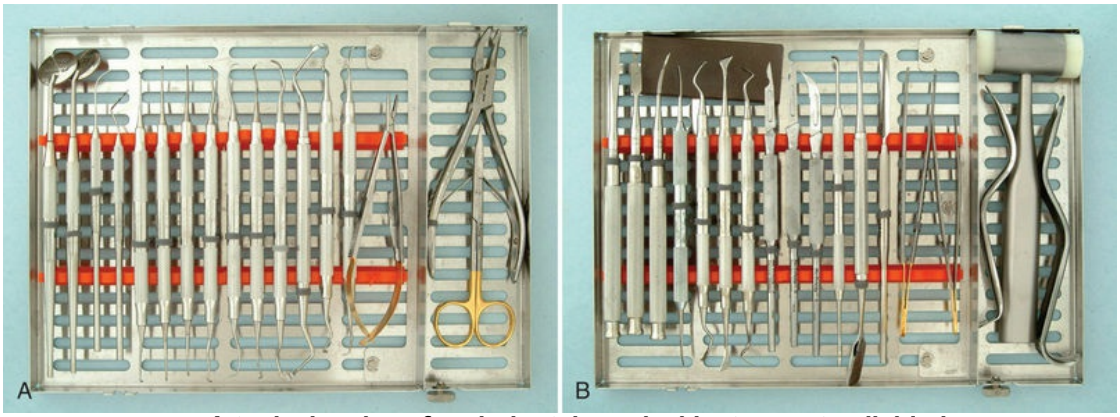

FIG. 59.5 **A typical series of periodontal surgical instruments, divided into two cassettes. (A) *From left,* Mirrors, explorer, probe, series of curettes, needleholder, rongeurs, and scissors. (B) *From left,* Series of chisels, Kirkland knife, Orban knife, scalpel handles with surgical blades (#15C, #15, and #12D), periosteal elevators, spatula, tissue forceps, cheek retractors, and mallet; also shown is a sharpening stone.** (A, Courtesy Hu-Friedy, Chicago, IL. B, Courtesy G. Hartzell & Son, Concord, CA.)

1. Excisional and incisional instruments
2. Surgical curettes and sickles
3. Periosteal elevators
4. Surgical chisels
5. Surgical files
6. Scissors
7. Hemostats and tissue forceps

Excisional and Incisional Instruments

Periodontal Knives (Gingivectomy Knives)

The Kirkland knife is representative of the knives that are typically used for gingivectomy. These knives can be obtained as either double-ended or single-ended instruments. The entire periphery of these kidney-shaped knives is the cutting edge (Fig. 59.6A).

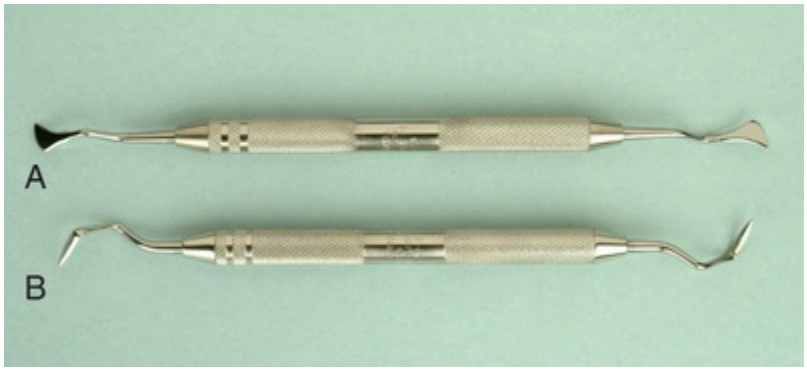

FIG. 59.6 Gingivectomy knives. (A) Kirkland knife. (B) Orban interdental knife.

Interdental Knives

The Orban knife (#1 and #2; Fig. 59.6B) and the Merrifield knife (#1 through #4) are examples of knives that can be used for interdental areas. These spear-shaped knives have cutting edges on both sides of the blade, and they are designed with either double-ended or single-ended blades.

Surgical Blades

Scalpel blades of different shapes and sizes are used in periodontal surgery. The most common blades are #12D, #15, and #15C (Fig. 59.7). The #12D blade is a beak-shaped blade with cutting edges on both sides that allow the operator to engage narrow, restricted areas with both pushing and pulling cutting motions. The #15 blade is used for thinning the flaps and is also used for general purposes. The #15C blade, which is a narrower version of the #15 blade, is useful for making the initial, scalloping-type incision. The slim design of this blade allows for incising into the narrow interdental portion of the flap. All of these blades are discarded after one use.

FIG. 59.7 **Surgical blades. *Top to bottom,* #15, #12D, and #15C. These blades are disposable.**

Electrosurgery (Radiosurgery) Techniques and Instrumentation

The terms *electrosurgery* and *radiosurgery*[39] are currently used to identify surgical techniques performed on soft tissue with the use of controlled, high-frequency electrical (radio) currents in the range of 1.5 to 7.5 million cycles per second (megahertz). Three classes of active electrodes are available: single-wire electrodes for incising or excising; loop electrodes for planing tissue; and heavier, bulkier electrodes for coagulation procedures.[16,28]

The four basic types of electrosurgical techniques are electrosection, electrocoagulation, electrofulguration, and electrodesiccation.

Electrosection, which is also referred to as *electrotomy* or *acusection,* is used for incisions, excisions, and tissue planing. Incisions and excisions are performed with single-wire active electrodes that can be bent or adapted to accomplish any type of cutting procedure.

Electrocoagulation provides a wide range of coagulation and hemorrhage control by using the electrocoagulation current. Electrocoagulation can prevent bleeding or hemorrhage at the initial entry into soft tissue, but it cannot stop bleeding after the blood is present. All forms of hemorrhage must be stopped first by some form of direct pressure (e.g., air, compress, hemostat). After bleeding has momentarily stopped, the final sealing of the capillaries or large vessels can be accomplished with a short application of the electrocoagulation current. The active electrodes that are used for coagulation are much bulkier than the fine tungsten wire used for electrosection. Electrosection and

electrocoagulation are the procedures that are most often used in all areas of dentistry. The two monoterminal techniques, electrofulguration and electrodesiccation, are not in general use in dentistry.

The most important basic rule of the use of electrosurgery is *always keep the tip moving*. The prolonged or repeated application of current to tissue induces heat accumulation and undesired tissue destruction, whereas interrupted application at intervals adequate for tissue cooling (5 to 10 seconds) reduces or eliminates heat buildup. Electrosurgery is not intended to destroy tissue; it is a controllable means of sculpturing or modifying oral soft tissue with little discomfort and hemorrhage for the patient. Electrosurgery is contraindicated for patients who have incompatible or poorly shielded cardiac pacemakers.

Surgical Curettes and Sickles

Larger and heavier curettes and sickles are often needed during surgery for the removal of granulation tissue, fibrous interdental tissues, and tenacious subgingival deposits. The Prichard curette (Fig. 59.8) and the Kirkland surgical instruments are heavy curettes, whereas the Ball scaler (#B2 and #B3) is a popular heavy sickle. The wider, heavier blades of these instruments are suitable for surgical procedures that require the removal of tenacious tissues and calculus.

FIG. 59.8 **A Prichard surgical curette. The curettes that are used in surgery have wider blades than those that are used for conventional scaling and root planing.**

Periosteal Elevators

The periosteal elevators are needed to reflect and move the flap after the incision has been made for flap surgery. The Woodson and Prichard elevators are well-designed periosteal instruments (Fig. 59.9).

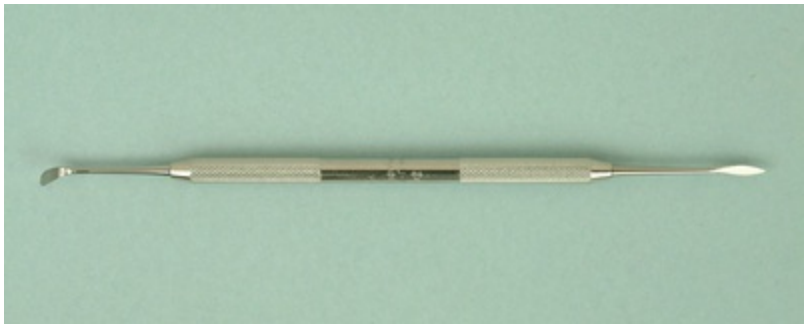

FIG. 59.9 **Woodson periosteal elevator.**

Surgical Chisels

The back-action chisel is used with a pull motion (Fig. 59.10), whereas the straight chisel (e.g., Wedelstaedt, Ochsenbein [#1 and #2]) are used with a push motion (Fig. 59.11). The Ochsenbein chisel is a useful chisel with a semicircular indentation on both sides of the shank that allows the instrument to engage around the tooth and into the interdental area. The Rhodes chisel is another popular back-action chisel.

FIG. 59.10 **Back-action chisel.**

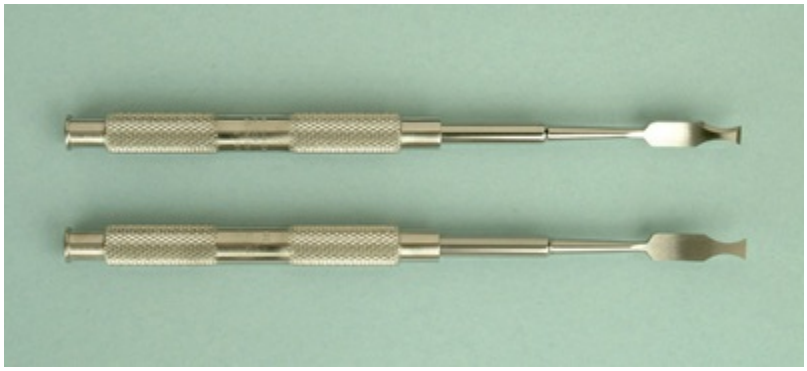

FIG. 59.11 Ochsenbein chisels are paired, with their cutting edges in opposite directions.

Tissue Forceps

The tissue forceps are used to hold the flap during suturing. This instrument is also used to position and displace the flap after the flap has been reflected. The DeBakey forceps are efficient instruments for this purpose (Fig. 59.12).

FIG. 59.12 DeBakey tissue forceps.

Scissors and Nippers

Scissors and nippers are used in periodontal surgery to remove tabs of tissue during gingivectomy, to trim the margins of flaps, to enlarge incisions in periodontal abscesses, and to remove muscle attachments in mucogingival surgery. Many types are available, and individual preference determines the choice. Goldman–Fox #16 scissors have a curved, beveled blade with serrations (Fig. 59.13).

FIG. 59.13 Goldman–Fox scissors.

Needleholders

Needleholders are used to suture the flap at the desired position after the surgical procedure has been completed. In addition to the regular types of needleholders (Fig. 59.14A), the Castroviejo needleholder is used for delicate, precise techniques that require quick and easy grasp and release of the suture (Fig. 59.14B).

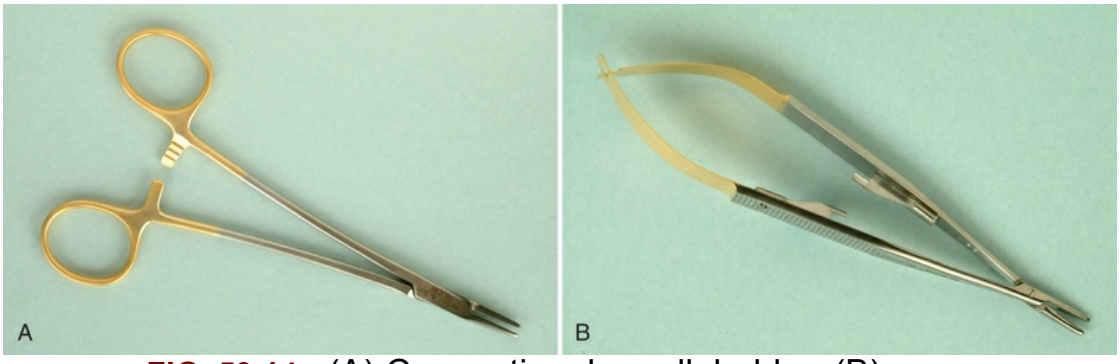

FIG. 59.14 (A) Conventional needleholder. (B) Castroviejo needleholder.

Conclusion

The majority of periodontal surgical procedures can be carried out with the thorough application of local anesthesia. Clinicians have

the obligation to ensure a patient-centered approach that includes oral, intravenous, and inhalational sedation in their spectrum of available services for their patients.

The efficient, precise, and minimally traumatic management of tissues is necessary to achieve the most predicable and comfortable result and outcome for the patient. Most patients need oral analgesic support, and they should be given the necessary pain-relieving medications so that an effective level of analgesia is present during the immediate postsurgical period. The use of longer-acting local anesthetic agents (e.g., bupivacaine) and protective periodontal dressings also helps to reduce postsurgical pain.

During the immediate postsurgical weeks, biofilm control and healing are enhanced by the use of antimicrobial mouthrinses such as chlorhexidine. Postsurgical root sensitivity is well controlled by ensuring that biofilm control is optimal, and occasionally desensitizing agents will be needed.

Case Scenario 59.1

Patient:
43-year-old white male

Chief Complaint:
"I need gum surgery."

Background:
Patient is healthy. He does not take any medications. He has smoked approximately one pack of cigarettes per day since he was 25 years old. He says that he was advised to see a periodontist about 5 years ago but did not follow the recommendation.

Current Findings:
Generalized marginal erythema with bleeding on probing. Probing pockets depths range from 2-4 cm, with localized 5-8 mm at interproximal sites between molars.

1. Which procedure should **not** be used to control hemorrhage	**Answer: 5** **Explanation:** The use of local anesthesia with

before dismissing the patient when the surgery is completed? 1. Pressure 2. Application of cold pressure 3. Removal of granulation tissue 4. Microfibrillar collagen 5. Local anesthesia with epinephrine 6. None of the above	epinephrine causes vasoconstriction. However, this effect has a short duration. The use of vasoconstriction should not be relied on for long-term hemostasis.

CHAPTER 60

Periodontal Surgical Therapy

Jonathan H. Do, Henry H. Takei, Michael Whang, Kitetsu Shin

CHAPTER OUTLINE

Rationale for Periodontal Access Surgery
Fundamentals of Periodontal Surgery
Periodontal Surgical Techniques
Conclusion

Rationale for Periodontal Access Surgery

In moderate to advanced cases, and in cases with furcation invasion and infrabony defects, it may be difficult and even impossible to resolve periodontal inflammation completely with nonsurgical therapy alone. Adjunctive periodontal access surgery is necessary in many of these cases to treat the periodontal disease definitively, create anatomies that are maintainable long-term by both the patient and the clinician, and, when feasible, reconstruct lost

periodontal structures. Periodontal access surgery enhances access for root instrumentation and allows for reduction of periodontal pockets and correction of osseous defects. However, periodontal access surgery frequently results in gingival recession and loss of interdental papillae.

In the anterior maxilla, where aesthetics is of high priority, recession and loss of interdental papillae can present major aesthetic problems that are both difficult and unpredictable to treat. As such, in the anterior aesthetic area, periodontal disease is treated first and foremost nonsurgically, and periodontal access surgery is reserved for instances where surgical access is absolutely necessary. Fortunately, the anterior location of these teeth and their single-rooted and convex root surface anatomies facilitate nonsurgical root instrumentation. When specialized instruments such as mini Gracey curettes and Vision Curvettes are used in conjunction with illumination and magnification, access to these periodontal pockets are enhanced, and nonsurgical periodontal therapy can be very efficacious.

In the posterior sextants, access for definitive root instrumentation is much more restricted due to multiple anatomic factors, especially around multirooted teeth. Wide proximal surfaces, root grooves and concavities, furcations, angulation and proximity of roots, depth of the periodontal pocket, the cheek, the tongue, and the opposing dentition can all contribute to hinder the removal of subgingival biofilm and calculus on these teeth. Fortunately, gingival recession and loss of interdental papillae generally do not present aesthetic problems for most patients. Many patients and clinicians are willing to accept recession and the associated transient root sensitivity and food impaction in exchange for periodontal health. As such, periodontal access surgery is a treatment modality that is essential and frequently used in the treatment of periodontal disease in the nonaesthetic area.

Periodontal access surgery is an adjunct to nonsurgical periodontal therapy and should occur only once the patient has demonstrated effective biofilm control. The *primary* objective of periodontal access surgery is to obtain access for root instrumentation to remove bacterial biofilm and calculus accretion on the root surfaces thoroughly. The *secondary* objective of

periodontal access surgery is pocket reduction via soft and hard tissue resection or periodontal regeneration to facilitate home care and long-term professional supportive maintenance. These objectives are achieved by two main modalities of periodontal access surgery, gingivectomy and periodontal flap surgery. Both gingivectomy and flap surgery provide access for root instrumentation. Pocket reduction is achieved only by resection of the suprabony soft tissue pocket in gingivectomy, whereas with periodontal flap surgery pocket reduction is achieved via soft tissue resection, osseous resection, or periodontal regeneration.

Learning Box 60.1

The primary objective of periodontal access surgery is access for root instrumentation. The secondary objective of periodontal access surgery is pocket reduction via soft and hard tissue resection or periodontal regeneration.

Fundamentals of Periodontal Surgery

Incisions

Periodontal surgery involves the use of horizontal (mesial-distal) and vertical (occlusal-apical) incisions. The #15 or #15C surgical blade is used most often to make these incisions.

Horizontal Incisions

Horizontal incisions are directed along the gingiva in a mesial or distal direction. Flaps can be reflected with the use of only horizontal incision if sufficient access can be obtained in this way and if apical, lateral, or coronal displacement of the flap is not anticipated. If vertical incisions are not made, the flap is called an *envelope flap.*

Straight and Scalloped Incisions

A horizontal incision that follows the scalloped morphology of the gingival architecture is called a scalloped incision, as opposed to a

straight incision, which follows a straight line (Fig. 60.1). The scalloped incision is advantageous in preserving the interdental architecture in gingivectomy and in creating surgical papillae and preserving soft tissue over the interdental areas to allow coverage of the interdental bone in flap surgery. Historically, the horizontal incisions were used in both gingivectomy and flap surgery to eliminate the interdental tissue, where periodontal disease and periodontal pockets frequently occur. The *interdental denudation procedure* used horizontal internal bevel incisions to remove the gingival papillae and to denude the interdental spaces.[3,4,25,29] This technique completely eliminates the inflamed interdental tissue. Healing is by secondary intention and results in excellent gingival contour and shallow probing depths. However, the initial healing is slow and uncomfortable due to exposure and necrosis of interdental bone. For this reason, the interdental denudation procedure has very limited clinical application. The use of scalloped incisions in flap surgery allows the interdental bone to be covered once the flap is coapted. This enhances patients' comfort and allows for faster closure of the wound.

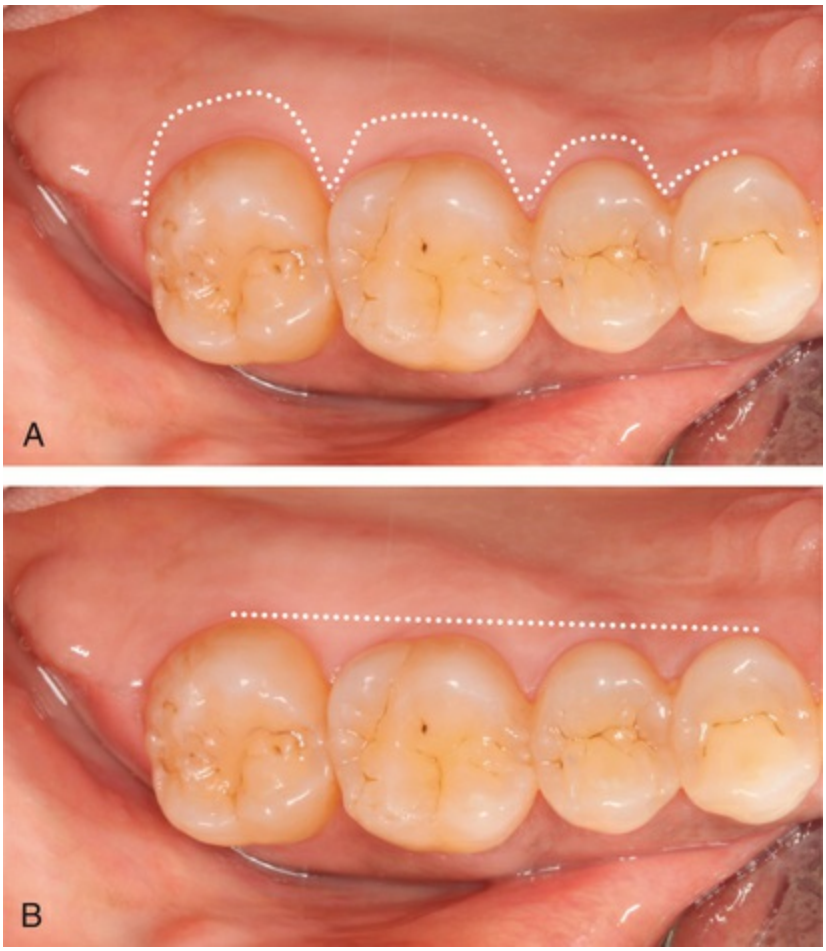

FIG. 60.1 (A) Scalloped incision. (B) Straight incision.

When scalloping the incision, the scallop is from the mesial line angle to the distal line angle to maximize the width of the surgical papillae and to allow tight adaptation of the flap to the roots once the flap is coapted. In the interdental areas, the incision is maintained close to or in the sulcus to maximize coverage of the interdental bone. The scallop incision should take into account root anatomy to optimize primary closure. For example, the mesial-distal palatal dimension of a maxillary molar decreases from the cementoenamel junction down to the palatal root as the tooth transitions from a root trunk to a single root. An aggressive scallop may leave bone around the palatal root of a maxillary molar exposed.

External Bevel and Internal Bevel Incisions

The external bevel incision starts at the surface of the gingiva apical to the periodontal pocket and is directed coronally toward the tooth

apical to the bottom of the periodontal pocket. The external bevel incision, or simply bevel incision, is used primarily in gingivectomy, and it can be made with a scalpel or a knife. The internal bevel incision, also called the reverse bevel incision and inverse bevel incision, is the opposite of the external bevel incision (Fig. 60.2). The internal bevel incision[28] starts at the surface of the gingiva and is directed apically to the bone crest. It is the incision from which the flap is reflected to expose the underlying bone and root. The internal bevel incision accomplishes three important objectives: (1) it removes the pocket lining; (2) it conserves the relatively uninvolved outer surface of the gingiva, which, if apically positioned, becomes attached gingiva; and (3) it produces a sharp, thin flap margin for adaptation to the bone–tooth junction. The internal bevel incision is basic to most periodontal flap procedures. Both bevel and internal bevel incisions can be straight or scalloped.

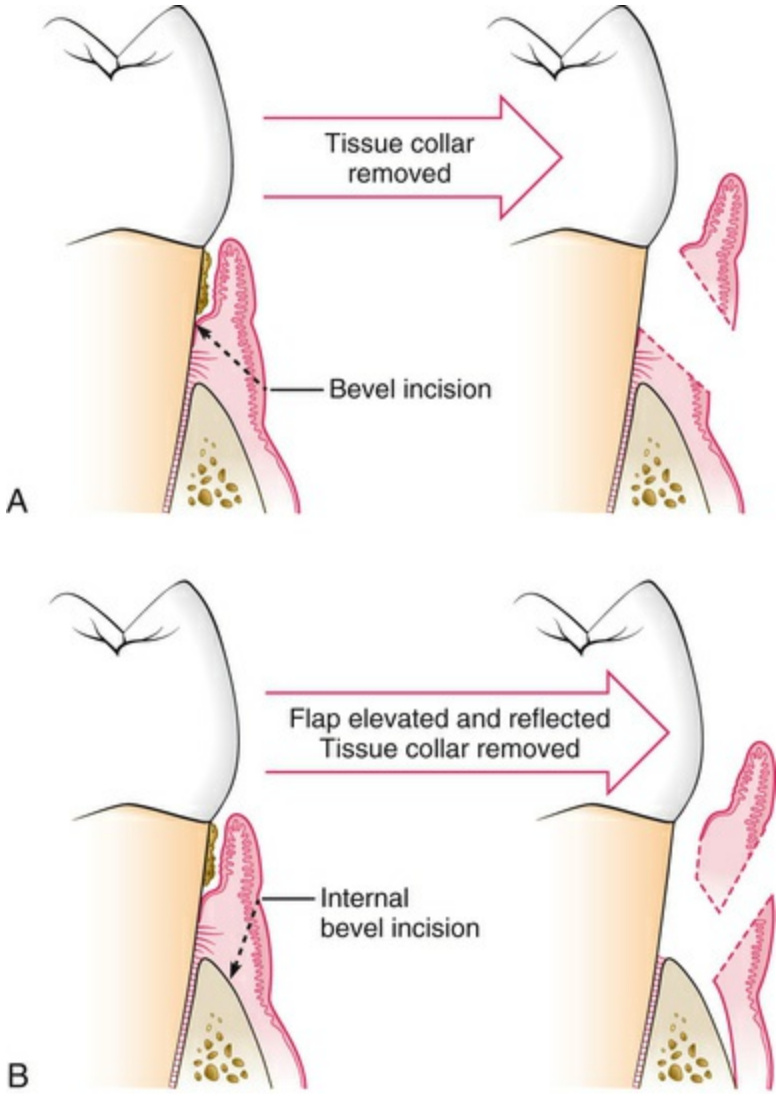

FIG. 60.2 (A) Bevel incision. (B) Internal bevel incision.

Crevicular, Crestal, and Submarginal Incisions

The crevicular incision is also called intercrevicular incision, intracrevicular incision, sulcular incision, intrasulcular incision, and intersulcular incision. It starts in the gingival crevice and is directed apically through the junctional epithelium and connective tissue attachment and down to the bone (Fig. 60.3). The crestal incision is also called the marginal incision. It starts at the surface of the gingiva at the gingival margin and is directed apically down through the epithelium and connective tissue to the bone. Both the crevicular and crestal incisions are internal bevel incisions. The submarginal incision starts at the surface of the gingiva apical to the gingival margin and can be external bevel or internal bevel. In flap

surgery, the submarginal incision is an internal bevel incision, whereas in gingivectomy, it is an external bevel incision.

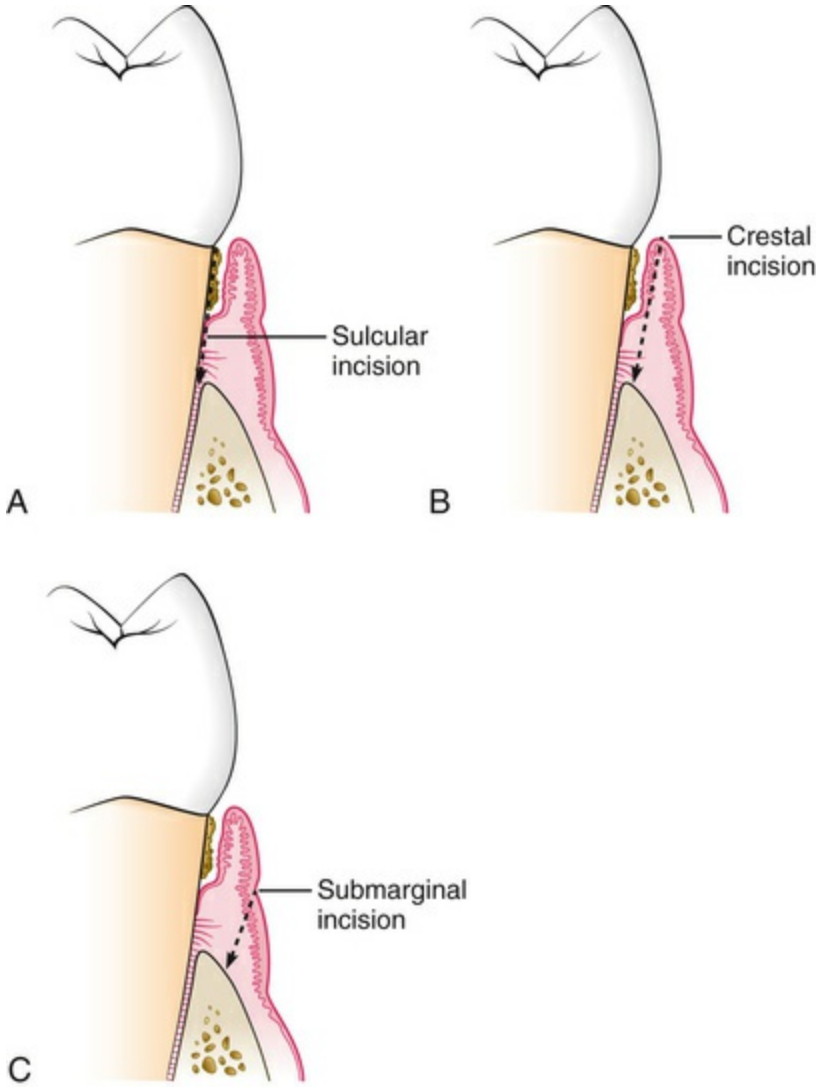

FIG. 60.3 (A) Sulcular incision. (B) Crestal incision. (C) Submarginal incision.

The use of a crevicular, marginal, or submarginal internal bevel incision in periodontal flap surgery depends on the objectives of the surgery and the anatomy of the area. The crevicular incision is frequently used in regenerative periodontal surgery to retain all gingival tissue to maximize blood supply and to obtain primary wound closure. The crevicular incision is also the incision of choice when recession is not desired. The anterior maxilla is an area where recession and loss of interdental papillae can compromise aesthetics. When flap surgery is required in the anterior maxilla, the

crevicular incision is recommended. In resective periodontal surgery, the marginal and submarginal scalloped incisions are frequently used to create flaps with thin margins and to leave a collar of tissue around the tooth that contains the epithelium of the pocket lining and the adjacent granulomatous tissue. This collar of tissue is discarded after flap elevation. The marginal incision maximizes the remaining keratinized tissue, whereas the submarginal scalloped incision allows for more aggressive soft tissue resection and reduction of the periodontal pocket.

When the submarginal scalloped incision is used, *how submarginal should be incision be?* The placement of the submarginal incision always depends on two of three factors, depending on the location: (1) the transgingival interdental probing depth, (2) the mucogingival junction, and (3) the depth of the palatal vault.

Learning Box 60.2

Placement of the submarginal scalloped incision depends on (1) the transgingival interdental probing depth, (2) the mucogingival junction, and (3) the depth of the palatal vault.

The transgingival interdental probing depth is used to provide a guide for the placement of the submarginal scalloped incision. The transgingival probing depth is the distance from the gingival margin down to the bone. It is measured by inserting the probe into the gingival crevice through the attachment apparatus and down to the bone. Transgingival probing is also called *bone sounding*. The submarginal scalloped incision is placed a distance of one-half to two-thirds the transgingival interdental probing depth away from the tooth surface (Fig. 60.4). For example, if the mesial and distal interdental probing depths are 6 mm, then the submarginal scalloped incision will be placed 3 mm apical to the gingival margin at the midbuccal and midlingual surface of the tooth. *Why is the transgingival interdental probing depth used as a guide for the placement of the submarginal scalloped incision in resective periodontal surgery?* Periodontal disease occurs most commonly in the interdental areas due to inadequate biofilm removal below the interdental proximal

contact. Interdental attachment and bone loss result in reverse/negative bony architecture. To reestablish positive architecture, the radicular bone is resected apical to the interdental bone, whereas the interdental bone is maintained. Therefore, the transgingival interdental probing depth is used as the guide for submarginal incision placement.

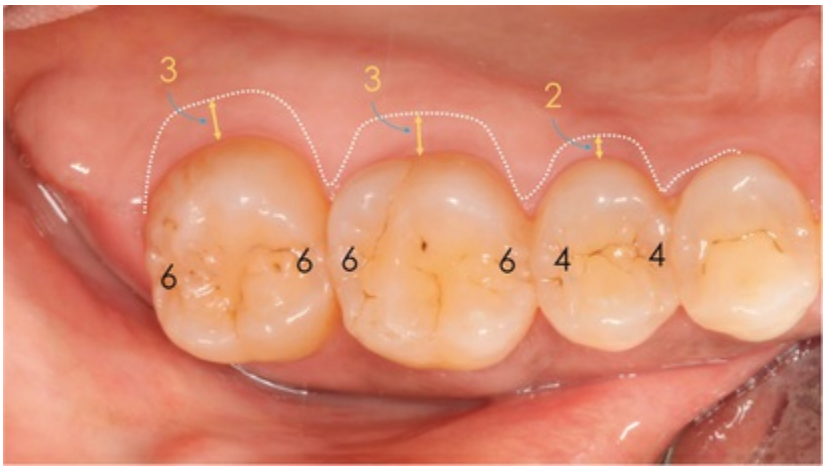

FIG. 60.4 The submarginal scalloped incision is placed a distance of one-half to two-thirds the transgingival interdental probing depth away from the tooth surface.

Although the presence of keratinized tissue is not required for periodontal health, its presence facilitates oral hygiene. Therefore, the submarginal scalloped incision will be placed depending on the mucogingival junction to preserve ≥3 mm of keratinized tissue. If the width of keratinized tissue is narrow, the submarginal scalloped incision will be placed closer to the gingival margin. A marginal incision would be used in lieu of a submarginal incision if the width of the keratinized tissue is <3 mm. If the width of the keratinized tissue is broad, then the submarginal scalloped incision will be placed based on the transgingival interdental probing depth (Fig. 60.5).

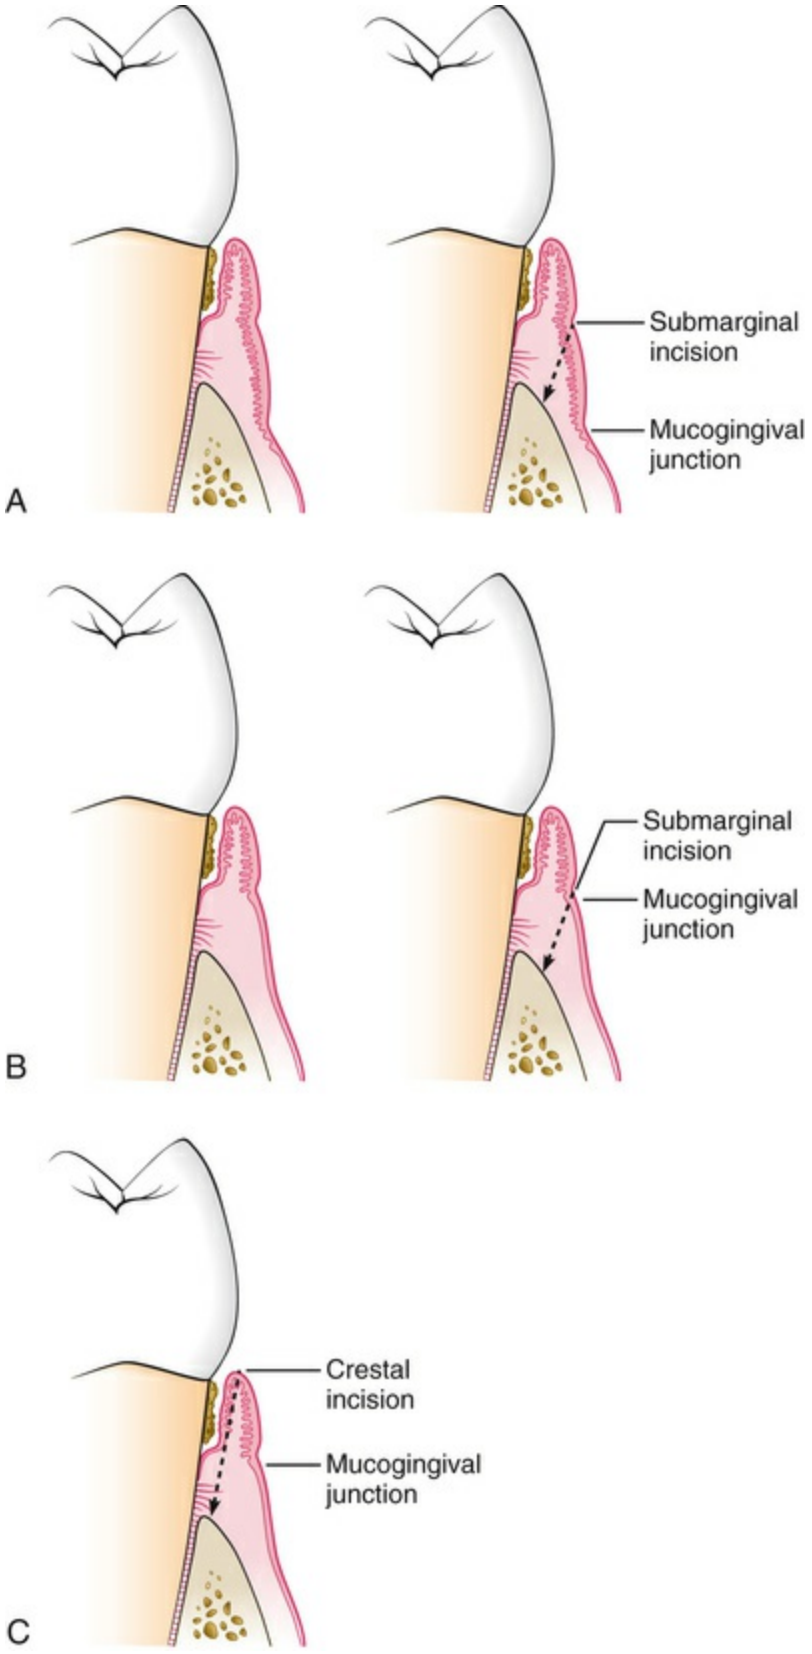

FIG. 60.5 (A) When keratinized tissue is abundant, a submarginal incision may be used. (B) When keratinized tissue is limited, a submarginal incision eliminates keratinized tissue that must be retained. (C)

A crestal incision maximizes the retained keratinized tissue.

On the *palatal maxilla*, where the lack of keratinized tissue is not a concern, placement of the submarginal scalloped incision must take into consideration the depth of the palatal vault (Fig. 60.6). A high palatal vault will allow the submarginal incision to be placed based on one-half to two-thirds the transgingival interdental probing depth. In shallow palates, the more submarginal an incision, the closer it will be to the midline and the farther away it will be from the tooth surface. A submarginal incision placed in a shallow palatal vault based on the transgingival probing depth may result in a palatal flap that is too short to provide complete coverage of the alveolar bone and primary closure once it is coapted. Therefore, the flatter the palatal vault, the closer the submarginal incision must be to the gingival margin. If the palatal flap is too long when it is coapted, it can always be trimmed and rescalloped.

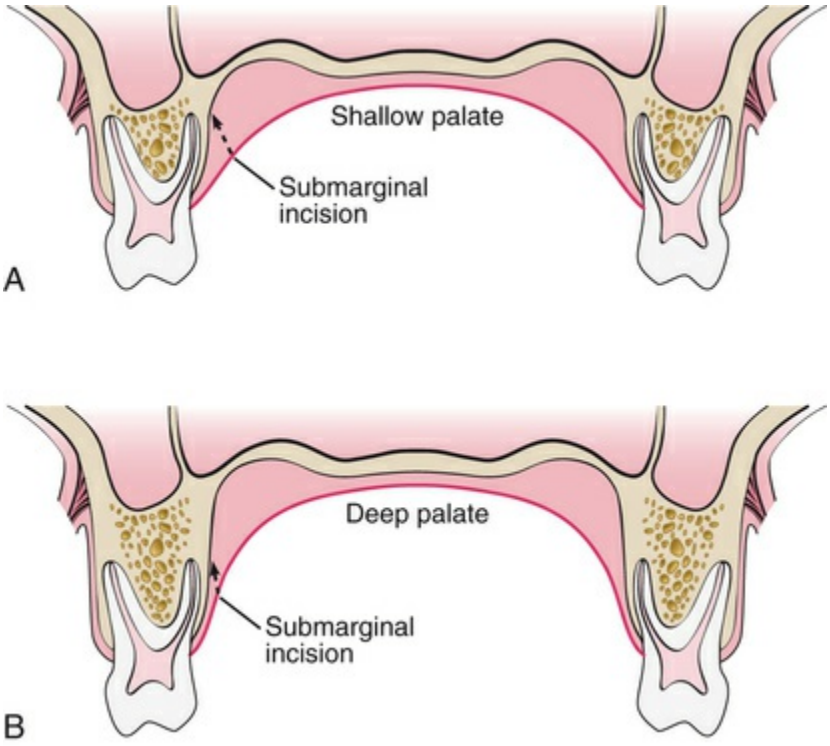

FIG. 60.6 (A) In a shallow palate, the more submarginal an incision, the closer it will be to the midline and the farther away it will be from the tooth surface. (B) In a high palate, a submarginal incision remains close to the tooth and allows for primary

closure of the flap.

In areas where a mucogingival junction is present, such as the buccal or facial maxilla and the buccal or facial and lingual mandible, resection of soft tissue with the submarginal scalloped internal bevel incision is not the only way to obtain pocket reduction. A marginal incision can be used to maximize remaining keratinized tissue, and reduction of soft tissue height can be achieved by apically repositioning the flap margin to the level of the alveolar crest. The only area in the mouth where the submarginal incision must be used to reduce soft tissue height is the palate, where it is not possible to reposition the soft tissue apically due to the absence of a mucogingival junction.

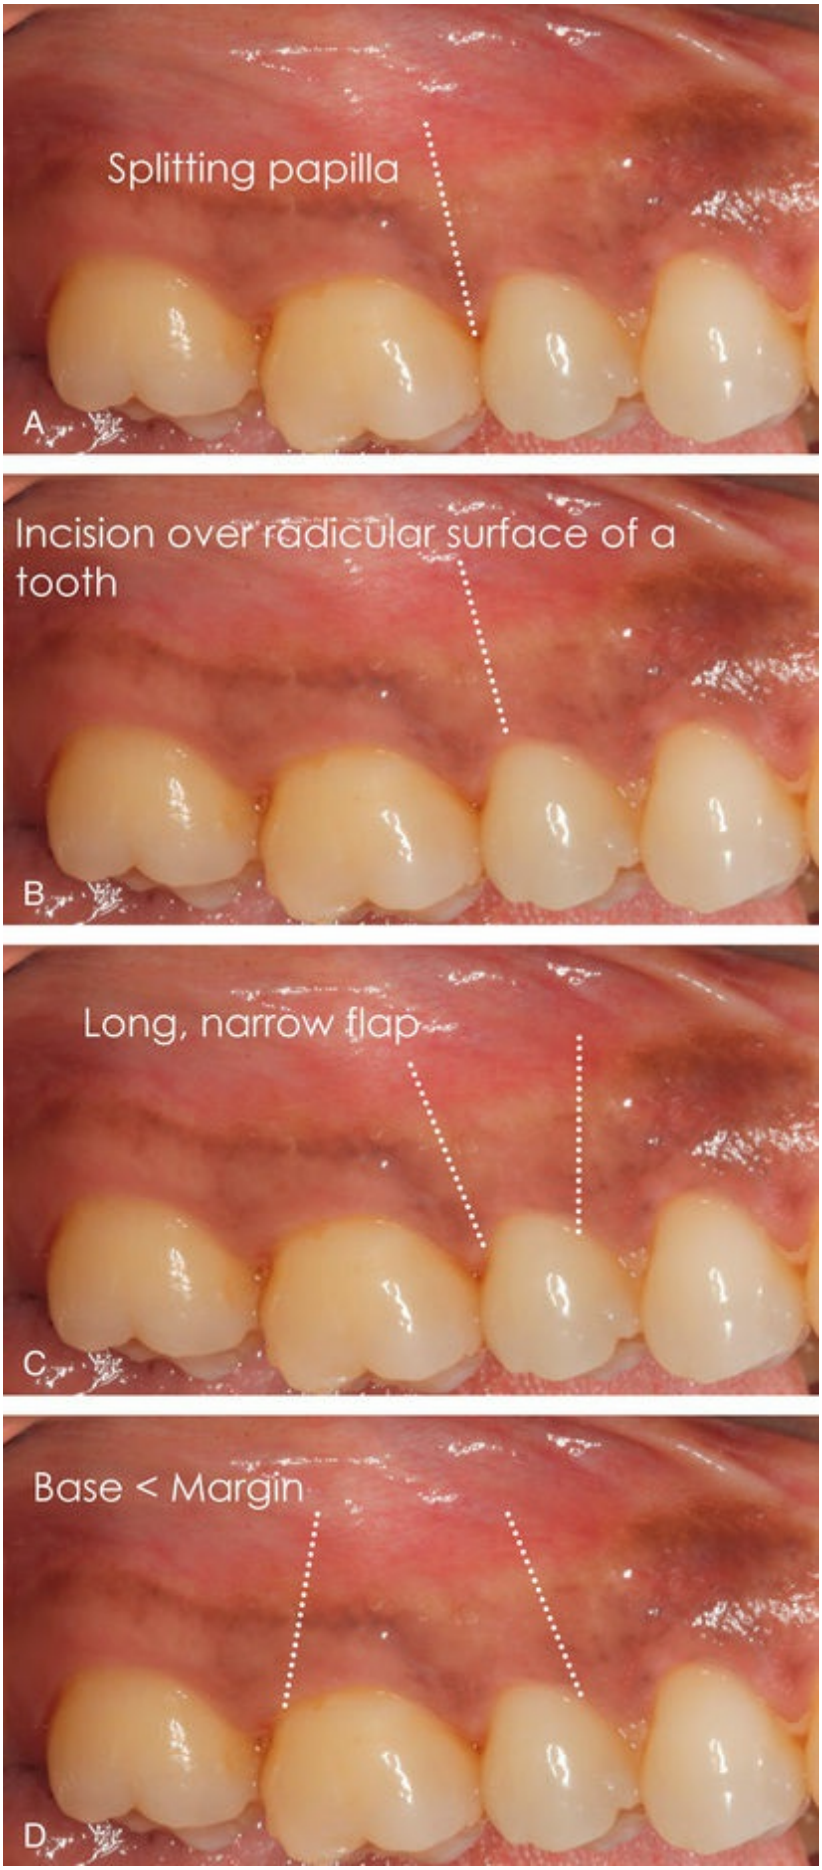
Learning Box 60.3

Reduction of soft tissue height may be achieved with the use of the submarginal scalloped incision or a combination of a marginal scalloped incision and an apically displaced flap.

Vertical Incisions

Vertical or oblique releasing incisions can be used on one or both ends of the horizontal incision, depending on the design and purpose of the flap. Vertical incisions at both ends may be necessary if the flap is to be apically displaced. Vertical incisions must extend beyond the mucogingival junction to reach the alveolar mucosa; this allows for the release of the flap to be displaced.

In general, vertical incisions in the lingual and palatal areas are avoided. Facial vertical incisions should not be made in the center of an interdental papilla or over the radicular surface of a tooth. Incisions should be made at the line angles of a tooth either to include the papilla in the flap or to avoid it completely. The vertical incision should also be designed to avoid long (coronal-apical) and narrow (mesial-distal) flaps, and flaps with the base narrower than the margin, because this could jeopardize the blood supply to the flap (Fig. 60.7).



Splitting papilla
A
Incision over radicular surface of a tooth
B
Long, narrow flap
C
Base < Margin
D

FIG. 60.7 Vertical incisions should not (A) split a papilla or (B) be placed over a root prominence. When two vertical incision are used, (C) the length of the flap should not be longer than the width of the flap, and (D) the base of the flap should not be narrower than the margin of the flap.

Papilla Management

The papilla may be thinned, preserved, or split beneath the contact point. Management of the papilla depends on the dimension of the interdental space, aesthetics, and the secondary objective of the surgery, which could be resective or regenerative. In resective surgery, the scalloped incision creates surgical papillae to cover the interdental bone. The surgical papilla may or may not include the original papilla, depending on submarginal placement of the scalloped incision. The surgical papilla is thinned to create the same thickness as the remainder of the flap to allow intimate adaptation of the papilla and the flap with the bone once the flap is coapted. In regenerative therapy and in aesthetic cases, the *papilla preservation technique*[35] (Fig. 60.8), which retains the entire papilla, is favored when the interdental space is adequate to allow the intact papilla to be reflected with the facial or lingual-palatal flap. When the interdental space is narrow and reflection of an intact papilla is not possible, the interdental papilla is split beneath the contact point of the two approximating teeth to allow for the reflection of the buccal and lingual flaps. The papilla is not thinned in these cases to minimize tissue shrinkage.

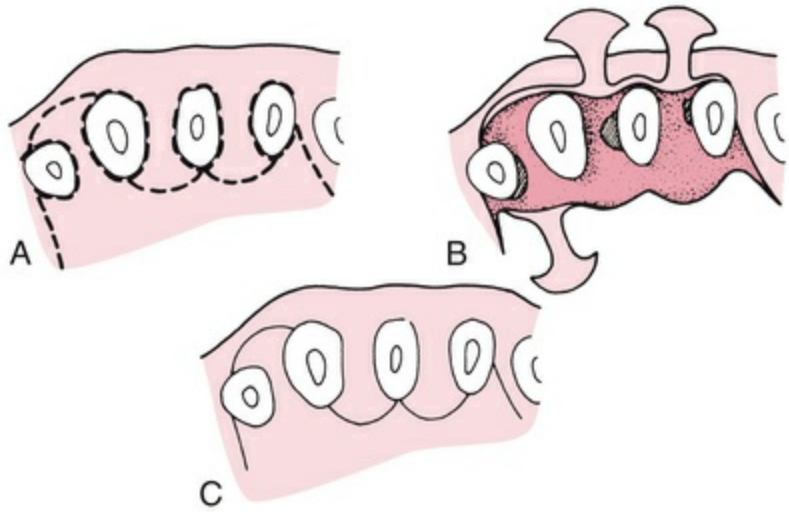


FIG. 60.8 **Flap design for a papilla preservation flap. (A) Incisions for this type of flap are depicted by interrupted lines. The preserved papilla can be incorporated into the facial or the lingual–palatal flap. (B) The reflected flap exposes the underlying bone. Several osseous defects are seen. (C) The flap has been returned to its original position, where it covers all of the interdental spaces.**

Flap Elevation

A periodontal flap may be elevated in full thickness or partial thickness (Fig. 60.9).

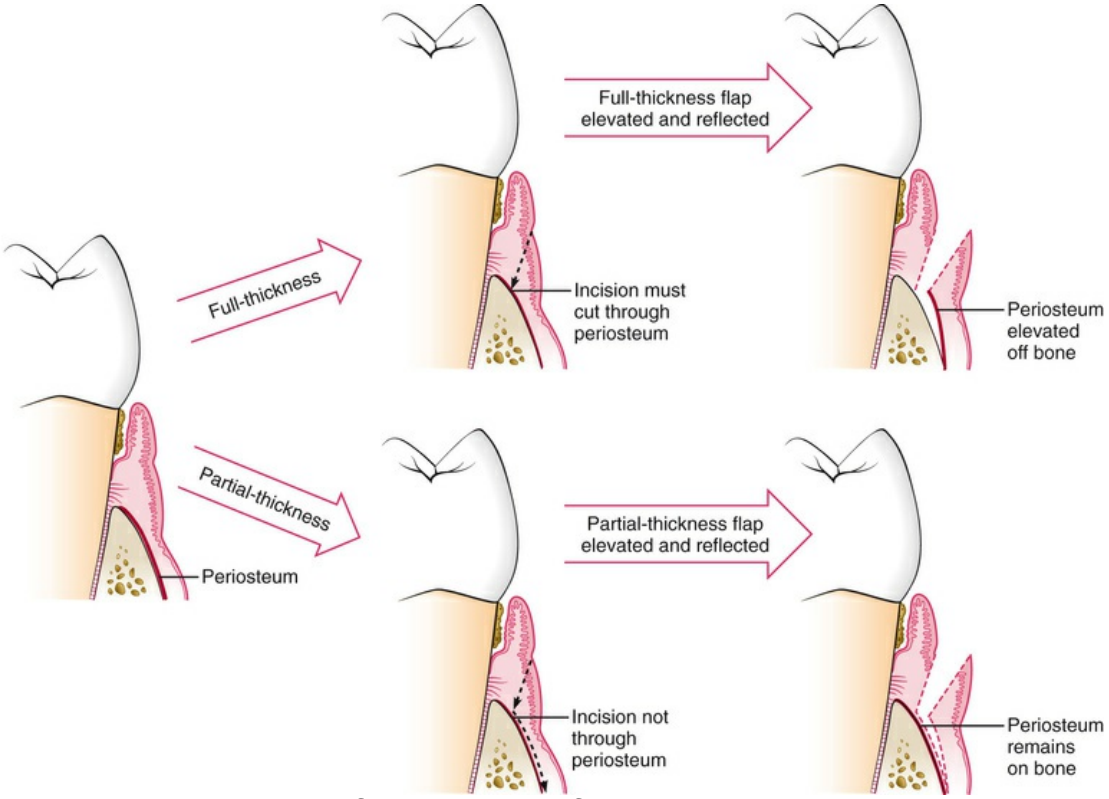

FIG. 60.9 In full-thickness flap elevation, the periosteum is elevated off the bone by blunt dissection. In partial-thickness flap elevation, the flap is split by sharp dissection to leave the periosteum and connective tissue intact over the bone.

In a *full-thickness flap,* all of the soft tissue, including the periosteum, is reflected to expose the underlying bone. This complete exposure of and access to the underlying bone are indicated when resective or regenerative osseous surgery is contemplated. This type of flap is also called the mucoperiosteal flap. Elevation of a full-thickness flap requires the internal bevel incision to penetrate the periosteum, the last tissue overlying the bone. Once the periosteum has been completely incised along the length of the flap, a full-thickness flap is reflected by elevating the periosteum off the bone via blunt dissection. A periosteal elevator or curette is used to separate the periosteum from the bone by moving it mesially, distally, and apically on the bone until the desired reflection is accomplished, usually a millimeter apical to the mucogingival junction. Elevation of the periosteum off the bone should be performed with ease, and it can even be done with gauze. Difficulty in elevating a full-thickness flap is usually due to

incomplete and noncontiguous incision of connective tissue and periosteum along the length of the flap.

The *partial-thickness flap* includes only the epithelium and a layer of the underlying connective tissue. The bone remains covered by a layer of connective tissue that includes the periosteum. This type of flap is also called the *split-thickness flap.* The partial-thickness flap is indicated when the flap is to be positioned apically or when exposure of bone is not desired. Elevation of a partial-thickness flap is completed by sharp dissection with a surgical scalpel (#15). When the tissue is thin, a flap may be elevated at full thickness slightly past the mucogingival junction and at partial thickness apical to the mucogingival junction. The combination of full-thickness and partial-thickness flaps reduces the risk of flap perforation at the mucogingival junction, where the tissue is often the thinnest. This also allows for access to bone around the teeth and preserves tissue over the bone apical to the mucogingival junction, which can be used to help stabilize the flap should it be apically displaced.

Conflicting data surround the advisability of uncovering the bone when this is not actually needed. When bone is stripped of its periosteum, a loss of marginal bone occurs, and this loss is prevented when the periosteum is left on the bone.[7] Although this is usually clinically insignificant,[14] the difference may be significant in some cases. The partial-thickness flap may be necessary when the crestal bone margin is thin or when dehiscences or fenestrations are present. An apically displaced flap may be stabilized by suturing it to the intact periosteum.

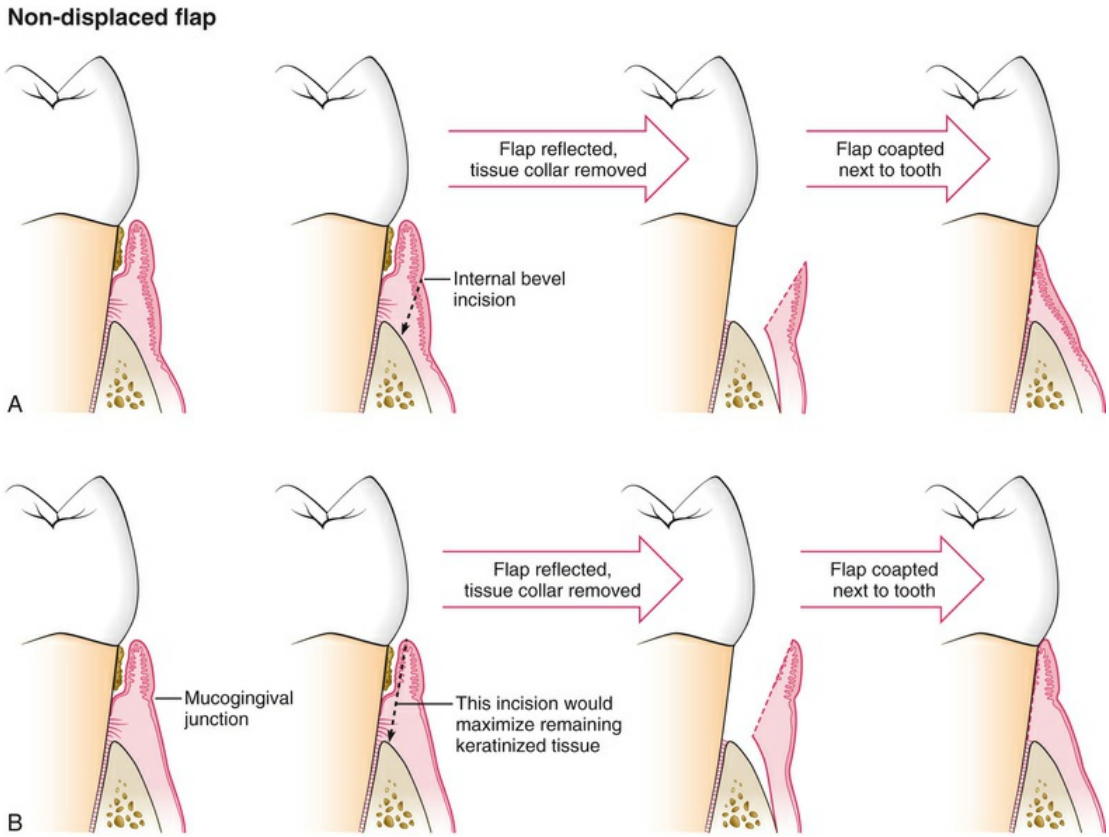
Learning Box 60.4

When the tissue is thin, a flap may be elevated at full thickness slightly past the mucogingival junction and at partial thickness apical to it to reduce flap perforation at the mucogingival junction and to use the advantages of each flap.

Flap Coaptation

For flap coaptation after surgery, flaps are classified as either (1) *nondisplaced flaps,* when the flap is placed and sutured in its original

position, or (2) *displaced flaps,* which are placed apically, coronally, or laterally to their original position (Fig. 60.10). Both full-thickness and partial-thickness flaps can be displaced. For a full-thickness flap to be displaced, the attached gingiva must be completely separated from the underlying bone and the flap must be elevated apical to the mucogingival junction, thereby enabling mobility of the flap. Flap mobility may also require the use of vertical incisions and the release of the periosteum, especially for full-thickness flaps. Although the periosteum is only a few cells thick, it is not elastic. The periosteum may be folded over itself to allow apical displacement of the flap. However, it does not stretch, and coronal flap displacement requires the periosteum to be incised along the length of the flap. Palatal flaps cannot be displaced due to absence of a mucogingival junction and mobile elastic tissue.



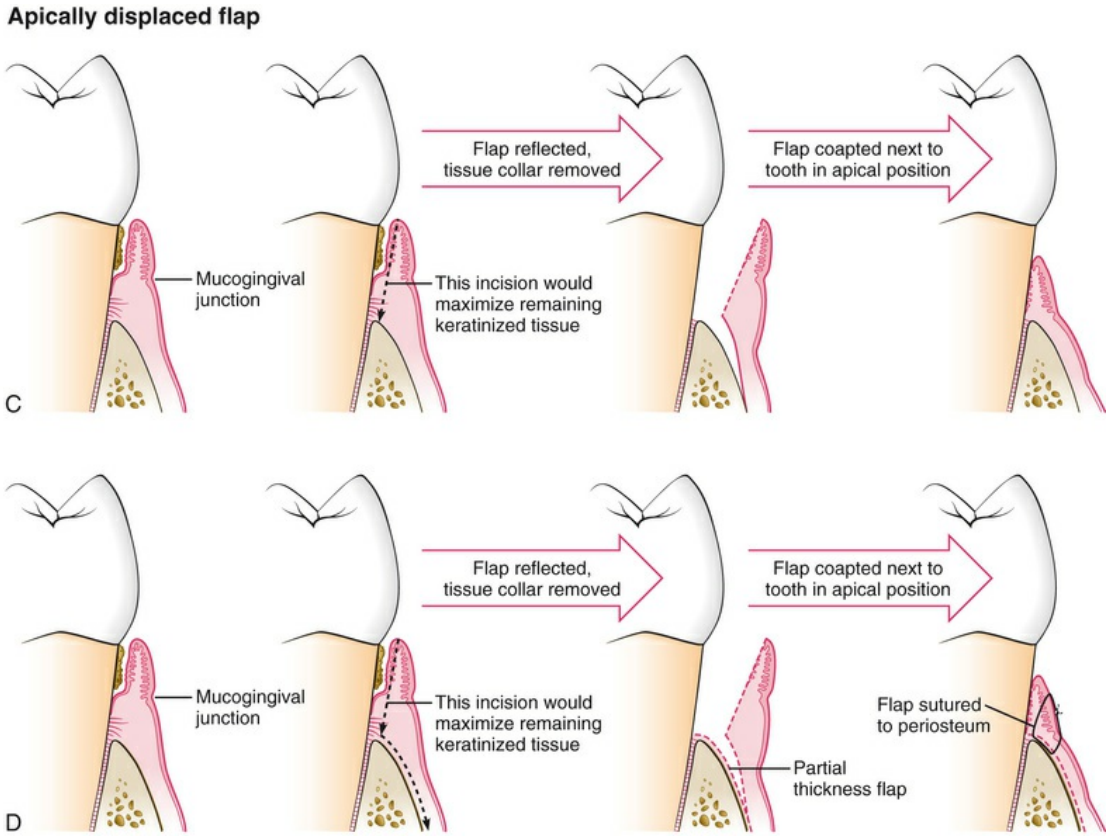


FIG. 60.10 (A) In the presence of abundant keratinized tissue, reduction in soft tissue height is obtained with a submarginal scalloped incision. (B) A marginal incision is used to maximize remaining keratinized tissue. A nondisplaced flap results in thick soft tissue height. This is desirable in an aesthetic area where recession needs to be minimized. (C) A marginal incision, to maximize keratinized tissue, is combined with an apically displaced flap to reduce soft tissue height. (D) A partial-thickness flap is used to allow stabilization of an apically positioned flap with a periosteal suture.

Apically displaced flaps have the important advantage of preserving the outer portion of the pocket wall and transforming it into attached gingiva. Therefore, these flaps accomplish the double objective of eliminating the pocket and increasing the width of the attached gingiva. The apically displaced flap also allows for pocket reduction in instances where keratinized tissue is limited and the internal bevel incision must be made close to or at the gingival margin.

At locations where keratinized tissue is abundant, and pocket reduction is desired, such as the palate, a nondisplaced flap is

created with a submarginal scalloped incision to eliminate marginal tissue.

Flap Closure

After all of the necessary procedures are completed, the area is reexamined and cleansed, and the flap is placed in the desired position. The flap should remain in this position without tension. It is convenient to keep the flap in place with light pressure via the use of a piece of gauze to allow the blood clot to form.

The purpose of suturing is to maintain the flap in the desired position until healing has progressed to the point at which sutures are no longer needed. Many types of sutures, suture needles, and materials are available.[9,20] Suture materials may be either *nonresorbable* or *resorbable,* and they may be further categorized as *braided* or *monofilament* (eBox 60.1). The resorbable sutures have gained popularity because they enhance patients' comfort and eliminate suture removal appointments. The monofilament type of suture alleviates the "wicking effect" of braided sutures that may allow bacteria from the oral cavity to be drawn through the suture to the deeper areas of the wound. The braided silk suture was the most common nonresorbable suture used in the past because of its ease of use and low cost. The expanded polytetrafluoroethylene, synthetic, monofilament suture is an excellent nonresorbable suture that is widely used today.

eBox 60.1

Sutures for Periodontal Flaps

Nonabsorbable (nonresorbable)
1. Silk: braided
2. Nylon: monofilament (Ethilon)
3. ePTFE: monofilament (Gore-Tex)
4. Polyester: braided (Ethibond)

Absorbable (resorbable)
1. Surgical: gut

2. Plain gut: monofilament (30 days)
3. Chromic gut: monofilament (45 to 60 days)

Synthetic

1. Polyglycolic: braided (16 to 20 days)
2. Vicryl (Ethicon)
3. Dexon (Davis & Geck)
4. Polyglycaprone: monofilament (90 to 120 days)
5. Monocryl (Ethicon)
6. Polyglyconate: monofilament (Maxon)

ePTFE, Expanded polytetrafluoroethylene.

The most common resorbable sutures used today are the plain and chromic gut sutures. Both are monofilaments, and both are processed from purified collagen of either sheep or cattle intestines. The chromic suture is a plain gut suture that has been processed with chromic salts to make it resistant to enzymatic resorption, thereby increasing the resorption time. The synthetic resorbable sutures are also often used.

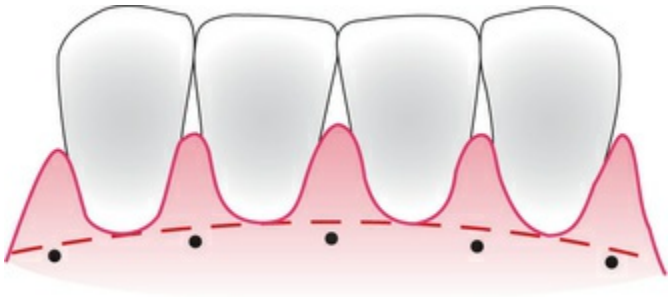
Technique

The needle is held with the needle holder, and it should enter the tissues at right angles and be no less than 2 to 3 mm from the incision. The needle is then carried through the tissue, where it follows the needle's curvature. The knot should not be placed over the incision.

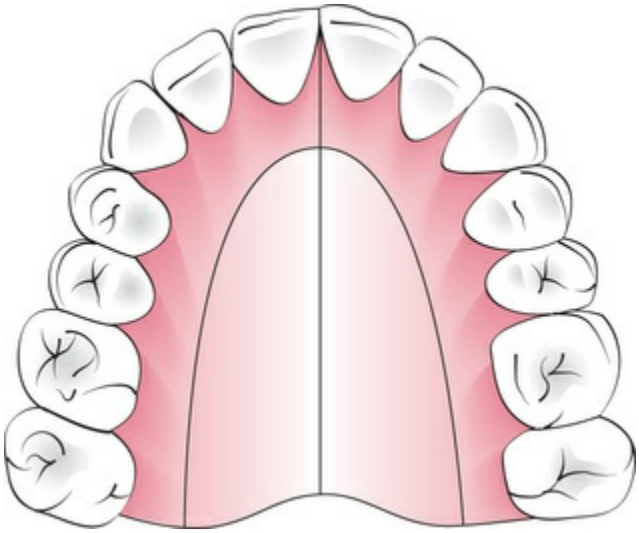
The periodontal flap is closed either with independent sutures or with continuous, independent sling sutures. The latter method eliminates the pulling of the buccal and lingual or palatal flaps together and instead uses the teeth as an anchor for the flaps. The flaps are less likely to buckle, and the forces on the flaps are better distributed.

Sutures of any type that are placed in the interdental papillae should enter and exit the tissue at a point located below the imaginary line that forms the base of the triangle of the interdental papilla (eFig. 60.1). The location of sutures for the closure of a palatal flap depends on the extent of flap elevation that has been performed. The flap is divided into four quadrants, as depicted in

eFig. 60.2.



EFIG. 60.1 **Placement of sutures in the interdental space below the base of an imaginary triangle in the papilla.**



EFIG. 60.2 **Placement of sutures to close a palatal flap. For slightly or moderately elevated flaps, the sutures are placed in the *shaded* areas. For the more substantial elevation of the flap, the sutures are placed in the central *(unshaded)* areas of the palate.**

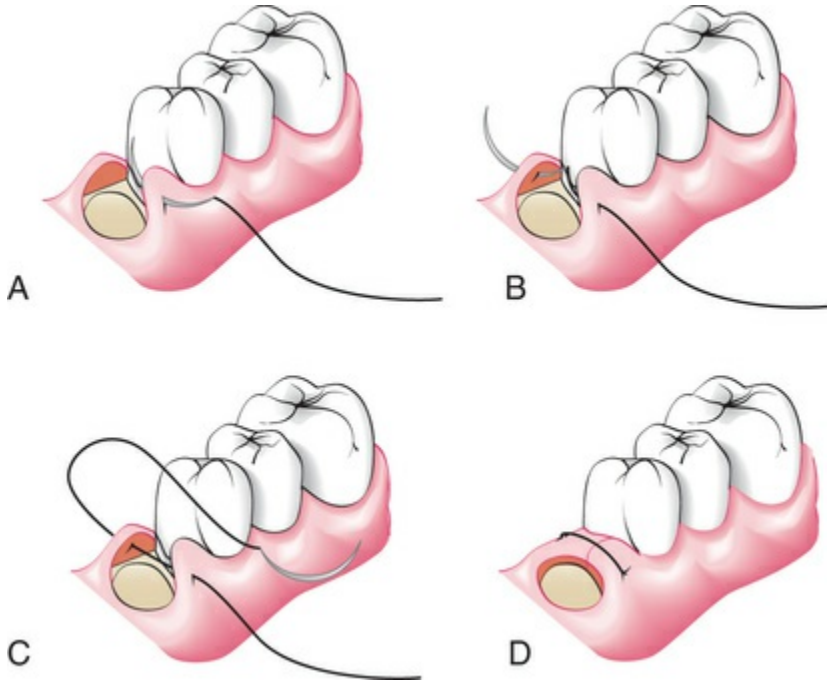
If the elevation of the flap is slight or moderate, the sutures can be placed in the quadrant closest to the teeth. If the flap elevation is substantial, the sutures should be placed in the central quadrants of the palate.

The clinician may or may not use periodontal dressings. When the flaps are not apically displaced, it is not necessary to use dressings other than those needed for patients' comfort.

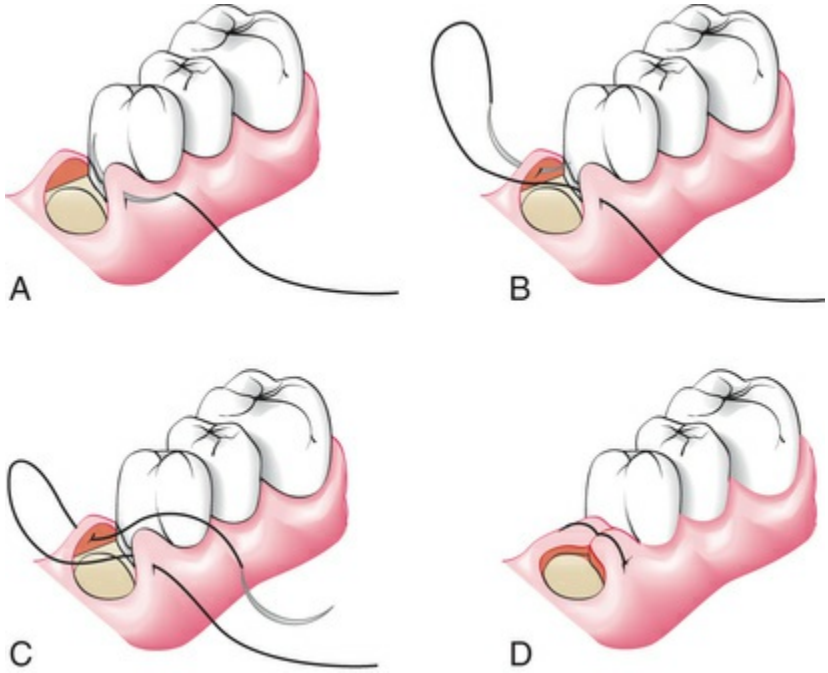
Ligation

Interdental Ligation

Two types of interdental ligation can be used: the direct loop suture (eFig. 60.3) and the figure-eight suture (eFig. 60.4). With the figure-eight suture, thread is placed between the two flaps. This suture is used when the flaps are not in close apposition as a result of apical flap position or nonscalloped incisions. This is simpler to perform than the direct ligation. The direct suture allows for a better closure of the interdental papilla. It should be performed when bone grafts are used or when close apposition of the scalloped incision is required.



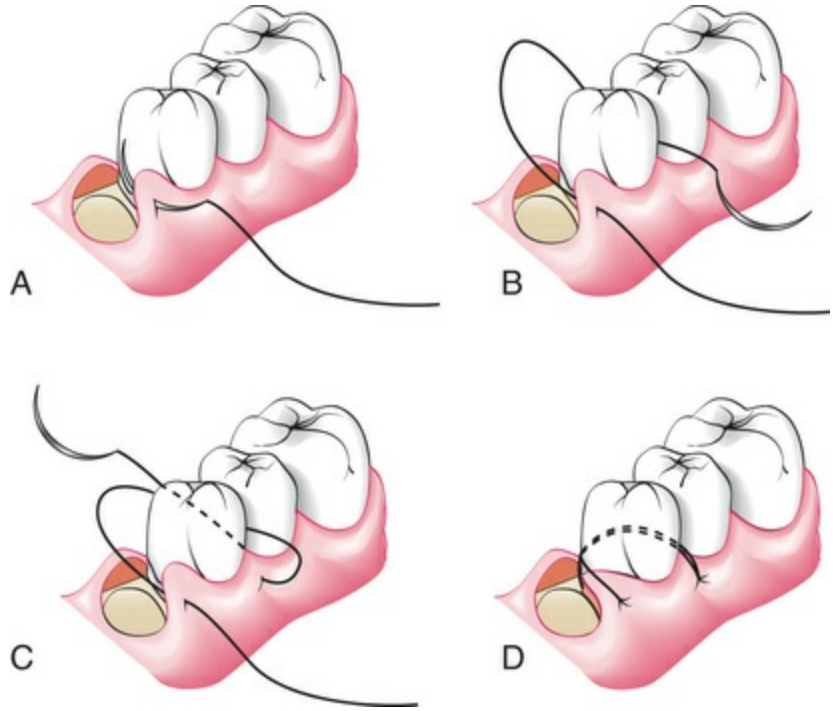
EFIG. 60.3 Simple loop suture is used to approximate the buccal and lingual flaps. (A) The needle penetrates the outer surface of the first flap. (B) The undersurface of the opposite flap is engaged, and (C) the suture is brought back to the initial side, where (D) the knot is tied.



EFIG. 60.4 Interrupted figure-eight suture is used to approximate the buccal and lingual flaps. The needle penetrates the (A) outer surface of the first flap and (B) the outer surface of the opposite flap. (C) The suture is brought back to the first flap, and (D) the knot is tied.

Sling Ligation

The sling ligation can be used for a flap on one surface of a tooth that involves two interdental spaces (eFig. 60.5).

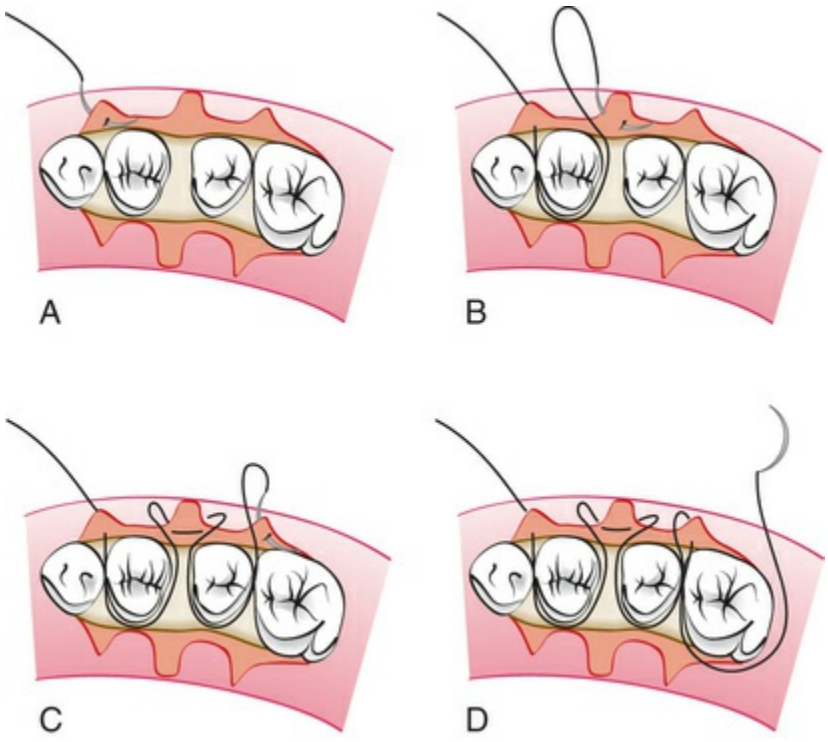


EFIG. 60.5 Single, interrupted sling suture is used to adapt the flap around the tooth. (A) The needle engages the outer surface of the flap and (B) encircles the tooth. (C) The outer surface of the same flap of the adjacent interdental area is engaged. (D) The suture is returned to the initial site, and the knot is tied.

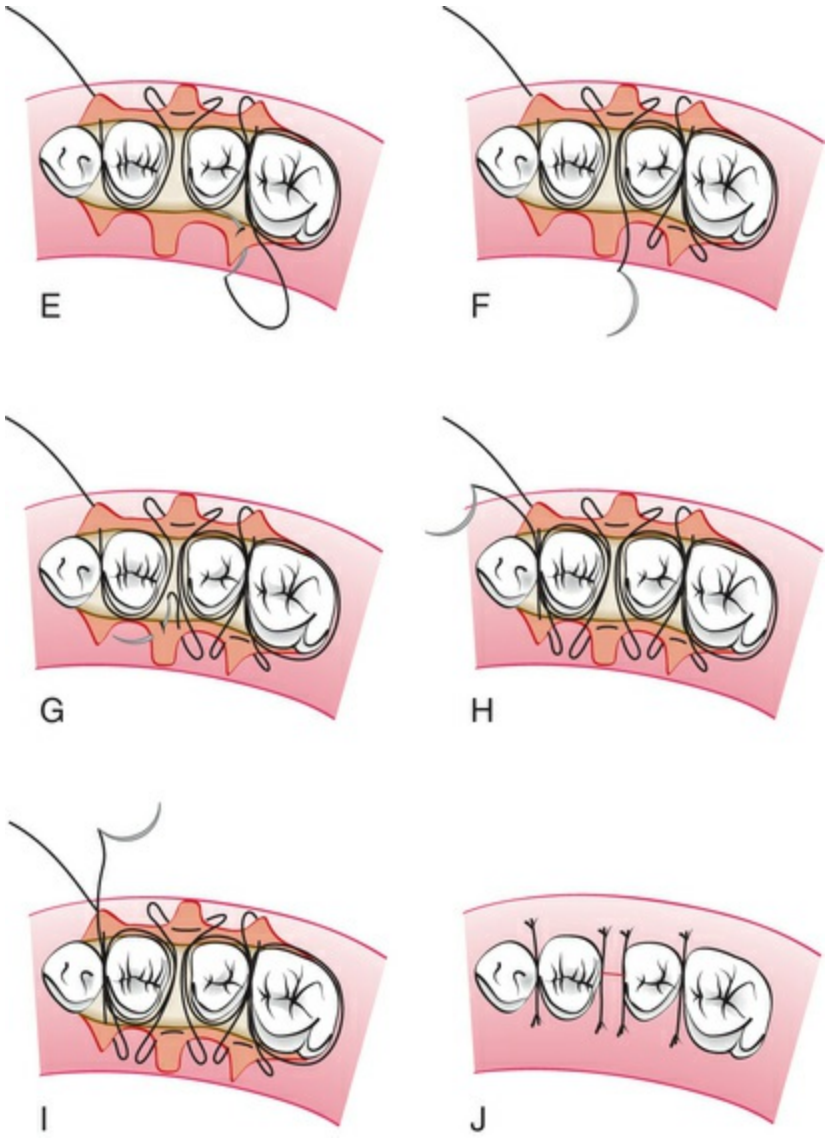
Types of Sutures

Horizontal Mattress Suture

The horizontal mattress suture is often used for interproximal areas of diastemata or for wide interdental spaces to adapt the interproximal papilla properly against the bone. Two sutures are often necessary. The horizontal mattress suture can be incorporated with the continuous, independent sling sutures, as shown in eFig. 60.6.



A
B
C
D

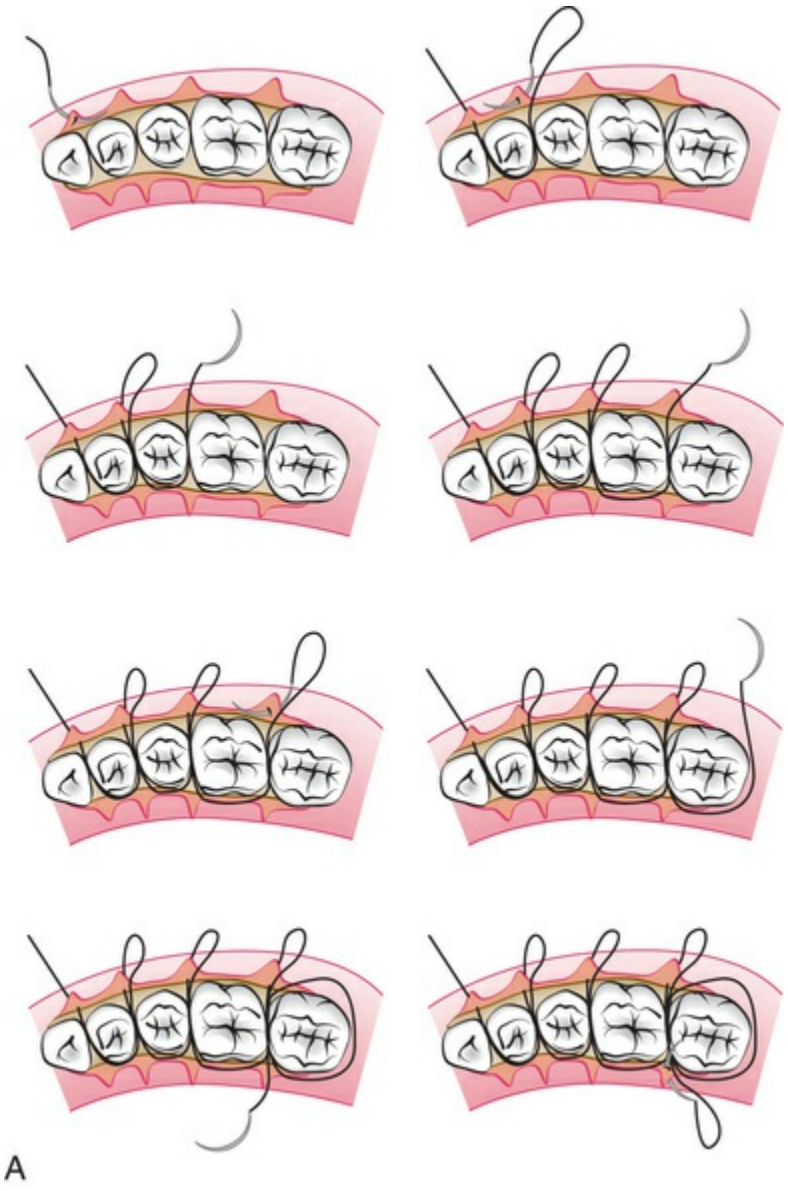


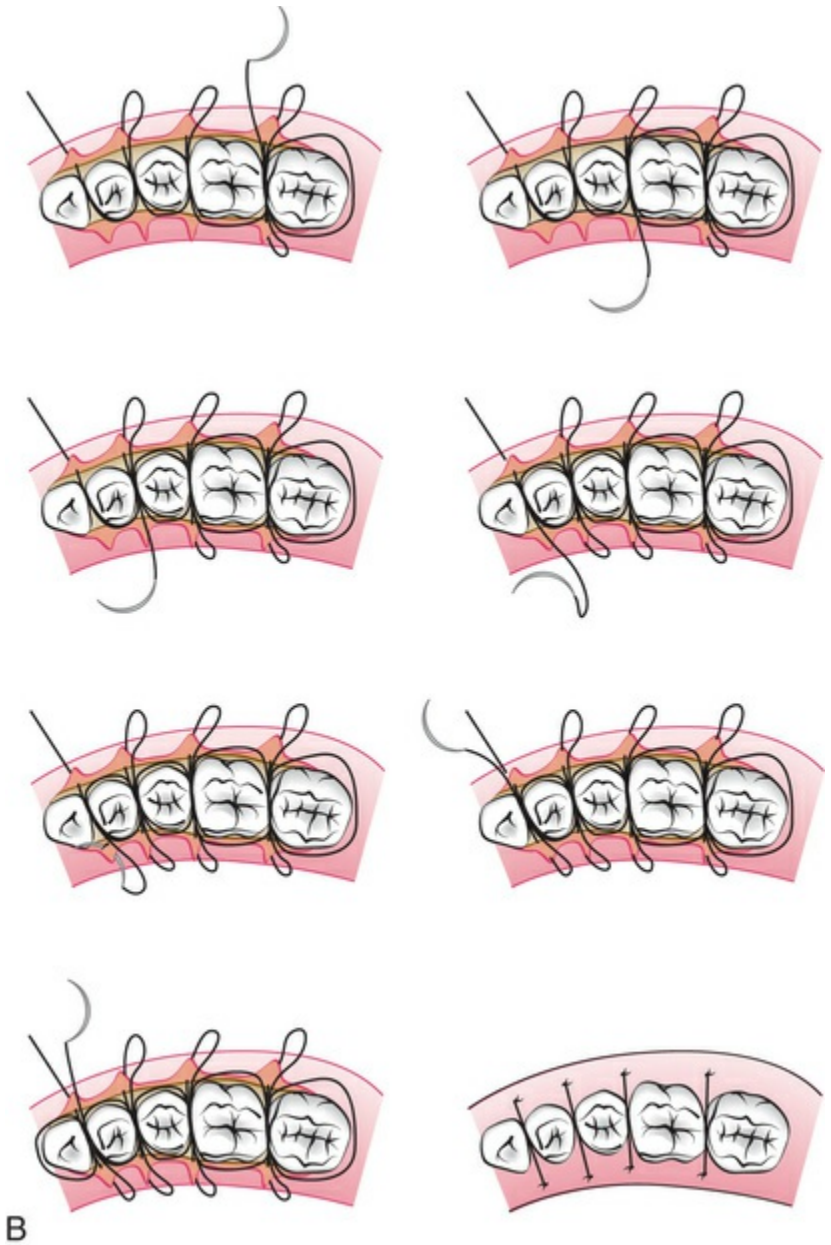
EFIG. 60.6 (A) Continuous, independent sling suture with the use of a horizontal mattress suture around (B) diastemata or (C) wide interdental areas. This mattress suture is used on both the (D) buccal and the (E) and (F) lingual surfaces. (G) to (I) Continuation of suture on the lingual surfaces. (J) Completed suture.

The penetration of the needle is performed in such a way that the mesial and distal edges of the papilla lie snugly against the bone. The needle enters the outer surface of the gingiva and crosses the undersurface of the gingiva horizontally. The mattress sutures should not be close together at the midpoint of the base of the papilla. The needle reappears on the outer surface at the other base of the papilla and continues around the tooth with the sling sutures.

Continuous, Independent Sling Suture

A sling suture is used when both a facial flap and a lingual flap are used and when they involve many teeth. The continuous, independent sling suture is initiated on the facial papilla closest to the midline because this is the easiest place to position the final knot (eFig. 60.7). A continuous sling suture is laced for each papilla on the facial surface. When the last tooth is reached, the suture is anchored around it to prevent any pulling of the facial sutures when the lingual flap is sutured around the teeth in a similar manner. The suture is again anchored around the last tooth before the final knot is tied.





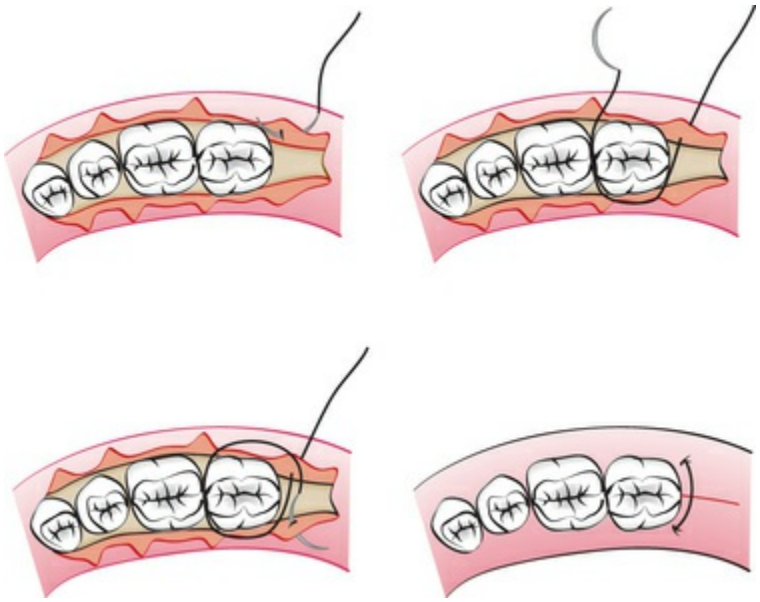
EFIG. 60.7 (A) and (B) Continuous, independent sling suture is used to adapt the buccal and lingual flaps without tying the buccal flap to the lingual flap. The teeth are used to suspend each flap against the bone. It is important to anchor the suture on the two teeth at the beginning and end of the flap so that the suture will not pull the buccal flap to the lingual flap.

This type of suture does not pull on the lingual flap when this flap is sutured. The facial and lingual flaps are completely independent of each other as a result of the anchoring around both the initial tooth and the final tooth. The flaps are tied to the teeth and not to each other because of the sling sutures.

Continuous, independent sling suturing is especially appropriate for the maxillary arch. This is true because the palatal gingiva is attached and fibrous, whereas the facial tissue is thinner and mobile.

Anchor Suture

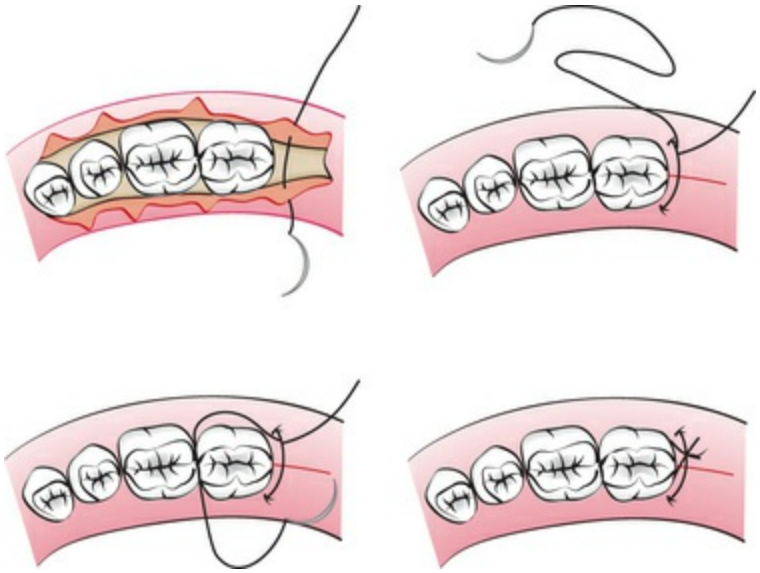
The closing of a flap mesial or distal to a tooth, as in the mesial or distal wedge procedures, is best accomplished by the anchor suture. This suture closes the facial and lingual flaps and adapts them tightly against the tooth. The needle is placed at the line–angle area of the facial or lingual flap adjacent to the tooth, anchored around the tooth, passed beneath the opposite flap, and tied. The anchor suture can be repeated for each area that requires it (eFig. 60.8).



EFIG. 60.8 **Distal wedge suture. This anchor suture is also used to close flaps that are mesial or distal to a lone-standing tooth.**

Closed-Anchor Suture

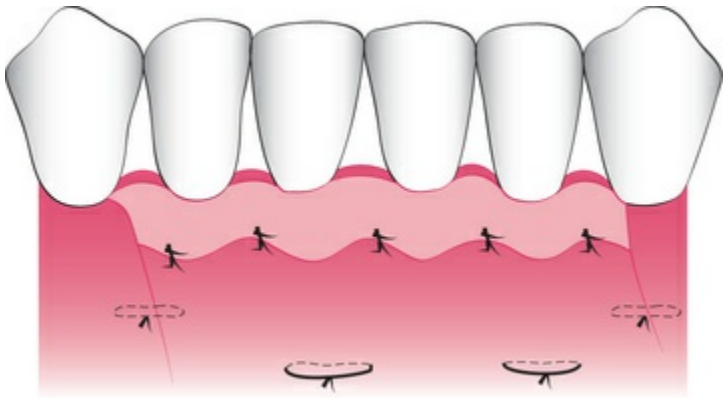
Another technique to close a flap that is located in an edentulous area mesial or distal to a tooth consists of tying a direct suture that closes the proximal flap, carrying one of the threads around the tooth to anchor the tissue against the tooth, and then tying the two threads (eFig. 60.9).



EFIG. 60.9 The closed-anchor suture, which is another technique that can be used to suture distal wedges.

Periosteal Suture

The periosteal suture is used to hold the apically displaced partial-thickness flaps on the periosteum. The two types of periosteal sutures are the holding suture and the closing suture. The holding suture is a horizontal mattress suture that is placed at the base of the displaced flap to secure it into the new position. Closing sutures are used to secure the flap edges to the periosteum. Both types of periosteal sutures are shown in eFig. 60.10.



EFIG. 60.10 **Periosteal sutures for an apically displaced flap. Holding sutures, which are shown at the *bottom,* are placed first. This is followed by the closing sutures, which are shown at the coronal edge of the flap.**

Periodontal Surgical Techniques

Periodontal surgery limited to the gingival tissues only without the use of periodontal flaps can be classified as *gingival curettage* and *gingivectomy*. The current understanding of disease etiology and therapy limits the use of both techniques, but their place in surgical therapy is essential.

Periodontal flap surgery is one of the most frequently employed procedures, particularly for moderate and deep pockets in the posterior areas. Periodontal flap surgery provides access for root instrumentation and pocket reduction via gingival resection, osseous resection, and periodontal regeneration.

Gingival Surgery

Gingival Curettage

The word *curettage* is used in periodontics to describe the scraping of the gingival wall of a periodontal pocket to remove the chronically inflamed tissue. The *excisional new attachment procedure*[22,41,42] is a definitive subgingival curettage procedure that is performed with a knife. Historically, it was thought this tissue hinders healing and new attachment, which necessitate gingival curettage. However, when the root is thoroughly scaled and planed, and the biofilm and calculus are removed, the inflammation in the tissue automatically resolves without tissue curettage. *Therefore, the use of curettage to eliminate the inflamed granulation tissue is unnecessary.* This should not be confused with the elimination of granulation tissue during flap surgery. The reason for the latter is to remove the bleeding tissue that obstructs visualization and prevents the necessary examination of the root surface and the bone. Thus, the removal of granulation tissue during surgery is accomplished for technical rather than biologic reasons. It has been shown that scaling and root planing with additional curettage do not improve the condition of the periodontal tissues beyond the improvement that results from scaling and root planing alone.

In the anterior maxilla, gingival curettage and root planing apical to the base of the periodontal pocket should be avoided. The removal of the junctional epithelium and the disruption of the

connective tissue attachment expose nondiseased cementum. Root planing and the removal of nondiseased cementum may result in attachment loss and gingival recession.

Gingivectomy

The word *gingivectomy* means "excision of the gingiva." By removing the pocket wall, gingivectomy provides visibility and accessibility for complete calculus removal and thorough root planing. This creates a favorable environment for gingival healing and restoration of a physiologic gingival contour.

Although gingivectomy was widely performed in the past, improved understanding of healing and the development of sophisticated flap techniques have relegated it to a lesser role in periodontal surgery. However, it remains an effective form of treatment when indicated (Fig. 60.11).

FIG. 60.11 Results obtained by treating a suprabony pocket with gingivectomy. (A) and (B) Preoperative facial and palatal views. (C) Marking of the depth of the suprabony pocket. (D) The bottoms of the pockets are indicated by pinpoint markings. (E) A beveled palatal incision with an Orban knife. (F) A facial beveled incision with a Bard–

Parker #15 blade extends apical to the perforations made by the pocket marker. Note that the beveled incision can also be made with a Kirkland knife. (G) The interdental incision and excision of the pocket wall with a Bard–Parker #12 blade. (H) A completed gingivectomy. (I) The surgical site covered with periodontal dressing. (J) One week after healing. (K) and (L) Results 22 months after the operation. (Courtesy Dr. Kitetsu Shin, Saitama, Japan.)

Gingivectomy may be performed for the following indications[11]:

1. Elimination of suprabony pockets if the pocket wall is fibrous and firm
2. Elimination of gingival enlargements

Contraindications to gingivectomy include the following:

1. Access to bone required
2. Narrow zone of keratinized tissue
3. Aesthetics
4. Patients with high postoperative risk of bleeding

The step-by-step technique for gingivectomy is as follows:

Step 1: The periodontal pocket is mapped out on the external gingival surface by inserting a probe to the bottom of the pocket and puncturing the external surface of the gingiva at the depth of probe penetration (see Figs. 60.11C and D; Figs. 60.12 and 60.13).

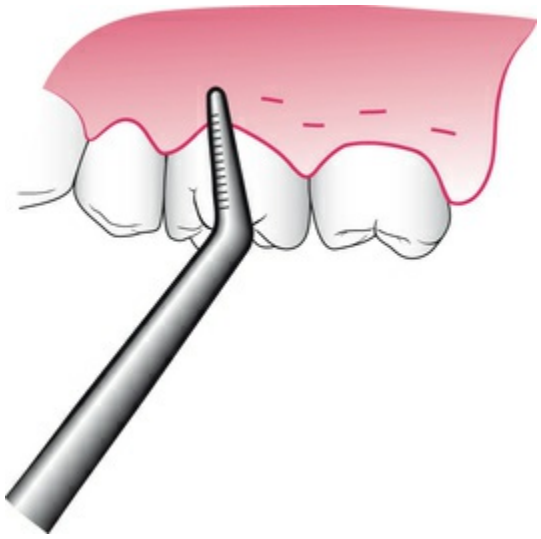


FIG. 60.12 The pocket marker makes pinpoint perforations that indicate pocket depth.

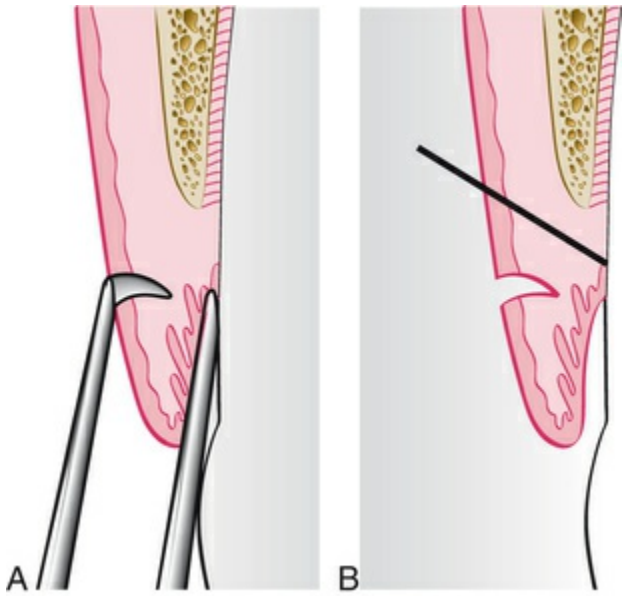

FIG. 60.13 **Marking the depth of a suprabony pocket. (A) A pocket marker in position. (B) The beveled incision extends apical to the perforation made by the pocket marker.**

Step 2: Periodontal knives (e.g., Kirkland) are used for incisions on the facial and lingual surfaces. Orban periodontal knives are used for interdental incisions (see Fig. 60.11E to G). Bard–Parker blades (#12 and #15), and scissors are used as auxiliary instruments.

The external bevel incision is started apical to the points marking the course of the pockets,[30,36] and it is directed coronally to a point between the base of the pocket and the crest of the bone. It should be as close as possible to the bone without exposing it to remove the soft tissue coronal to the bone. Exposure of bone is undesirable. If this occurs, healing usually presents minimal complications if the area is adequately covered by the surgical dressing.

Either interrupted or continuous incisions may be used. The incision should be beveled at approximately 45 degrees to the tooth surface, and it should re-create the normal festooned pattern of the gingiva. Failure to bevel the incision will leave a broad, fibrous plateau that will delay development of a physiologic contour.

Step 3: Remove the excised pocket wall, irrigate the area, and examine the root surface.
Step 4: Scale and root plane.
Step 5: Cover the area with a surgical dressing (see Fig. 60.11I and Chapter 59).

Gingivoplasty

Gingivoplasty is *recontouring the gingiva* in the absence of pockets.[12] It may be accomplished with a periodontal knife, a scalpel, or rotary coarse diamond stones.[24]

Healing After Gingivectomy

The *initial response* after gingivectomy is the formation of a protective surface blood clot. The underlying tissue becomes acutely inflamed with necrosis. The clot is then replaced by granulation tissue. In 24 hours, an increase occurs in new connective tissue cells, which are mainly angioblasts beneath the surface layer of inflammation and necrotic tissue. By the third day, numerous young fibroblasts are located in the area.[27] The highly vascular granulation tissue grows coronally and creates a new free gingival margin and sulcus.[23] Capillaries derived from the blood vessels of the periodontal ligament migrate into the granulation tissue, and within 2 weeks they connect with the gingival vessels.[37]

After 12 to 24 hours, epithelial cells at the margins of the wound begin to migrate over the granulation tissue, thereby separating it from the contaminated surface layer of the clot. Epithelial activity at the margins reaches a peak after 24 to 36 hours.[10]

The new epithelial cells arise from the basal and deeper spinous layers of the epithelial wound edge and migrate over the wound over a fibrin layer that is later resorbed and replaced by a connective tissue bed.[15] The epithelial cells advance by a tumbling action, with the cells becoming fixed to the substrate by hemidesmosomes and a new basement lamina.[13,16]

After 5 to 14 days, surface epithelialization is generally complete (see Fig. 60.11J). During the first 4 weeks after gingivectomy, keratinization is less than it was before surgery. Complete epithelial repair takes about 1 month.[34] Vasodilation and vascularity begin to

decrease after the fourth day of healing, and they appear to be almost normal by the 16th day.[21] Complete repair of the connective tissue takes about 7 weeks.[34]

The flow of gingival fluid in humans is initially increased after gingivectomy, and it diminishes as healing progresses.[2,32] Maximal flow is reached after 1 week, which coincides with the time of maximal inflammation.

Although the tissue changes that occur during postgingivectomy healing are the same in all individuals, the time required for complete healing varies considerably among sites and individuals. In patients with physiologic gingival melanosis, the pigmentation is diminished in the healed gingiva.

Flap Surgery

Periodontal flaps are used in surgical periodontal therapy to accomplish the following:

1. Access for root instrumentation
2. Gingival resection
3. Osseous resection
4. Periodontal regeneration

To fulfill these purposes, five different flap techniques are used: (1) the modified Widman flap,[28] (2) the undisplaced flap, (3) the apically displaced flap, (4) the papilla preservation flap,[8,35] (5) and the distal terminal molar flap.

The modified Widman flap facilitates root instrumentation. It does not attempt to reduce the pocket depth, but it does eliminate the pocket lining. The objectives of the undisplaced and apically displaced flaps include root surface access and the reduction of probing depth. The choice of which procedure to use depends on two important anatomic landmarks: the transgingival probing depth and the location of the mucogingival junction. These landmarks establish the presence and width of the attached gingiva, which are the basis for the decision. The papilla preservation flap is used when possible in regenerative and aesthetic cases to minimize recession and loss of interdental papillae. The distal terminal molar

flap is used for treating pockets and osseous defects on the distal surface of the terminal maxillary and mandibular molars.

Modified Widman Flap

The original Widman[38] flap used two vertical releasing incisions connected by a submarginal scalloped internal bevel incision to demarcate the area of surgery. A full-thickness flap was reflected and the marginal collar of tissue was removed to provide access for root instrumentation and osseous recontouring. In 1974, Ramfjord and Nissle[28] published the "modified Widman flap" (Fig. 60.14), which used only horizontal incisions. This technique offers the possibility of establishing an intimate postoperative adaptation of healthy collagenous connective tissue to tooth surfaces,[5,18,26,28] and it provides access for adequate instrumentation of the root surfaces and immediate closure of the area.

FIG. 60.14 **Modified Widman flap technique. (A) Facial view before surgery. The probing of pockets revealed interproximal depths that ranged from 4 to 8 mm and facial and palatal depths of 2 to 5 mm. (B) Radiographic survey of the area. Note the generalized horizontal bone loss. (C) Facial internal bevel incision. (D) Palatal incision. (E) Elevation of the flap, which left a wedge of tissue attached to its base. (F) Removal of tissue. (G) Tissue removed and ready for scaling and root planing. (H) Scaling and root planing of exposed root surfaces. (I) Continuous, independent sling suture of facial portion of surgery. (J) Continuous, independent sling suture of palatal portion of surgery. (K) Postsurgical result.** (Courtesy Dr. Kitetsu Shin, Saitama, Japan.)

The step-by-step technique for the modified Widman flap is as follows:

Step 1: The first incision (Fig. 60.15A) parallel to the long-axis of the tooth is a scalloped internal bevel incision to the alveolar crest starting 0.5 to 1 mm away from the gingival margin (see Fig. 60.14C). The papillae are dissected and thinned to have a thickness similar to that of the remaining flaps.

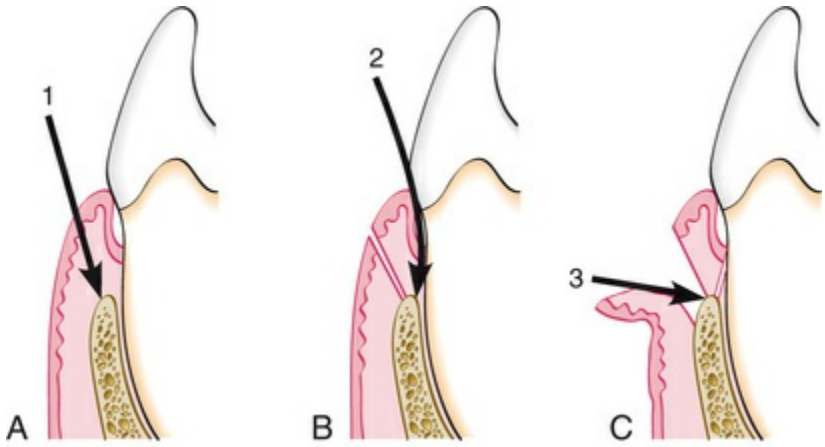

FIG. 60.15 **The three incisions necessary for flap surgery. (A) First (internal bevel) incision; (B) second (crevicular) incision; and (C) third (interdental) incision.**

Step 2: Full-thickness flaps are reflected 2 to 3 mm away from the alveolar crest (see Fig. 60.14D).

Step 3: The second, crevicular incision (Fig. 60.15B) is made in the gingival crevice to detach the attachment apparatus from the root.

Step 4: The interdental tissue and the gingival collar are detached from the bone with a third incision (Fig. 60.15C; see

Fig. 60.14E and F).

Step 5: The gingival collar and granulation tissue are removed with curettes. The root surfaces are scaled and planed (see Fig. 60.14G and H). Residual periodontal fibers attached to the tooth surface should not be disturbed.

Step 6: Bone architecture is not corrected unless it prevents intimate flap adaptation. Every effort is made to adapt the facial and lingual interdental tissue in such a way that no interdental bone remains exposed at the time of suturing. The flaps may be thinned to allow for close adaptation of the gingiva around the entire circumference of the tooth.

Step 7: The flaps are stabilized with sutures (see Fig. 60.14I and J) and covered with a surgical dressing.

Ramfjord[26] performed an extensive longitudinal study that compared the modified Widman procedure with the curettage technique and the pocket elimination (gingivectomy and osseous surgery) methods. Patients were assigned randomly to one of the techniques, and results were analyzed yearly for up to 7 years after therapy. The researchers reported similar results for each of the three methods tested. Pocket depth was initially similar for all methods, but it was maintained at shallower levels with the modified Widman flap; the attachment level remained higher with the modified Widman flap.

Undisplaced Flap

Currently, the undisplaced flap may be the most frequently performed type of periodontal surgery. For the undisplaced flap, the submarginal scalloped internal bevel incision is initiated at a distance from the tooth that is roughly one-half to two-thirds the interdental transgingival probing depth. This incision can be accomplished only if sufficient attached gingiva remains apical to the incision. Therefore, the two anatomic landmarks, the transgingival interdental probing depth and the mucogingival junction, must be considered to evaluate the amount of attached gingiva that will remain after surgery. The internal bevel incision should be scalloped to create surgical papillae, which are essential to covering the interdental bone (see Fig. 60.4). If the tissue is too

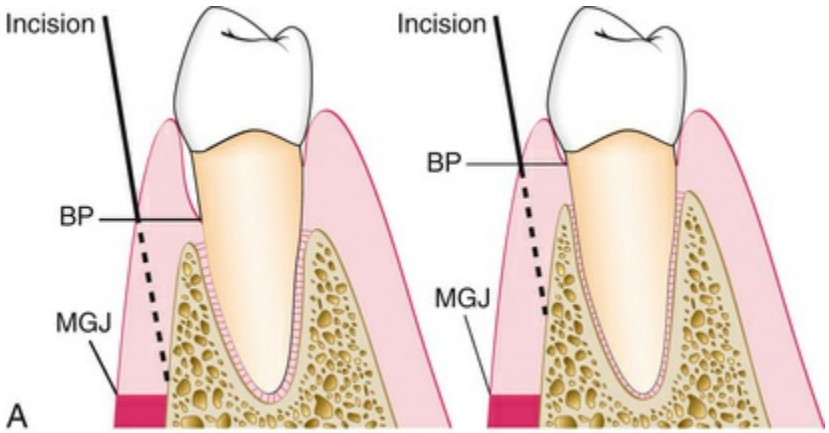
thick, the flap margin should be thinned with the initial incision. Proper placement of the flap margin at the alveolar crest during closure is important to prevent either recurrence of the pocket or exposure of bone.

The step-by-step technique for the undisplaced flap is as follows:

Step 1: The periodontal probe is inserted into the gingival crevice and penetrates the junctional epithelium and connective tissue down to bone.

Step 2: The mucogingival junction is assessed to determine the amount of keratinized tissue.

Step 3: The initial placement of the submarginal scalloped internal bevel incision is based on the transgingival interdental probing depth and the mucogingival junction (Fig. 60.16). The incision is made parallel to the long axis of the tooth and directed down to the alveolar bone. The angulation of the incision may be altered depending on the thickness of the gingiva, as well as the initial placement of the submarginal scalloped incision, to produce a thin flap margin. The thicker the tissue, the more apically the incision will end (see Fig. 60.16). A short mesial vertical incision may be employed to allow flap release on the palate or to avoid extension of the horizontal incision into the aesthetic area.



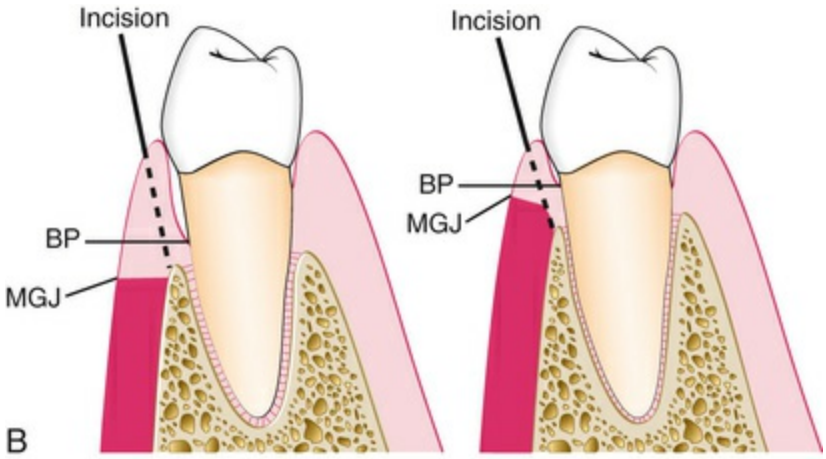


FIG. 60.16 (A) and (B) The location of two different areas where the internal bevel incision is made in an undisplaced flap. The incision is made at the level of the pocket to discard the tissue coronal to the pocket if remaining attached gingiva is sufficient. *BP,* Bottom of pocket; *MCJ,* mucogingival junction.

Step 4: Full-thickness flaps are reflected 1 mm apical to the mucogingival junction.
Step 5: The crevicular is made in the gingival crevice to detach the attachment apparatus from the root.
Step 6: The gingival collar and granulation tissue are removed with curettes. The root surfaces are scaled and planed.
Step 7: Osseous recontouring is performed to eliminate defects and reestablish positive architecture.
Step 8: The flaps are coapted on the alveolar crest with the flap margin well adapted to the roots. The flaps may be trimmed and rescalloped if necessary.
Step 9: The flaps are stabilized with sutures and covered with a surgical dressing.

Apically Displaced Flap

The apically displaced flap is selected for cases that present with a minimal amount (<3 mm) of attached gingiva. For this reason, the internal bevel incision should be made as close to the tooth as possible (i.e., 0.5 to 1.0 mm). No need exists to determine where the bottom of the pocket is in relation to the incision for the apically displaced flap as one would for the undisplaced flap. The flap is placed at the tooth–bone junction by apically displacing the flap. Its final position is not determined by the placement of the first

incision.

With some variants, the apically displaced flap can be used for pocket eradication, widening the zone of attached gingiva, or both. Depending on the purpose, the apically displaced flap can be a full-thickness flap or a split-thickness flap. The split-thickness flap requires more precision and finesse, as well as a gingiva that is thick enough to split. The split-thickness flap can be more precisely positioned and sutured in an apical position with the use of a periosteal suturing technique.

The step-by-step technique for the apically displaced flap is as follows:

Step 1: A marginal scalloped internal bevel incision parallel to the long axis of the tooth is made down to the crest of bone (Fig. 60.17).

FIG. 60.17 **An apically displaced flap. (A) and (B) Facial and lingual preoperative views. (C) and (D) The facial and lingual flaps have been elevated. (E) and (F) After debridement of the areas. (G) and (H) The sutures are in place. (I) and (J) Healing after 1 week. (K) Healing after 2 months. Note the preservation of attached gingiva displaced to a more apical position.** (Courtesy Dr. Thomas Han, Los Angeles, CA.)

Step 2: If used, vertical incisions are made extending beyond the mucogingival junction. It is important that the vertical

incisions—and therefore the flap elevation—reach past the mucogingival junction to provide adequate mobility to the flap for its apical displacement.

Step 3: The flap is reflected in full thickness or partial thickness, depending on the thickness of the gingiva and the objective of the surgery.

Step 4: Crevicular and interdental incisions are made, and the marginal collar of tissue is removed.

Step 5: After degranulation, scaling and root planing, and osseous surgery if needed, the flap is displaced apically.

Step 6: If a full-thickness flap was reflected, an independent sling suture positions the flap margin at the alveolar crest, and a surgical dressing can prevent its coronal movement. If a partial-thickness flap was reflected, it can be apically displaced with an independent sling suture, and further stabilized with periosteal sutures. A periodontal dressing can prevent its coronal movement.

After 1 week, dressings and sutures are removed. The area is usually repacked for another week, after which the patient is to brush gently along the gingival margin with a soft brush and interdentally with interdental brushes.

Distal Terminal Molar Flap

The treatment of periodontal pockets on the distal surface of terminal molars is often complicated by the presence of bulbous fibrous tissue over the maxillary tuberosity or prominent retromolar pads in the mandible. Some of these osseous lesions may result from incomplete repair after the extraction of impacted third molars (Fig. 60.18).

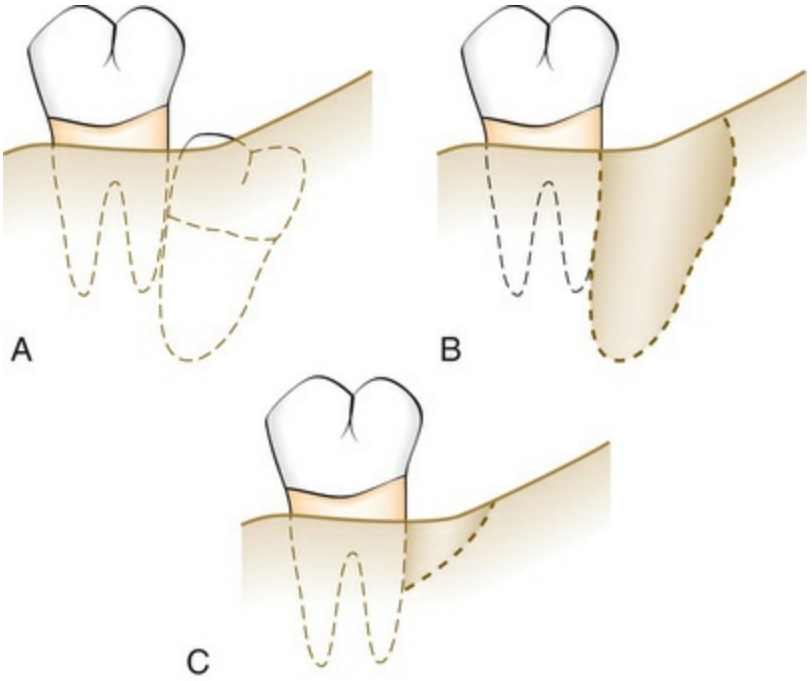

FIG. 60.18 (A) Impaction of a third molar distal to a second molar with little or no interdental bone between the two teeth. (B) Removal of the third molar creates a pocket with little or no bone distal to the second molar. (C) This often leads to a vertical osseous defect distal to the second molar.

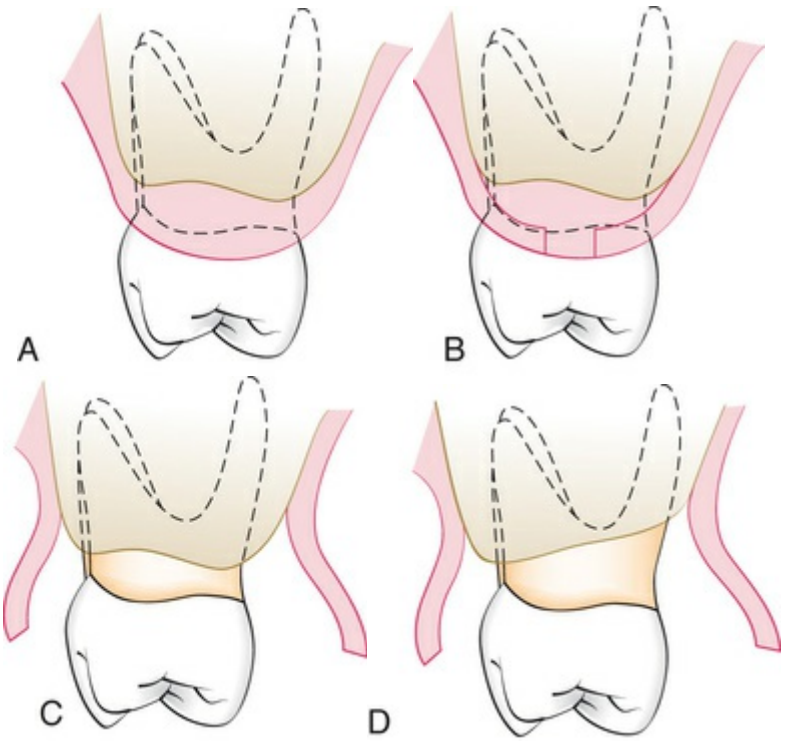
Access to these distal areas may be obtained by a single horizontal incision, two converging horizontal incisions, or two parallel incisions extending distally from the distal surface of the terminal molar to the mucogingival junction distal to the tuberosity or the retromolar pad. The distal horizontal incision is connected with the crevicular incision on the distal surface of the terminal molar, which merges mesially with the buccal and lingual or palatal scalloped incisions. If the secondary objective of surgery is regenerative or the buccolingual width of the distal keratinized tissue is limited, a single horizontal incision in keratinized tissue is used. If the secondary objective of surgery is resective and adequate keratinized tissue is present buccolingually, two distal horizontal incisions are placed in keratinized tissue. The two horizontal incisions technique were described by Robinson[31] and Braden[5] and modified by several other investigators. These techniques are called the *distal wedge* and the *modified distal wedge*.

The distal wedge technique employs two horizontal incisions that begin at the distal surface of the terminal molar and *converge*

distally at the mucogingival junction distal to the tuberosity or the retromolar pad. The modified distal wedge technique employs two *parallel* horizontal incisions that extend distally from the distal surface of the terminal molar and are connected by a transverse incision distal to the mucogingival junction distal to the tuberosity or retromolar pad. The buccolingual distance between the two horizontal incisions in both techniques depends on the transgingival probing depth and the amount of fibrous tissue involved. When the flaps are thinned and the tissue between the two incisions is removed, the two flap edges must approximate each other at a new apical position without overlapping (Fig. 60.19). Generally, the distance between the two parallel incisions is roughly one-half to two-thirds the distal transgingival probing depth and should never be farther apart than the distance between the buccal and lingual line angles of the tooth.



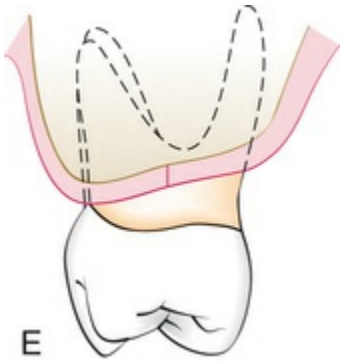


FIG. 60.19 (A) Coronal view from behind a maxillary second molar with an osseous defect. (B) Distal terminal flap surgery employing two horizontal incisions; both buccal and lingual flaps are thinned. (C) Buccal and lingual flaps are elevated, and the "wedge" of tissue is removed. (D) The bone is sloped to the palatal side to eliminate the osseous defect. (E) The flaps are coapted on the bone in the apical position.

To ensure primary closure of the distal flaps, especially in the tuberosity, it is advantageous to use one horizontal incision or two horizontal incisions that are closer together rather than farther apart. Flaps that overlap when they are coapted can be easily trimmed by placing one flap over the other, grabbing the superficial flap with a hemostat, and cutting away the overlapped tissue with a sharp scalpel or scissors.

In regenerative therapy, the distal flaps are not thinned; they are reflected in full thickness. Whereas in resective therapy, before the flaps are completely reflected, they are undermined and thinned with a #15 blade. It is easier to thin the flap before it is completely reflected and mobile. The flaps are then reflected in full thickness.

Maxillary Molars

The treatment of distal pockets in the maxilla is usually less challenging than that in the mandible. The tuberosity presents a greater amount of fibrous attached gingiva than does the retromolar pad. The use of the distal wedge with two converging incisions causes the tissue next to the tooth to be displaced more apically than the tissue away from the tooth. Consequently, healing of a distal wedge in the maxilla results in an acute angle between the distal tooth surface and the tuberosity that is biofilm retentive and difficult to clean (Fig. 60.20B). In contrast, the use of the

modified distal wedge with two parallel distal incisions allows the soft tissue along the whole length of the distal flap to be evenly displaced apically (Fig. 60.20C). This is advantageous in the maxilla in maintaining a wide angle between the tooth and the tuberosity that is much easier to clean. Therefore, the modified distal wedge is preferred in the maxilla. The two parallel incisions are usually made at the midline of the tuberosity where the tissue is the thickest or slightly to the palatal side to maximize buccal keratinized tissue and to provide easier access for flap closure (Fig. 60.21).

Learning Box 60.5

The two parallel distal horizontal incisions in the maxillary tuberosity are advantageous in allowing the soft tissue along the whole length of the distal flap to be evenly displaced. This results in a wide angle between the tooth and the tuberosity that is much easier to clean.

Mandibular Molars

Incisions in the distal mandible differ from those in the tuberosity due to differences in the anatomy of the area. The retromolar pad usually has limited attached gingiva and vestibular depth. The attached gingiva, if present, may not be found directly distal to the

molar. The greatest amount may be distolingual or distobuccal, and it may not be over the bony crest. The ascending ramus of the mandible may also create a short or completely eliminate the horizontal area distal to the terminal molar (Fig. 60.22). The shorter this area, the more difficult it is to treat any deep distal lesion around the terminal molar. The anatomy of the posterior mandible is further discussed in Chapter 58.

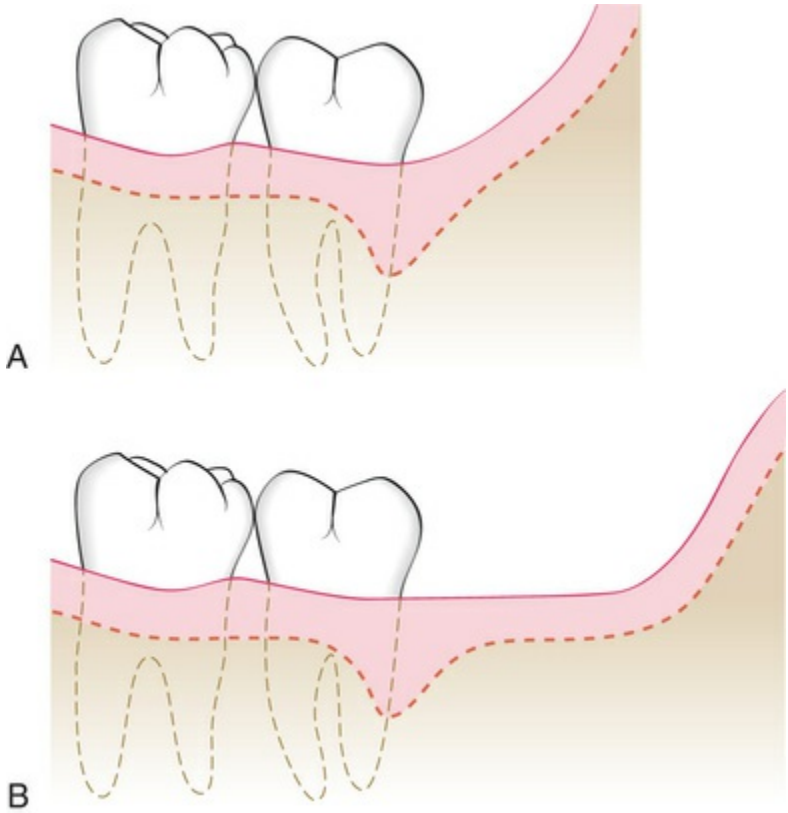

FIG. 60.22 (A) Pocket eradication distal to a mandibular second molar with minimal attached gingiva and a close ascending ramus is anatomically difficult. (B) For surgical procedures distal to a mandibular second molar, abundant attached gingiva and distal space are ideal.

The mandibular retromolar tissue ascends distally to merge with the ascending ramus. This anatomy favors the distal wedge technique in the mandible, although the parallel distal incisions and the single horizontal incision may be used. The two distal incisions should follow the area with the greatest amount of attached gingiva and must be made over bone (Fig. 60.23). Therefore, the incisions

could be directed distally or distobuccally, depending on which area has more attached gingiva. Incisions directing distolingually should be avoided due to the potential presence of the lingual nerve.

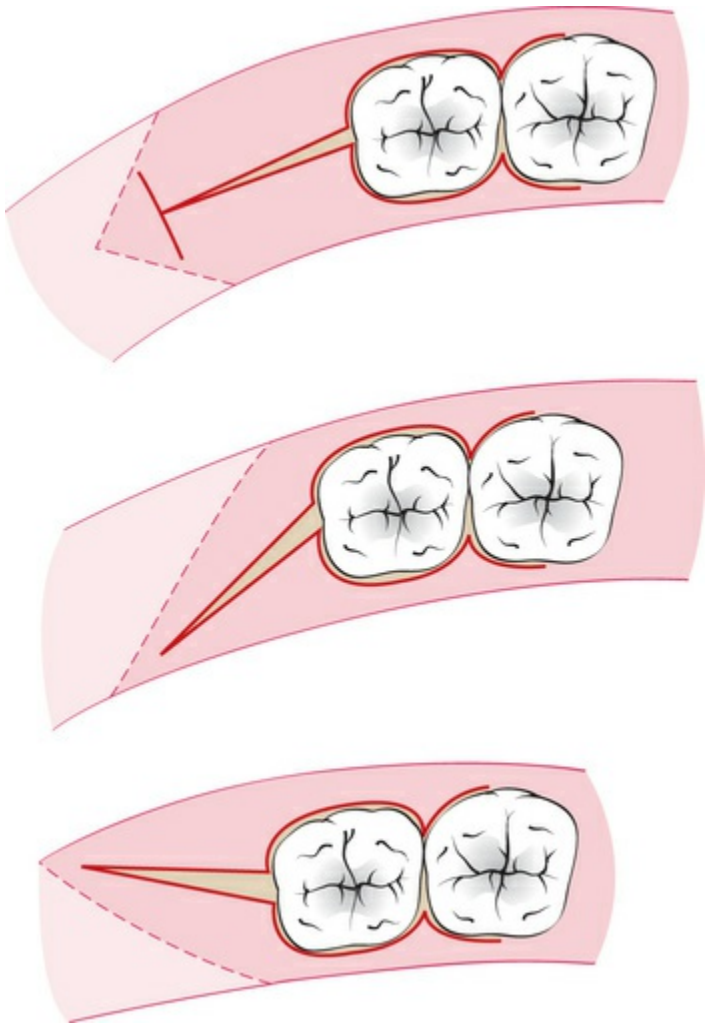

FIG. 60.23 **Incision designs for surgical procedures distal to the mandibular second molar. The incision should follow the areas of greatest attached gingiva and underlying bone.**

Papilla Preservation Flap

In current regenerative therapy, bone grafts, membranes, or a combination of these are used with or without other biologics (see Chapter 63). The flap design should maximize the amount of gingival tissue and papilla retained to cover the material placed in the osseous defect. In the aesthetic area, when surgery is necessary,

flap design must minimize recession and loss of interdental papillae. As such, the crevicular incision is the incision of choice for the anterior aesthetic area and regenerative therapy. The interdental papilla is retained with the papilla preservation technique when the interdental space is adequate for reflection of the intact papilla; otherwise, it is split beneath the contact point of the two approximating teeth. The flap is elevated in full thickness without thinning of the flap or the papilla.

The step-by-step technique for the papilla preservation flap (see Fig. 60.8; Fig. 60.24) is as follows:

FIG. 60.24 Papilla preservation flap. (A) Facial view after sulcular incisions have been made. (B) Straight-line incision in the palatal area about 3 mm from the gingival margins. This incision is then connected to the margins with vertical incisions at the midpart of each tooth. (C) Papillae are reflected with the facial flap. (D) Lingual view after the reflection of the flap. (E) Lingual view after the flap is brought back to its original position. It is then sutured with independent sutures. (F) Facial view after healing. (G) Palatal view after healing. (Courtesy Dr. Thomas Han, Los Angeles, CA.)

Step 1: A crevicular incision is made around each tooth, with no incisions across the interdental papilla.

Step 2: The preserved papilla can be incorporated into the

facial-buccal flap (original papilla preservation technique[35]) or lingual-palatal flap (modified papilla preservation technique[8]). If the preserved papilla is reflected with the facial-buccal flap, the semilunar incision at the base of the papilla is on the lingual-palatal side of the interdental space. If the preserved papilla is reflected with the lingual-palatal flap, the semilunar incision at the base of the papilla is on the facial-buccal side of the interdental space. This semilunar incision dips apically from the line angles of the tooth so that the incision is at least 5 mm from the crest of the papilla.

Step 3: The papilla is then elevated with an Orban knife or curettes and is reflected intact with the flap.

Step 4: The flap is reflected without thinning the tissue.

Healing After Flap Surgery

Immediately after suturing (≤24 hours), a connection between the flap and the tooth or bone surface is established by a blood clot, which consists of a fibrin reticulum with many polymorphonuclear leukocytes, erythrocytes, debris of injured cells, and capillaries at the edge of the wound.[6] Bacteria and an exudate or transudate also result from tissue injury.

One to 3 days after flap surgery, the space between the flap and the tooth or bone is thinner. Epithelial cells migrate over the border of the flap, and they usually contact the tooth at this time. When the flap is closely adapted to the alveolar process, the inflammatory response is minimal.[6]

One week after surgery, an epithelial attachment to the root has been established by means of hemidesmosomes and a basal lamina. The blood clot is replaced by granulation tissue derived from the gingival connective tissue, the bone marrow, and the periodontal ligament.

Two weeks after surgery, collagen fibers begin to appear parallel to the tooth surface.[6] Union of the flap to the tooth is still weak because of the presence of immature collagen fibers, although the clinical aspect may be almost normal.

One month after surgery, a fully epithelialized gingival crevice with a well-defined epithelial attachment is present. A functional

arrangement of the supracrestal fibers is beginning.

Full-thickness flaps, which denude the bone, result in superficial bone necrosis after 1 to 3 days. Osteoclastic resorption follows and reaches a peak at 4 to 6 days and then declines thereafter.[33] This results in a loss of bone of about 1 mm^3; the bone loss is greater if the bone is thin.[39,40]

Osteoplasty with the use of diamond burs results in areas of bone necrosis with a reduction in bone height, which is later remodeled by new bone formation. The final shape of the crest is determined more by osseous remodeling than by surgical reshaping.[17] Therefore, osseous surgery around the crestal areas must be carefully managed.

This may not be the case when osseous remodeling does not include excessive thinning of the radicular bone.[19] Bone repair reaches its peak after 3 to 4 weeks.[40]

A loss of bone occurs during the initial healing stages both in the radicular bone and in the interdental bone areas. However, in the interdental areas, which have cancellous bone, the subsequent repair stage results in total restitution without any loss of bone; in radicular bone (particularly if it is thin and unsupported by cancellous bone), bone repair results in the loss of marginal bone.[40]

Conclusion

Periodontal access surgery is an adjunct to nonsurgical periodontal therapy, and should occur only once the patient has demonstrated effective biofilm control. The primary objective of periodontal access surgery is access for root instrumentations. The secondary objective of periodontal access surgery is pocket reduction through soft tissue resection, osseous resection, or periodontal regeneration. The clinician must also take aesthetics into consideration; in some areas, such as the anterior maxilla, periodontal disease should be treated nonsurgically, and periodontal access surgery is rendered only when absolutely necessary.

Periodontal surgical therapy has a long history and evolution. It started with subgingival curettage and pocket elimination with gingivectomy. Understanding of healing, development of sophisticated periodontal flap techniques, and aesthetic demands

have made gingival curettage obsolete and have relegated gingivectomy to limited cases of gingival enlargement or instances where flap surgery is not possible.

Periodontal flap surgery is the most widely used surgical procedure for periodontal pocket therapy. Periodontal flaps are advantageous and versatile in providing not only access for root instrumentation but also access for osseous surgery and periodontal regeneration. Flap surgery also allows for primary closure, which enhances wound healing and minimizes patients' discomfort. Papilla preservation techniques are useful in regenerative therapy, as well as minimizing recession and loss of interdental papilla in the aesthetic area.

Although the submarginal scalloped incision is useful in reducing periodontal pockets, it must be used with caution. Placement of a submarginal scalloped incision without regard for the mucogingival junction and the width of keratinized tissue may result in a mucogingival problem. The only area in the mouth where the submarginal scalloped incision is necessary is the palatal maxilla. In places where a mucogingival junction is present, marginal incisions and apically displaced flaps may be used in lieu of submarginal scalloped incisions to maximize remaining keratinized tissue and reduce soft tissue height. The palatal maxilla is unique in that all the tissue is keratinized, attached, and immobile. Pocket reduction must be obtained by tissue resection. The precise placement of the submarginal scalloped incision on the palatal maxilla is essential for intimate adaptation of the flap and primary closure.

Although the “distal wedge” procedure is popular and widely practiced, it is perhaps one of the most difficult procedures to execute well due to the location of the surgical site, as well as the challenges presented by the anatomy of the mandibular retromolar pad and the maxillary tuberosity. The distal wedge procedure is not simply removing a “wedge of tissue” distal to the terminal molar to reduce or eliminate a pocket. Well-executed distal terminal molar flap surgery requires the flaps to approximate intimately to allow for primary closure and in an apical position to achieve pocket reduction. Execution of distal terminal molar flap surgery requires understanding of the anatomy and behavior of the tissue, as well as

surgical finesse.

Short-term and long-term success of periodontal access surgery is dependent on biofilm control and long-term maintenance. The patient must understand the etiology of the periodontal disease and its prevention. Surgery in the absence of effective biofilm control and maintenance will result in failure and recurrence of disease.

CHAPTER 61

Treatment of Gingival Enlargement

Paulo M. Camargo, Flavia Q. Pirih, Henry H. Takei, Fermin A. Carranza

CHAPTER OUTLINE

Chronic Inflammatory Enlargement
Periodontal and Gingival Abscesses
Drug-Induced Gingival Enlargement
Leukemic Gingival Enlargement
Gingival Enlargement During Pregnancy
Gingival Enlargement During Puberty

The treatment of gingival enlargement is based on an understanding of the cause and underlying pathologic changes of this condition (see Chapter 19). Gingival enlargements are of special concern to the patient and the dentist because they pose problems that include biofilm control, impaired function (mastication, tooth

eruption, and speech), and aesthetics. Because gingival enlargements differ with regard to etiology, the treatment of each type is best considered individually.

Chronic Inflammatory Enlargement

Chronic inflammatory enlargements, which are characterized by gingival tissues that are soft and have an altered gingival color, are usually caused by edema and cellular infiltration. Typical therapy consists of scaling and root planing, provided the size of the enlargement does not interfere with the complete removal of deposits from the involved tooth surfaces.

When chronic inflammatory gingival enlargements include a significant fibrotic component that does not undergo shrinkage after scaling and root planning, or if the extent of the gingival enlargement is so severe that access to the deposits on the tooth surface is impossible, surgical removal is the treatment of choice. Two techniques exist for this purpose: gingivectomy and the flap operation. Before instituting surgical therapy, biofilm control, scaling, and root planing should always be completed, and sufficient time should be allowed to heal before reevaluating the periodontal status. It is important that the decision to implement surgical therapy should be made after this reevaluation.

Once the decision is made that surgical therapy is necessary, the selection of the appropriate surgical technique will depend on the extent of the enlargement and the status of the gingival tissues. When the enlarged gingiva remains soft and friable even after scaling and root planing, the gingivectomy technique may be preferable because management of the periodontal flap may be technically difficult on the friable tissues. If the gingival tissue is firm and fibrotic, preference is given to the flap operation, which is always the favorable choice because the healing is by primary intention and the keratinized tissue is better preserved. Therefore, conservation of the keratinized, attached gingiva must be considered along with removal of the excessive gingival tissue.

Tumor-like, localized, and severe inflammatory enlargements (Fig. 61.1) can be treated by gingivectomy as follows. With the patient under local anesthesia, the tooth surfaces beneath the mass

are scaled to remove calculus and other debris. The lesion is separated from the mucosa at its base by using a surgical blade. If the lesion extends interproximally, the interdental gingiva is included in the incision to ensure the exposure of deposits. After the enlarged tissues are removed and access is sufficient, the root surfaces are scaled and planed, and the area is irrigated with saline solution. A periodontal dressing is applied and removed after a week, but in some cases, depending on the extent of the surgery, the postoperative appointment may have to be scheduled in 2 weeks to allow for further healing. It is important at this time that proper biofilm control is instituted.

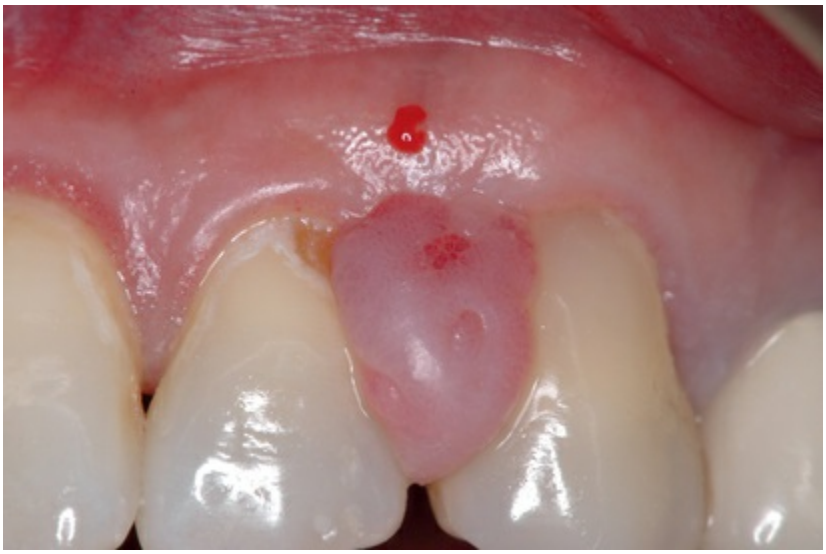

FIG. 61.1 **Localized, fibrotic, tumor-like gingival enlargement on a female young adult. This lesion may be treated via gingivectomy.**

For more information regarding the surgical techniques, see Chapters 59 and 60.

Periodontal and Gingival Abscesses

Periodontal and gingival abscesses result in areas of gingival enlargement. However, the enlargement due to abscesses is usually localized around the area of the lesion, and the content of the enlarged area is purulent material, which must be drained and the area curetted.

The reader is referred to Chapter 45 for a complete discussion of

abscess treatment.

Drug-Induced Gingival Enlargement

Gingival enlargement has primarily been associated with the administration of three different types of drugs: anticonvulsants, calcium channel blockers, and the immunosuppressant cyclosporine. Chapter 16 provides a comprehensive review of the clinical and microscopic features and the pathogenesis of gingival enlargement induced by these drugs. Although the clinical presentation of the gingival enlargement induced by the three drug categories listed here may be similar, evidence suggests that their cellular and molecular mechanisms may differ.[29] Limited evidence indicates that other drugs may also induce gingival enlargement, albeit at a lower prevalence and with a lesser severity.[5]

The examination of cases of drug-induced gingival enlargement reveals the overgrown tissues to have two components: fibrotic, which is the result of the action of the drug on the physiologic gingival collagen turnover; and inflammatory, which is induced by the bacterial biofilm. Although the fibrotic and inflammatory components present in the enlarged gingiva are the result of distinct pathologic processes, they almost always are observed as gingival enlargement induced by the combination of drugs and biofilm. The role of bacterial biofilm in the overall pathogenesis of drug-induced gingival enlargement is not clear. Some studies indicate that biofilm is a prerequisite for gingival enlargement,[13] whereas others suggest that the presence of biofilm is a consequence of biofilm accumulation caused by the enlarged gingiva. In patients taking calcium channel blockers, termination and/or substitution of the drug with another class of medication resulted in significant decreases in gingival enlargement, with no differences observed between patients with poor or good oral hygiene.[11] These studies suggest that the gingival enlargement process is independent of biofilm-related inflammation.

Learning Box 61.1

The inflammatory components present in the enlarged gingiva are the result of plaque biofilm accumulating beneath the enlarged gingiva, and the fibrotic portion may be drug induced. The enlarged gingiva is almost always the result of the combination of both the biofilm and the drug.

Treatment Options

The treatment of drug-induced gingival enlargement should be based on the medication used and the clinical features of the case.

First, consideration should be given to the possibility of discontinuing the drug[10,14] or changing the medication. These possibilities should be examined in consultation with the patient's physician. Simple discontinuation of the offending drug is often not practical, but substitution of the drug with another medication may be an option. If any drug substitution is attempted, it is important to allow a 6- to 12-month period to elapse between discontinuation of the offending drug and substitution with an alternative drug. The changes instituted with the drug should always be in combination with oral hygiene instructions, scaling, and root planing. Reevaluation of the gingival enlargement after the alteration of drug therapy is necessary before any surgical treatment is planned.

Alternative medications to the anticonvulsant phenytoin include carbamazepine[2,9] and valproic acid, both of which have been reported to induce gingival enlargement to a lesser degree. A murine study suggested that lovastatin may attenuate the onset of gingival enlargement induced by phenytoin.[2] Further research is necessary to confirm the therapeutic value of lovastatin.

For patients who are taking nifedipine, which has a reported prevalence of gingival enlargement of up to 86%, other calcium channel blockers such as diltiazem or verapamil may be viable alternatives. The reported prevalence of inducing gingival enlargement is 20% for diltiazem and 4% for verapamil.[4,12,19] In addition, consideration should be given to the use of another class of antihypertensive medications rather than calcium channel blockers. None of these drugs are known to induce gingival enlargement.

Drug substitutions for cyclosporine are more limited. Tacrolimus is another immunosuppressant that is used in organ transplant recipients.[26] The incidence of gingival enlargement in patients receiving tacrolimus therapy is approximately 65% lower than that in individuals who are receiving cyclosporine.[1] Clinical trials have also shown that the substitution of cyclosporine with tacrolimus results in a significant decrease in the severity of gingival enlargement as compared with patients who continue cyclosporine therapy.[15,24,30] In another study,[17] the same drug substitution resulted in a strong decrease or complete resolution of gingival enlargement in more than 70% of the patients who initially presented with cyclosporine-induced gingival enlargement. Therefore, the dental practitioner should consult with the treating physician to investigate the possibility of a change in immunosuppressant therapy as one of the steps in the treatment of cyclosporine-induced gingival enlargement. Patients who take cyclosporine in combination with a calcium channel blocker tend to have an overall lower prevalence of and less severe gingival enlargement if the antihypertensive drug is amlodipine as compared with nifedipine.[16]

Learning Box 61.2

The prescribing of a substitute drug can help reduce gingival enlargement. The drug tacrolimus, which is another drug used as an immunosuppressant, if used as a substitute for cyclosporine can reduce the amount of gingival enlargement by almost 65%.

The administration of the antibiotic azithromycin has been shown to decrease the severity of gingival enlargement induced by cyclosporine. A 3-day course of systemic azithromycin significantly decreased gingival enlargement, and the effect was observed as early as 7 to 30 days after the initiation of antibiotic therapy.[28] The use of azithromycin to decrease cyclosporine-induced gingival enlargement resulted in significantly greater changes than those observed with an improvement in oral hygiene.[22] The topical administration of azithromycin in the form of a toothpaste also

decreased the severity of cyclosporine-induced gingival enlargement.[1]

Learning Box 61.3

The decrease in gingival enlargement with the administration of antibiotics indicates the association of plaque biofilm (bacteria) as one cause of gingival enlargement, along with medications such as cyclosporine.

Second, the clinician should emphasize biofilm control as the first step in the treatment of drug-induced gingival enlargement. Although the exact role played by bacterial biofilm is not fully understood, evidence suggests that good oral hygiene, chemotherapeutic agents,[25] and the frequent professional removal of biofilm decrease the degree of gingival enlargement and improve overall gingival health.[10,13,27] The presence of drug-induced enlargement is associated with pseudo-pocket formation, frequently with abundant biofilm accumulation, which may lead to the development of periodontitis. Therefore, meticulous biofilm control helps to maintain attachment levels. In addition, adequate biofilm control may help to prevent the recurrence of gingival enlargement in surgically treated cases.

Third, in many patients, gingival enlargement persists after careful consideration of the previous two approaches. With these patients, surgical removal of the enlarged gingiva must be considered.

Fig. 61.2 is a decision tree that outlines the sequence of events and options for the treatment of drug-induced gingival enlargement.

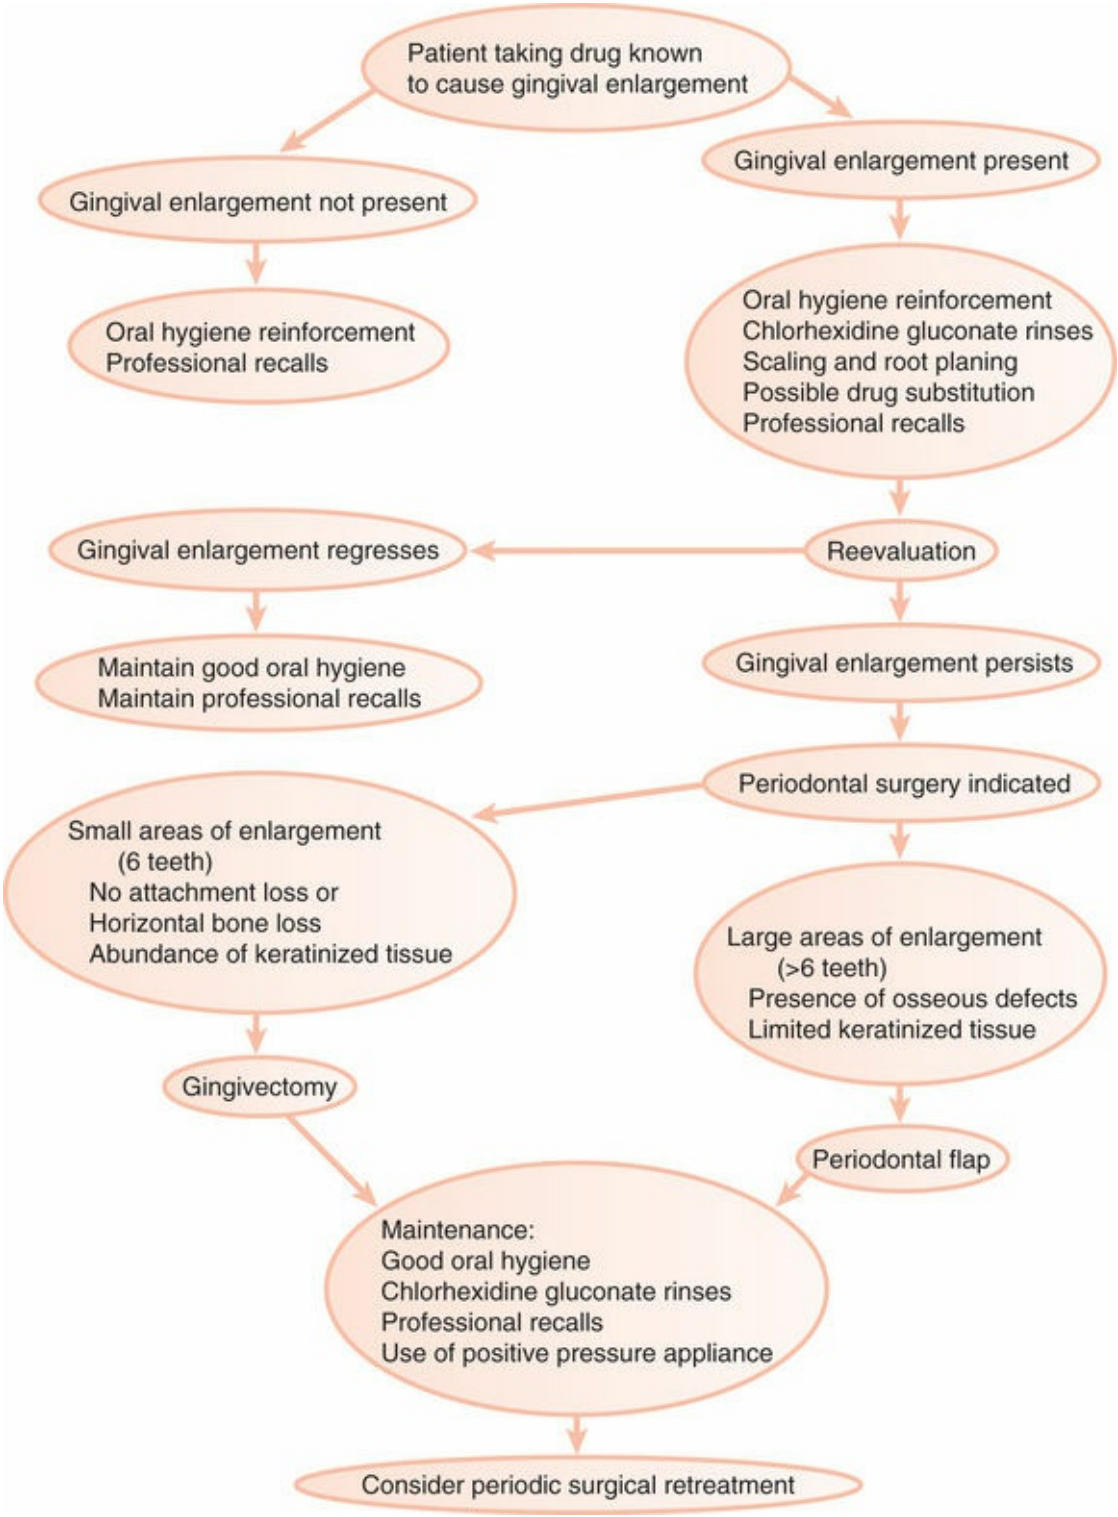

FIG. 61.2 **Decision tree for treatment of drug-induced gingival enlargements.**

Gingivectomy

The advantages of gingivectomy are the ease and simplicity of the procedure, but it has the disadvantages of more postoperative

discomfort and an increased chance of postoperative bleeding. It also sacrifices keratinized tissue and does not allow for osseous recontouring. The flap operation, in contrast, is more technically demanding, but it tends to create less postoperative discomfort and bleeding, besides preserving keratinized tissue. The clinician's decision between the two surgical techniques available should include the extent of the area to be operated on, the severity of the enlargement, the presence of periodontitis and osseous defects, and the location of the base of the pockets in relation to the mucogingival junction.

Learning Box 61.4

Gingivectomy is a simple surgical procedure to excise the enlarged gingiva, but postsurgical management such as bleeding and pain can be a problem. Primary closure of the wound is not possible, and healing is by secondary intention.

In general, small areas (i.e., up to six teeth) of drug-induced gingival enlargement with no evidence of clinical attachment loss (and therefore no anticipated need for osseous surgery) can be effectively treated with the gingivectomy technique. An important consideration is the amount of keratinized tissue present. The removal of excessive amount of keratinized gingiva will create a mucogingival problem.

Chapters 59 and 60 describes the gingivectomy technique in detail. Fig. 61.3 depicts the procedure diagrammatically, and Fig. 61.4 illustrates a case of cyclosporine-induced gingival enlargement treated with the gingivectomy technique.

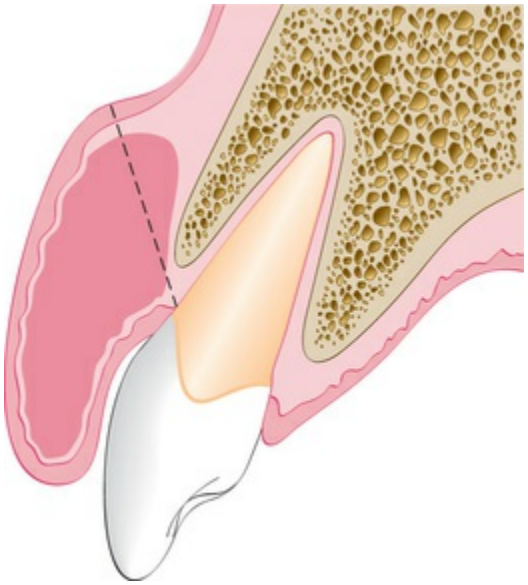

FIG. 61.3 **Gingivectomy technique as used to treat patients with drug-induced gingival enlargement. The *dashed line* represents the external bevel incision, and the *shaded area* corresponds to the tissue to be excised. The gingivectomy incision may not remove the entire hyperplastic tissue *(shaded area)*. This may leave a wide wound of exposed connective tissue.**

FIG. 61.4 Surgical treatment of cyclosporine-induced gingival enlargement with the use of the gingivectomy technique on a 16-year-old girl who had received a kidney allograft 2 years earlier. (A) Enlarged gingival tissues and pseudo-pocket formation. No attachment loss or radiographic evidence of bone loss existed. (B) Initial external bevel incision performed with a Kirkland knife. (C) Interproximal tissue release achieved with an

Orban knife. (D) and (E) Gingivoplasty performed with tissue nippers and a round diamond at high speed with abundant cooling. (F) Aspect of the surgical wound at conclusion of the surgical procedure. (G) Placement of noneugenol periodontal dressing. (H) The surgical area 3 months postoperatively. Note the successful elimination of the enlarged gingival tissue, the restoration of a physiologic gingival contour, and the maintenance of an adequate band of keratinized tissue.

Gingivectomy or gingivoplasty can also be performed with electrosurgery or via a laser device[8] (see Chapter 60). Some evidence indicates that recurrence of drug-induced gingival enlargement is reduced in patients treated via laser as compared with conventional gingivectomy or flap surgery.[18]

Flap Operation

For larger areas of gingival enlargement (i.e., more than six teeth), and where attachment loss and osseous defects are present, flap surgery is recommended.

The periodontal flap technique used for the treatment of gingival enlargements is a simple variation of the one used to treat periodontitis, as described in Chapters 59 and 60. Fig. 61.5 shows the basic surgical steps in the use of the flap technique.

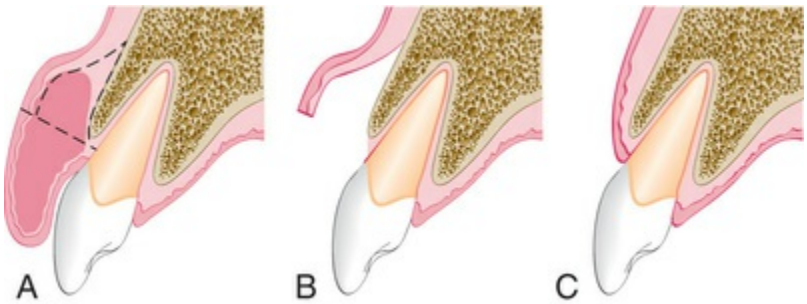

FIG. 61.5 Periodontal flap treatment for drug-induced gingival enlargement. (A) Initial reverse bevel incision followed by thinning of the enlarged gingival tissue; *dotted lines* represent incisions, and the *shaded area* represents the tissue portion to be excised. (B) After flap elevation, the enlarged portion of the gingival tissue is removed. (C) The flap is placed on top of the alveolar bone and sutured.

The flap surgical technique is as follows:

1. After anesthetizing the area, sounding of the underlying alveolar bone is performed with a periodontal probe to determine the presence and extent of the osseous defects.
2. On the buccal and lingual aspects, with a #15 surgical blade, the initial scalloped internal bevel incision is made at least 3 mm coronal to the mucogingival junction, which includes the creation of new surgical interdental papillae in each interproximal space.
3. The same blade is used to thin the gingival tissues in the buccolingual direction to the mucogingival junction. At this point, the blade establishes contact with the alveolar bone, and a full-thickness or split-thickness flap is elevated.
4. On the palatal aspect, a scalloped internal bevel incision is made at the level of the intended postoperative gingival margin level, which is usually the cementoenamel or more apical in cases where periodontitis is combined with gingival enlargement. The whole extent of the palatal flap is thinned as needed in the apical direction. The base of the flap is then scored to bone and elevated.
5. With the use of an Orban knife, the base of each papilla that connects the facial and the lingual incisions is released.
6. Intrasulcular incisions are made on buccal, lingual, and palatal areas that are being treated to release the tissue collar.
7. The marginal and interdental tissues are removed with curettes.
8. After all tissue tags are removed, the roots are thoroughly scaled and planed, and the bone is recontoured as needed.
9. The flap is replaced or apically displaced and, if necessary, retrimmed to reach the bone–tooth junction exactly (palatal flaps). The flaps are then sutured with an interrupted or a continuous mattress technique, and the area is protected with periodontal dressing.

Sutures and periodontal dressing are removed after 1 to 2 weeks, depending on the extent of the surgery. The patient is instructed to begin biofilm control practices. Usually it is convenient for the patient to use chlorhexidine oral rinses once or twice daily for 2 to 4

weeks.

Fig. 61.6 shows a kidney transplant recipient who was receiving cyclosporine and nifedipine therapy and was treated with the flap technique. Fig. 61.7 depicts the treatment of a 9-year-old kidney transplant recipient whose upper anterior teeth could not break through the enlarged gingival tissues because of their overgrowth, which was induced by cyclosporine therapy; treatment via flap operation allowed for exposure of the anatomic crowns and for the maintenance of keratinized tissue, which could have been completely eliminated if the case had been treated with gingivectomy.

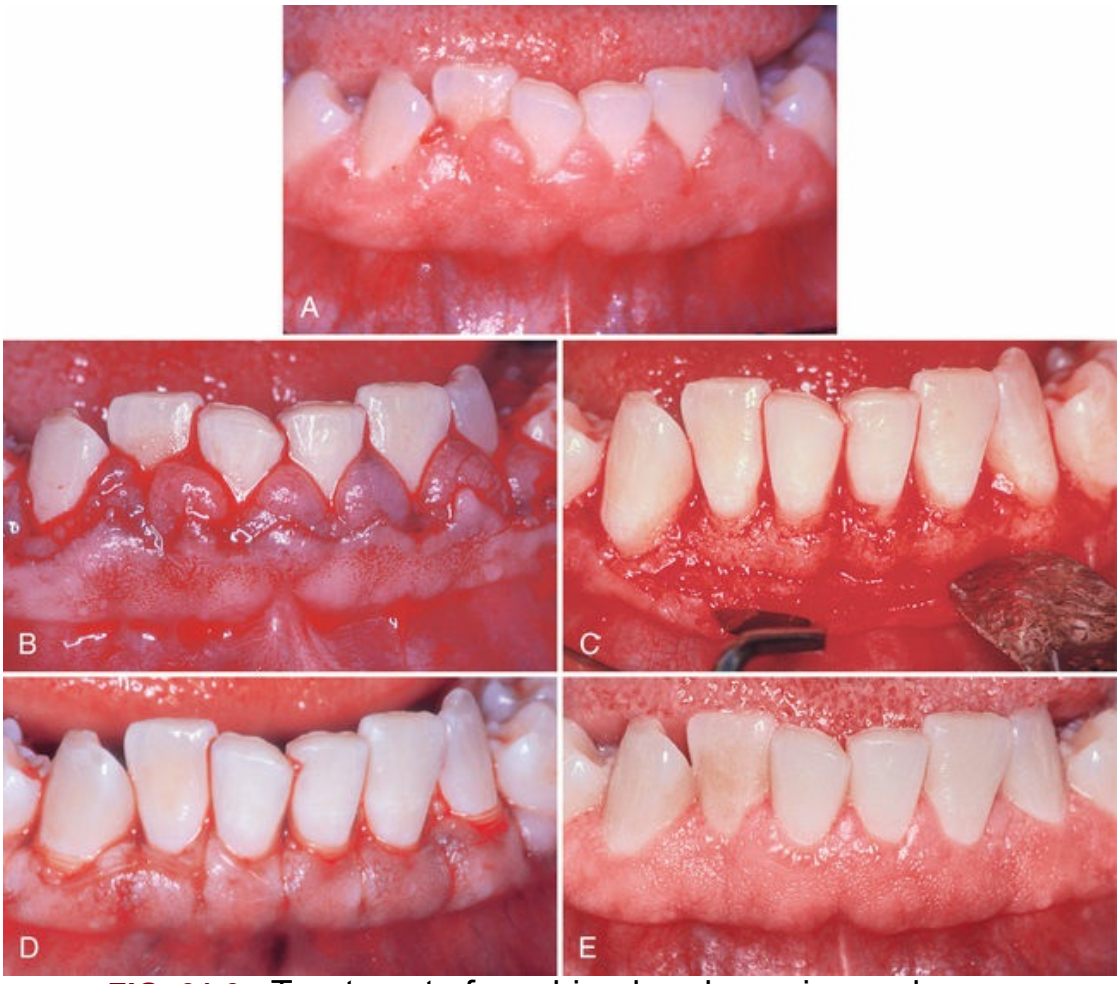

FIG. 61.6 Treatment of combined cyclosporine and nifedipine–induced gingival enlargement with a periodontal flap on a 35-year-old female patient who had received a kidney allograft 3 years earlier. (A) Presurgical clinical aspect of the lower anterior teeth, showing severe gingival enlargement. (B) Initial

scalloped reverse bevel incision, including maintenance of keratinized tissue and creation of surgical papillae. (C) Elevation of a full-thickness flap and removal of the inner portion of the previously thinned gingival tissue. After scaling and root planing, osseous recontouring can be performed if necessary. (D) The flap is positioned on top of the alveolar crest. (E) Postsurgical aspect of the treated area at 12 months. Note the reduction of enlarged tissue volume and acceptable gingival health.

FIG. 61.7 Treatment of a 9-year old recipient of an allogeneic kidney transplant who had been receiving Cyclosporin A and nifedipine therapy for 2½ years. Surgical treatment was with an apically positioned flap.

(A) Upper incisors were in an occluding position, but they did not erupt through the drug-enlarged gingival tissues. (B) Crestal reversed bevel incision maintaining most of the buccal keratinized tissue. (C) Flap thinning via split-thickness dissection. (D) Removal of excess gingival connective tissue on the buccal surfaces of the anterior teeth and interproximal spaces. (E) Clinical crowns fully exposed; periosteum preserved over alveolar bone. (F) Flap was apically positioned and sutured to periosteum with 5-0 plain gut. (G) Healing at 14 days after surgery. (H) Healing at 3 months postoperatively with acceptable gingival health and presence of adequate buccal keratinized tissue.

The recurrence of drug-induced gingival enlargement is a reality in surgically treated cases.[23] The major cause of the recurrence of gingival enlargement is the difficulty with postsurgical oral hygiene. Meticulous home care,[7,20] with a soft, postsurgical brush and chlorhexidine gluconate rinses,[27]is indicated. Frequent professional cleanings can also help reduce the degree of recurrence. A hard, rubber, custom-fitted occlusal guard worn at night may also be helpful to control recurrence.[3,31]

Although the periodontal flap approach may be technically more difficult than the gingivectomy procedure, as indicated previously, the postsurgical healing of the flap technique causes less discomfort and decreases the chances of postoperative bleeding. The primary closure of the surgical site with the flap procedure is a great advantage over the secondary open wound that results from the gingivectomy technique. In addition, postsurgical home care can be instituted earlier with the periodontal flap.[6]

Recurrence may occur as early as 3 to 6 months after surgical treatment. In general, surgical results with minimal recurrence are possible for at least 12 months. In one study, healing of flap surgery was compared with that of gingivectomy after a 6-month postsurgical examination. This comparative study of the recurrence of cyclosporine-induced gingival enlargement after periodontal flap surgery compared with that of the gingivectomy technique indicated that the return of the pocket depth took longer with flap surgery.[21]

Learning Box 61.5

The use of flap surgery to reduce gingival enlargement is favored over the gingivectomy technique. By using flap surgery, recurrence of gingival tissue is minimized both in amount of tissue and in time to recurrence.

Leukemic Gingival Enlargement

Leukemic enlargement occurs with acute or subacute leukemia (Fig. 61.8), and it is uncommon among patients in the chronic leukemic state. The patient's bleeding and clotting times and platelet count should be checked before treatment, and the hematologist should be consulted before periodontal treatment is instituted (see Chapters 19 and 39). Gingival bleeding, sometimes spontaneous, is often associated with leukemic gingival enlargement.

FIG. 61.8 **A 74-year-old patient with acute leukemia. Gingival enlargement is observed in combination with a hemorrhagic appearance, which sometimes causes spontaneous bleeding.**

The treatment of periodontal conditions in patients with leukemia is described in Chapters 19 and 30. After acute symptoms subside, attention is directed to correction of the gingival enlargement. The rationale is to remove the local irritating factors to control the inflammatory component of the enlargement, and this is

achieved by scaling and root planing. The initial treatment steps consist of gently removing all loose debris with cotton pellets, performing superficial scaling, and instructing the patient in oral hygiene for biofilm control. This hygiene should include, at least initially, the daily use of chlorhexidine mouthrinses. Oral hygiene procedures are extremely important for these patients and, if necessary, may require the assistance of a nurse.

Definitive scaling and root planing are carried out at subsequent visits using local anesthesia. Treatment sessions are confined to a small area of the mouth if hemostasis poses a challenge. Antibiotics are administered systemically the evening before and for a week after each treatment to reduce the risk of infection.

Gingival Enlargement During Pregnancy

Treatment requires the elimination of all local irritants that may be responsible for precipitating the gingival changes that occur during pregnancy. The elimination of local irritants early in pregnancy is a preventive measure against gingival disease, and prevention is preferable to treatment of gingival enlargement after it occurs. Marginal and interdental gingival inflammation and enlargement are treated by scaling and root planing (see Chapters 48, 50, and 51). Treatment of tumor-like gingival enlargements consists of surgical excision, as well as the scaling and planing of the tooth surfaces adjacent to the lesion. The enlargement may recur unless all irritants are removed. Food impaction is frequently an inciting factor.

Gingival lesions during pregnancy should be treated as soon as they are detected, although not necessarily by surgical means. Scaling and root planing procedures and adequate oral hygiene measures may reduce the extent of the enlargement. Gingival enlargements do shrink after pregnancy, but they usually do not disappear. After pregnancy, the entire periodontal status of the patient should be reevaluated, and comprehensive treatment should be undertaken.

Lesions should be removed surgically during pregnancy if they

interfere with mastication or produce an aesthetic disfigurement that bothers the patient.

During pregnancy, the emphasis should be on (1) preventing gingival disease before it occurs and (2) treating existing gingival disease before it worsens. All patients should be seen as early as possible after becoming pregnant. Patients without gingival disease should be examined for potential sources of local irritation and should be instructed on meticulous oral hygiene procedures. In addition, patients who already have signs and symptoms of periodontal disease should be treated promptly, before the effect of pregnancy on the gingiva becomes manifest. Chapter 41 presents the necessary precautions for the periodontal treatment of pregnant women.

Every pregnant patient should be scheduled for periodic maintenance visits. The importance of such visits in the prevention of serious periodontal disturbances should be stressed.

Gingival Enlargement During Puberty

Gingival enlargement during puberty is treated by performing scaling and root planing, removing all sources of irritation, and controlling biofilm. Surgical removal may be required in severe cases. The most important problem in these young patients is recurrence, for which close maintenance therapy is recommended.

Case Scenario 61.1

Patient:

A 7-year-old female patient

Chief Complaint:

Reported by the patient's father, “She cannot eat anymore and is having speech difficulties.”

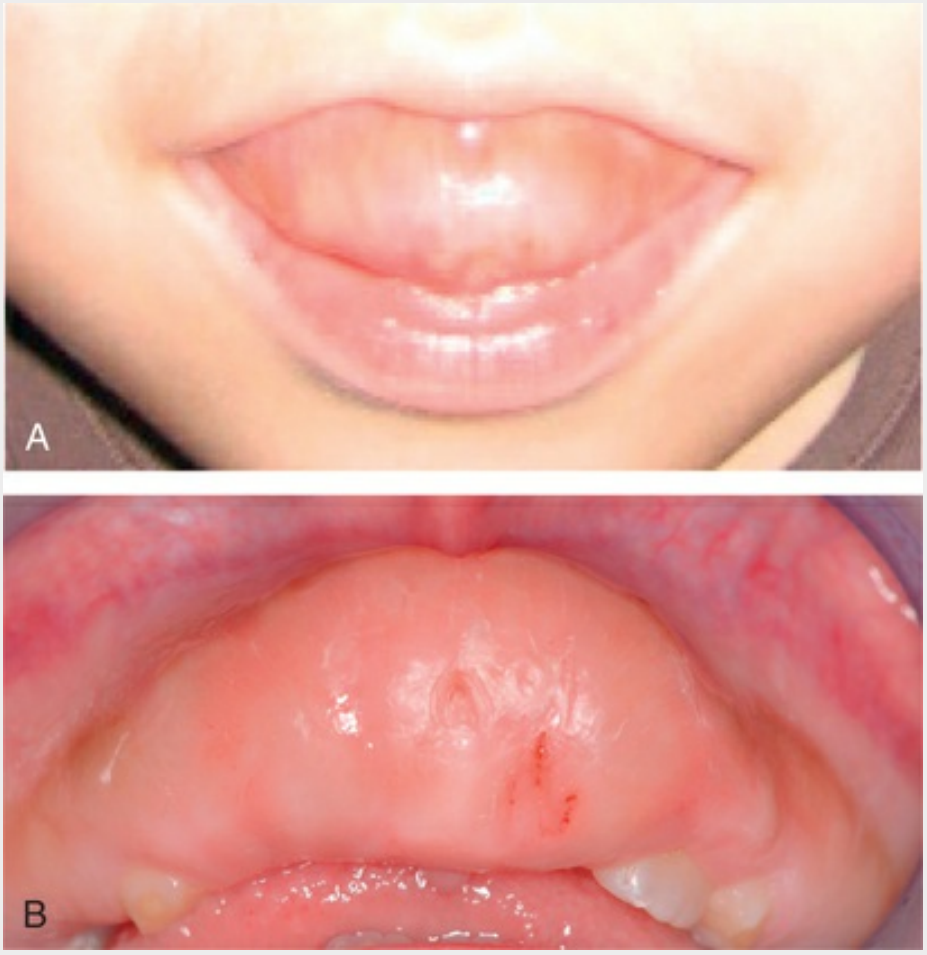
Background Information:

The patient was born with an undefined congenital condition, which included mild mental retardation and frequent seizures. She

was placed on the anticonvulsive medication phenytoin shortly after birth. According to her parents, gingival enlargement has been always present, but it worsened in the last 2 years to the point that it is affecting her feeding and sleeping patterns. The patient is moderately cooperative, and previous dental work was performed using general anesthesia.

Initial Presentation Findings:

Generalized severe fibrotic gingival enlargement. The upper anterior segment is the most severely affected area, and the central incisors are completely covered by soft tissue. The lower incisors are occluding against the upper masticatory mucosa. The presence of local factors (biofilm) is minimal, and there is no bleeding on probing around the erupted teeth.



CASE-BASED

QUESTIONS	
1. The first step in treating the patient is to plan for surgical resection of the enlarged, fibrotic gingival tissues. A. Yes B. No	**Answer: B** **Explanation:** The gingival condition is induced by phenytoin. The first step in managing the case should involve a consultation with the patient's physician to consider the possibility of changing the patient's anticonvulsive medication, in which case the gingival enlargement may decrease or resolve without surgical therapy.
2. Once is determined that periodontal surgery is the therapy of choice, which would be the preferred technique? A. Gingivectomy B. Apically positioned flap	**Answer: B** **Explanation:** The advantages of apically positioned flap over gingivectomy include the maintenance of keratinized tissue and primary wound closure. This decreases the degree of postoperative pain or discomfort and minimizes the possibility of postoperative bleeding, important considerations in a pediatric patient whose cooperation with dental treatment is limited.
3. The role of local factors should be considered in the treatment of drug-induced gingival enlargement. A. True B. False	**Answer: A** **Explanation:** Local factors, such as dental biofilm and calculus, may aggravate the clinical presentation of gingival enlargement induced by medications, either by being preexistent or by accumulating after the onset of gingival overgrowth. These factors should be eliminated by nonsurgical periodontal therapy before the final decision is made to institute surgical treatment

One-Year Posttreatment Findings:

As reported by her parents, the patient did not present with any masticatory or speech impairment. Oral hygiene can be performed normally. Minor inflammatory changes are present in the marginal gingiva of the upper anterior teeth. As of 6 months before this dental visit, the patient started taking valproic acid in place of phenytoin.

CASE-BASED QUESTIONS	SOLUTIONS AND EXPLANATIONS
1. Recurrence is not a concern because valproic acid is not associated with gingival enlargement. A. True B. False	**Answer: B** **Explanation:** Although the prevalence of gingival enlargement in patients taking valproic acid is lower than in patients taking phenytoin, reports exist of tissue overgrowth with valproic acid.
2. Localized gingival enlargement recurrence, such as that observed in interdental areas, can be treated by gingivectomy. A. True B. False	**Answer: A** **Explanation:** Gingivectomy and gingivoplasty are viable techniques to treat areas with mild gingival enlargement. They are less technique sensitive and can be performed faster than the periodontal flap, but they always carry the risk of postoperative pain, discomfort, bleeding, and the iatrogenic mucogingival problems.

Postoperative Maintenance *(e-only)*
Specific Osseous Reshaping Situations *(e-only)*
Conclusion

The damage resulting from periodontal disease manifests in

variable destruction of the tooth-supporting bone. Generally, bony deformities are not uniform; they are not indicative of the alveolar housing of the tooth before the disease process and do not reflect the overlying gingival architecture. Bone loss has been classified as either "horizontal" or "vertical," but in fact, bone loss is most often a combination of horizontal and vertical loss. Horizontal bone loss generally results in a relative thickening of the marginal alveolar bone because bone tapers as it approaches its most coronal margin.

The effects of this thickening and the development of vertical defects leave the alveolar bone with countless combinations of bony shapes. If these various topographic changes are to be altered to provide a more physiologic bone pattern, a method for osseous recontouring must be followed.

Osseous surgery may be defined as the procedure by which changes in the alveolar bone can be accomplished to rid it of deformities induced by the periodontal disease process or other related factors such as exostosis and tooth supraeruption.

Osseous surgery can be either additive or subtractive. *Additive osseous surgery* includes procedures directed at restoring the alveolar bone to its original level, whereas *subtractive osseous surgery* is designed to restore the form of preexisting alveolar bone to the level present at the time of surgery or slightly more apical to this level (Fig. 62.1).

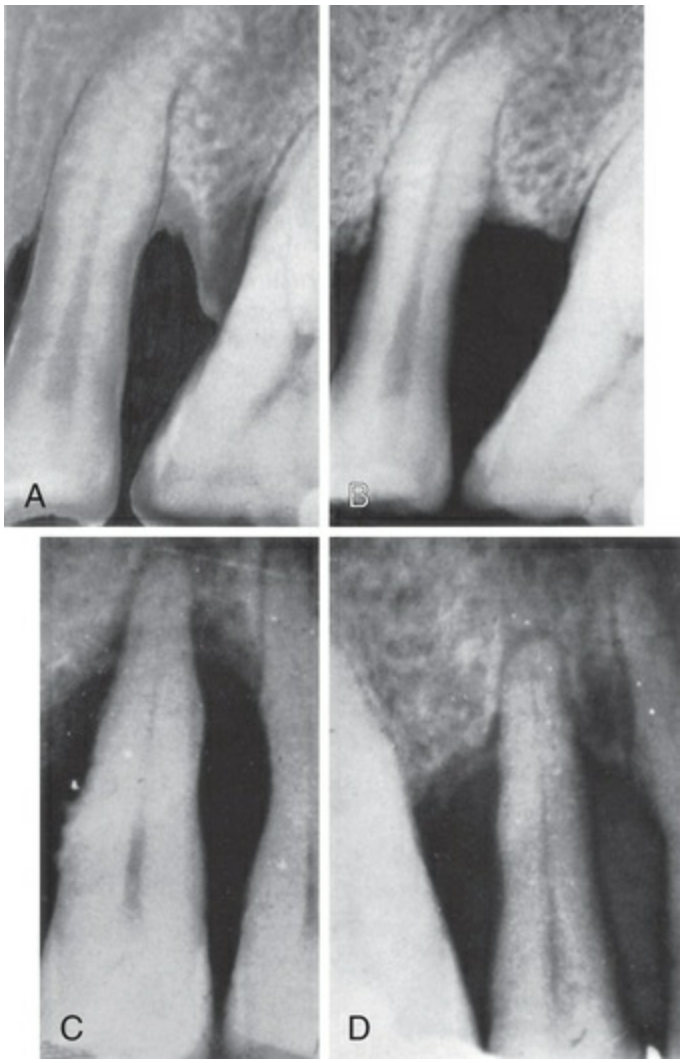

FIG. 62.1 Additive and subtractive osseous surgery. (A) Before and (B) immediately after subtractive osseous surgery; the osseous wall of the two adjoining infrabony pockets has been removed. (C) Before and (D) 1 year after additive osseous surgery; the area has been flapped and thoroughly instrumented, resulting in reconstruction of the interdental and periapical bone. (Courtesy Drs. E.A. Albano and B.O. Barletta, Buenos Aires, Argentina.)

Additive osseous surgery brings about the ideal result of periodontal therapy; it implies regeneration of lost bone and reestablishment of the periodontal ligament, gingival fibers, and junctional epithelium at a more coronal level. This type of osseous surgery is discussed in Chapter 63.

Subtractive osseous surgery procedures provide an alternative to additive methods and should be used when additive procedures are not feasible.[4] These subtractive procedures are discussed in this chapter.

Selection of Treatment Technique

The morphology of the osseous defect largely determines the treatment technique to be used. *One-wall angular defects* usually need to be recontoured surgically. *Three-wall defects,* particularly if they are narrow and deep, can be successfully treated with techniques that strive for new attachment and bone reconstruction. *Two-wall angular defects* can be treated with either method, depending on their depth, width, and general configuration. Therefore, except for one-wall defects and wide, shallow two-wall defects, and interdental craters, osseous defects are treated with the objective of obtaining optimal repair by natural healing processes.

Rationale

Osseous resective surgery necessitates following a series of strict guidelines for proper contouring of alveolar bone and subsequent management of the overlying gingival soft tissues. The specifics of these techniques are discussed later in this chapter. The techniques discussed here for osseous resective surgery have limited applicability in deep intrabony or hemiseptal defects, which could be treated with a different surgical approach (see Chapter 63). Osseous surgery provides the purest and surest method for reducing pockets with bony discrepancies that are not overly vertical and also remains one of the principal periodontal modalities because of its long-term success and predictability.

Osseous resective surgery is the most predictable pocket reduction technique.[10–12] However, more than any other surgical technique, osseous resective surgery is performed at the expense of bony tissue and attachment level.[1,2,8] Thus its value as a surgical approach is limited by the presence, quantity, and shape of the bony tissues and by the amount of attachment loss that is acceptable.

The major rationale for osseous resective surgery is based on the tenet that discrepancies in level and shapes of the bone and gingiva predispose patients to the recurrence of pocket depth postsurgically.[6] Although this concept is not universally accepted,[3,5] and the procedure induces loss of radicular bone in the healing

phase, recontouring of bone is the only logical treatment choice in some cases. The goal of osseous resective therapy is to reshape the marginal bone to resemble that of the alveolar process undamaged by periodontal disease. The technique is performed in combination with apically positioned flaps, and the procedure eliminates periodontal pocket depth and improves tissue contour to provide a more easily maintainable environment.[4] The relative merits of pocket reduction procedures are discussed in Chapter 60; this chapter discusses the osseous resective technique and how and where it may be accomplished.

Key Fact

Bone dictates the form of the gingiva and determines much of the residual pocket depth.

It is proposed that the conversion of the periodontal pocket to a shallow gingival sulcus enhances the patient's ability to remove plaque and oral debris from the dentition. Similarly, the ability of dental professionals to maintain the periodontium in a state free of gingivitis and periodontitis is more predictable in the presence of shallow sulci. The more effective the periodontal maintenance therapy, the greater is the longitudinal stability of the surgical result. The efficacy of osseous surgery therefore depends on its ability to affect pocket depth and to promote periodontal maintenance.[11,22,23] The merits of resection versus other treatment procedures are discussed in Chapter 63.

Normal Alveolar Bone Morphology

Knowledge of the morphology of the bony periodontium in a state of health is required to perform resective osseous surgery correctly (Fig. 62.2). The characteristics of a normal bony form are as follows:

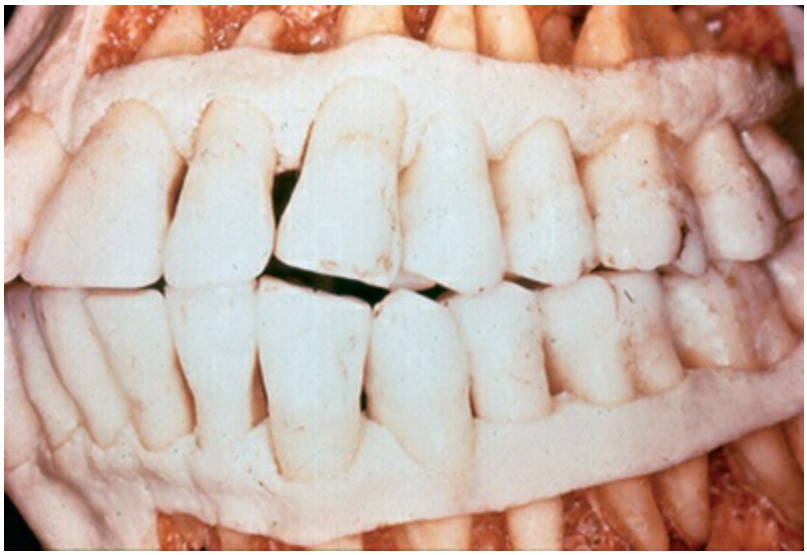

FIG. 62.2 **Photograph of a healthy bony periodontium in a skull. Although a slight amount of attachment may have been lost, this skull demonstrates the characteristics of normal form.**

1. The interproximal bone is more coronal in position than the labial or lingual-palatal bone and pyramidal in form.
2. The form of the interdental bone is a function of the tooth form and the embrasure width. The more tapered the tooth, the more pyramidal is the bony form. The wider the embrasure, the more flattened is the interdental bone mesiodistally and buccolingually.
3. The position of the bony margin mimics the contours of the cementoenamel junction. The distance from the facial bony margin of the tooth to the interproximal bony crest is flatter in the posterior than the anterior areas. This “scalloping” of the bone on the facial surfaces and lingual-palatal surfaces is related to tooth and root form, as well as tooth position within the alveolus. Teeth with prominent roots or those displaced to the facial or lingual side may also have fenestrations or dehiscences (Fig. 62.3). The molar teeth have less scalloping and a flatter profile than bicuspids and incisors.

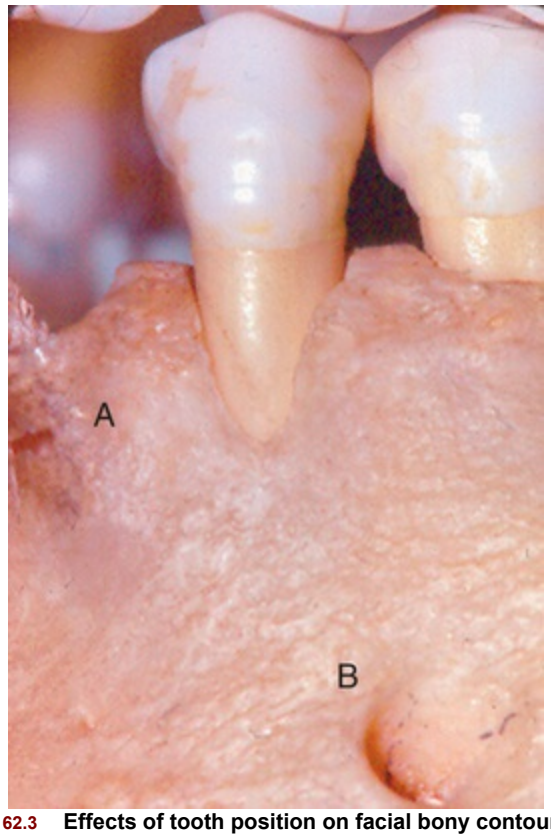

FIG. 62.3 **Effects of tooth position on facial bony contours. Bony dehiscence *(A)* and bony fenestration *(B)*. These deformities can and should be detected by palpation, probing, and sounding before flap surgery.**

Although these general observations apply to all patients, the bony architecture may vary from patient to patient in the extent of contour, configuration, and thickness. These variations may be both normal and healthy.

Terminology

Numerous terms have been developed to describe the topography of the alveolar housing, the procedure for its removal, and the resulting correction. These terms should be clearly defined.

Procedures used to correct osseous defects have been classified in two groups: osteoplasty and ostectomy.[7] *Osteoplasty* refers to reshaping the bone without removing tooth-supporting bone. *Ostectomy,* or *osteoectomy,* includes the removal of tooth-supporting bone. One or both of these procedures may be necessary to produce the desired result.

Terms that describe the bone form after reshaping can refer to

morphologic features or to the thoroughness of the reshaping performed. Examples of morphologically descriptive terms include *negative, positive, flat,* and *ideal*. These terms all relate to a preconceived standard of ideal osseous form.

Positive architecture and *negative architecture* refer to the relative position of interdental bone to radicular bone (Fig. 62.4). The architecture is "positive" if the radicular bone is apical to the interdental bone. The bone has "negative" architecture if the interdental bone is more apical than the radicular bone. *Flat architecture* is the reduction of the interdental bone to the same height as the radicular bone.

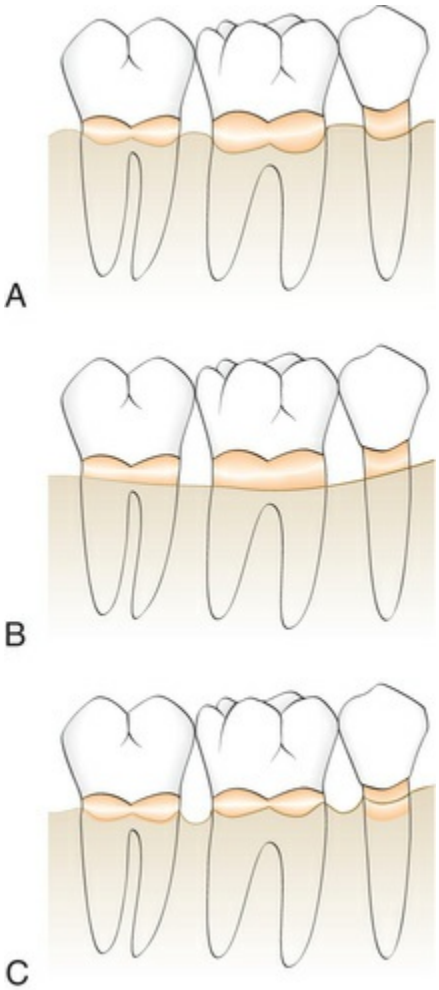

FIG. 62.4 Diagram of types of bony architecture. (A) Positive bony architecture. (B) Flat bony architecture. (C) Reversed, or negative, bony form.

Osseous form is considered to be "ideal" when the bone is

consistently more coronal on the interproximal surfaces than on the facial and lingual surfaces. The ideal form of the marginal bone has similar interdental height, with gradual, curved slopes between interdental peaks (Fig. 62.5).

FIG. 62.5 **Skull photograph of healthy periodontium. Note the shape of the alveolar bone housing. This bone is considered to have ideal form. It is more coronal in the interproximal areas, with a gradual slope around and away from the tooth.**

Terms that relate to the thoroughness of the osseous reshaping techniques include "definitive" and "compromise." *Definitive osseous reshaping* implies that further osseous reshaping would not improve the overall result. *Compromise osseous reshaping* indicates a bone pattern that cannot be improved without significant osseous removal that would be detrimental to the overall result. References to compromise and definitive osseous architecture can be useful to the clinician, not as description of a morphologic feature, but as terms that express the expected therapeutic result.

Factors in Selection of Resective Osseous Surgery

The relationship between the depth and configuration of the bony lesion or lesions with root morphology and the adjacent teeth

determines the extent that bone and attachment are removed during resection. Bony lesions have been classified according to their configuration and number of bony walls.[9] The technique of ostectomy is best applied to patients with early to moderate bone loss (2 to 3 mm) with moderate-length root trunks[18] that have bony defects with one or two walls. These shallow to moderate bony defects can be effectively managed by osteoplasty and ostectomy. Patients with advanced attachment loss and deep intrabony defects are not candidates for resection to produce a positive contour. To simulate a normal architectural form, so much bone would have to be removed that the survival of the teeth could be compromised.

Two-walled defects, or craters, occur at the expense of the interseptal bone. As a result, they have buccal and lingual or palatal walls that extend from one tooth to the adjacent tooth. The interdental loss of bone exposes the proximal aspects of both adjacent teeth. The buccal-lingual interproximal contour that results is opposite to the contour of the cementoenamel junction of the teeth (Fig. 62.6A and B). *Two-walled defects* (*craters*) *are the most common bony defects found in patients with periodontitis.*[14,20] If the facial and lingual plates of this bone are resected, the resultant interproximal contour would become more flattened or ovate (Fig. 62.6C and D). However, confining resection only to ledges and the interproximal lesion results in a facial and lingual bone form in which the interproximal bone is located more apically than the bone on the facial or lingual aspects of the tooth. This resulting anatomic form is reversed, or negative, architecture[17,18,22] (see Fig. 62.6C and D).

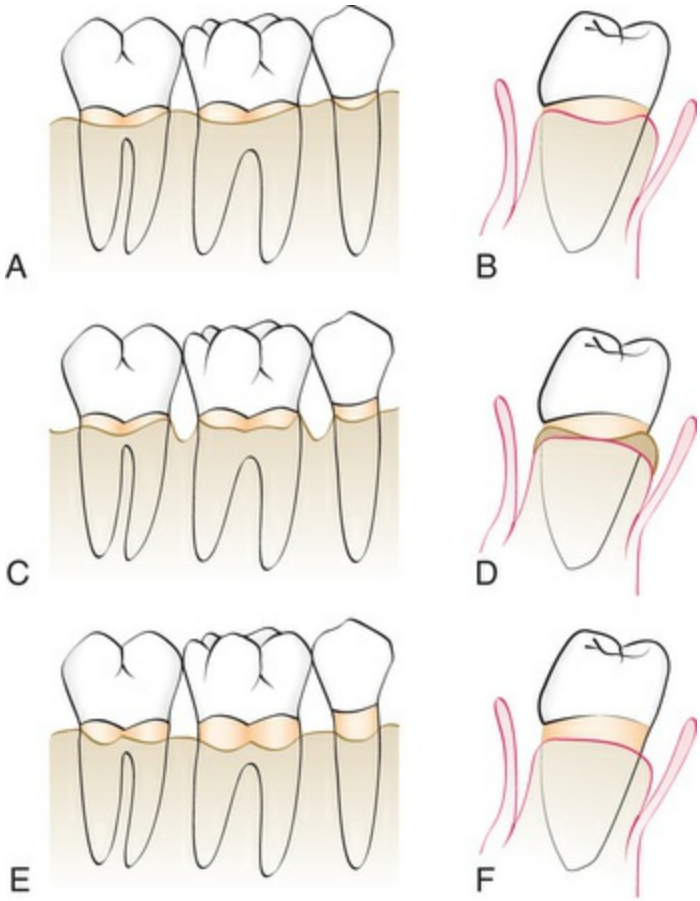

FIG. 62.6 **Effect of correction of craters. (A) and (B) Facial and interproximal bony contours after flap reflection. Note the loss of some interproximal bone and cratering. (C) and (D) Line angles; this is only osteoplasty and has resulted in a reversed architecture. (E) and (F) Ostectomy on the facial and lingual bone and the removal of the residual widow's peaks to produce a positive bony architecture.**

Although the production of a reversed architecture minimizes the amount of ostectomy that is performed, it is not without consequences.[5] Peaks of bone typically remain at the facial and lingual-palatal line angles of the teeth (*widow's peaks*). During healing, the soft tissue tends to bridge the embrasure from the most coronal height of the bone on one tooth to the most coronal heights on the adjacent teeth. The result is therefore the tendency to replicate the attachment contour on the tooth. The interproximal soft tissues invest these peaks of bone, which may subsequently resorb with a tendency to rebound without gain in attachment over time. Interproximal pocket depth can recur.[22,24]

Ostectomy to a positive architecture requires the removal of the line–angle inconsistencies (widow's peaks), as well as some of the facial, lingual, and palatal and interproximal bone. The result is a

loss of some attachment on the facial and lingual root surfaces but a topography that more closely resembles normal bone form before disease (see Fig. 62.6E and F). Proponents of osseous resection to create a positive contour believe that this architecture, devoid of sharp angles and spines, is conducive to the formation of a more uniform and reduced soft tissue dimension postoperatively.[17,21] The therapeutic results are less pocket depth and increased ease of periodontal maintenance by the patient, dental hygienist, or dentist.

The amount of attachment lost from the use of ostectomy varies with the depth and configuration of the treated osseous defects. Osseous resection applied to two-wall intrabony defects (craters), the most common osseous defects, results in attachment loss at the proximal line angles and the facial and lingual aspects of the affected teeth without affecting the base of the pocket. The extent of attachment loss during resection to a positive architecture has been measured. When the technique is properly applied to appropriate patients, the mean reduction in attachment circumferentially around the tooth has been determined to be 0.6 mm at six probing sites.[22] In practical terms, this means that the technique is best applied to interproximal lesions 1 to 3 mm deep in patients with moderate to long root trunks.[17] Patients with deep, multiwalled defects are not candidates for resective osseous surgery. They are better treated with regenerative therapies or by combining osteoplasty to reduce bony ledges and to facilitate flap closure with new attachment and regeneration procedures.

Key Fact

Osseous resective surgery should never compromise the prognosis of the tooth.

Examination and Treatment Planning

The potential for the use of resective osseous surgery is usually identified during a comprehensive periodontal examination. Suitable patients display the signs and symptoms of periodontitis (see Chapter 32). The gingiva may be inflamed, and deposits of

plaque, calculus, and oral debris may be present. An increased flow of crevicular fluid may be detected, and bleeding on probing and exudation are often observed.

Periodontal probing and exploration are key aspects of the examination. Careful probing reveals the presence of (1) pocket depth greater than that of a normal gingival sulcus, (2) the location of the base of the pocket relative to the mucogingival junction and attachment level on adjacent teeth, (3) the number of bony walls, and (4) the presence of furcation defects. Transgingival probing, or sounding, using local anesthesia confirms the extent and configuration of the intrabony component of the pocket and of furcation defects.[6,16]

Routine dental radiographs do not identify the presence of periodontitis and do not accurately document the extent of bony defects. Radiographs cannot accurately document the number of bony walls and the presence or extent of bony lesions on the facial-buccal or lingual-palatal walls. Well-made radiographs provide useful information about the extent of interproximal bone loss, the presence of angular bone loss, caries, root trunk length, and root morphology. Films also facilitate the identification of other dental pathoses that require treatment. In addition, a radiographic survey serves as a means of evaluating the success of therapy and documenting the patient's longitudinal stability.[19]

Treatment planning should provide solutions for active periodontal diseases and correction of deformities that result from periodontitis. Planning should also facilitate the performance of other dental procedures included in a comprehensive dental treatment plan. The extent of periodontal involvement can vary significantly from tooth to tooth in the same patient. The response to therapy from patient to patient may also vary, as may the treatment objectives for the patients. Therefore a treatment plan may encompass a number of steps and combinations of procedures in the same surgical area.

After oral hygiene instruction, scaling and root planing, and other disease control procedures, the response of the patient to these treatment procedures is evaluated by reexamination and recording the changes in the periodontium. Because the extent of periodontal involvement can vary significantly from tooth to tooth

in the same patient, the local response to therapy is also variable. The resolution of inflammation and decrease in edema and swelling may have resulted in a return to normal depth and configuration of some pockets, and additional therapy beyond periodic maintenance may not be required.

The patient with moderate to advanced periodontitis and bony defects may display a persistence of pocket depth bleeding on probing and suppuration, although the overt signs of periodontitis may be reduced. These signs may indicate the presence of residual plaque and calculus, attributable to the difficulty of achieving instrumentation in these deep pockets or the patient's inability or unwillingness to perform adequate oral hygiene in these sites. Patients with inadequate oral hygiene are not good candidates for periodontal surgery. If the supragingival plaque or biofilm control is good and the residual pocket depths are 5 mm or more, patients with such areas may be candidates for periodontal surgery.[13]

Resective osseous surgery is also used to facilitate certain restorative and prosthetic dental procedures. Dental caries can be exposed for restoration; fractured roots of abutment teeth can be exposed for removal; and bony exostoses and ridge deformities can be altered in contour to improve the performance of removable or fixed prostheses (Fig. 62.7). Severely decayed teeth or teeth with short anatomic crowns can be lengthened by resection or by a combination of orthodontic tooth extrusion and osseous resection. Such procedures allow the therapist to expose more tooth for restoration, prevent an invasion of the biologic width of attachment, and create a periodontal attachment of normal dimension.[8,15] Resection can also provide a means of producing optimal crown length for cosmetic purposes.

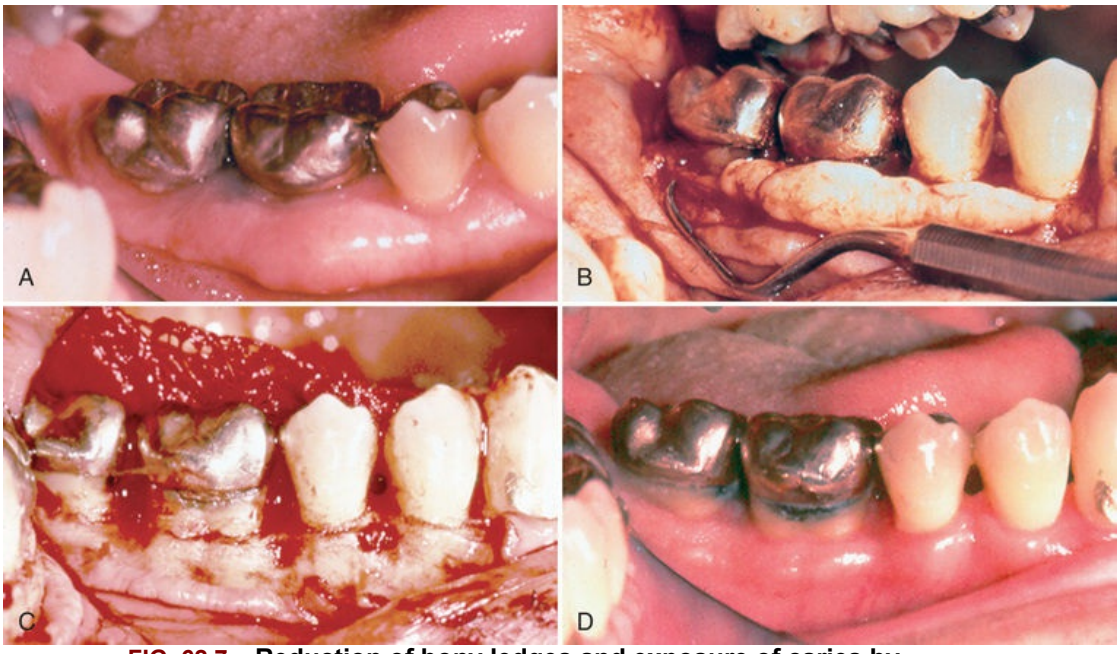

FIG. 62.7 **Reduction of bony ledges and exposure of caries by osteoplasty. (A) Buccal preoperative photograph showing two crowns, exostoses, and caries. (B) Flap reflected to reveal caries on both molars at the restoration margins, interdental cratering, and a facial exostosis. (C) After osseous surgery; the bulk of the bony removal was by osteoplasty, with minor ostectomy between the two molars. The caries is now exposed, and the crowns are lengthened for restoration. (D) Postoperative photograph at 6 weeks. Plaque control is deficient, but the teeth should be readily restorable at this time.** (Courtesy Dr. Joseph Schwartz, Portland, OR.)

Clinical Correlation

Some teeth cannot be restored without the assistance of resective osseous surgery.

Methods of Resective Osseous Surgery

The reshaping process is fundamentally an attempt to gradualize the bone sufficiently to allow soft tissue structures to follow the contour of the bone. The soft tissue predictably attaches to the bone within certain specific dimensions. The length and quality of connective tissue and junctional epithelium that reform in the surgical site depend on numerous factors, including the health of the tissue, condition and topography of the root surface, and

proximity of the bone surrounding the tooth. Each of these factors must be controlled to the best of the clinician's ability to obtain the optimal result, making osseous resective surgery an extremely precise technique.

It is assumed in this chapter that the gingival tissue has been reflected by the apically positioned flap described in Chapter 60. Reshaping of the bone may necessitate selective changes in gingival height. These changes must be calculated and accounted for in the initial flap design. For this reason, it is important for the clinician to know about the underlying bone tissue before flap reflection. The clinician must gain as much indirect knowledge as possible from soft tissue palpation, radiographic assessment, and transgingival probing (sounding).

Radiographic examination can reveal the existence of angular bone loss in the interdental spaces; these areas usually coincide with intrabony pockets. The radiograph does not show the number of bony walls of the defect or document with any accuracy the presence of angular cone defects on facial or lingual surfaces. Clinical examination and probing are used to determine the presence and depth of periodontal pockets on any surface of any tooth and can also provide a general sense of the bony topography, although intrabony pockets can go undetected by probing. Both clinical and radiographic examinations can indicate the presence of intrabony pockets when the clinician finds (1) angular bone loss, (2) irregular bone loss, or (3) pockets of irregular depth in adjacent areas of the same tooth or adjacent teeth.

The experienced clinician can use transgingival probing to predict many features of the underlying bony topography. The information thus obtained can change the treatment plan. For example, an area that had been selected for osseous resective surgery may be found to have a narrow defect that was unnoticed in the initial probing and radiographic assessment and is ideal for augmentation procedures. Such findings can and do change the flap design, osseous procedure, and results expected from the surgical intervention. Transgingival probing is extremely useful just before flap reflection. It is necessary to anesthetize the tissue locally before inserting the probe. The probe should be “walked” along the tissue–tooth interface so that the operator can feel the bony

topography. The probe may also be passed horizontally through the tissue to provide three-dimensional information regarding bony contours (i.e., thickness, height, and shape of the underlying base). However, this information is still "blind," and although it is undoubtedly better than probing alone, it has significant limitations. Nevertheless, this step is recommended immediately before the surgical intervention.

The situations that can be encountered after periodontal flap reflection vary greatly. When all soft tissue is removed around the teeth, there may be larger exostoses, ledges, troughs, craters, vertical defects, or combinations of these defects. Therefore, each osseous situation presents uniquely challenging problems, especially if reshaping to the optimal level is contemplated.

Osseous Resection Technique

Instrumentation

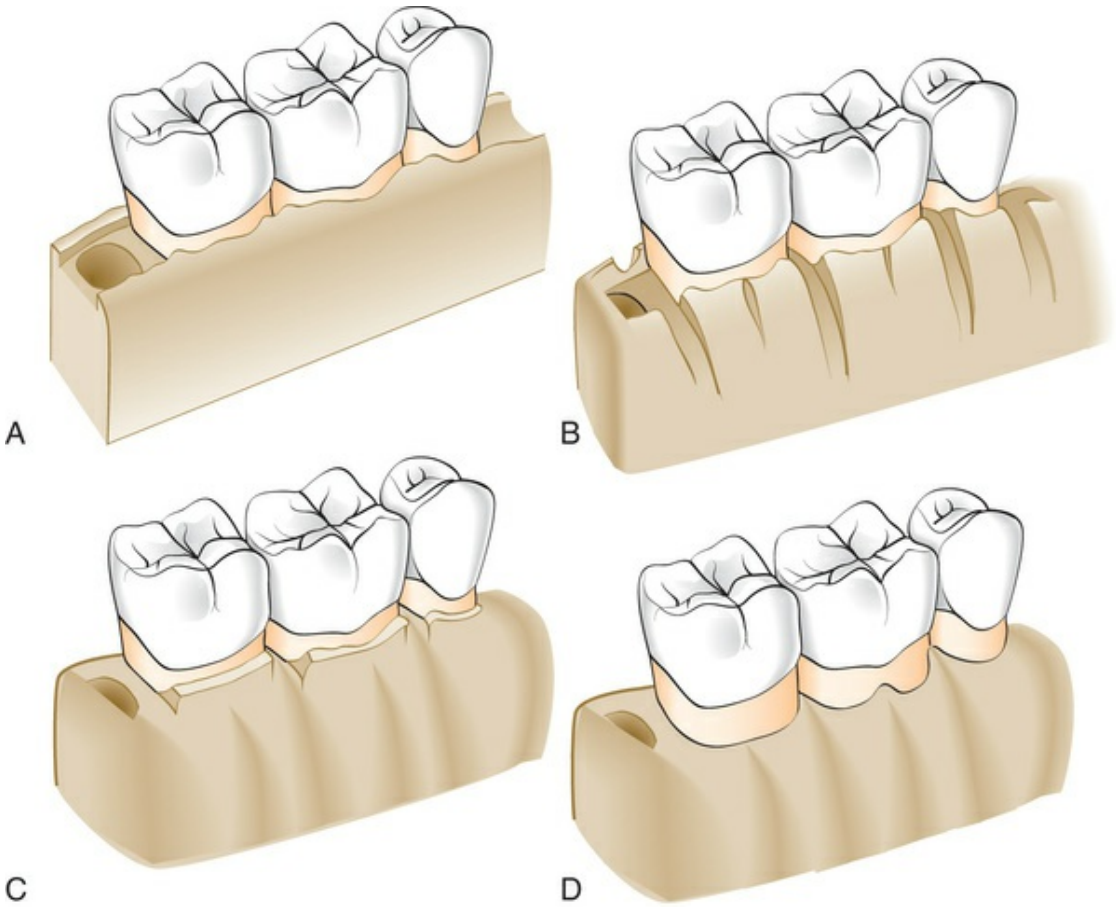
Numerous hand and rotary instruments have been used for osseous resective surgery. Some excellent clinicians use only hand instruments and rongeurs, whereas others prefer a combination of hand and rotary instruments. Rotary instruments are useful for the osteoplastic steps outlined previously, whereas hand instruments provide the most precise and safest results with ostectomy procedures.

Piezoelectric surgical techniques, described in Chapter 83, have also been used with success for osseous surgical resective techniques[25,26] (eFig. 62.1A). Regardless of instrumentation used, care and precision are required for each step of the procedure to prevent excessive bone removal or root damage, both of which are irreversible. eFig. 62.1 illustrates some of the instruments commonly used for osseous resection techniques.

EFIG. 62.1 **Instruments often used in osseous surgery. (A) The piezoelectric surgical instrument has been used successfully in osseous resective surgery. (B) Rongeurs. (C) Carbide round burs. *Left to right,* Friction grip, surgical-length friction grip, and slow-speed handpiece. (D) Diamond burs. (E) Interproximal files: Schluger and Sugarman. (F) Back-action chisels. (G) Ochsenbein chisels.**

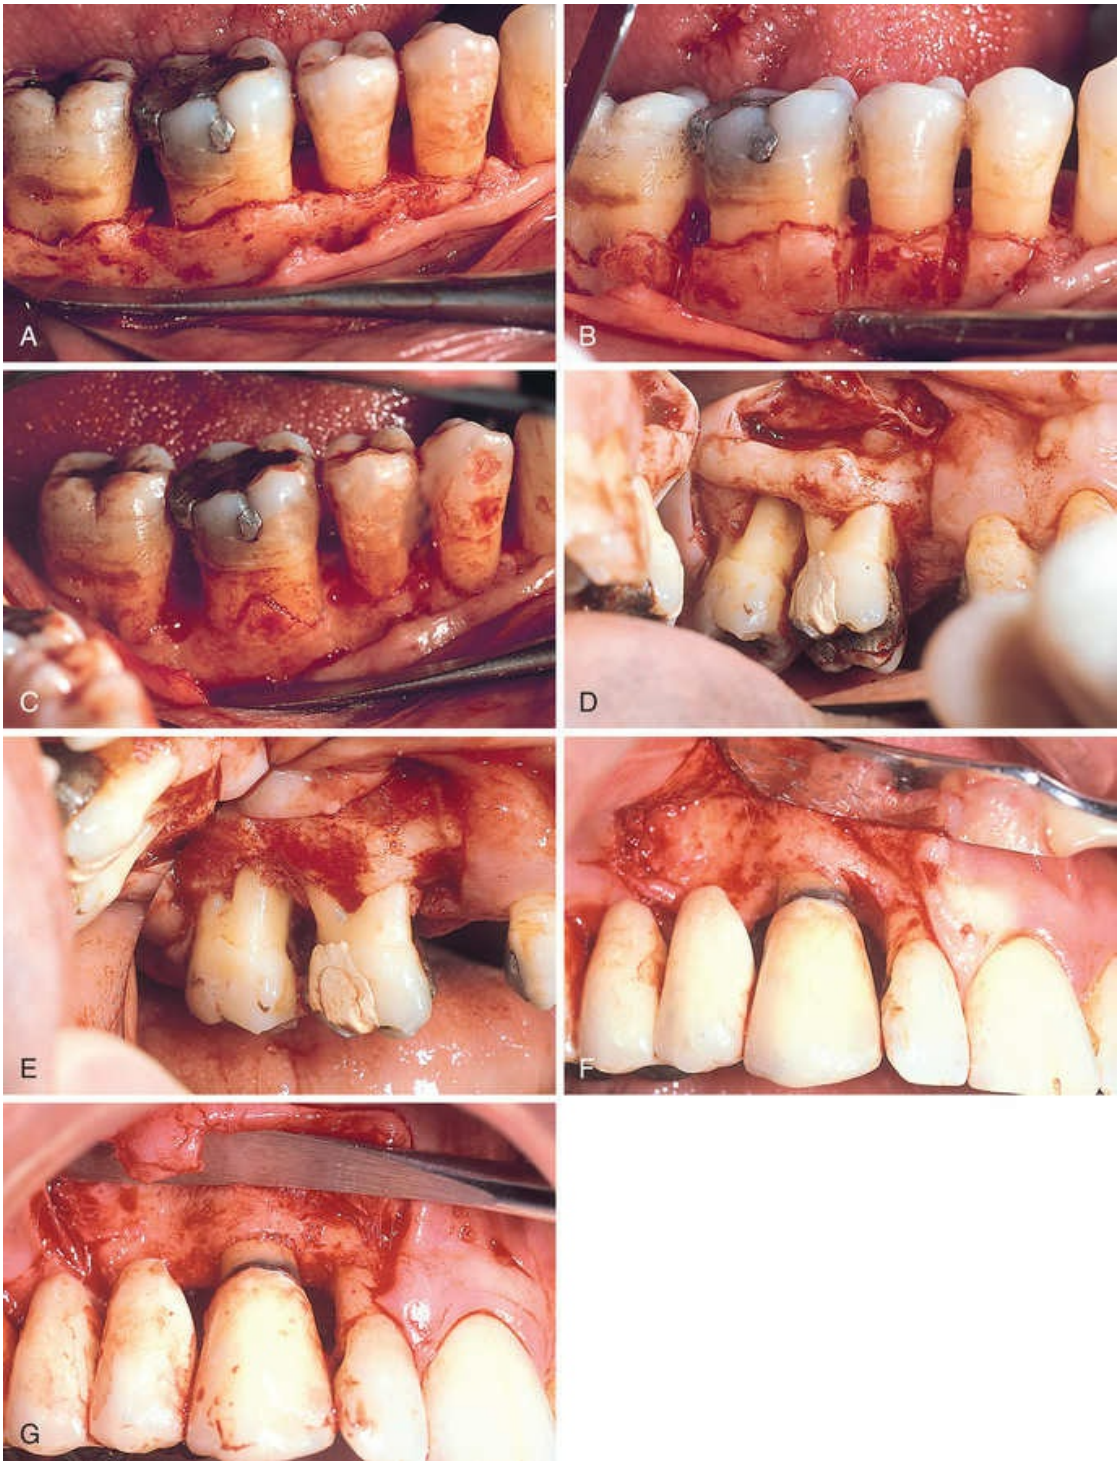
To address the many clinical situations, the following sequential steps are suggested for resective osseous surgery (eFig. 62.2):

1. Vertical grooving
2. Radicular blending
3. Flattening interproximal bone
4. Gradualizing marginal bone



EFIG. 62.2 (A) Bony topography in moderate periodontitis with interdental craters. (B) Vertical grooving, the first step in correction by osseous reshaping. (C) Radicular blending and flattening of interproximal bone. (D) Gradualizing the marginal bone. Note the area of the furcation on the first molar where the bone is preserved.

Not all steps are necessary in every case, but the sequencing of the steps in the order given is necessary to expedite the reshaping procedure, as well as to minimize the unnecessary removal of bone. eFig. 62.3 illustrates bone reshaping in flap surgery for specific anatomic defects.



EFIG. 62.3 **Bone contouring in flap surgery. (A) to (C) Bone contouring in interdental craters. (D) and (E) Bone contouring in exostoses. (F) and (G) Bone contouring in one-wall vertical defect.**

Vertical Grooving

Vertical grooving is designed to reduce the thickness of the alveolar housing and to provide relative prominence to the radicular aspects

of the teeth (see eFig. 62.2B). It also provides continuity from the interproximal surface onto the radicular surface. It is the first step of the resective process because it can define the general thickness and subsequent form of the alveolar housing. This step is usually performed with rotary instruments, such as round carbide burs or diamonds. The advantages of vertical grooving are most apparent with thick bony margins, shallow crater formations, or other areas that require maximal osteoplasty and minimal ostectomy. Vertical grooving is contraindicated in areas with close roots or thin alveolar housing.

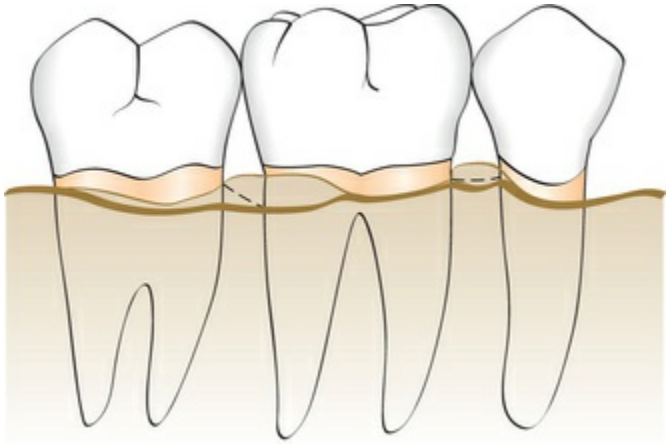
Radicular Blending

Radicular blending, the second step of the osseous reshaping technique, is an extension of vertical grooving (see eFig. 62.2C). Conceptually, it is an attempt to gradualize the bone over the entire radicular surface to provide the best results from vertical grooving. This provides a smooth, blended surface for good flap adaptation. The indications are the same as for vertical grooving (i.e., thick ledges of bone on the radicular surface, where selective surgical resection is desired). Naturally, this step is not necessary if vertical grooving is very minor or if the radicular bone is thin or fenestrated. Both vertical grooving and radicular blending are purely osteoplastic techniques that do not remove supporting bone. In most situations, these two procedures compose the bulk of resective osseous surgery. Classically, shallow crater formations, thick osseous ledges of bone on the radicular surfaces, and class I and early class II furcation involvements are treated almost entirely with these two steps.

Flattening Interproximal Bone

Flattening of the interdental bone requires the removal of very small amounts of supporting bone (eFig. 62.4). It is indicated when interproximal bone levels vary horizontally. By definition, most of the indications for this step are one-walled interproximal defects or hemiseptal defects. The omission of flattening in such cases results in increased pocket depth on the most apical side of the bone loss. This step is typically not necessary with interproximal crater

formations or flat interproximal defects. It is best used in defects that have a coronally placed, one-walled edge of a predominantly three-walled angular defect, and it can be helpful in obtaining good flap closure and improved healing in the three-walled defect. The limitation of this step, as with resective osseous surgical therapy in general, is in the treatment of advanced lesions. Large hemiseptal defects would require removal of inordinate amounts of bone to provide a flattened architecture, and the procedure would be too costly in terms of bony support. Compromised osseous architecture is the only logical solution (eFig. 62.5).



EFIG. 62.4 **Diagrammatic representation of bone irregularities in periodontal disease. The *thick line* is the proposed correction of the defect. Note the flattening of the interproximal bone between the molars and the protection of the furcal bone on the first molar. Facial crest height is reduced in both interproximal areas to the depth of the defect.**

EFIG. 62.5 **Compromise osseous surgery. (A) and (B) Preoperative views of the buccal and lingual surfaces. (C) and (D) Preoperative and postoperative views of the buccal osseous recontouring of class I buccal furcation defects, a moderate crater between the two molars, and a deep one-two-three–walled defect at the mesial of the first involvements. (D) Buccal aspects of these lesions were corrected with osteoplasty and a small amount of ostectomy. (E) and (F) Preoperative and postoperative views of the lingual osseous management. In (E) note the combination one-two-three–walled defect between the second bicuspid and first molar, as well as the irregular pattern of bone loss with ledging. (F) These defects were corrected by osteoplasty and ostectomy, except for the deep defect at the mesial surface of the molar. This area was resected until the residual defect was of two and three walls only and left to repair. (G) and (H) Buccal and lingual 5-year postoperative views of tissue configuration. Note the residual soft tissue defect between the bicuspid and first molar.**

Gradualizing Marginal Bone

The final step in the osseous resection technique is also an ostectomy process. Bone removal is minimal but necessary to provide a sound, regular base for the gingival tissue to follow. Failure to remove small bony discrepancies on the gingival line angles (widow's peaks) allows the tissue to rise to a higher level than the base of the bone loss in the interdental area (see eFig. 62.2C and D). This may make the process of selective recession and subsequent pocket reduction incomplete. This step of the procedure also requires gradualization and blending on the radicular surface (see eFigs. 62.3C and 62.4). The two ostectomy steps should be performed with great care so as not to produce nicks or grooves on the roots. When the radicular bone is thin, it is extremely easy to overdo this step, to the detriment of the entire surgical effort. For this reason, various hand instruments, such as chisels and curettes, are preferable to rotary instruments for gradualizing marginal bone.

Flap Placement and Closure

After performing resection, the clinician positions and sutures the flaps. Flaps may be replaced to their original position, to cover the new bony margin, or they may be apically positioned. Replacing the flap in areas that previously had deep pockets may result initially in greater postoperative pocket depth, although a selective recession may diminish the depth over time. Positioning the flap apically to expose marginal bone is one method of altering the width of the gingiva (denudation). However, such flap placement results in more postsurgical resorption of bone and patient discomfort than if the newly created bony margin were covered by the flap. Positioning the flap to cover the new margin minimizes postoperative complications and results in optimal postsurgical pocket depths (eFig. 62.6).

EFIG. 62.6 **Ostectomy and osteoplasty to a positive contour with flap placement at the newly created bony crest for minimal pocket depth. (A) and (B) Buccal and lingual preoperative views. (C) and (D) Buccal preoperative view and postoperative correction. Osteoplasty and ostectomy were used to produce a positive contour. Note the osteoplasty into the buccal furcation of the first molar. This is about the extent of craters that can be corrected to a positive contour in teeth with moderate root trunk length. (E) and (F) Lingual preoperative**

view and postoperative correction. Osteoplasty and ostectomy were done to produce a positive contour. Note the lingual ledge, which was reduced. Such ledges are common in this area. (G) and (H) Buccal and lingual flaps sutured with continuous sling sutures to allow placement of the flaps to cover the bony margins. Ostectomy and osteoplasty were performed to produce a positive contour, with flap placement at the newly created bony crest for minimal pocket depth. (I) and (J) Buccal and lingual postoperative views at 1 week. Soft tissue thickness is minimal, and the interdental areas are granulating in over the positive bony form. Minimal pocket depth results from such management.

Suturing may be accomplished using a variety of different suture materials and suture knots[4] (see Chapter 60). The sutures should be placed with minimal tension to coapt the flaps, prevent their separation, and maintain the position of the flaps. Sutures placed with excessive tension rapidly pull through the tissues.

Postoperative Maintenance

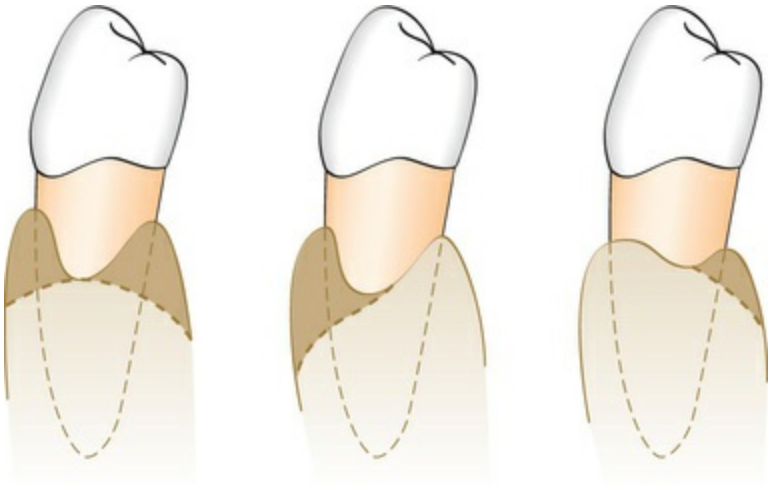
Sutures may be removed at various times after placement. Nonresorbable sutures such as silk are usually removed after 1 week of healing, although some of the newer synthetic materials may be left for up to 3 weeks or longer without adverse consequences. Resorbable sutures maintain wound approximation for varying periods of 1 to 3 weeks or more, depending on the type of suture material. At the suture removal appointment the periodontal dressing, if present, is removed, and the surgical site is gently cleansed of debris with a cotton pellet dampened with saline. Nonresorbable sutures are then cut and removed. If sutures of a resorbable material were used, the area should be inspected carefully to ensure that no suture fragments remain. Suture removal should be accomplished without dragging contaminated portions of the suture through the periodontal tissues. This may be accomplished by lightly compressing the soft tissue immediately adjacent to the suture. This exposes (extrudes) a portion of the suture that was previously under the gingival tissues and less likely to be contaminated by plaque. The suture is then cut at the gingival surface. Removal of the pressure from the site results in the cut surface being slightly submerged in the tissue. The sutures are then removed with cotton pliers by pulling the suture from its contaminated end.

After suture removal the surgical site is examined carefully, and any excessive granulation tissue is removed with a sharp curette. The patient is provided with postsurgical maintenance instructions and the instruments needed to maintain the surgical site in a plaque-free state. These instruments should not produce additional trauma to the healing tissues. Many therapists find the use of a plaque-suppressive agent such as chlorhexidine digluconate to be a valuable adjunct to postsurgical maintenance. A second postoperative visit is often performed at the second or third week, and the surgical site is lightly debrided for optimal results. Professional prophylaxis for complete plaque removal should be done every 2 weeks until healing is complete or the patient is maintaining appropriate levels of plaque control.

Healing should proceed uneventfully, with the attachment of the flap to the underlying bone completed in 14 to 21 days. Maturation and remodeling can continue for up to 6 months. It is usually advisable to wait at least 6 weeks after completion of healing of the last surgical area before beginning dental restorations. For those patients with a major cosmetic concern, it is wise to wait as long as possible to achieve a postoperative soft tissue position and a stable sulcus.

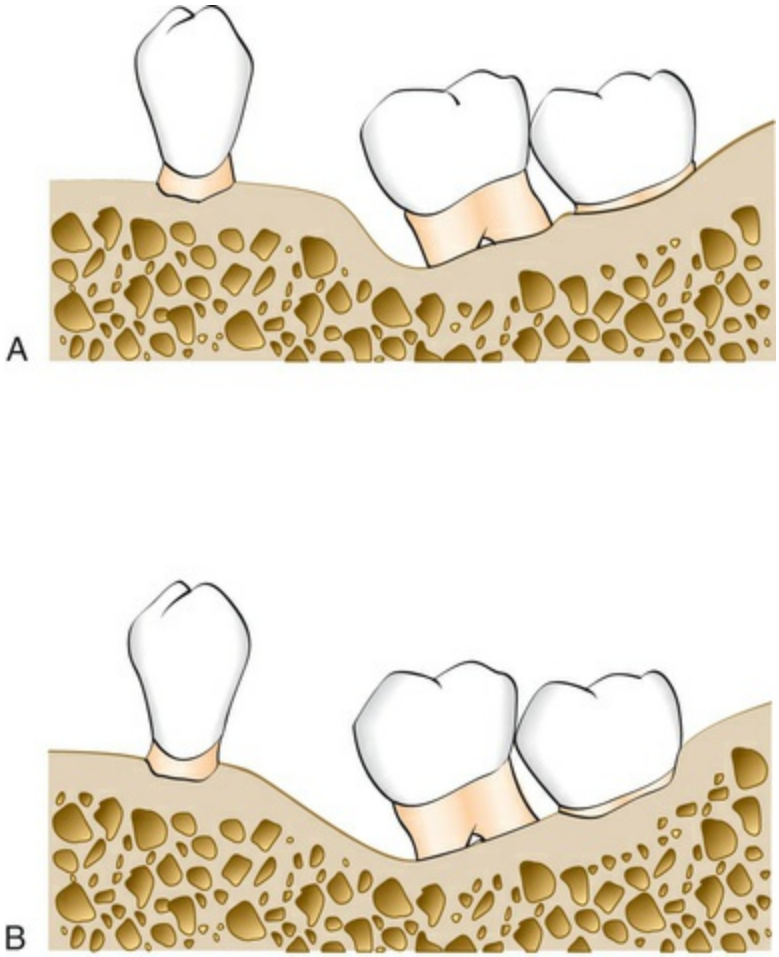
Specific Osseous Reshaping Situations

The osseous corrective procedure previously described is classically applied to shallow craters with heavy faciolingual ledges (eFig. 62.7). The correction of other osseous defects is also possible; however, careful case selection for definitive osseous surgery is extremely important.



EFIG. 62.7 Interproximal craters. The *shaded areas* illustrate different techniques for the management of such defects. The technique that reduces the least amount of supporting bone is preferable.

Correction of one-walled hemiseptal defects requires that the bone be reduced to the level of the most apical portion of the defect. Therefore, great care should be taken to select the appropriate case. If one-walled defects occur next to an edentulous space, the edentulous ridge is reduced to the level of the osseous defect (eFig. 62.8).

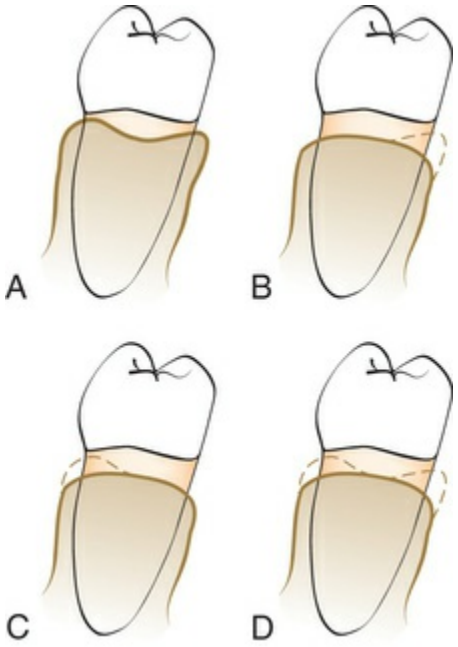


EFIG. 62.8 Reduction of a one-wall angular defect. (A) Angular bone defect mesial to the tilted molar. (B) Defect reduced by "ramping" angular bone.

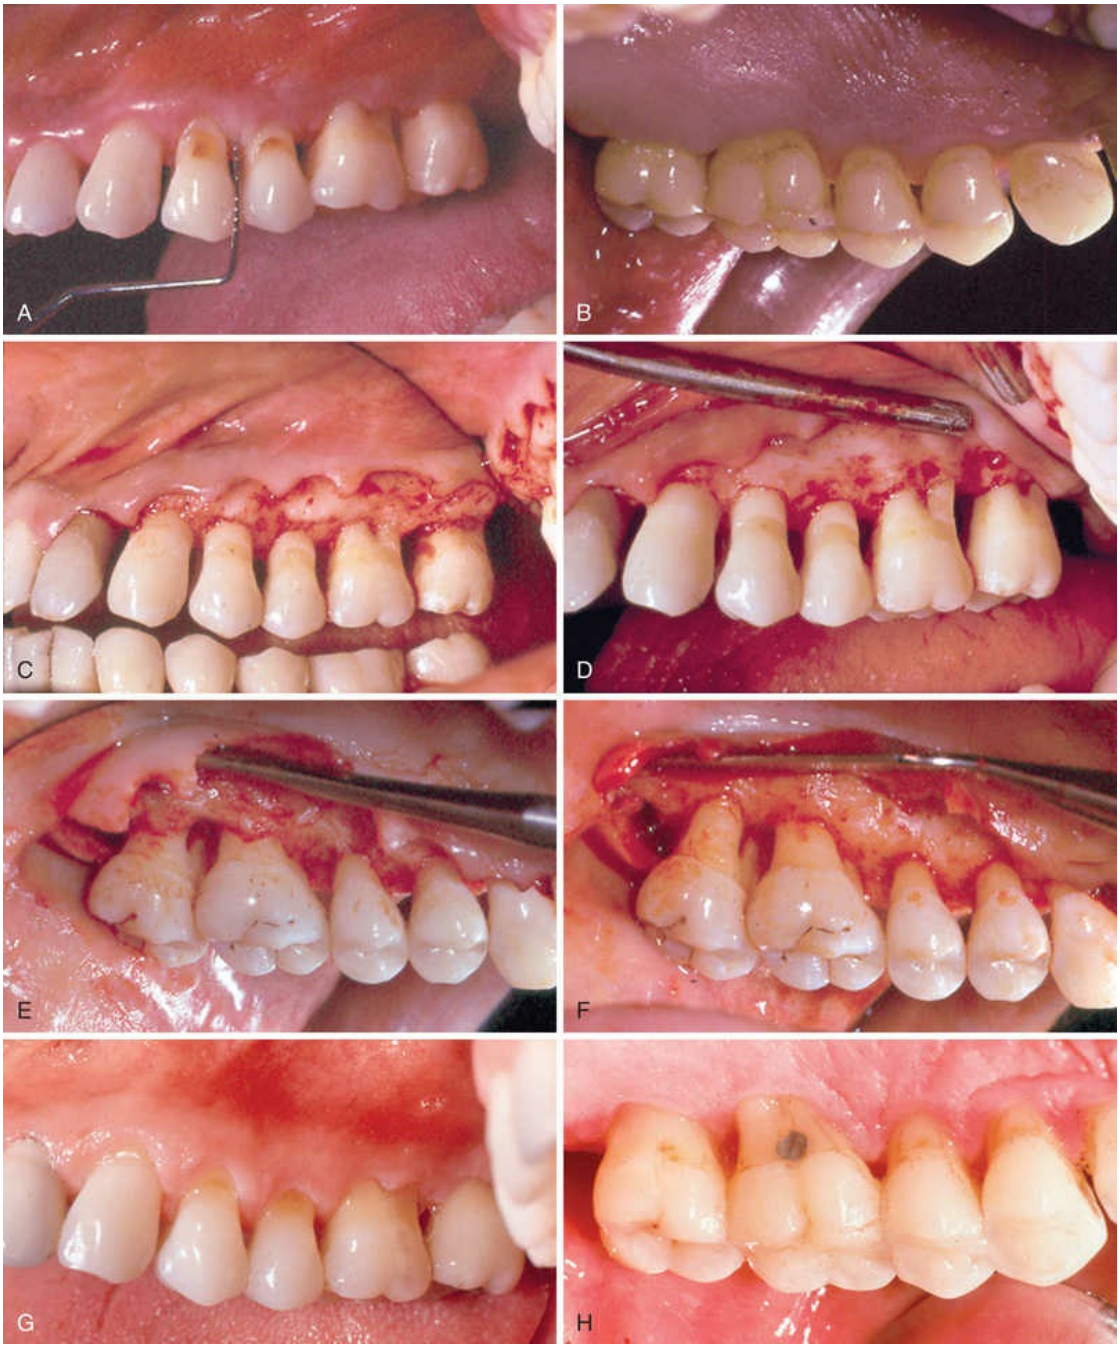
Other situations that complicate osseous correction are exostoses (see eFig. 62.3D and E), malpositioned teeth, and supraerupted teeth. Following the four steps previously outlined best controls each of these situations. In most situations, the unique feature of the bony profile is well managed by prudently applying the same principles (see eFig. 62.3). However, some situations require deviation from the definitive osseous reshaping technique; examples include dilacerated roots, root proximity, and furcations that would be compromised by osseous surgery.

In the absence of ledges or exostoses, elimination of the bony lesion begins with reduction of the interdental walls of craters, the one-walled component of angular defects, and wells (moats) and grooving into sites of early involvement.[10] The walls of the crater may be reduced at the expense of the buccal, lingual, or both walls (eFig. 62.9). The reduction should be made to remove the least

amount of alveolar bone required to (1) produce a satisfactory form, (2) prevent the therapeutic invasion of furcations, and (3) blend the contours with the adjacent teeth. The selective reduction of bony defects by "ramping" the bone to the palatal or lingual to avoid involvement of the furcations has been advocated by Ochsenbein and Bohannan[18] and Tibbetts and colleagues[23] (eFig. 62.10).



EFIG. 62.9 **Diagram of crater reduction patterns. (A) Preoperative bony form after flap reflection. (B) Reduction of craters to the lingual wall. (C) Reduction of craters to the facial wall. (D) Reduction of craters to both the buccal and the lingual walls.**



EFIG. 62.10 **Correction of osseous defects largely to the palatal wall. (A) and (B) Buccal and palatal preoperative views, 6 weeks after completion of scaling and root planing. (C) and (D) Buccal preoperative and postoperative views. In (C), note the ledging on the facial wall of molars and the one-wall defects on both molars. (D) Postoperative view shows the elimination of these defects by osteoplasty on the ledges and ostectomy of the one-wall defects to produce a positive buccal architecture. (E) and (F) Palatal preoperative and postoperative views. In (E), note the pattern of bony loss, which is more severe on the palatal wall. In addition to the facial one-wall defects, an incipient furcation defect is present at the mesial wall of the first molar and a class II furcation is present at the mesial wall of the second molar. (F) Configuration of the defects was such that ostectomy was performed on the palatal roots of both molars to**

produce a compromise architecture. (G) and (H) Ten-year postoperative views of the buccal and palatal areas showing the pattern of soft tissue adaptation to the surgically produced bony form.

In the presence of heavy ledges of bone, it is usually wise to do osteoplasty first to eliminate any exostoses or reduce the buccal or lingual bulk of the bone (eFig. 62.11). It is common practice to incorporate a degree of vertical grooving during the reduction of bony ledges because this facilitates the process of blending the radicular bone into the interproximal areas at the next step.

EFIG. 62.11 Reduction of bony ledges by osteoplasty before correction of interdental defects. (A) Buccal preoperative view. (B) Buccal flap reflection. Note the buccal ledge and the class II buccal furcation. (C) Buccal correction largely by osteoplasty with minor ostectomy over the root prominence to produce a positive architecture. (D) Ten-year postoperative view of soft tissue form. Minimal pocket depth is present.

One-walled or hemiseptal defects usually require the removal of some bone from the tooth with the greatest coronal bony height. This removal of bone may result in a significant reduction in attachment on relatively unaffected adjacent teeth to eliminate the defect. However, if a tooth in the surgical field has one-walled defects on both its mesial and its distal surface and this is recognized during examination, the severely affected tooth may be

extruded by orthodontic therapy during disease control treatment to minimize or eliminate the need for resection of bone from the adjacent teeth.

Conclusion

Although osseous surgical techniques cannot be applied to every bony abnormality or topographic modification, it has been clearly demonstrated that properly used osseous surgery can eliminate and modify defects, as well as gradualize excessive bony ledges, irregular alveolar bone, early furcation involvement, excessive bony exostosis, and circumferential defects. When properly performed, resective osseous surgery achieves a physiologic architecture of marginal alveolar bone conducive to gingival flap adaptation with minimal probing depth. The advantages of this surgical modality include a predictable amount of pocket reduction that can enhance oral hygiene and periodic maintenance. It also preserves the width of the attached tissue while removing granulomatous tissue and providing access for debridement of the radicular surfaces. In addition, the osseous resection technique permits recontouring of bony abnormalities, including hemiseptal defects, tori, and ledges. Its substantial benefits include proper assessment for restorative procedures (e.g., crown lengthening) and assessment of restorative overhangs and tooth abnormalities (e.g., enamel projections, enamel pearls, perforations, fractures). Consequently, resective osseous surgery can be an important technique in the armamentarium necessary to provide a maintainable periodontium for periodontal patients.

Case Scenario 62.1

Question: Which of the following is helpful in determining the amount of osseous respective surgery that should be done?

A. Sounding
B. Radiographs
C. Probing depths

D. All the above

Answer: D

Case Scenario 62.2

Note the three illustrations in eFig. 62.7 and the shaded areas on each. The shaded areas indicate where bone has been removed to eliminate the interdental osseous craters.

Question: Of the three illustrations (*left*, *center*, or *right*), which one shows the greatest amount of ostectomy?

Answer: Left

CHAPTER 63

Periodontal Regeneration and Reconstructive Surgery

Richard T. Kao, Henry H. Takei, David L. Cochran

CHAPTER OUTLINE

Assessment of Periodontal Wound Healing
Reconstructive Surgical Techniques
Factors That Influence Therapeutic Success
Future Directions for Periodontal Regeneration
Conclusion

Intrabony and furcation defects are sequelae of periodontal disease. Ideally, these defects are managed in a timely fashion through periodontal regeneration. In the past, the results of regenerative

therapy were inconsistent and unpredictable. The current status of regenerative therapy has dramatically changed and improved due to research and a better understanding of the biology of the tissues that comprise the periodontal attachment. The various surgical approaches including bone replacement grafts, guided tissue regeneration (GTR), and a better understanding of biologic mediators and tissue engineering have improved the predictability of regeneration as another choice for therapy. This chapter reviews the current strategies and clinical decision making for optimizing regenerative success.

When the periodontium is damaged by inflammation or as a result of surgical treatment, the defect heals either through periodontal regeneration or repair.* In periodontal regeneration, healing occurs through the reconstitution of a new periodontium, which involves the formation of alveolar bone, functionally aligned periodontal ligament, and new cementum. Alternatively, repair due to healing by replacement with epithelial and/or connective tissue that matures into various nonfunctional types of scar tissue is termed *new attachment*. Histologically, patterns of repair include long junctional epithelium, ankylosis, and/or new attachment (see Chapter 3). Although the stability of periodontal repair is not clear, the ideal goal of periodontal surgical therapy is periodontal regeneration.

Today, several highly reproducible regenerative approaches are used, as evidenced by clinical attachment gain, decreased pocket probing depth, radiographic evidence consistent with bone fill, and overall improvements in periodontal health. These clinical improvements can be maintained over long periods (>10 years).[2,9,136,243]

Assessment of Periodontal Wound Healing

It is sometimes difficult in clinical and experimental situations to determine whether regeneration or new attachment has occurred and the extent to which it has occurred. Although various types of evidence of reconstruction exist, the *proof of principle* for the type of

healing is determined by histologic studies. Once defined, the evidence found subsequently by clinical, radiographic, and surgical reentry findings is implied.[36,37,168] All these methods have advantages and shortcomings that should be well understood and considered in individual cases and when critically evaluating the literature. A comparative analysis of regenerative approaches is detailed in Table 63.1.

TABLE 63.1
Comparative Analysis of Regenerative Approaches

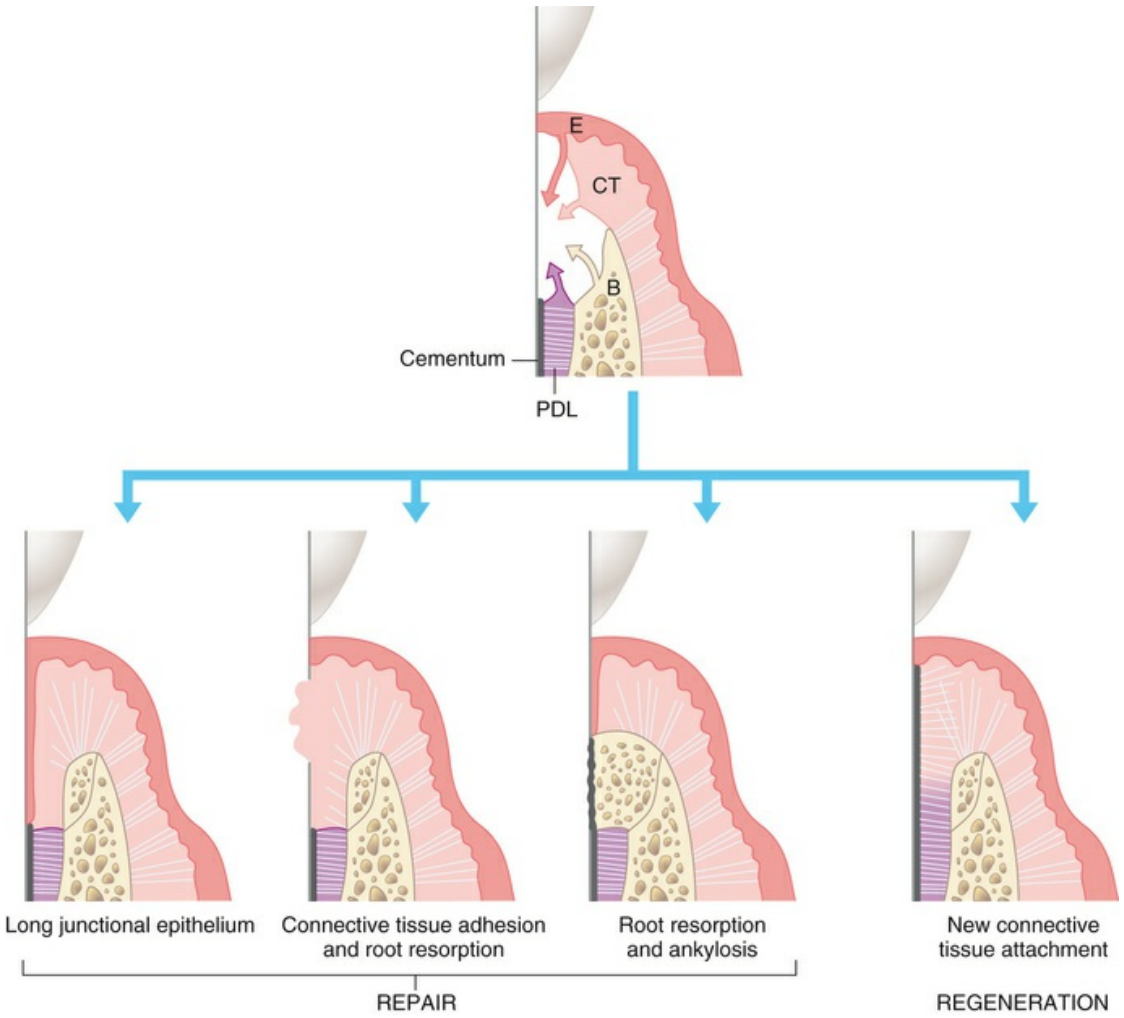
Learning Box 63.1

It is difficult to obtain *proof of principle* for periodontal regeneration with today's bioethics because of the *human* histologic requirements for the regeneration of new bone, cementum, and periodontal ligament. A need exists for redefining periodontal regeneration with a broader basis for acceptance of *proof of principle.* This may include proofs through animal models.

Histologic Methods

Only through histologic analysis can one define the nature of the reparative tissue (eFig. 63.1). In periodontal reconstructive surgery, the goal is to achieve periodontal regeneration. Classically, experimental animal model systems[34,218] are used whereby reference notches are placed at the base of bony defects or at the apical extent

of calculus deposits. Periodontal regeneration is considered to have occurred when the newly formed functionally aligned periodontium is coronal to the apical extent of the notches. Reparative tissue response may include long junctional epithelium, connective tissue adhesion, and root resorption associated with ankylosis. The healing may be dominated by periodontal regeneration; localized areas of repair may be present.[236] Unfortunately, this approach cannot be used in human studies because it would be unethical to extract the treated tooth, especially when it responded positively to therapy. In rare circumstances, human histologic evidence is available if the tooth is to be extracted in conjunction with orthodontic or restorative therapy (eFig. 63.2).



EFIG. 63.1 Possible healing patterns for a periodontal wound. These patterns are dependent on the four possible cell types that predominate the wound site. The downgrowth of epithelial cells *(E)* results in a long junctional epithelium. The proliferation of connective tissue *(CT)* may result in connective tissue adhesion with or without

root resorption. With the predominance of bone cells *(B)*, root resorption and/or ankylosis will occur. With the ingress of periodontal ligament *(PDL)* and perivascular cells from the bone, a regenerated periodontium develops. Clinical Methods

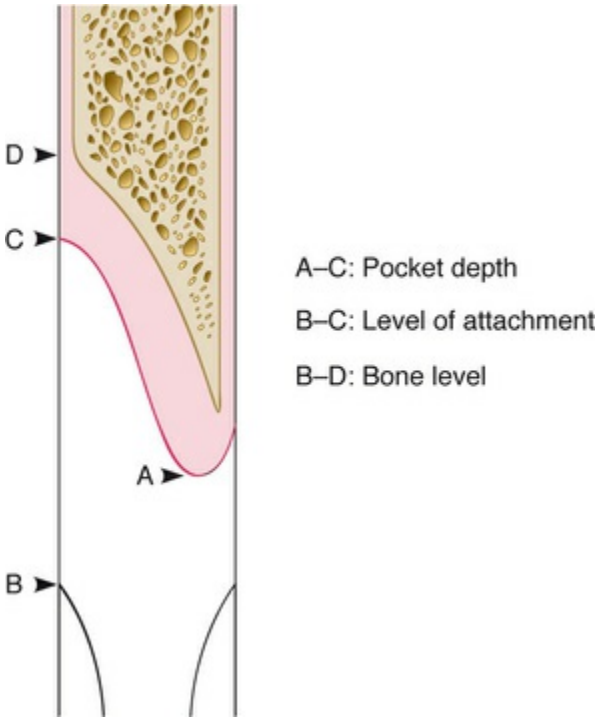
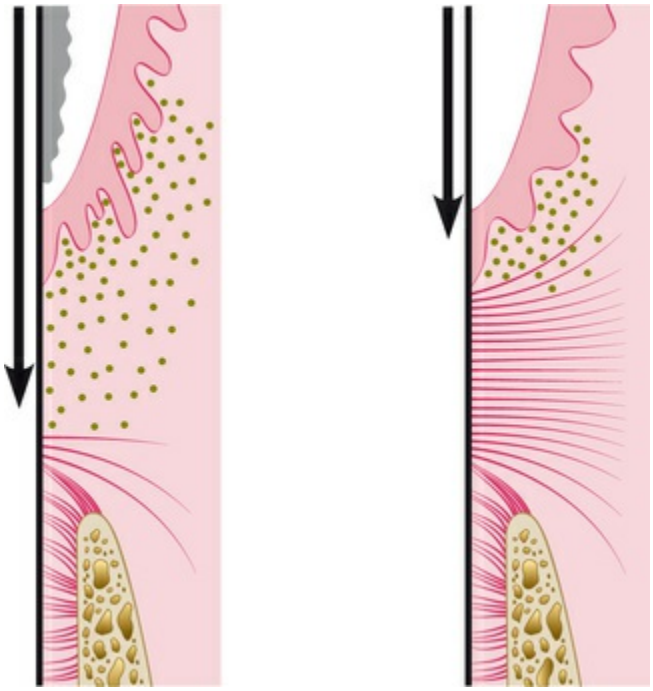
Clinical methods to evaluate periodontal reconstruction consist of comparisons between pretreatment and posttreatment pocket

probings and determinations of clinical gingival findings. The probe can be used to determine pocket depth, attachment level, and bone level (eFig. 63.3). Clinical determinations of attachment level are more useful than probing pocket depths because the latter may change as a result of displacement of the gingival margin (see Chapter 32).



EFIG. 63.3 Different types of probings in an interdental space. Several studies have determined that the depth of penetration of a probe in a periodontal pocket varies according to the degree of inflammatory involvement of the tissues immediately beneath the bottom of the pocket (eFig. 63.4). Therefore, even though the forces used may be standardized with pressure-sensitive probes, an inherent margin of error in this method is difficult to overcome. Fowler and associates[73] have calculated this error to be 1.2 mm, but it is even greater when furcations are probed.

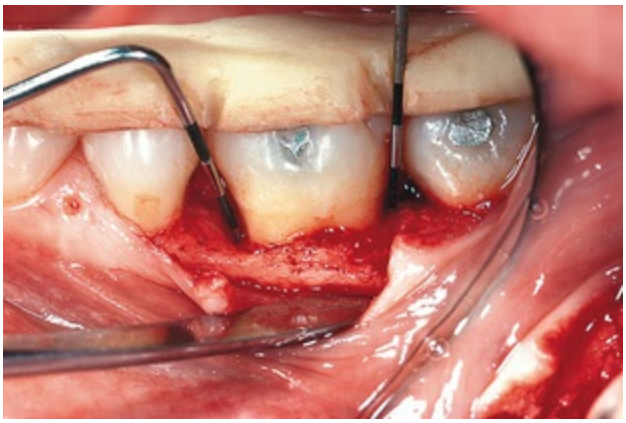
Several studies have determined that the depth of penetration of a probe in a periodontal pocket varies according to the degree of inflammatory involvement of the tissues immediately beneath the pocket (eFig. 63.4). Therefore, even though the forces used may be standardized with pressure-sensitive probes, an inherent margin of error in this method is difficult to overcome. Fowler and colleagues[73] calculated this error to be 1.2 mm, but it is even greater when furcations are probed.[194]



EFIG. 63.4 *Left,* Arrow pointing downward depicts penetration of a probe in an untreated periodontal pocket. The probe tip goes past the junctional epithelium and the inflamed tissue and is stopped by the first intact, attached collagen fibers. *Right,* After thorough scaling and root planing, the location of the bottom of the pocket has not changed, but the probe penetrates to only about one-third the length of the junctional epithelium (see Chapter 32). The reduction in probing depth may not reflect a change in attachment level.

Bone probing performed with the patient under anesthesia is not subject to this error and has been found to be as accurate as bone height measurements made on surgical reentry.[95,239,316]

Measurements of the defect should be made before and after treatment from the same point within the defect and with the same angulation of the probe. This reproducibility of probe placement is difficult and may be facilitated in part by using a grooved stent to guide the introduction of the probe (eFig. 63.5). Preoperative and postoperative comparability of probing measurements that do not use this standardized method may be open to question.



EFIG. 63.5 **Grooved acrylic stent used in clinical research to standardize the direction of introduction of the probe.**

Radiographic Methods

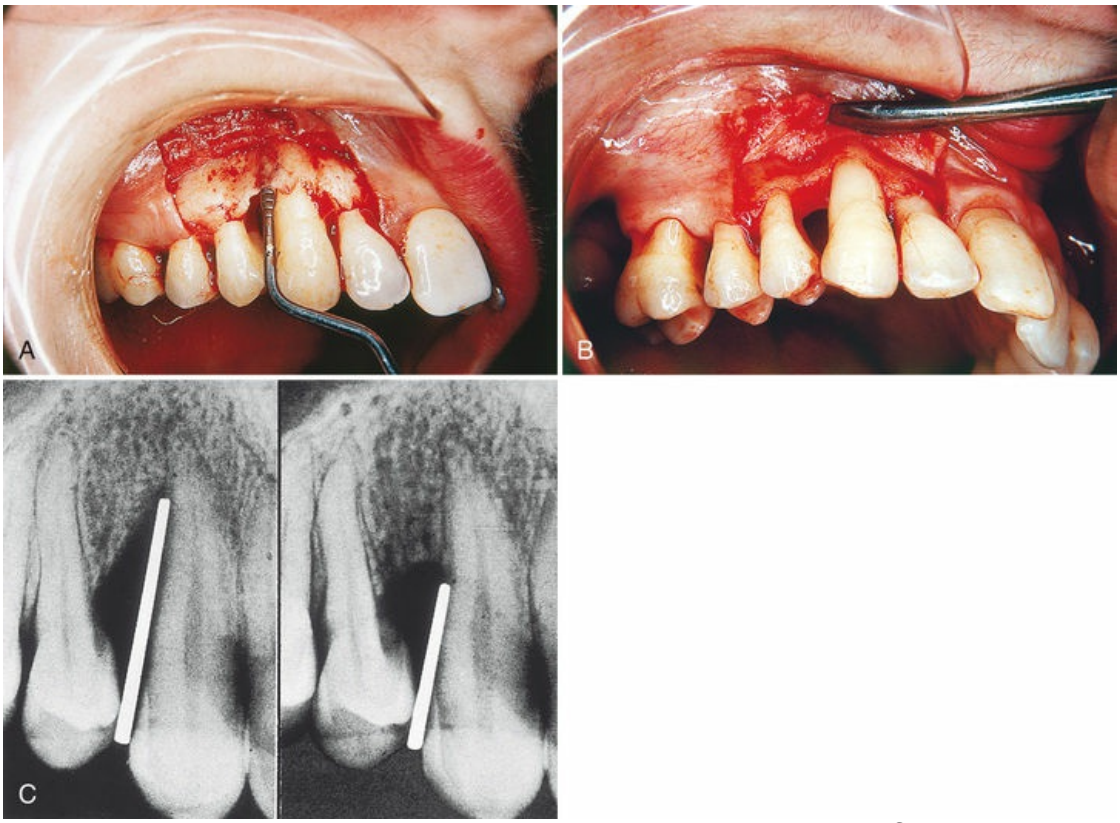
Radiographic evaluation of periodontal regeneration allows assessment of the bone tissue adjacent to the tooth. This technique also requires carefully standardized techniques for reproducible positioning of the film and the tube.[220,252] Even with standardized techniques (see Chapter 33), the radiograph does not show the entire topography of the area before or after treatment. Furthermore, thin bone trabeculae may exist before treatment and may go undetected radiographically because a certain minimal amount of mineralized tissue must be present to register on the radiograph. Several studies have demonstrated that radiographs, even those taken with standardized methods, are less reliable than clinical probing techniques.[156,302] A comparative study of pretreatment bone levels and posttherapy bone fill with 12-month reentry bone measurements showed that linear radiographic analysis significantly underestimates pretreatment bone loss and posttreatment bone fill.[303]

Studies with subtraction radiography have enhanced the usefulness of radiographic evaluation.[62,63,322] A comparative study of linear measurement, computer-assisted densitometric image analysis (CADIA), and a method combining the two reported that the combination method offers the highest level of accuracy.[306]

Surgical Reentry

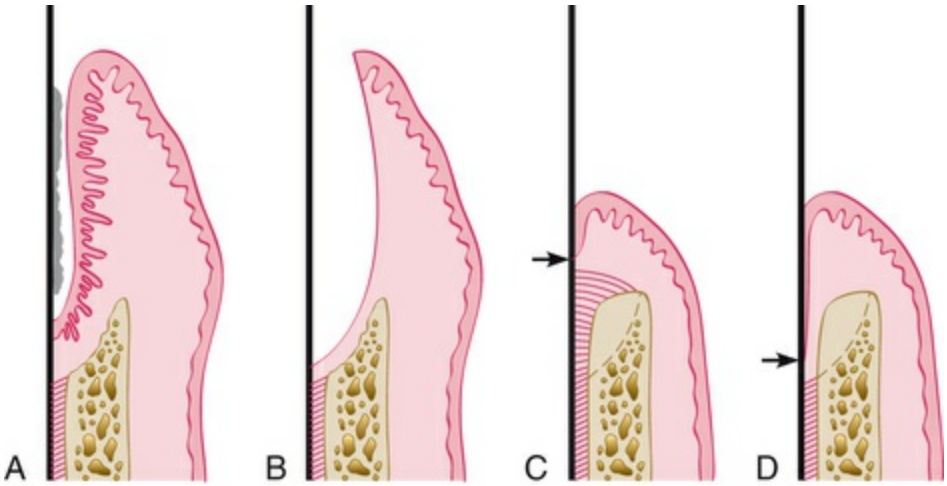
The surgical reentry of a treated defect after a period of healing can

provide a good view of the state of the bone crest that can be compared with the view taken during the initial surgical intervention and can also be subject to measurements (eFig. 63.6). Models from impressions of the bone taken at the initial surgery and later at reentry can be used to assess the results of therapy.



EFIG. 63.6 (A) Deep three-wall vertical osseous defect with measuring probe inserted. (B) Reentry surgery 9 months after treatment shows repaired bone defect. (C) Radiographs before and after treatment showing fill of angular osseous defect; gutta-percha points extend to the base of the pocket. (From Glickman I: *Clinical periodontology,* ed 3, Philadelphia, 1964, Saunders.)

This method is very useful but has two shortcomings: It requires a frequently unnecessary second procedure, and it does not show the type of attachment that exists (i.e., new attachment or long junctional epithelium[36]) (eFig. 63.7).



EFIG. 63.7 (A) Periodontal pocket preoperatively. (B) Periodontal pocket immediately after scaling, root planing, and curettage. (C) New attachment. The *arrow* indicates the most apical part of the junctional epithelium. Note regeneration of bone and periodontal ligament. (D) Healing by long junctional epithelium. Again, the *arrow* indicates the most apical part of the junctional epithelium. Note that the bone is new, but the periodontal ligament is not.

Reconstructive Surgical Techniques

Reconstructive techniques can be subdivided into three major therapeutic approaches: non–bone graft–associated, graft-associated, and biologic mediator–associated new attachment and regeneration. In clinical practice, it is common for clinicians to combine these various approaches.[†]

All recommended techniques include careful case selection and complete removal of all irritants on the root surface. Although this can be done in some cases as a closed procedure, in most cases it should be done after exposure of the area with a flap.[5,6] Flap design and incisions should follow the description given in Chapter 60 for flaps used in reconstructive surgery. Trauma from occlusion, as well as other factors, may impair posttreatment healing of the supporting periodontal tissues, thus reducing the likelihood of new attachment. Occlusal adjustment or splinting, if needed, is therefore indicated.

Systemic antibiotics are generally used after reconstructive

periodontal therapy, although definitive information on the advisability of this measure is still lacking. Case reports have shown extensive reconstruction of periodontal lesions after scaling, root planing, and curettage, with systemic and local treatment using penicillin or tetracycline, in combination with other forms of therapy.[32,197]

Non–Graft-Associated Reconstructive Procedures

The following sections discuss the rationale and techniques that must be considered for a successful outcome in achieving new attachment or periodontal bone regeneration in response to non–graft-associated reconstructive surgical therapy. This approach is used in Europe and Asia where human bone graft is not available due to regulatory restraints. Of these procedures, GTR is the main procedure used in clinical practice. More recent evidence suggests that the laser-assisted new attachment procedure (LANAP) may also result in new attachment and regeneration, but further clinical trials are needed to test its efficacy and parameters for success. Additionally, several procedures are of historical interest: (1) the removal of the junctional and pocket epithelium; (2) the prevention of their migration into the healing area after therapy; (3) clot stabilization, wound protection, and space creation; and (4) biomodification of the root surfaces. Although these procedures are not used individually as reconstructive approaches, some of these strategies are currently incorporated into reconstructive surgery as adjuncts.

Guided Tissue Regeneration

GTR is used for the prevention of epithelial migration along the cemental wall of the pocket and for maintaining space for clot stabilization. Derived from the classic studies of Nyman, Lindhe, Karring, and Gottlow, this method is based on the assumption that periodontal ligament and perivascular cells have the potential for regeneration of the attachment apparatus of the tooth.[‡] GTR consists of placing barriers of different types (membranes) to cover the bone and periodontal ligament, thus temporarily separating

them from the gingival epithelium and connective tissue. Excluding the epithelium and the gingival connective tissue from the root surface during the postsurgical healing phase not only prevents epithelial migration into the wound but also favors repopulation of the area by cells from the periodontal ligament and the bone[38] (see also Chapter 3). In the United States, GTR is often performed with some type of bone graft as a scaffolding agent, so it is a combined therapy. As indicated earlier, in Europe and in other parts of the world, because of regulatory and religious constraints, human graft materials are not available, so it is performed as a traditional GTR procedure and may be occasionally used in conjunction with other graft materials as combined therapy.

Initial animal experiments using Millipore filters (Millipore Sigma, Burlington, MA) and Teflon membranes resulted in regeneration of cementum and alveolar bone and a functional periodontal ligament.[32,33,38,129] Clinical case reports indicate that GTR results in a gain in attachment level.[15,16] Histologic studies in humans provided evidence of periodontal reconstruction in most cases, even with horizontal bone loss.[93,294,296]

The use of polytetrafluoroethylene (PTFE) membranes has been tested in controlled clinical studies in mandibular molar furcations and has shown statistically significant decreases in pocket depths and improvement in attachment levels after 6 months, but bone level measurements have been inconclusive.[162,227] A study of maxillary molar furcations did not result in significant gain in attachment or bone levels.[186]

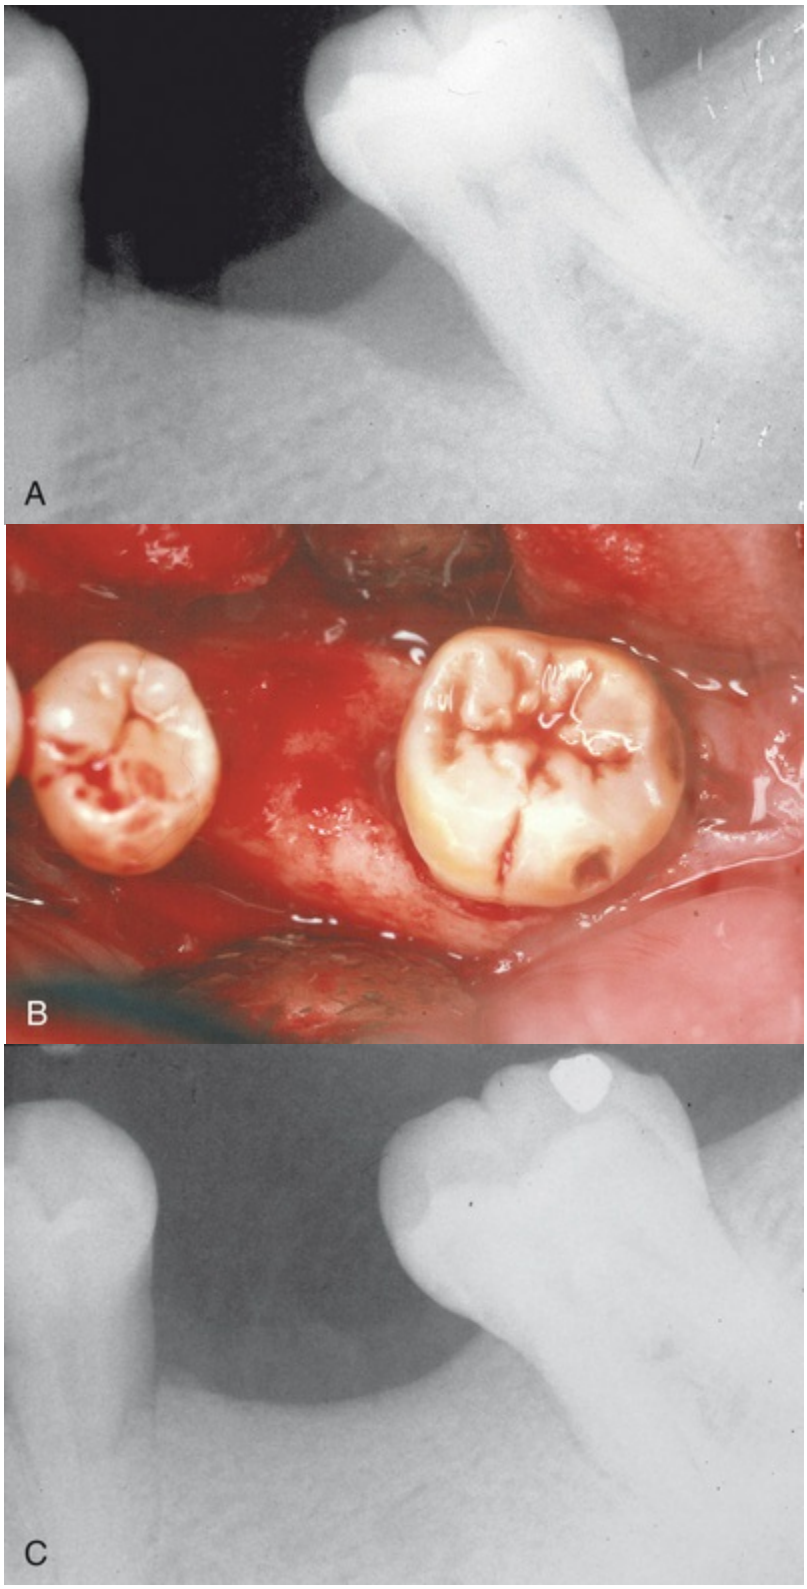
With the regenerative success associated with the use of nonresorbable membrane, the advantages and disadvantages of this approach became apparent. Notably, problems such as membrane exposure, which resulted in no or limited regeneration and the need for a secondary procedure for surgical removal, resulted in the development of biodegradable membranes.[277] Today in clinical practice, most GTR procedures use biodegradable membranes, whereas the nonresorbable membranes, especially those with titanium reinforcement struts, are used for regeneration of large intrabony defects and implant site development. Nevertheless, the historical research using nonresorbable membranes and the development of various types of biodegradable membranes are

valuable.

Nonresorbable Membranes

In classic animal and human studies demonstrating the efficacy of GTR, cellulose acetate filters were used. As this technique became more prevalent, the first commercial membrane was produced from expanded PTFE (ePTFE). This membrane has all the properties necessary for GTR barriers in that it (1) is a cellular barrier, (2) is biocompatible, (3) provides space for the healing tissue, (4) permits tissue integration, and (5) is clinically manageable. Much of our current understanding of GTR is based on studies using ePTFE membranes. Although these membranes are used less frequently now, they are still popular for guided bone regeneration and ridge preservation, so it is important to understand the clinical procedures for managing these membranes.

The clinical effectiveness of ePTFE membranes is dependent on technique. Preservation of the keratinized gingiva and a relatively thick overlying surgical flap are critical to avoid perforation of the flap by the membrane during healing. After the surgical area has been flapped, the defect is degranulated and the root surface scaled and root planed. The ePTFE membrane is trimmed to adapt to tooth configuration, secured by ePTFE sutures, and the flap is repositioned. Although much of the emphasis in the literature is on adapting the membrane to the defect, no membrane can ever be perfectly adapted. Despite gaps, these membranes appear to be successful. After membrane placement, healing is allowed to proceed for 4 to 6 weeks. Barring any membrane exposure, a second surgery is performed to remove the membrane. During this removal, the healing tissue appears reddish and granulomatous. After membrane removal, the area should not be probed for 3 months. Radiographic evidence of bone fill is usually present after 6 months and should continue over the course of 1 year (eFig. 63.8).

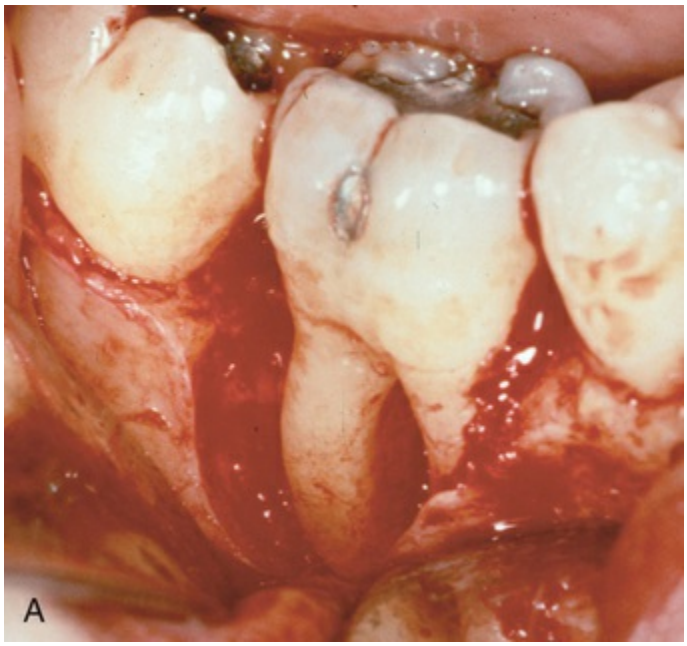


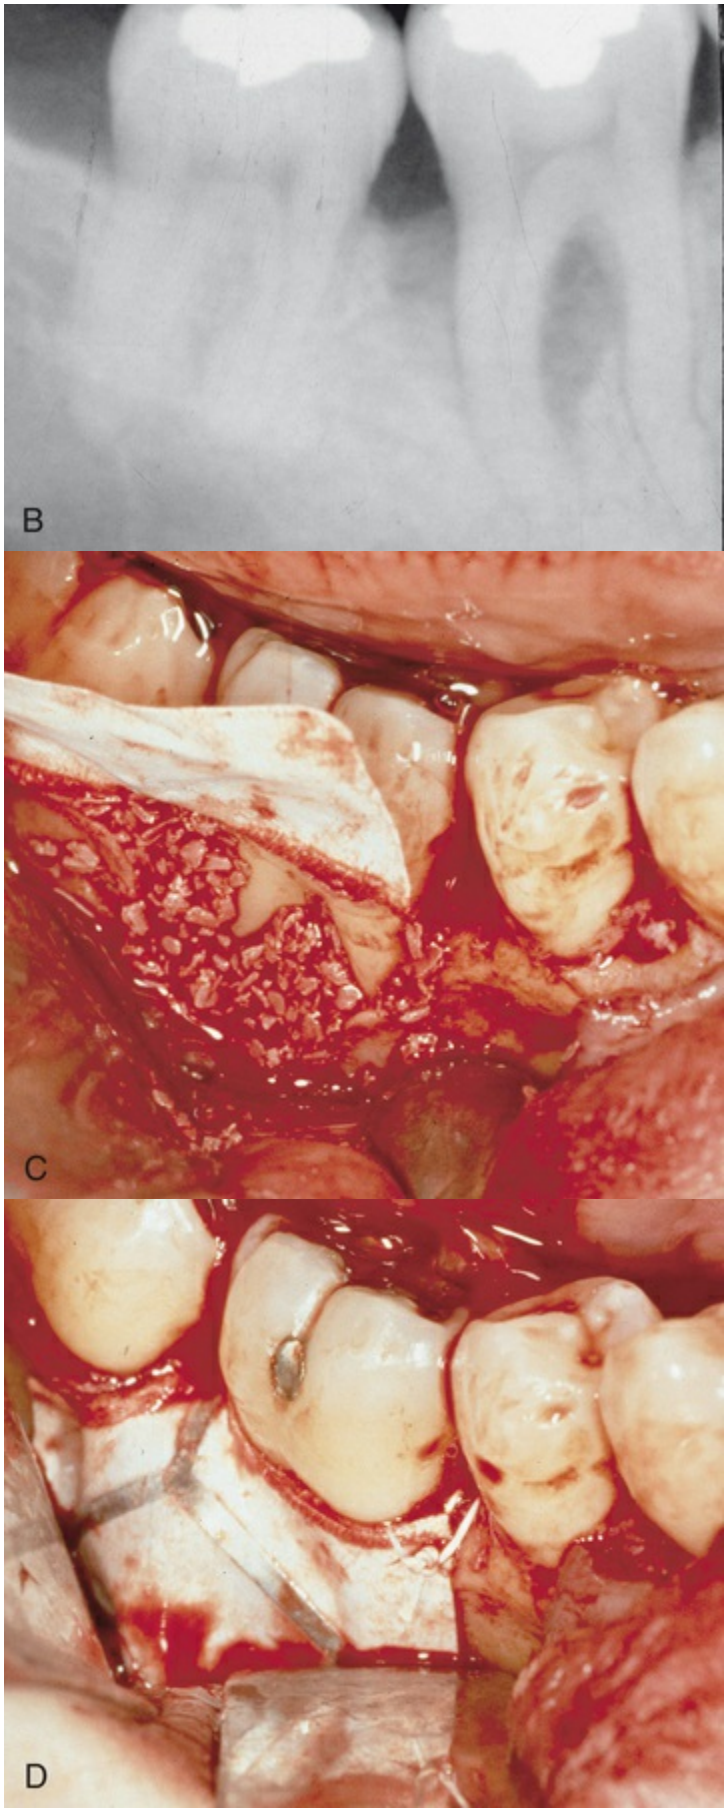
EFIG. 63.8 Radiographs of a guided tissue regeneration (GTR) case using a nonresorbable expanded polytetrafluoroethylene (ePTFE) membrane. (A) and (B) The mesially inclined molar is associated with a three-walled intraosseous defect. The defect was filled with demineralized freeze-dried bone

allograft, and ePTFE was used. Membrane was exposed after 8 weeks and removed 2 weeks later. Radiographic "fill" was halfway after 6 months, and (C) maximum fill was present after 12 months with minimal probing depth. (Courtesy of Rose LF, Meaney BL, Genco RJ, Cohen DW: *Periodontics: medicine, surgery, and implants,* St. Louis, 2004, Mosby.)

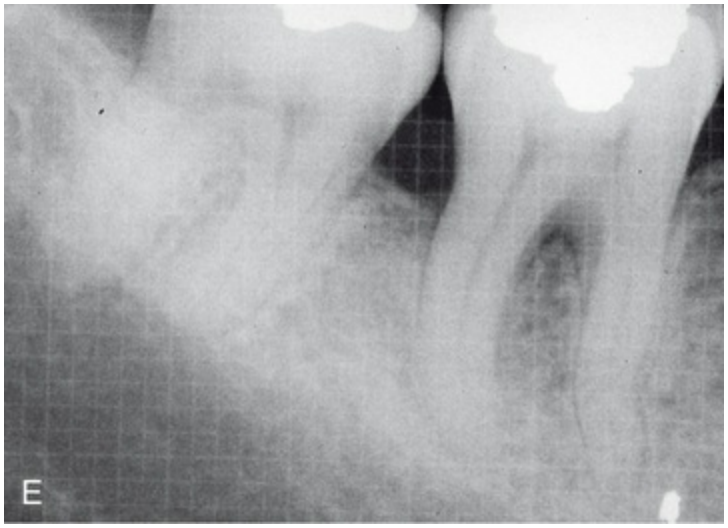
Clinical studies have shown that ePTFE membranes used in GTR procedures are more effective than surgical debridement in correcting intrabony defects.[§] In intrabony and furcation defects, gains are made in clinical attachment level (3 to 6 mm), improved bone levels (2.4 to 4.8 mm), and probing depth reductions (3.5 to 6 mm). Studies have demonstrated that these regenerative results can be maintained over the course of several years.[53,91,264,320]

The advent of titanium-reinforced ePTFE allowed for the formation of larger spaces, thus permitting correction of larger defects (eFig. 63.9).[52] This resulted in significant clinical improvements using titanium-reinforced ePTFE compared with ePTFE.





B
C
D



EFIG. 63.9 Clinical photographs and radiographs of a guided tissue regeneration case using expanded polytetrafluoroethylene (ePTFE) with titanium-reinforced membrane. (A) and (B) The osseous defect was along the distal interproximal area wrapping buccally over the furcation. (C) and (D) To prevent the membrane from collapsing over the root surfaces, demineralized freeze-dried bone allograft (DFDBA) and adjustment of the titanium membrane provide a larger space for regeneration. (E) One year afterward, the radiographic and clinical signs are consistent with achieving regeneration in this defect. (Courtesy of Rose LF, Meaney BL, Genco RJ, Cohen DW: *Periodontics: medicine, surgery, and implants,* St. Louis, 2004, Mosby.)

To determine how regeneration can be enhanced with GTR technique, the prolonged retention of ePTFE membranes was evaluated.[201] After allowing the membrane to be retained for 4 months, surgical reentry after 1 year determined that the mean bone fill of intrabony defects was 95%. This suggests that prolonged retention of a barrier membrane is desirable if no tissue perforation is present. This finding is consistent with many clinical reports of the improved bone quality associated with guided bone regeneration in implant site development.

The major problem with using nonresorbable membranes is that the membrane is exposed to the oral environment during healing. On exposure, the membrane is contaminated and colonized by oral microflora.[192,212,218,285] Several studies have shown that contamination of the surgical field can result in decreased formation of new

attachment. If the membrane is exposed, the infection can be temporarily managed with topical application of chlorhexidine. This may minimize the infection and extend the time the membrane can be retained in place.

Biodegradable Membranes

Bioresorbable membranes have replaced the routine use of ePTFE membranes in GTR. There are basically three types of bioresorbable membranes: (1) polyglycoside synthetic polymers (i.e., polylactic acid, polylactate-polygalactate copolymers), (2) collagen, and (3) calcium sulfate. Polyglycoside membranes degrade as the result of random nonenzymatic cleavage of the polymer, to produce polylactide and polyglycolide, which are converted to lactic acid and pyruvate, respectively, and metabolized by the enzymes of the Krebs cycle. Porcine collagen membranes are degraded by collagenases and subsequently by gelatinases and peptidase. A resurgence has occurred in the use of calcium sulfate as a regeneration material because it can be used as a pavable resorbable barrier in combination with bone or bone substitutes. The calcium sulfate is bioresorbed through a giant cell reaction. Several features make these bioresorbable membranes easier to manage clinically: (1) they are more tissue compatible than nonresorbable membranes, (2) the timing for resorption can be regulated by the amount of cross-linkage in the synthetic polymer and collagen membrane or the amount of heat-processed calcium sulfate chips in calcium sulfate barrier, and (3) a second surgical procedure is not required to retrieve the nonresorbable membrane.

One GTR study compared the use of bioresorbable membranes (polylactate-polygalactate copolymer) versus ePTFE membranes, with surgical debridement as a control.[47] After 1 year, significant gains in clinical attachment level (CAL) were observed in all three groups. There was no difference in CAL gain between the two membrane groups, with both of them gaining 2 mm or more. In both membrane groups, 83% of the sites improved 4 mm or more, which was significantly better than the surgical debridement control group. These findings indicate that GTR procedures are equally effective when using resorbable and nonresorbable membranes. This finding has been confirmed by other

investigators.[41,42,321]

A large, multicenter clinical study reported the use of bioresorbable membranes in 203 consecutively treated intrabony defects.[68] After 1 year, investigators found that CAL improved by 79%, and 78% of the sites improved by 4 mm or more. An average of 3 mm of bone fill was measured radiographically. Compromised clinical results occurred when membranes were exposed or patients had poor plaque control.

The search for resorbable membranes has included trials and tests with numerous materials and collagens from different species such as bovine, porcine, Cargile membrane derived from the cecum of an ox, polylactic acid, polyglactin 910 (Vicryl, Johnson & Johnson Dental Care Division, New Brunswick, NJ), synthetic skin (Biobrane, Smith & Nephew, London, United Kingdom), and freeze-dried dura mater. Clinical studies with a mixture of copolymers derived from polylactic acid and acetyl tributyl citrate resorbable membranes (Guidor membrane, no longer on the market) and a poly-D,L-lactide-co-glycolide (Resolut membrane, also no longer on the market) showed significant gains in clinical attachment and bone fill.[42,69,203]

The potential of using autogenous periosteum as a membrane and also to stimulate periodontal regeneration was explored in two controlled clinical studies, one of grade II furcation involvements in mandibular molars and another of interdental defects.[155,161] The periosteum was obtained from the patient's palate by means of a window flap. Both studies reported that autogenous periosteal grafts can be used in GTR and result in significant gains in clinical attachment and osseous defect fill.

Laser-Assisted New Attachment Procedure

The role of laser in periodontal therapy remains controversial (see Chapter 68). Nevertheless, the use of neodymium:yttrium-aluminum-garnet (Nd:YAG) to perform surgical LANAPs has been reported for the management of chronic periodontitis,[139,191] and it can potentially result in new attachment and periodontal regeneration (see Chapter 68).[210,334]

Many questions remain about LANAP. The first refers to the exact mechanism and parameter by which healing by new

attachment versus regeneration occurs with LANAP therapy. The frequency, consistency, and extent of regeneration have not been defined, nor has this approach been compared with other established regenerative therapies. This comparison, along with other randomized controlled trials, will be needed for meta-analysis to determine whether LANAP is equivalent or superior to other conventional therapy. As with all periodontal therapy, the long-term stability of the regeneration also needs to be explored.

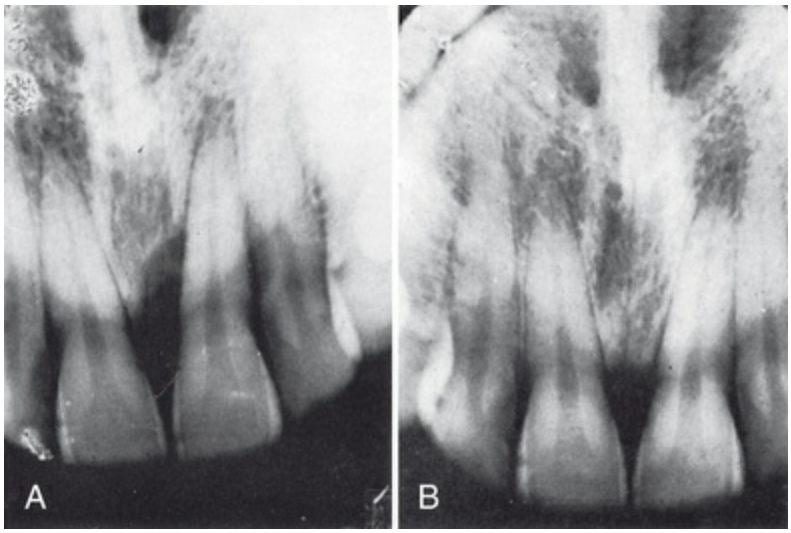
Non–Graft-Associated Procedures of Historical Interest

Removal of Junctional and Pocket Epithelium

Since the earliest attempts at periodontal new attachment, the presence of junctional and pocket epithelium has been perceived as a barrier to successful therapy because its presence interferes with the direct apposition of connective tissue and cementum, thus limiting the height to which periodontal fibers can insert to the cementum.[88,130,160,217] Several methods have been recommended to remove the junctional and pocket epithelium. These include curettage, chemical agents, ultrasonics, lasers, and surgical techniques.

Curettage

Results of removal of the epithelium by means of curettage vary from complete removal to persistence of as much as 50%.[288] Although curettage is not a reliable procedure, occasional bone regeneration does occur (eFig. 63.10). Ultrasonic methods, lasers, and rotary abrasive stones have also been used, but their effects cannot be controlled because of the clinician's lack of vision and tactile sense when using these methods.



EFIG. 63.10 **Bone regeneration after closed scaling, root planing, and curettage. (A) Before and (B) after radiographs are shown. This is a classic case from Dr. Fermin Carranza Sr. in 1954.** (From Carranza FA Sr: A technic for reattachment. *J Periodontol* 25:272, 1954.)

Chemical Agents

Chemical agents have also been used to remove pocket epithelium, usually in conjunction with curettage. The drugs used most often have been sodium sulfide, phenol camphor, antiformin, and sodium hypochlorite. However, the effect of these agents is not limited to the epithelium, and their depth of penetration cannot be controlled. These drugs are mentioned here for their historical interest.

Biomodification of Root Surface

Changes in the tooth surface wall of periodontal pockets (e.g., degenerated remnants of Sharpey fibers, accumulation of bacteria and their products, disintegration of cementum and dentin) interfere with new attachment. Although these obstacles to new attachment can be eliminated by thorough root planing, the root surface of the pocket can be treated to improve its chances of accepting the new attachment of gingival tissues.

Several substances have been proposed for this purpose, including citric acid, fibronectin, and tetracycline.

Citric Acid.

One in a series of studies applied citric acid to the roots to

demineralize the surface, thereby attempting to induce cementogenesis and attachment of collagen fibers.

The following actions of citric acid have been reported:

1. Accelerated healing and new cementum formation occur after surgical detachment of the gingival tissues and demineralization of the root surface by means of citric acid.[238]
2. Topically applied citric acid on periodontally diseased root surfaces has no effect on nonplaned roots, but after root planing, the acid produces a 4-μm-deep demineralized zone with exposed collagen fibers.[85]
3. Root-planed, non–citric acid–treated roots are left with a surface smear layer of microcrystalline debris. Citric acid application not only removes the smear layer, exposing the dentinal tubules, but also makes the tubules appear wider and with funnel-shaped orifices.[225]
4. Citric acid has also been shown in vitro to eliminate endotoxins and bacteria from the diseased tooth surface.[56,72]
5. An early fibrin linkage to collagen fibers exposed by the citric acid treatment prevents the epithelium from migrating over treated roots.[226]

This technique using citric acid has been extensively investigated in animals and humans. Studies in dogs have shown encouraging results, especially for the treatment of furcation lesions, but the results in humans have been contradictory.[//]

The recommended citric acid technique is as follows:

1. Raise a mucoperiosteal flap and thoroughly instrument the root surface, thus removing calculus and underlying cementum.
2. Apply cotton pledgets soaked in a saturated solution of citric acid (pH of 1.0) for 2 to 5 minutes.
3. Remove pledgets, and irrigate root surface profusely with water.
4. Replace the flap and suture.

The use of citric acid has also been recommended in conjunction with coverage of denuded roots using free gingival grafts (see Chapter 65).

Fibronectin.

Fibronectin is the glycoprotein that fibroblasts require to attach to root surfaces. The addition of fibronectin to the root surface may promote new attachment.[28,42,70,301] However, increasing fibronectin above plasma levels produces no obvious advantages. Adding fibronectin and citric acid to lesions treated with GTR in dogs did not improve the results.[27,289]

Tetracycline.

In vitro treatment of the dentin surfaces with tetracycline increases binding of fibronectin, which in turn stimulates fibroblast attachment and growth while suppressing epithelial cell attachment and migration.[292,300] Tetracycline also removes an amorphous surface layer and exposes the dentin tubules. In vivo studies, however, have not shown favorable results.[323,324] A human study showed a trend for greater connective tissue attachment after tetracycline treatment of roots. Tetracycline gave better results when used alone than when combined with fibronectin.[4] Tetracycline has been used as an adjunctive procedure in preparation of the root in regenerative procedures and is a recommended step for use with biologic mediators.

Surgical Techniques

Surgical techniques have been recommended to eliminate the pocket and junctional epithelium. The excisional new attachment procedure (ENAP) consists of an internal bevel incision performed with a surgical knife, followed by removal of the excised tissue.[332] No attempt is made to elevate a flap. After careful scaling and root planing, interproximal sutures are used to close the wound. This approach has been modified and is used in conjunction with the ND:YAG laser in the previously described LANAP procedure.

Glickman[89] and Prichard[231] advocated performing a *gingivectomy to the crest of the alveolar bone* and debriding the defect. Excellent results have been obtained with this technique in uncontrolled

human studies.[17,232]

The modified Widman flap, as described by Ramfjord and colleagues,[235] is similar to the excisional new attachment procedure but is followed by elevation of a flap for better exposure of the area. The internal bevel incision eliminates the pocket epithelium (see Chapter 60).

Preventing or Impeding the Epithelial Migration

Elimination of the junctional and pocket epithelium may not be sufficient because the epithelium from the excised margin may rapidly proliferate to become interposed between the healing connective tissue and the cementum.

For experimental purposes, several investigators have analyzed, in animals and humans, the effect of excluding the epithelium by amputating the crown of the tooth and covering the root with the flap ("root submergence").[18,19,22,35] This experimental technique not only excludes the epithelium but also prevents microbial contamination of the wound during the reparative stages. Successful repair of osseous lesions in the submerged environment was reported, but obviously this method has little or no clinical application.

Two other methods have been proposed to prevent or impede the migration of the epithelium. One consists of the total removal of the interdental papilla covering the defect and its replacement with a free autogenous graft obtained from the palate.[65] During healing, the graft epithelium necroses and is slowly replaced by proliferating epithelium from the gingival surface. The graft simply delays the epithelium from proliferating into the healing area. This method has not been widely used.

The second approach is the use of *coronally displaced flaps,* which increase the distance between the epithelial wound edge and the healing area. This technique is particularly suitable for the treatment of mandibular molar furcations and has been used mostly in conjunction with citric acid treatment of the roots.[82,170] Periodontal regeneration after the use of this technique has been demonstrated histologically in humans.[278]

Learning Box e63.1

If one considers that the basic strategy of these surgical approaches is *mechanical* curetting, which excludes epithelial and connective tissue migration, this basically is akin to the biologic principle of guided tissue regeneration. Due to the need for multiple visits and supplemental surgical procedures, mechanical curetting is clearly not reasonable with better alternatives such as guided tissue regeneration and the use of biologic agents.

Clot Stabilization, Wound Protection, and Space Creation

Some investigators have attributed the successful results reported with graft materials, barrier membranes, and coronally displaced flaps to the findings that these techniques protect the wound and create a space for undisturbed and stable maturation of the clot.[83,160,161] This hypothesis suggests that preservation of the root surface fibrin clot interface prevents apical migration of the gingival epithelium and allows for connective tissue attachment during the early wound healing period.[83,218,226]

The importance of space creation for bone repair has long been recognized in orthopedic and maxillofacial surgery. Transference of this concept to periodontal therapy has been explored for treatment of periodontal and peri-implant osseous defects and for root coverage. The space can be created by using a titanium-reinforced ePTFE membrane to prevent its collapse. For the study of reconstructive techniques, these membranes were placed over experimentally created supra-alveolar bone defects in dogs, and considerable bone reconstruction was reported.[282] The following is a discussion of the GTR technique.

Graft Materials and Procedures

Numerous therapeutic grafting modalities for restoring periodontal osseous defects have been investigated. Periodontal reconstruction can be attained without the use of bone grafts in meticulously treated three-wall defects (intrabony defects) and in periodontal and endodontic abscesses.[32,117,138,232] New attachment is more likely to occur when the destructive process has occurred rapidly, such as

after treatment of pockets complicated by acute periodontal abscesses and after treatment of acute necrotizing ulcerative lesions.[204] The use of graft materials at one time was to provide regenerative inductive effect, but it should be viewed primarily as providing a scaffold for healing.

The following classifications of bone graft material are important. Grafts are categorized either by their origins or function during healing. Categorizations by origin include the following: (1) *autografts* are bone obtained from the same individual; (2) *allografts* are bone obtained from a different individual of the same species; and (3) *xenografts* are bone from a different species. Bone graft materials are also evaluated based on their osteogenic, osteoinductive, or osteoconductive potential. *Osteogenesis* refers to the formation or development of new bone by cells contained in the graft. *Osteoinduction* is a chemical process by which molecules contained in the graft (e.g., bone morphogenetic proteins) convert the neighboring cells into osteoblasts, which in turn form bone. *Osteoconduction* is a physical effect by which the matrix of the graft forms a scaffold that favors outside cells to penetrate the graft and form new bone.

Periodontal defects as sites for transplantation differ from osseous cavities surrounded by bony walls. Saliva and bacteria may easily penetrate along the root surface, and epithelial cells may proliferate into the defect, thus resulting in contamination and possible exfoliation of the grafts. Therefore the principles established to govern transplantation of bone or other materials into closed osseous cavities are not fully applicable to transplantation of bone into periodontal defects.[64]

Schallhorn[263] defined the considerations that govern the selection of a material as follows: biologic acceptability, predictability, clinical feasibility, minimal operative hazards, minimal postoperative sequelae, and patients' acceptance. It is difficult to find a material with all these characteristics, and to date, no ideal material or technique exists.

Graft materials have been developed and tried in many forms. To familiarize the reader with various types of graft material, as defined by either the technique or the material used, a brief discussion of each is provided.

All grafting techniques require presurgical scaling, occlusal adjustment as needed, and exposure of the defect with a full-thickness flap. The flap technique best suited for grafting purposes is the *papilla preservation flap* because it provides complete coverage of the interdental area after suturing (see Chapter 60). The use of antibiotics after the procedure is generally recommended.

Autogenous Bone Grafts

Historically, extraoral sites for bone harvesting have been from the iliac crest, but this approach is seldom performed due to medical and legal concerns. Intraoral sites can be effective, especially when donor sites adjacent to the defects are available. Despite the popularity of using allograft, this should always be a consideration, especially as one reviews the historical development of the use of autografts from intraoral sites.

Bone From Intraoral Sites

In 1923, Hegedüs [113] attempted to use bone grafts for the reconstruction of bone defects produced by periodontal disease. The method was revived by Nabers and O'Leary[203] in 1965, and numerous efforts have been made since that time to define its indications and technique.

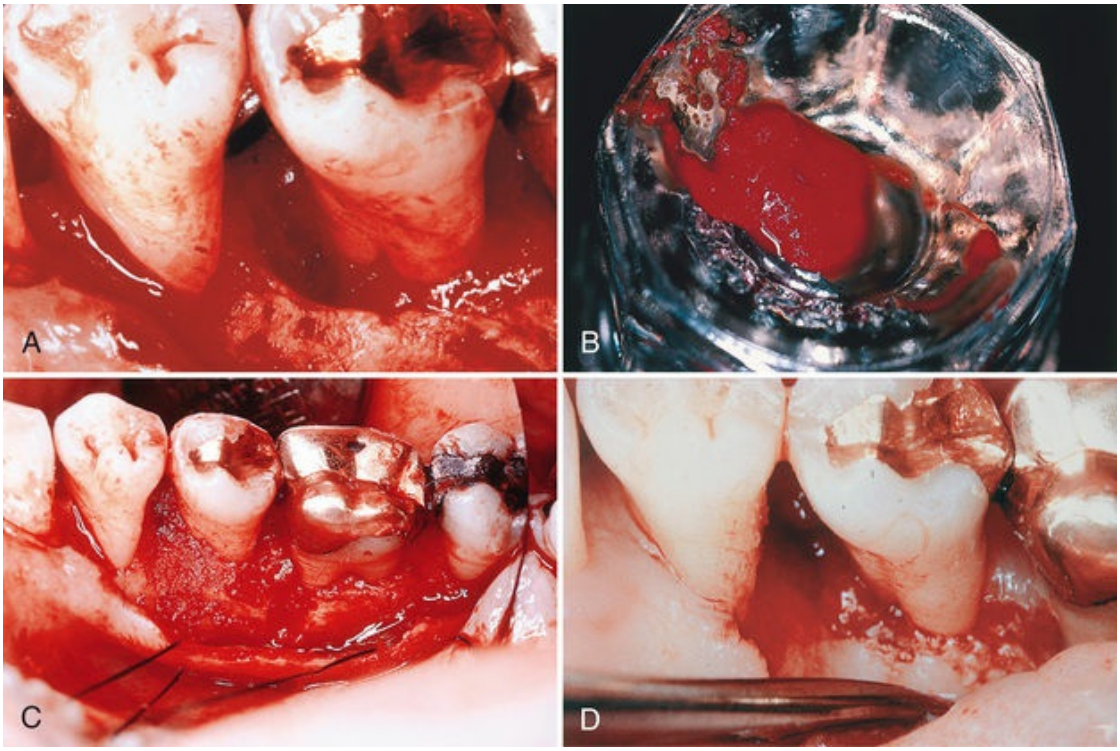
Sources of bone include bone from healing extraction wounds, bone from edentulous ridges, bone trephined from within the jaw without damaging the roots, newly formed bone in wounds especially created for the purpose, bone removed from tuberosity, and the ramus and bone removed during osteoplasty and ostectomy.[33,103,117,118,249,331]

Osseous Coagulum.

Robinson[249] described a technique using a mixture of bone dust and blood that he termed *osseous coagulum*. The technique uses small particles ground from cortical bone. The advantage of the particle size is that it provides additional surface area for the interaction of cellular and vascular elements.

Sources of the graft material include the lingual ridge on the mandible, exostoses, edentulous ridges, the bone distal to a terminal tooth, bone removed by osteoplasty or ostectomy, and the

lingual surface of the mandible or maxilla at least 5 mm from the roots. Bone is removed with a carbide bur #6 or #8 at speeds between 5000 and 30,000 rpm, placed in a sterile dappen dish and used to fill the defect (eFig. 63.11). The obvious advantage of this technique is the ease of obtaining bone from an area already exposed during surgery. The disadvantages are its relatively low predictability and the inability to procure adequate material for large defects.[65] Although notable success has been reported by many individuals, studies documenting the efficacy of the technique are still inconclusive.[54,74,79,248]



EFIG. 63.11 (A) Osseous defect mesial to a second premolar. (B) Graft material placed in dappen dish before transfer to the graft site. (C) Material in place. (D) Reentry 6 months later. (Courtesy Dr. E. Earl Robinson.)

Bone Blend.

Some disadvantages of osseous coagulum derive from the inability to use aspiration during accumulation of the coagulum. Another problem is the unknown quantity and quality of the bone fragments in the collected material. To overcome these problems, the bone

blend technique has been proposed.[57]

The bone blend technique uses an autoclaved plastic capsule and pestle. Bone is removed from a predetermined site, triturated in the capsule to a workable, plastic-like mass, and packed into bony defects. Froum and associates[77–79] found osseous coagulum–bone blend procedures to be at least as effective as iliac autografts and open curettage.

Cancellous Bone Marrow Transplants

Cancellous bone can be obtained from the maxillary tuberosity, edentulous areas, and healing sockets.[111] The maxillary tuberosity frequently contains abundant cancellous bone, particularly if the third molars are not present. After a ridge incision is made distally from the last molar, bone is removed with a curved rongeur. Care should be taken not to extend the incision too far distally to avoid entering the mucosal tissue of the pharyngeal area. In addition, the location of the maxillary sinus must be analyzed on the radiograph to avoid entering or disturbing it.

Edentulous ridges can be approached with a flap, and cancellous bone and marrow are removed with curettes, back-action chisels, or trephine. Extraction sockets are allowed to heal for 8 to 12 weeks before reentering and removing the newly formed bone from the apical portion, which is used as the donor material.

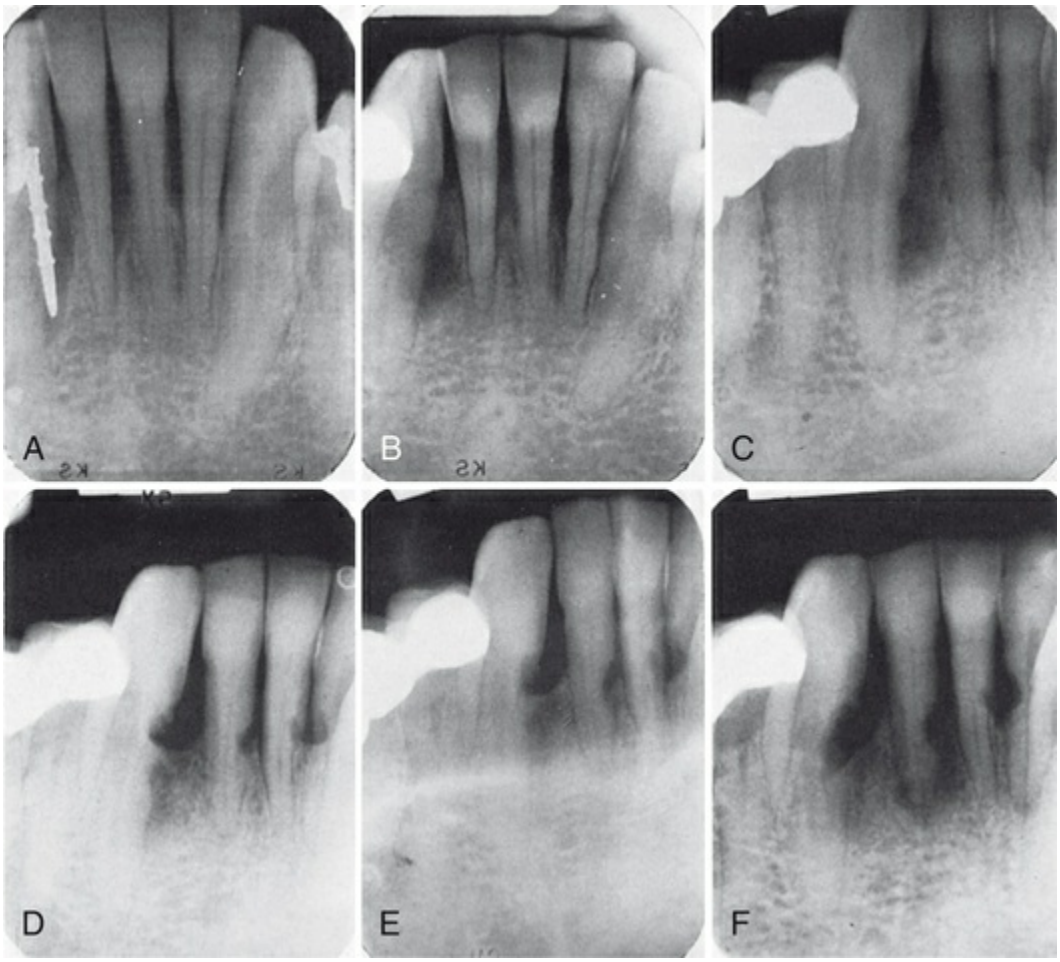
Bone Swaging

The bone swaging technique requires an edentulous area adjacent to the defect, from which the bone is pushed into contact with the root surface without fracturing the bone at its base.[67,254] Bone swaging is technically difficult, and its usefulness is limited.

Bone From Extraoral Sites

The use of fresh or preserved iliac cancellous marrow bone has been extensively investigated. This material has been used by orthopedic surgeons for years. Data from human and animal studies support its use, and the technique has proved successful in osseous defects with various numbers of walls. It has also been successful in furcations and even supracrestally to some extent.[8,25,60,260,261] However, because of numerous problems

associated with its use, the technique is no longer in use.[261] Some of the problems were postoperative infection, bone exfoliation, sequestration, varying rates of healing, root resorption, and rapid recurrence of the defect (eFig. 63.12). Other problems were increased patient expense and difficulty in procuring the donor material.[22,52,180,182]



EFIG. 63.12 (A) November 1973: Radiograph of a patient immediately before placement of a fresh iliac autograft. (B) Two months later, bone repair is evident. Note the early radiolucent areas on the mesial aspect of the canine. (C) After 7 months, "bone fill" is occurring, but obvious root resorption is present. (D) April 1975: Root resorption is apparent on all grafted teeth. Note the obvious degree of fill of the original bone defects. (E) February 1976: Further involvement. (F) October 1977: Four years later, root resorption has progressed into the pulp of the lateral incisor, thus causing a periosteal-endosteal complication.

Bone Allografts

Obtaining donor material for autograft purposes necessitates inflicting surgical trauma on another part of the patient's body. Obviously, it would be to the patient's and therapist's advantage if a suitable substitute could be used for grafting purposes that would offer similar potential for repair and not require the additional surgical removal of donor material from the patient. However, both allografts and xenografts are foreign to the patient and therefore have the potential to provoke an immune response. Attempts have been made to suppress the antigenic potential of allografts and xenografts by radiation, freezing, and chemical treatment.[24]

Bone allografts are commercially available from tissue banks. They are obtained from cortical bone within 12 hours of the death of the donor, defatted, cut in pieces, washed in absolute alcohol, and deep-frozen. The material may then be demineralized, subsequently ground and sieved to a particle size of 250 to 750 μm, and freeze-dried. Finally, it is vacuum-sealed in glass vials.

Numerous steps are also taken to eliminate viral infectivity. These include exclusion of donors from known high-risk groups and various tests on the cadaver tissues to exclude individuals with any type of infection or malignant disease. The material is then treated with chemical agents or strong acids to inactivate the virus, if still present. The risk of human immunodeficiency virus (HIV) infection has been calculated as 1 in 1 to 8 million and is therefore characterized as highly remote.[184]

Freeze-Dried Bone Allograft

Several clinical studies by Mellonig, Bowers, and coworkers reported bone fill exceeding 50% in 67% of the defects grafted with freeze-dried bone allograft (FDBA) and in 78% of the defects grafted with FDBA in combination with autogenous bone.[21,182,203,257,278] FDBA, however, is considered an osteoconductive material, whereas demineralized FDBA (DFDBA) is considered an osteoinductive graft. Laboratory studies have found that DFDBA has a higher osteogenic potential than FDBA and is therefore preferred.[178,180,181]

Demineralized Freeze-Dried Bone Allograft

Experiments by Urist[312–315] established the osteogenic potential of DFDBA. Demineralization in cold, diluted hydrochloric acid exposes the components of bone matrix, which are closely associated with collagen fibrils and have been termed *bone morphogenetic proteins* (BMPs).[40,315]

In 1975, Libin and colleagues[163] reported three patients with 4 to 10 mm of bone regeneration in periodontal osseous defects. Subsequent clinical studies were made with cancellous DFDBA and cortical DFDBA.[221,230,233] DFDBA resulted in more desirable results (2.4 mm vs. 1.38 mm of bone fill).

Bowers and associates,[22] in a histologic study in humans, showed new attachment and periodontal regeneration in defects grafted with DFDBA. Mellonig and colleagues[180,181,183] tested DFDBA against autogenous materials in the calvaria of guinea pigs and showed it to have similar osteogenic potential.

These studies provided strong evidence that DFDBA in periodontal defects results in significant probing depth reduction, attachment level gain, and osseous regeneration. The combination of DFDBA and GTR has also proved to be very successful[264]; however, limitations of the use of DFDBA include the possible, although remote, potential of disease transfer from the cadaver.

A bone-inductive protein isolated from the extracellular matrix of human bones, termed *osteogenin* or *BMP-3*, has been tested in human periodontal defects and seems to enhance osseous regeneration.[23] This bone-inductive protein is discussed later in this chapter.

Xenografts

Bone products from other species have a long history of use in periodontal therapy. A few of these xenograft products are mentioned here for historical purposes but are no longer used today. Bovine-derived bone (Bio-Oss, Geistlich Pharma, Princeton, NJ) is used in combination with GTR for periodontal regeneration. This material is also used in combination with autologous bone for ridge augmentation.

Calf bone (Boplant), treated by detergent extraction, sterilized, and freeze-dried, has been used for the treatment of osseous

defects.[8,259] Kiel bone is calf or ox bone denatured with 20% hydrogen peroxide, dried with acetone, and sterilized with ethylene oxide. Anorganic bone is ox bone from which the organic material has been extracted by means of ethylenediamine; it is then sterilized by autoclaving.[177] These materials have been tried and discarded for various reasons.

Currently, an anorganic, bovine-derived bone marketed under the brand name Bio-Oss (Geistlick Pharma) has been successfully used both for periodontal defects and in implant surgery. It is an osteoconductive, porous bone mineral matrix from bovine cancellous or cortical bone. The organic components of the bone are removed, but the trabecular architecture and porosity are retained.[30,176] The physical features permit clot stabilization and revascularization to allow for migration of osteoblasts, leading to osteogenesis. Bio-Oss is biocompatible with the adjacent tissues, and it elicits no systemic immune response.

Learning Box 63.2

Due to the osteoconductive nature and slow resorption rate of anorganic, bovine-derived bone graft, it acts as a bioexclusive graft material in that it excludes epithelial mesenchymal cell migration into the regeneration site. The slow resorption rate is also advantageous for grafting in implant surgical sites in that it may be corrective for soft tissue defects and remain fairly stable. However, the use of this material in implant placement sites must be cautioned because overcompaction of this material may result in such low volume of native bone that it will not provide an adequate level of osseointegration for implant stability.

Several studies have reported successful bone regeneration and new attachment with Bio-Oss in periodontal defects,[30,179] as well as regeneration around implants and sinus grafting (see Chapter 80).

Periodontally, Bio-Oss has been used as a graft material covered with a resorbable membrane (Geistlich Bio-Gide, Geistlich Pharma). The membrane prevents the migration of fibroblasts and connective tissues into the pores and between the granules of the graft.

Histologic studies of this technique have shown significant osseous regeneration and cementum formation.

Yukna and associates[336] have used Bio-Oss in combination with a cell-binding polypeptide (P-15) that is a synthetic analogue of a 15-amino acid sequence of type I collagen marketed as PepGen P-15 (Dentsply Sirona, York, PA); this combination seems to enhance the bone regenerative results of the matrix alone in periodontal defects.

Graft-Associated Reconstructive Procedures of Historical Interest

In addition to bone graft materials, many nonbone graft materials have been used in an attempt to restore the periodontium. These include sclera, dura, cartilage, cementum, dentin, plaster of Paris, plastic materials, ceramics, and coral-derived materials.[26,158,159] None offers a reliable substitute for bone graft materials; some of these materials are briefly presented here to offer a complete picture of the many attempts that have been made to solve the critical problem of periodontal regeneration.

Sclera

Sclera was originally used in periodontal procedures because it is a dense, fibrous connective tissue with poor vascularity and minimal cellularity.[150–152] This affords a low incidence of antigenicity and other untoward reactions.[130] In addition, sclera may provide a barrier to apical migration of the junctional epithelium and serve to protect the blood clot during the initial healing period.

Although some studies show that sclera is well accepted by the host and is sometimes invaded by host cells and capillaries and replaced by dense connective tissue, it does not appear to induce osteogenesis or cementogenesis.[69,196,219] The available scientific research does not warrant the use of sclera in periodontal therapy.

Cartilage

Cartilage has been used for studies in monkeys and treatment of periodontal defects in humans.[258,259] It can serve as a scaffold, and when so used, new attachment was obtained in 60 of 70 case

studies.[259] However, cartilage has received only limited evaluation and is not used today in periodontal therapy.

Plaster of Paris

Plaster of Paris (calcium sulfate) is biocompatible and porous, thereby allowing fluid exchange, which prevents flap necrosis. Plaster of Paris resorbs completely in 1 to 2 weeks. One study in surgically created three-wall defects in dogs showed significant regeneration of bone and cementum.[143] Plaster of Paris was found to be useful in one uncontrolled clinical study,[290] but other investigators have reported that it does not induce bone formation.[3,262] Its usefulness in human cases, however, has not been proved.

Learning Box e63.2

Due to slow resorption rate of calcium sulfate, which is similar in range to some of the resorbable guided tissue regeneration membranes, this approach when used with allografts is in alignment with the bioexclusion principle found with guided tissue regeneration.

Plastic Materials

Hard tissue replacement (HTR) polymer is a nonresorbable, microporous, biocompatible composite of polymethylmethacrylate and polyhydroxyethylmethacrylate. A clinical 6-month study showed significant defect fill and improved attachment level. Histologically, this material is encapsulated by connective tissue fibers, with no evidence of new attachment.[297,333]

Calcium Phosphate Biomaterials

Several calcium phosphate biomaterials have been tested since the mid-1970s and are currently available for clinical use. Calcium phosphate biomaterials have excellent tissue compatibility and do not elicit any inflammation or foreign body response. These materials are osteoconductive; therefore, they act as a scaffold for blood clots to be retained to allow bone formation.

Two types of calcium phosphate ceramics have been used, as follows:

1. Hydroxyapatite (HA) has a calcium-to-phosphate ratio of 1.67, similar to that found in bone material. HA is generally nonbioresorbable.
2. Tricalcium phosphate (TCP), with a calcium-to-phosphate ratio of 1.5, is mineralogically B-whitlockite. TCP is at least partially bioresorbable.

Case reports and uncontrolled human studies have shown that calcium phosphate bioceramic materials are well tolerated and can result in clinical repair of periodontal lesions. Several controlled studies were conducted on the use of hydroxylapatite (Periograf, Sterling Drug, New York, NY) and Calcitite (Zimmer Dental, Carlsbad, CA); clinical results were good, but histologically these materials appeared to be encapsulated by collagen.[31,76,175,234,293,335,337]

Bioactive Glass

Bioactive glass consists of sodium and calcium salts, phosphates, and silicon dioxide. For its dental applications, it is used in the form of irregular particles measuring 90 to 170 μm (PerioGlas, Block Drug, Jersey City, NJ) or 300 to 355 μm (BioGran, Ortho Vita, Malvern, PA). When this material comes into contact with tissue fluids, the surface of the particles becomes coated with hydroxy-carbonate apatite, incorporates organic ground proteins such as chondroitin sulfate and glycosaminoglycans, and attracts osteoblasts that rapidly form bone.[206]

Coral-Derived Materials

Two different coralline materials have been used in clinical periodontics: natural coral and coral-derived porous HA. Both are biocompatible, but whereas natural coral is resorbed slowly (several months), porous HA is not resorbed or takes years for resorption.

Clinical studies on these materials showed pocket reduction, attachment gain, and bone level gain.[33,54,119,140,141] Coral-derived materials have also been studied in conjunction with membranes,

with good results.[160,295] Both materials have demonstrated microscopic cementum and bone formation, but their slow resorbability or lack of resorption has hindered clinical success in practice.

Tissue Engineering With Biologic Mediators

In wound healing, the natural healing process usually results in tissue scarring or repair. By using tissue engineering, the wound healing process is manipulated so that tissue regeneration occurs.[95] This manipulation usually involves one or more of the three key elements: the signaling molecules, scaffold or supporting matrices, and cells (Fig. 63.1). The use of tissue engineering for periodontal regeneration and dental implant site preparation has been reviewed.[86,135,137]

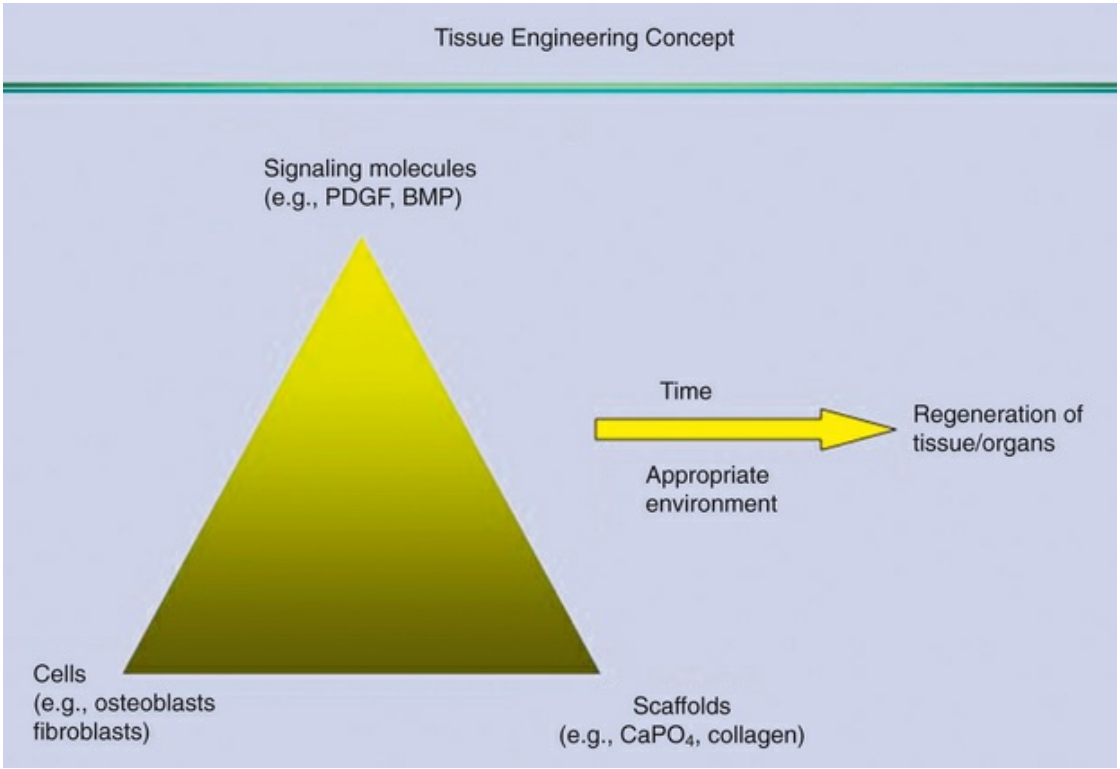


FIG. 63.1 Tissue engineering is the manipulation of one or more of the three elements: signaling molecules, scaffolds, or cells. *BMP,* Bone morphogenetic protein; *$CaPO_4$,* calcium phosphate; *PDGF,* platelet-derived growth factor. (Courtesy Dr. Samuel Lynch.)

Early clinical examples involving tissue engineering principles include the use of bone allografts and autologous platelet-rich plasma (PRP). Investigations indicated that the success rates with these materials were inconsistent. With the development of recombinant growth factors and morphogens, and the use of synthetic scaffolds, the level of success has improved. Once considered experimental, tissue engineering is now clinically applicable with two commercially available tissue engineering systems for periodontal regeneration that involve the use of enamel matrix derivative (EMD) and platelet-derived growth factor-BB (PDGF-BB)–beta-TCP (β-TCP).[136] The ability of BMP type I collagen sponge to enhance periodontal regeneration has been studied, but the mixed results and the concern for ankylosis have relegated this differentiation factor to be used primarily for implant site development. The development of a fourth promising system using basic fibroblast growth factor (FGF-2) is completing multicenter clinical trials.

Because tissue engineering approaches are likely to improve clinical results, clinicians need to understand the biology and clinical parameters and limitations of these techniques. In the following sections, each of the three key elements of tissue engineering and how they are applied to the spectrum of periodontal and other orofacial surgery procedures are reviewed.

Enamel Matrix Derivative for Periodontal Regeneration

EMD has been effective in the treatment of infrabony defects (Fig. 63.2). The histologic evidence of EMD-induced periodontal regeneration has been confirmed in a clinical case report.[114,115] A mandibular lateral incisor destined for orthodontic extraction was treated with acid etching and EMD. After 4 months, the tooth was extracted and examined histologically. Regenerated cementum covered 73% of the defect, and regenerated alveolar bone covered 65%. This histologic finding was later confirmed in other case reports,[268,338] whereas new connective tissue attachment was reported in another case series where EMD was used in combination with a bone-derived xenograft.[275]

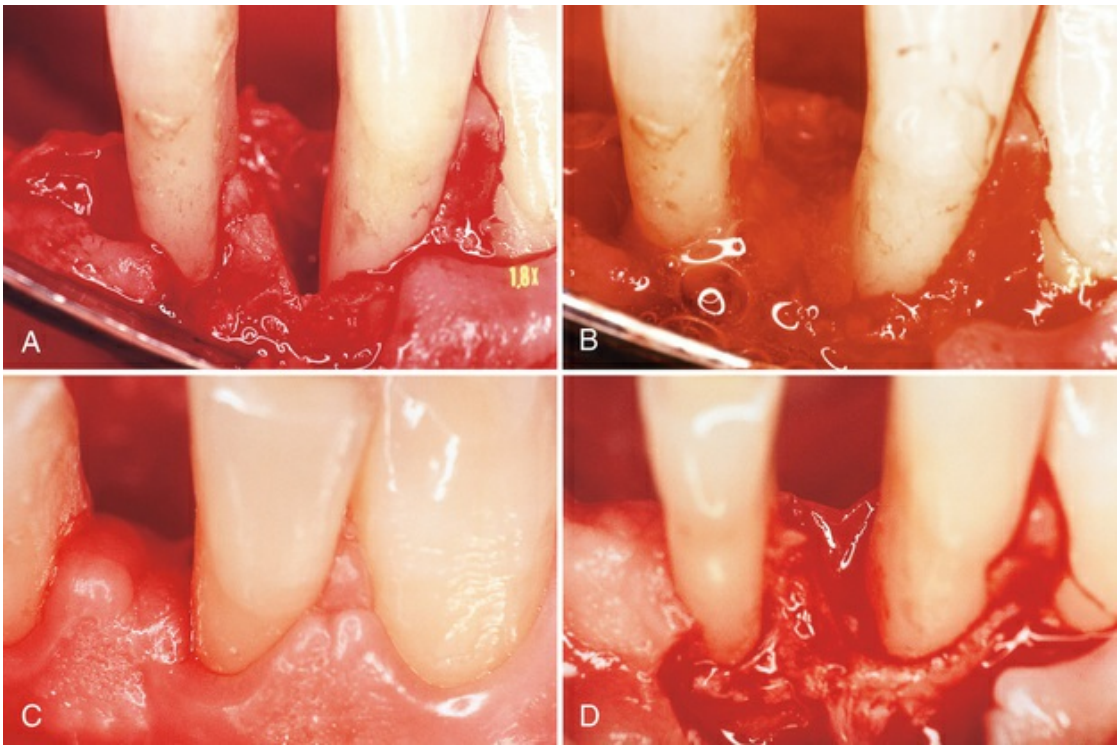

FIG. 63.2 (A) Deep vertical bone loss distal to the lower left central incisor. (B) Area flapped, root prepared, and defect filled with enamel matrix protein (Emdogain, Straumann, Andover, Mass.). (C) Postoperative photograph 6 months later. (D) Reentry surgery showing extensive bone fill. (Courtesy Dr. Marco Orsini, Aquila, Italy.)

EMD has been shown to be safe for clinical use.[110,339] Evidence of clinical efficacy was first reported in a multicenter study consisting of 33 patients with at least 2 defects, which were treated in a split-mouth design. The experimental site was treated with acid etching and EMD, whereas the control site was treated with a placebo.[114] Patients were examined at 8, 16, and 36 months after surgery. Increased bone fill of the osseous defect was observed over time for 25 of the 27 (93%) EMD-treated teeth, but no bone fill was detected in the controls. The mean radiographic bone fill was greater for the EMD-treated defects compared with the control sites treated with open flap debridement (2.7 mm vs. 0.7 mm, respectively). Statistically significant improvements were also observed for EMD-treated sites over control sites in mean pocket reduction (3.1 mm vs. 2.3 mm, respectively) and mean attachment level gain (2.2 mm vs. 1.7 mm, respectively). These clinical findings have been supported by additional studies.[¶] However, one randomized, double-masked,

placebo-controlled clinical trial failed to show significant differences in clinical and radiographic measure between EMD and control.[251] Long-term stability of EMD regenerative therapy was reported in a case series that followed 106 EMD-treated defects in 90 patients.[112] The data suggest that radiographic bone level, clinical attachment level gain, and reduced pocket depth reached near-maximal response after 1 year, and the results remained stable over 5 years. Other long-term studies have confirmed these findings.[72,237,270,271]

Several studies have compared the use of EMD alone or in conjunction with other regenerative approaches. When EMD treatment was compared with GTR using bioresorbable membranes, the clinical results were comparable and stable over as much as a 10-year period.[59,179,270,271,273,284,287] In a study comparing EMD, GTR, or EMD in combination with GTR with open flap debridement, all three had results superior to those of open flap surgery, with no additional improvement when EMD was used in conjunction with GTR.[274] Other investigators have confirmed this finding.[188,269,287]

The use of EMD in combination with other graft materials is controversial. When EMD is used in conjunction with autogenous bone, DFDBA, xenograft, and bioactive glass, additional improvements in clinical parameters were observed as compared with the use of either EMD or DFDBA alone.[#] However, others studies failed to demonstrate clinical improvement when EMD was used in conjunction with TCP or bioactive glass.[20,127,159]

EMD remains a very intriguing biologic mediator.[136,205] As we better understand the mechanism of action of the potpourri of proteins and growth factors, this may strengthen the biologic rationale for clinical use of this material. The concern remains whether commercial batches of EMD will be consistent and provide comparable clinical results in all cases. Perhaps the message is that the achievement of maximum regenerative response will require a mixture of biologic mediators. With further characterization of EMD, we may better develop a synergistic blend that will provide an optimal result.

Recombinant Human Platelet-Derived Growth Factor

for Periodontal Regeneration

PDGF is one of the earliest growth factors studied for its effect on wound healing because it is a potent mitogenic and chemotactic factor for mesenchymal cells in cell culture. Histologic evidence of periodontal regeneration was first reported in experimental defects in beagle dog.[163,167] During the development of PDGF for clinical use, recombinant human PDGF (rhPDGF) was used in conjunction with allogenic bone to correct class II furcations and interproximal intrabony defects on hopeless teeth.[29,207] Histologic evidence of successful periodontal regeneration in the furcation lesion with excellent fill has been noted.

A human clinical trial was conducted using rhPDGF and recombinant human insulin-like growth factor 1 (rhIGF-1).[121] Using a split-mouth design, defects were treated with either a low dose (50 μg/mL) or high dose (150 μg/mL) of rhPDGF–rhIGF-1. After 9 months, the high-dose rhPDGF–rhIGF-1 induced 2.08 mm of new bone and 43.2% defect fill, compared with 0.75 mm vertical bone height and 18.5% bone fill in controls. Low-dose rhPDGF–rhIGF-1 results were statistically similar to those of the controls. Additionally, this study demonstrated that no adverse immunologic or clinical reaction resulted from use of these agents. A primate study examined the regenerative effects of PDGF–IGF-1 individually and in combination.[166] PDGF alone was found to be as effective as the PDGF–IGF-1 combination in producing new attachment after 3 months. No significant effect was found when IGF was used alone. This study suggests that IGF may not be important at the dose level tested.

Subsequently, the effectiveness of 0.3 mg/mL of rhPDGF in combination with β-TCP to improve attachment level gain, bone level, and bone volume significantly compared with β-TCP alone was demonstrated after 6 months in a multicenter clinical trial.[208] A subset of these patients was followed for 24 months, and a representative case series was reported to be stable, with increases in radiographic bone fill compared with the end results after 6 months (Fig. 63.3).[174] A review of these cases indicates that the results were stable after 3 and 5 years.[134,209] Another case series suggested that rhPDGF with freeze-dried bone allograft can be combined to achieve excellent results in severe periodontal

intrabony defects.[29] These findings were confirmed by another randomized control trial.[126]

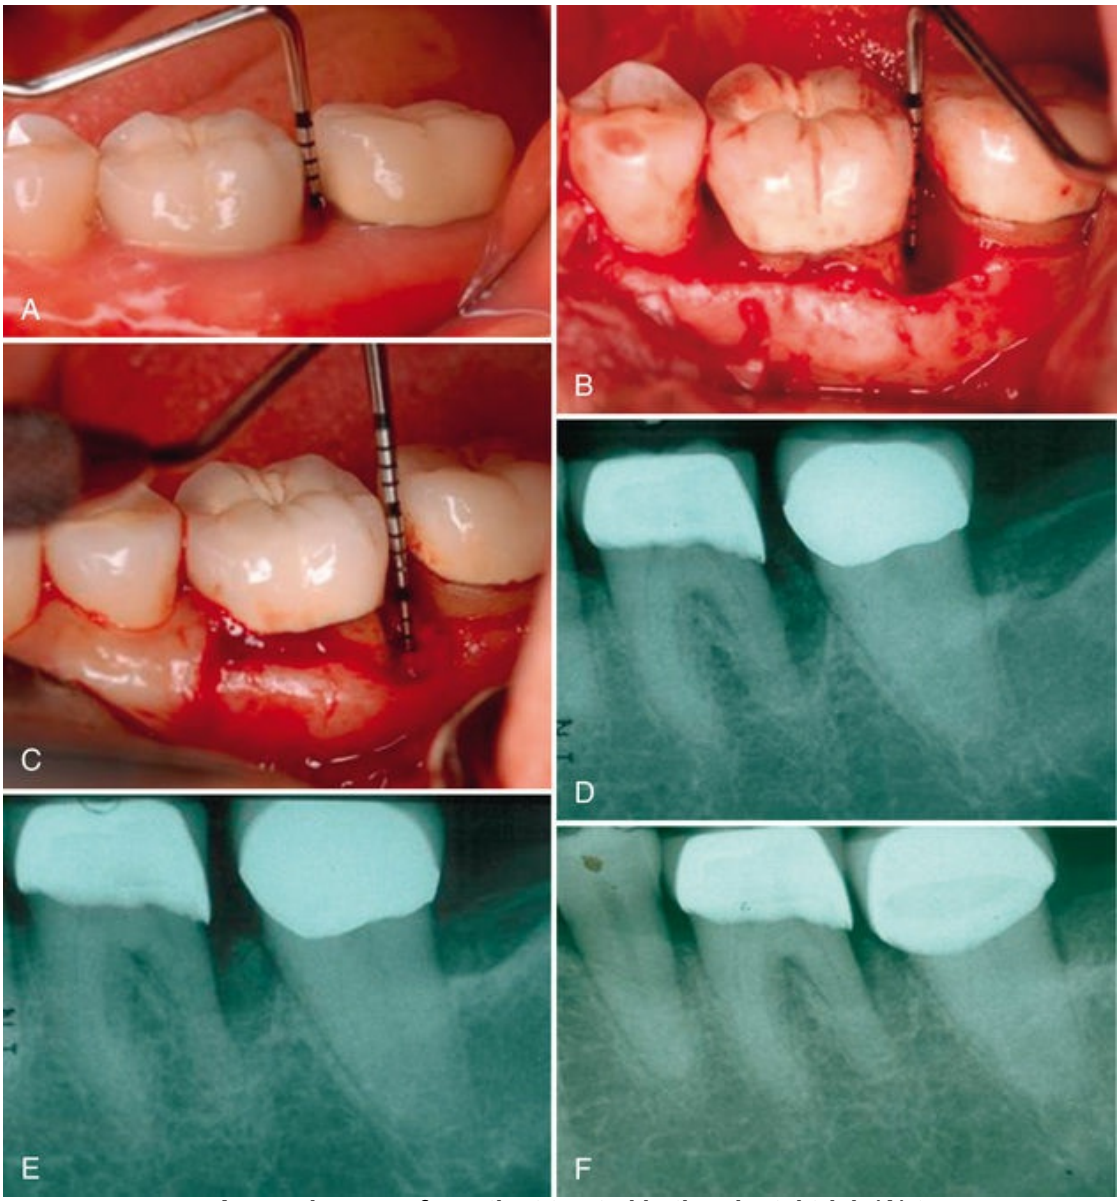

FIG. 63.3 **A sample case of a patient treated in the pivotal trial. (A) to (C) The pretreatment situation preoperatively, at surgical debridement, and at postsurgical reentry. (D) to (F) The radiographic appearance after 12, 24, and 60 months. Surgical reentry after 12 months indicates good bone fill of the circumferential intrabony defect (C). The clinical pocket depth was 3 mm after 5 years.**

The combination of rhPDGF with a β-TCP carrier is now commercially available (GEM 21S, Osteohealth, Shirley, NY). These preliminary studies using rhPDGF-TCP suggest that it is easy to use, requires no barrier membranes, and has results comparable or

superior to those of other regenerative graft materials. The potential for using rhPDGF for regeneration of furcation defects and implant site preparation still needs to be evaluated. Additionally, considerable clinical interest has been expressed in combining rhPDGF-BB with other bone replacement grafts, particularly bone allografts and xenografts.

Learning Box 63.3

Note that the use of biologic agents such as enamel matrix derivative and platelet-derived growth factor is a relatively recent concept for periodontal regeneration. The process can proceed even with the short biologic half-life of these materials; this means that it is often not present in the later stages of development. Readers should appreciate that these stimulated cells can somehow organize themselves to differentiate and in a timely fashion become three histologic structures: new bone, cementum, and periodontal ligament. In addition, it is amazing that these three histologic structures "intertwine" with each other and stimulate regeneration using a different mechanism from the bioexclusion principle, as demonstrated with the use of guided tissue regeneration membranes. Finally, randomized controlled studies indicate that the addition of guided tissue regeneration membranes confers no advantage. All these factors indicate that the use of biologic agents can stimulate stem cells to be recruited to the intrabony or furcation defect site, proliferate, and differentiate into a newly regenerated periodontal apparatus. It is also interesting that this occurs in very rapid fashion, faster than the migration of epithelial and mesenchymal cells.

Combined Techniques

Periodontal new attachment and bone reconstruction have been challenges for clinicians throughout the history of periodontal therapy. To take advantage of the different bone graft materials and biologic mediators, clinicians have combined these graft materials with the use of membranes in an attempt to find a predictable technique to regenerate bone.

Several clinicians have proposed a combination of the techniques previously described in an attempt to enhance their results.[11,104,160,177] A classic paper published by Schallhorn and McClain[264] in 1988 described a combination technique using graft material, root conditioning with citric acid, and coverage with a nonresorbable membrane (the only available one at the time). More recently, with the advent of osteopromotive agents, such as the EMD (Emdogain, Straumann, Andover, MA) and osteoconductive bovine-derived anorganic bone (Bio-Oss) graft materials, other combination techniques have been advocated.[158] The combined use of these products, along with autogenous bone with resorbable membrane coverage, has resulted in an increased percentage of cases with successful new attachment and periodontal reconstruction. Many of these combination techniques were reviewed in previous sections of this chapter. Whereas the use of combination technique may be appealing, it is important for clinicians to remember that these added materials often escalate the cost of the procedure and should be balanced with the quality and the long-term stability of the clinical results.

Factors That Influence Therapeutic Success

Factors that adversely affect periodontal regeneration were reviewed at the 1996 World Workshop in Periodontics and the 1997 Proceedings of the Second European Workshop on Periodontology.[217,232] Some of the therapeutic factors that have been implicated or shown to influence periodontal regenerative therapy adversely include (1) the selection of the appropriate surgical technique, accurate assessment of the periodontal defect, and the clinician's clinical experience (Fig. 63.4); (2) the importance of the tooth in the overall restorative treatment plan; and (3) the patient's selection of the regenerative options.

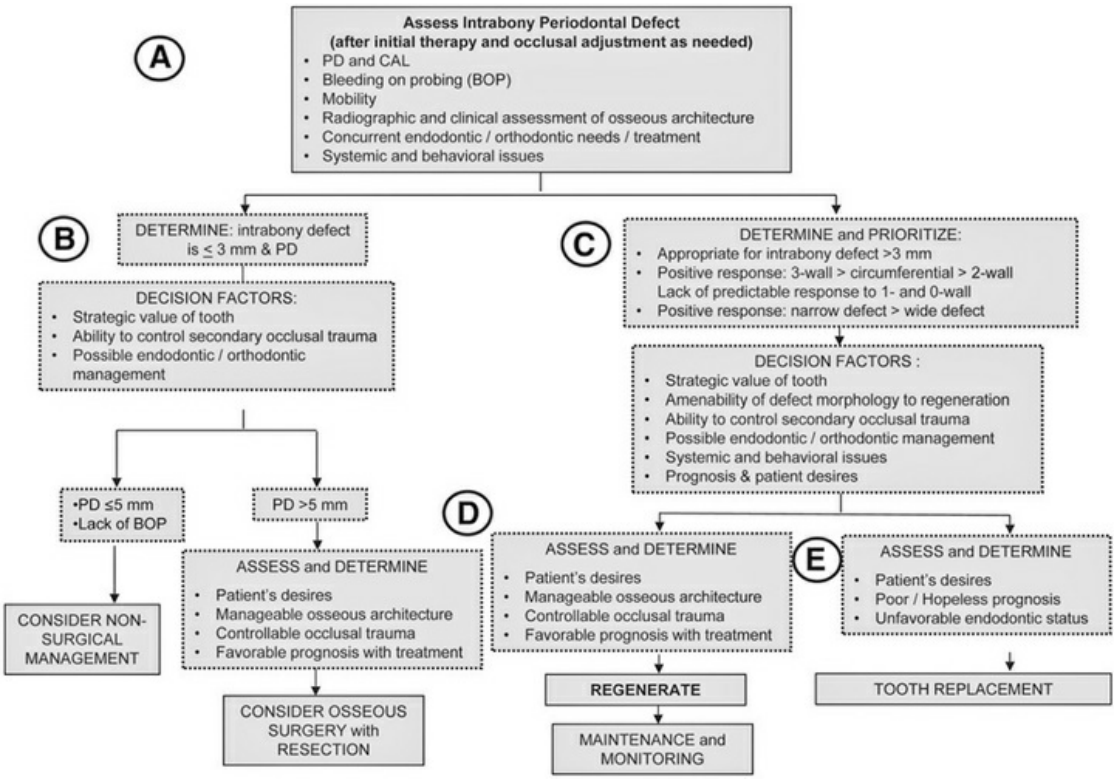

FIG. 63.4 Clinical decision tree for the management of advanced periodontal defects. *A* to *E* are explained in the text in the section titled "Clinical Guidelines to Guide Clinicians in Their Patient Management." *CAL*, Clinical attachment level; *PD*, periodontal defect. (From American Academy of Periodontology: *J Periodontol* 86[Suppl]:S77, 2015.)

Therapeutic Considerations

The selection of an appropriate therapeutic approach is one that is based on accurate assessment of the periodontal defect, one's past clinical experience, familiarity with the various regenerative and resective techniques, and the patient's selection of the regenerative options.

Successful regenerative surgery requires delicate and timely tissue management to minimize tissue shrinkage. Some of these important surgical considerations are good passive flap closure for encasement of the graft materials and a flap design to allow tension-free suture placement. These concepts of using conservative and minimally invasive flap approaches have been introduced as minimally invasive surgery (MIS).[107] By using these surgical principles, several modifications have developed and evolved into the MIS technique (MIST), the modified MIST (M-MIST),[48] and the single-flap approach (SFA).[309] The flap design for these techniques

minimizes the number of incisions and as a result the surgical trauma, especially when the operation is performed with the use of magnification and microsurgical techniques. Several minimally invasive approaches have shown statistical improvements when used in conjunction with EMD,[71,108,109,245] although with no difference when used with rhPDGF.[189] Most of these studies were of short duration, whereas one study reported that the 12-month result remained stable at 6 years.[108,109] Of special interest is that the recession values for these conservative or minimally invasive procedures tend to be lower than those reported with other access flap surgery techniques. GTR studies suggest that the MIS approach may be better suited for regeneration in the aesthetic zone. Large-scale randomized controlled trials are needed to evaluate emerging treatment approaches such as MIS regarding its safety, efficacy, and patient-reported outcomes including pain, postoperative complications, aesthetics, and patients' satisfaction.

Tooth and Defect Related Considerations

Therapeutic success is influenced by the tooth's importance in prosthetic rehabilitation, its endodontic status, and the osseous defect characteristics.

The critical question to be addressed is whether the involved dentition is strategically important to treat and maintain by using regenerative periodontal theapy.[305] If the tooth has little or no importance in the overall treatment plan, extraction may be indicated to avoid potential technical difficulties, postsurgical complications, and expenses. Strategic extraction may also improve access for better plaque or biofilm removal by the patient and compliance.[102]

If a tooth is deemed essential, it is important to assess its endodontic status before the clinician proceeds with periodontal regenerative therapy. A positive endodontic status is necessary before one proceeds with regenerative therapy.[124,125] The financial consideration is also important for undertaking regenerative therapy. In a clinical scenario, if endodontic therapy, periodontal regenerative therapy, and restorative therapy are all necessary to retain a tooth, the financial commitment may indicate the possible

extraction and replacement with a dental implant or a prosthesis.

Characteristics of the defect, such as the overall osseous pocket depth, width, and walls, can influence clinical outcome in response to regenerative surgery.** Studies have consistently indicated that a deeper defect is correlated with increased clinical attachment level and probing depth.[61,77] One is more likely to achieve improved regenerative results when the osseous defects are narrow, circumferential, and with a three- or two-walled configuration. Conversely, a wide osseous lesion with one wall or no wall is less amenable to regenerative procedures.[7,10,149,235,276] Even with the use of iliac and autologous grafts, current regenerative approaches have not been successful in regenerating one- or zero-walled osseous defects.

The role of tooth mobility in regenerative therapy remains controversial. Clinical experience suggests that regenerative therapy is successful when the tooth is not mobile before regenerative therapy. Numerous studies support the positive attribute of controlling mobility through presurgical splinting as compared with mobile teeth before regenerative therpy.[46,281,308] A study by Schultz and colleagues[265] evaluated mobile teeth stabilized by splinting versus mobile teeth before regenerative surgery. Presplinting of mobile teeth treated with bone replacement graft resulted in significantly improved clinical parameter as compared with nonsplinted teeth after a year. These studies suggest the importance of appropriate presurgical management of tooth mobility before regenerative procedures.

Patient-Related Considerations

Classic studies of poor plaque control and poor postoperative recall compliance have indicated that much of the therapeutic gain from periodontal surgery will deteriorate.[10,185,215,253,325,326] Similarly, the positive results from GTR regenerative procedure have been shown to deteriorate with poor compliance.[49–51,91,320] Progressive deterioration in these patients have been demonstrated to be associated with a higher incidence of infection with putative periodontal pathogens (*Porphyromonas gingivalis, Prevotella intermedia,* and *Aggregatibacter actinomycetemcomitans*)[112,169] Areas

such as furcation and root proximity situations have also been shown to be difficult to maintain, and as a result, the risk for deterioration is higher.[122,185,242,244] As a clinician in practice, it is important to remember that the patient presented to the clinician with behavioral (plaque or biofilm) and anatomic problems, which resulted in periodontal disease. After therapy, the difficult challenge is to motivate patients to be skilled, enthusiastic, and passionate about their oral hygiene and compliant with periodontal maintenance.

Smoking is a behavioral challenge that the therapist must always assess if the patient is a smoker. Smoking not only promotes disease progression, but also results in adverse therapeutic outcomes.[97,98,101,131] It has been implicated as having a detrimental effect on periodontal wound healing following surgical procedures,[1,229] as well as to influence periodontal regeneration adversely.[305]

Studies examining the regenerative outcomes in diabetic patients are lacking due to ethical considerations. Despite the lack of direct evidence in humans, animal studies confirm the detrimental effects on poor wound healing capacity in diabetic animals as compared with controls.[39,279,311] Of special interest is that the use of biomimetic agents, such as EMD, did not improve the compromised healing response of animals with diabetes.[279]

Clinical Guidelines to Guide Clinicians in Their Patient Management

Clinical guidelines for the management of patients with periodontal disease are depicted in Fig. 63.4.[136] The ideal management of periodontal defects consists of the early diagnosis and appropriate addressing of the defect (Fig. 63.4, *A*). When defects are detected early, before the formation of intrabony and furcation lesions, a predictable outcome can be obtained with scaling, root planing, and conventional osseous surgery (Fig. 63.4, *B*). Even early narrow intrabony (<3 mm) and furcation defects can be blended in with the adjacent osseous contour. When the intrabony and furcation defects are >3 mm, periodontal regeneration should be considered (Fig. 63.4, *C*). Assessment of defect morphology and the patient's clinical

and systemic-behavioral determinants is critical for regenerative success. Consideration of these issues, in addition to the patient's desires, will define the selection of the regenerative approach to be used (Fig. 63.4, *D*). Long-term stability is possible, but the individual outcome is influenced by patient-related considerations such as smoking and compliance with periodontal maintenance and monitoring. Should patient-related or clinical determinants be unfavorable for periodontal regeneration, appropriate therapy must be selected in place of regeneration that may consist of long-term maintenance or the removal of the tooth and replacement with a prosthesis such as a dental implant or another form of prosthesis. (Fig. 63.4, *E*).[133]

Before regenerative therapy, it is important to perform an endodontic assessment. This is to eliminate the possibility that the defect is the result of an endodontic-periodontal lesion. Should this be case, endodontic treatment may resolve that portion of the defect due to the endodontic lesion. If a residual defect still persists, periodontal therapy should be initiated.

A common misconception is that regenerative therapy ends with a postoperative assessment a few months after treatment. Most therapeutic approaches have maximal healing results after 12 months. As such, postoperative monitoring should occur at least 12 months later. Additionally, these regenerated areas should be monitored at every recall visit because poor hygiene, uncorrectable tooth anatomy, and undiagnosed endodontic problems will cause these areas to relapse. Should failures due to these causes be determined, it may be prudent to consider strategic extraction.[133]

The endpoint for active periodontal therapy should comprise a stable periodontal attachment level, absence of inflammation or bleeding, and a periodontal anatomic environment that is conducive for the patient and the clinician to maintain excellent oral hygiene. A successful long-term periodontal outcome is also dependent on a patient who will be compliant with the maintenance visits.

Future Directions for Periodontal Regeneration

In wound healing, the natural healing process usually results in tissue scarring or repair. By using tissue engineering, the wound healing process is manipulated so that tissue regeneration occurs.[87,165] This manipulation usually involves one or more of the three key elements: (1) the signaling molecules, (2) scaffold or supporting matrices, and (3) cells (see Fig. 63.1). The cellular responses to these biologic mediators in vitro have been studied and are summarized in Table 63.2. Some of these biologic mediators are commercially available (recombinant human bone morphogenetic protein [rhBMP], rhPDGF, EMD). The potential of tissue engineering in periodontal regeneration has been reviewed.[164,246]

Bone Morphogenetic Proteins for Periodontal and Implant Site Regeneration

BMPs comprise a group of regulatory glycoproteins that are members of the transforming growth factor beta superfamily that function as differentiation factors. These proteins induce cellular differentiation of stem cells into chondroblastic and osteogenic cells. Much of the research interest has focused on BMP-2 (OP-2), BMP-3 (osteogenin), and BMP-7 (OP-1).[40] BMPs have been demonstrated to be present in FDBA and DFDBA, but the levels are so low that BMP is not biologically active. In fact, the amount of BMP is so low that it takes approximately 10 kg of bovine bone to yield only 2 μg of BMP.[266,267] It is only through recombinant DNA technology that BMP has been made available for clinical use.

Although early studies using crude preparations of BMP-2 and BMP-3 applied in surgically induced furcation defects appeared to stimulate periodontal regeneration,[247] more recent study with rhBMP-2 indicated that periodontal regeneration was associated with areas of ankylosis.[283] Healing through ankylosis has been a concern, so most of the research using rhBMPs has involved correction of intrabony, supra-alveolar, furcation, and fenestration defects,[††] as well as implant site preparation.[‡‡]

Use of Recombinant Human Fibroblast Growth Factor 2 for Periodontal Regeneration

The potential use of recombinant human FGF-2 (rhFGF-2) for periodontal regeneration has been reviewed.[198–200] Preliminary beagle and nonhuman primate studies demonstrated that topical application of FGF-2 into intraosseous defects in alveolar bones induces significant periodontal tissue regeneration.[299] Histologic observation revealed new cementum with Sharpey fibers, new functionally oriented periodontal ligament fibers, and new alveolar bone.[199] These findings suggest that topical application of FGF-2 may be efficacious in regeneration of human periodontal tissue that has been destroyed by periodontitis.

A randomized, controlled, double-masked Phase II clinical trial at

13 Japanese dental facilities compared therapeutic response to varying doses of FGF-2 as compared with control.[147,148] Eighty patients with a two- or three-walled vertical bone defect 3 mm or more from the alveolar crest were randomly divided into four groups: (group A) placebo control, (group B) 0.03% FGF-2, (group C) 0.1% FGF-2, and (group D) 0.3% FGF-2. The subjects underwent periodontal surgery during which 200 μL of the investigational drug or placebo carrier was applied to each test site. After 9 months, a significant increase ($P = 0.021$) in alveolar bone height was demonstrated by standardized radiographs between group A (23.92%) and group D (58.62%). No adverse effects were observed throughout this multicenter trial. This finding suggests that topical application of FGF-2 can be efficacious in regenerating periodontal tissue of patients with two- or three-walled intrabony defects. This has led to a subsequent larger clinical trial that has been completed, and the results are forthcoming. These trials will provide crucial information regarding the safety and efficacy of using FGF-2 for periodontal regeneration.

Cell Therapy

Cell therapy has been used in periodontal surgery (Osteocel Plus, NuVasive, San Diego, CA). Stem cells have the potential to improve current bone regeneration. These cells can expedite cell recruitment, be target cells for growth factor delivery, and promote early extracellular matrix formation. All of these cellular activities increase the bioactivity of the graft. The concentration of multipotential stromal cells (MSCs) in a commercially available cellular bone allograft was compared with fresh age-matched iliac crest bone and bone marrow aspirate.[11] Without cultivation or expansion, this allograft contains cells with cell surface markers called *cluster differentiation (CD) markers* that are found with immunotyping of osteoprogenitor cells and osteoblasts. These cells displayed an "osteoinductive" molecular signature and the presence of $CD45^{-}CD271^{+}CD73^{+}CD90^{+}CD105^{+}$ MSCs surface markers that were more than 100-fold of what are found in iliac crest bone. In comparison with bone marrow, MSC numbers enzymatically released from 1 g of cellular allograft were equivalent

to approximately 45 mL of bone marrow aspirate. This MSC cellular allograft bone represents a unique, nonimmune material rich in MSCs, osteoblasts, and osteocytes. This osteoinductive cellular graft represents an attractive alternative to autograft bone by eliminating a secondary surgical harvest site and morbidity risk.

This stem cell preparation with bone scaffold has been used for implant site preparation by increasing increase alveolar ridge volume and sinus grafting,[90,172,286] Additionally, this cellular allograft has been used successfully in regenerative treatment of periodontal defects in both a single-rooted tooth and a multirooted tooth.[171] In the single-rooted case, a significant reduction in probing was obtained with radiologic evidence of approximately 4 mm of vertical bone fill at 6 months following grafting. In the multirooted case, clinical evidence showed decreased probing depths and radiographic bone improvement at 6 months. A cone beam computed tomography scan taken at 14 months demonstrated three-dimensional bone fill. A similar result was presented in a case report, where this allograft cellular bone matrix was used in the successful treatment of a severe periodontal defect.[153] These case reports indicate a potential resolution of periodontal defects using cellular allograft material.

Learning Box e63.3

The use of stem cells provides a third mechanism; this suggests that by grafting multipotential stem cells, they can organized themselves to form a new periodontium. This need for a *proof of evidence,* and the need for or possible improvement with bioexclusion still need to be explored.

Scaffold or Supporting Matrices

The use of scaffolding matrices to deliver growth factors to promote periodontal tissue regeneration has been an active area of research.[86,157] Supporting matrices for engineering bone and soft tissue have included processed bone allografts, synthetic and natural polymers, synthetic ceramics, bovine type I collagen, and calcium sulfate (commercially available scaffolds are found in

eTable 63.1). The major roles for the supporting matrices are to:

eTABLE 63.1

Commercially Available Scaffold Materials Potentially Available for Oral Tissue Engineering Application

Biomaterials	Commercial Names
Allografts	
Demineralized freeze-dried bone allograft (DFDBA)	Distributed under various names by tissue banks
Freeze-dried bone allograft (FDBA)	Distributed under various names by tissue banks
Xenografts	
Anorganic bovine bone	Bio-Oss, OsteoGraf, Pep-Gen P-15
Hydroxyapatite (HA)	
Alloplasts	
Tricalcium phosphate	Synthograft
Hydroxyapatite	Periograf, Osteogen, ProOsteone
Bioactive glass polymers	PerioGlas, BioGran
Hard tissue replacement polymer	Bioplant
Coralline calcium carbonate	Biocoral
Polymers and Collagens	
Collagen	CollaPlug, CollaCote, Gelfoam, Helistat
Poly(lactide-co-polyglycolide)	
Methylcellulose	
Hyaluronic acid ester	HY
Chitosan	

1. Provide physical support for the healing area so that no collapse of the surrounding tissue into the wound site occurs. Examples of this would be bone allografts and synthetic ceramics such as TCP.
2. Serve as a barrier to restrict cellular migration selectively. This is best exemplified by principles of GTR and guided bone regeneration (GBR) where nonresorbable PTFE and resorbable polylactate, polyglycolic acid, and calcium sulfate are used. The exclusive properties of cell barrier membranes have been reviewed[134,135,217] and are not addressed here.
3. Serve as a scaffold for cellular migration and proliferation. Examples include the collagen matrix. Potentially, this scaffold can be further enhanced by selectively defining the types of cells permitted to attach to and proliferate on this matrix with the additions of adhesins and/or integrins.[96,244]

4. Potentially serve as a time-release mechanism for signaling molecules.

Allogenic and Alloplastic Bone-Grafting Materials

The classic approach to orofacial regeneration since the 1980s has been the use of bone grafts or substitutes to repair periodontal and maxillofacial defects. The literature contains several excellent reviews on the use of autografts, allografts, and alloplastic graft materials.[134,135,217]

Since 2000, mineralized and demineralized freeze-dried bone allografts (FDBA and DFDBA) have often been the regeneration material of choice. In addition to their availability and putative osteogenic potential, various clinical studies indicate that 2 to 3 mm of bone fill is possible with FDBA[177,178,257,258,278] and DFDBA.[106,255] However, other studies have questioned the osteogenic potential of bone allografts by suggesting that this may vary depending on the bone bank or batch,[266,267] processing procedures used, and donor characteristics.[128,280,340,341] Due to varying osteoinductive properties, which are not areas the US Food and Drug Administration regulates, growth factors and morphogens with FDBA and DFDBA are not commercially available. However, off-label use of this combination is common both in orthopedic and oral-periodontal surgical procedures.

Alternatively, a variety of xenograft and alloplastic grafting materials is available as scaffolding agents for tissue engineering. Alloplastic bone grafts consist of ceramics, such as HA, porous HA, β-TCP, and biocompatible composite polymers (e.g., hard tissue replacement). Of these allografts, β-TCP is used in combination with rhPDGF-BB. In the development of rhPDGF-BB for clinical use, the biosynthetic β-TCP was used because it possessed defined and reproducible properties as required by the Food and Drug Administration. Allografts were not desirable because of varying osteogenic potential and properties.[209] Extensive animal and human studies demonstrated biocompatibility of β-TCP with no reports of adverse reactions.[13,75] This material physically fills bone defects, provides a scaffold for new bone formation, and prevents soft tissue collapse into the wound site.[75] Clinically, β-TCP is osteoconductive and supports early healing. β-TCP resorbs at varying rates

depending on the chemical structure, porosity, and particle size. Absorption, release, and bioactivity studies indicate that either β-TCP or calcium sulfate can be an effective carrier for PDGF-BB. Approximately 45% of the adsorbed PDGF-BB was released after 10 days.[10] In clinical studies with rhPDGF-BB, this material resorbs and is replaced with regenerated periodontium. Superficial granules at the soft tissue interface appear to resorb at a slower rate. More recently, the use of β-TCP coated with recombinant human growth and differentiation factor-5 was evaluated for its osteoinductive and osteoconductive properties in an experimental rat calvarial critical size defect.[223] Histomorphometric results suggest that this proprietary coating of growth factor on β-TCP achieved superior bone regeneration compared with conventional materials. These latter two studies indicate that the absorption and release kinetics of signaling agents are areas that require further elucidation if we are to achieve optimal regenerative response.

Collagen Carriers

Collagen is the main structural protein for tissue support. It also plays an essential role in wound healing by providing a biologic scaffold for cellular activities such as cell attachment, migration, and proliferation.[328,329] Collagen has been widely used in tissue engineering for seeding of mesenchymal stem cells,[23,132] as well as incorporation of growth factors.[120,121] Because most collagens are derived from bovine dermal or skeletal tissue, concerns related to the purity, quality, immunogenicity, and potential for prion transmission have been raised.[116] Studies addressed these issues by further purifying bovine collagen and modifying the molecules to remove antigenic N- and C-terminal telopeptides.[120,256] Two variations of this collagen were produced to create an atelocollagen scaffold where both constructs were effective in supporting rhBMP-induced bone formation.

Calcium Sulfate

Calcium sulfate is one of the oldest bone graft materials. Early clinical and animal studies indicate that calcium sulfate is biocompatible, degrades over time, is subsequently replaced with regenerated bone, and may be used in an infected area with no

complications.[224] More recent studies indicate that it also has barrier properties,[135,143,222] enhances angiogenesis,[298] and may be effective as a delivery vehicle for antibiotics, as well as growth factors.[14,58,250] Rosenblum and associates[250] demonstrated that FGF was observed to be released at a rate directly proportional to the rate of calcium sulfate dissolution. A secondary benefit of calcium sulfate dissolution is a local decrease in pH. An interesting study in the orthopedic literature reported that when an experimental sheep distal femoral cancellous defect was filled with calcium sulfate, increased immunostaining for BMP-2, BMP-7, transforming growth factor beta, and PDGF-BB was observed.[319] All of these growth factors have been demonstrated to stimulate bone formation and development. Calcium sulfate was found to be a suitable carrier for rhPDGF-BB with a longer release kinetic profile (~16 days) as compared to β-TCP.[13] Because both materials are resorbable, the current debate centers on whether a longer sustained release of rhPDGF-BB would be more advantageous to periodontal and bone regeneration.

Other Carriers

Bioresorbable polymers of poly lactic-co-glycolic acid and polyglycolic acid have been considered as scaffolding agents for tissue engineering due to their biodegradable and tissue compatibility properties. Although these agents were promising as carriers for osteogenic factors in animals,[193,303] variable tissue responses have made clinical application of these materials problematic. These tissue responses include inflammation, foreign body reaction, and local acid accumulation during polymer degradation.[144,145,155,190]

Conclusion

Since the 1980s, the periodontal literature has been filled with numerous reports related to periodontal regeneration. This therapeutic goal, although ideal, is difficult to achieve. Various graft materials and regenerative strategies are now available; however, they all have limitations. The surgical procedure can be technically demanding, and when success is achieved, maintenance of positive

results is highly dependent on patients' oral hygiene habits and compliance with periodontal maintenance. Despite all these difficulties, periodontal regeneration is a clinical possibility that can be offered to patients. The clinician must carefully evaluate the various regenerative and reparative approaches and decide which technique may result in the best clinical outcome. With the advent of new regenerative approaches, such as biologic modifiers such as EMD and growth factors, we must critically evaluate how they may improve our ability to regenerate periodontal defects.

Treatment planning in periodontics also has changed dramatically because of the acceptance of dental implants as viable long-term options for replacing missing teeth. With the increased predictability of implants, questions arise regarding when to treat severe periodontal defects with regenerative procedures and when to perform strategic extraction in preparation for implant placement. Sometimes the best management of a periodontal defect may be extraction in lieu of periodontal regeneration or when regenerative efforts have been unsuccessful. Extraction would minimize further bone loss and provide the maximum volume of bone at the future implant healing site. This paradigm shift has complicated our views about regeneration. With dental implants as viable alternatives, we need to redefine periodontal prognosis and consider strategic extraction more often. Conversely, heroic regenerative procedures would be contraindicated.

Periodontal regeneration continues to be one of the primary therapeutic approaches toward the management of periodontal defects. Although evidence suggests that present regenerative techniques can lead to periodontal regeneration, the use of GTR and biologic modifiers can enhance these results. The crucial challenge for the clinician is to assess critically whether a periodontal defect can be corrected with a regenerative approach, or whether it would be better managed with osseous resection for a slight periodontal defect and with strategic extraction for an advanced diseased state. In this assessment, the clinician should attempt to differentiate between techniques that have been studied in depth and with acceptable results and those that are still experimental and promising. Research articles must be critically evaluated for adequacy of controls, selection of cases, methods of evaluation, and

long-term postoperative results. In addition, the clinician should remember that we treat patients on the basis of "clinical" success and not "statistical" success. A resulting clinical attachment gain of half a millimeter may be a "statistical" success, but it is meaningless for the patients we treat and manage over the long term.

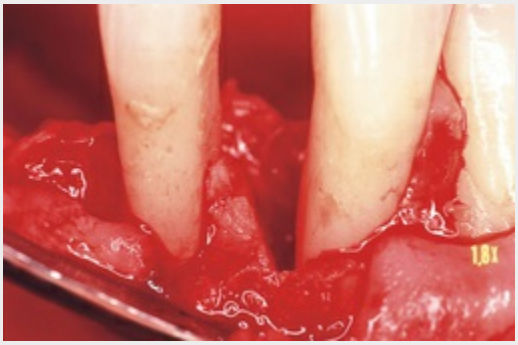
Case Scenario 63.1

Patient:
A 38-year-old female patient.

Chief Complaint:
"This tooth (lower first bicuspid, #21) bleeds with flossing and brushing."

Treatment History:
The patient was referred to a periodontist, who identified this tooth as having an intrabony defect. The area was debrided and treated with platelet-derived growth factor and beta-tricalcium phosphate. After 9 months of healing, this tooth was strategically extracted for orthodontic purposes. Unfortunately, the buccal and proximal area bone fractured in traumatic fashion. The area was grafted, and orthodontic treatment proceeded uneventfully.

Current Findings:
The extraction site healed uneventfully. Orthodontic treatment was completed, resulting in closure of the extraction site.



CASE-BASED QUESTIONS	SOLUTIONS
Assume this extracted tooth with surrounding bone fracture was submitted to oral pathology.	
1. The notch observed was from the aggressive scaling and root planing that was performed during the debridement; can you identify the histologic landmarks?	**Answers are identified in the legend for the figure.**
2. How would this wound healing differ with apical migration of the long junctional epithelium? A. The junctional epithelium would be exactly the same as in the figure. B. The junctional epithelium would be longer, but new cementum and bone would still be present. C. The junctional epithelium would be longer, and the zone of connective tissue would be shorter, with no new cementum and bone. D. The junctional epithelium would be longer, with an adjacent zone of new cementum.	**Answer: C**
3. How would healing by connective tissue attachment be different? A. The zone of connective tissue would be exactly the same as in figure. B. The zone of connective tissue would be larger, but new cementum and bone would still be present. C. The zone of connective tissue would be larger, and the zone of connective tissue would be shorter, with no new cementum and bone. D. The zone of connective tissue would be larger, with an adjacent zone of new cementum.	**Answer: D**

Case Scenario 63.2

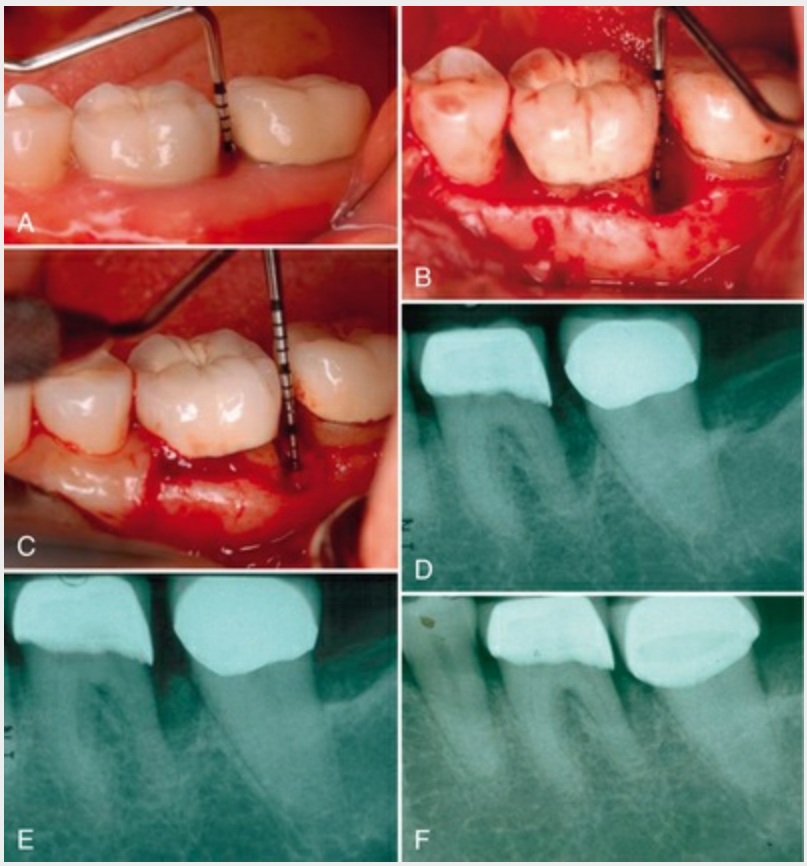
Patient:
A 48-year-old female patient.

Chief Complaint:
"This area bleeds a little, but I don't have any pain or problem around the area. I came because my dentist referred me to you [periodontist]."

Treatment History:
The patient was referred to a periodontist, who identified this tooth as having an intrabony defect. The area was debrided and treated with platelet-derived growth factor and beta-tricalcium phosphate. After 1.5 years, crown lengthening was needed for tooth #18 for restorative purpose. Surgical photographs and radiographs are presented.

Current Findings:

Crown lengthening proceeded smoothly, and a new crown was fabricated. The area of regeneration has been stable for more than 10 years.



CASE-BASED QUESTIONS	SOLUTIONS
Using the surgical photographs and radiographs,	
1. How does one determine that a three-wall intrabony defect is present on the distal of tooth #19? A. Based on deep clinical probing and bleeding on probing. B. Based on deep clinical probing only on the distal, which changes to 2 mm on the distal buccal and distal lingual line angle. C. Based on deep clinical probing only on the distal, which changes to 2 mm on the distal buccal and distal lingual line angle, along with radiographic evidence of the mesial wall of #18 at the normal level. D. Based on the radiograph that the mesial wall of #18 and furcation areas of #19 are at the normal level.	**Answer: C**
2. What are the clinical signs that healing has resulted and the condition is stable? A. Based on improved clinical probing. B. Based on improved clinical probing supported by radiographic evidence of defect bone fill. C. Based on improved clinical probing supported by radiographic evidence of defect bone fill over time (i.e., >2 years). D. Based on improved clinical probing supported by radiographic	**Answer: D**

evidence of defect bone fill and a consistent lack of bleeding on probing over time (i.e., >2 years).

CHAPTER 64

Furcation

Involvement and Treatment

Thomas N. Sims, Henry H. Takei

CHAPTER OUTLINE

Etiologic Factors
Diagnosis and Classification of Furcation Defects
Local Anatomic Factors
Anatomy of the Bony Lesions
Indices of Furcation Involvement
Treatment
Nonsurgical Therapy
Surgical Therapy
Prognosis

Editors' note: An animation (slide show) has been added by the editors as a supplement to the chapter. It was produced by My Dental Hub as a patient education tool and covers the basic

elements in a conceptual manner. It is not intended to be a procedural guide for dental professionals.

Inflammatory periodontal disease, if unabated, ultimately progresses to attachment loss sufficient to affect the bifurcation or trifurcation of multirooted teeth. The furcation is an area of complex anatomic morphology[5,6,11] that may be difficult or impossible to debride by routine periodontal instrumentation.[29,36] Routine home care methods may not keep the furcation area free of plaque[17,23] (Video 64.1).

The presence of furcation involvement is a clinical finding that can lead to a diagnosis of advanced periodontitis and potentially to a less favorable prognosis for the affected tooth or teeth. Thus furcation involvement presents both diagnostic and therapeutic dilemmas.

Etiologic Factors

The primary etiologic factor in the development of furcation defects is *bacterial plaque* and the inflammatory consequences that result from its long-term presence. The extent of attachment loss required to produce a furcation defect is variable and related to local anatomic factors (e.g., root trunk length, root morphology)[13,27] and local developmental anomalies (e.g., cervical enamel projections [CEPs]).[22,27] Local factors may affect the rate of plaque deposition or complicate the performance of oral hygiene procedures, thereby contributing to the development of periodontitis and attachment loss. Studies indicate that prevalence and severity of furcation involvement increase with age.[21,22,36] Dental caries and pulpal death may also affect a tooth with furcation involvement or even the area of the furcation. All of these factors should be considered during the diagnosis, treatment planning, and therapy of the patient with furcation defects.

Diagnosis and Classification of Furcation Defects

A thorough clinical examination is the key to diagnosis and treatment planning. Careful probing is required to determine the presence and extent of furcation involvement, the position of the attachment relative to the furca, and the extent and configuration of the furcation defect.[38] The Nabors probe may be helpful to enter and measure difficult to access furcal areas (Fig. 64.1). Transgingival sounding may further define the anatomy of the furcation defect.[29] The goals of this examination are to identify and classify the extent of furcation involvement and to identify factors that may have contributed to the development of the furcation defect or that could affect treatment outcome. These factors include (1) the morphology of the affected tooth, (2) the position of the tooth relative to adjacent teeth, (3) the local anatomy of the alveolar bone, (4) the configuration of any bony defects, and (5) the presence and extent of other dental diseases (e.g., caries, pulpal necrosis).

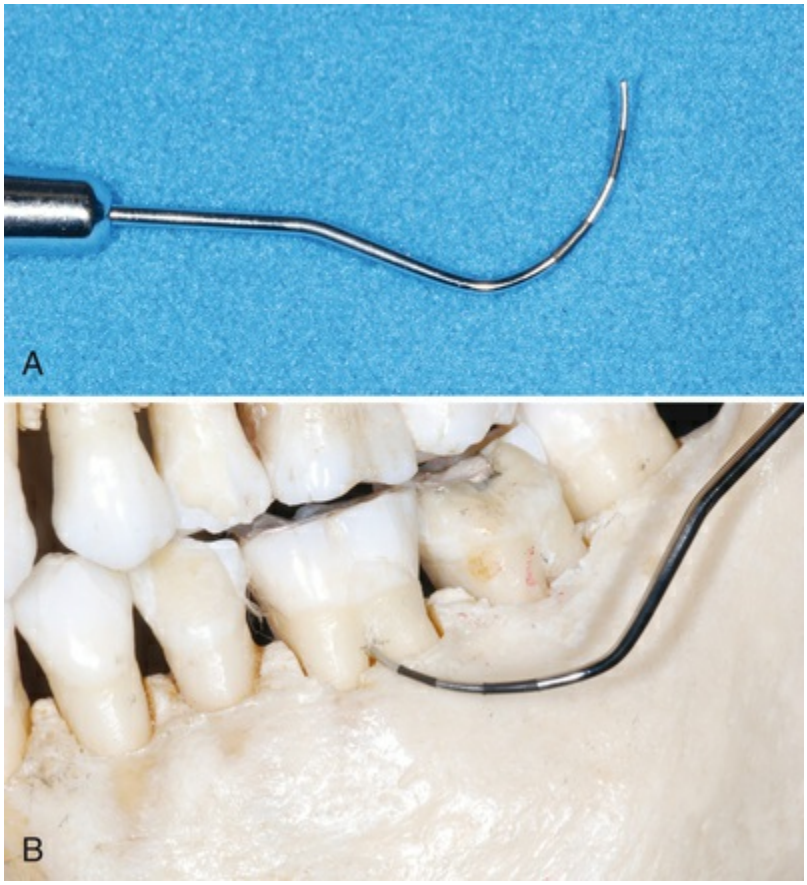

FIG. 64.1 (A) The Nabors probe is designed to probe into the furcation. (B) The probe placed into a class II furcation of a dried skull.

The dimension of the furcation entrance is variable but usually quite small; 81% of furcations have an orifice of l mm or less, and 58% are 0.75 mm or less.[5,6] The clinician should consider these dimensions, and the local anatomy of the furcation area,[11–13] when selecting instruments for probing. A probe of small cross-sectional dimension is required if the clinician is to detect early furcation involvement.

Local Anatomic Factors

Clinical examination of the patient should allow the therapist to identify not only furcation defects but also many of the local anatomic factors that may affect the result of therapy (prognosis). Well-made dental radiographs, although not allowing a definitive classification of furcation involvement, provide additional information vital for treatment planning (Fig. 64.2). Important local factors include anatomic features of the affected teeth, as described next.

FIG. 64.2 Different degrees of furcation involvement in radiographs. (A) Grade I furcation on the mandibular first molar and a grade III furcation on the mandibular second molar. The root approximation on the second molar may be sufficient to impede accurate probing of this defect. (B) Multiple furcation defects on a maxillary first molar. Grade I buccal furcation involvement and grade II mesiopalatal and distopalatal furcations are present. Deep developmental grooves on the maxillary second molar simulate furcation involvement in this molar with fused roots. (C) Grades III and IV furcations on mandibular molars.

Root Trunk Length

A key factor in both the development and the treatment of furcation

involvement is the root trunk length. The distance from the cementoenamel junction to the entrance of the furcation can vary extensively. Teeth may have very short root trunks, moderate root trunk length, or roots that may be fused to a point near the apex (Fig. 64.3). The combination of root trunk length with the number and configuration of the roots affects the ease and success of therapy. The shorter the root trunk, the less attachment needs to be lost before the furcation is involved. Once the furcation is exposed, teeth with short root trunks may be more accessible to maintenance procedures, and the short root trunks may facilitate some surgical procedures. Alternatively, teeth with unusually long root trunks or fused roots may not be appropriate candidates for treatment once the furcation has been affected.

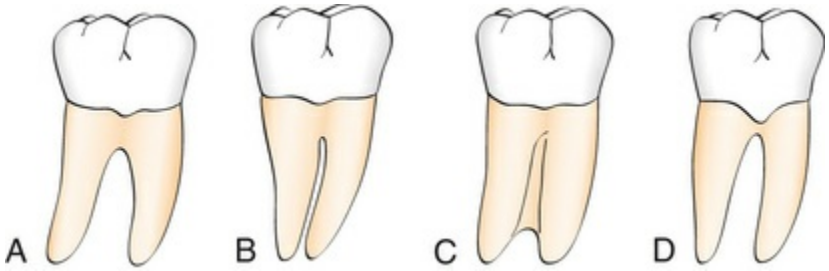

FIG. 64.3 **Different anatomic features that may be important in prognosis and treatment of furcation involvement. (A) Widely separated roots. (B) Roots are separated but close. (C) Fused roots separated only in their apical portion. (D) Presence of enamel projection that may be conducive to early furcation involvement.**

Root Length

Root length is directly related to the quantity of attachment supporting the tooth. Teeth with long root trunks and short roots may have lost a majority of their support by the time that the furcation becomes affected.[12,20] Teeth with long roots and short to moderate root trunk length are more readily treated because sufficient attachment remains to meet functional demands.

Root Form

The mesial root of most mandibular first and second molars and the

mesiofacial root of the maxillary first molar are typically curved to the distal side in the apical third. In addition, the distal aspect of this root is usually heavily fluted. The curvature and fluting may increase the potential for root perforation during endodontic therapy or complicate post placement during restoration.[1,25] These anatomic features may also result in an increased incidence of vertical root fracture. The size of the mesial radicular pulp may result in removal of most of this portion of the tooth during preparation.

Interradicular Dimension

The degree of separation of the roots is also an important factor in treatment planning. Closely approximated or fused roots can preclude adequate instrumentation during scaling, root planing, and surgery. Teeth with widely separated roots present more treatment options and are more readily treated.

Anatomy of Furcation

The anatomy of the furcation is complex. The presence of bifurcational ridges, a concavity in the dome,[11] and possible accessory canals[16] complicates not only scaling, root planing, and surgical therapy,[28] but also periodontal maintenance. Odontoplasty to reduce or eliminate these ridges may be required during surgical therapy for an optimal result.

Cervical Enamel Projections

Cervical enamel projections (CEPs) are reported to occur on 8.6% to 28.6% of molars.[26,27,35] The prevalence is highest for mandibular and maxillary second molars. The extent of CEPs was classified by Masters and Hoskins[27] in 1964 (Box 64.1). Fig. 64.4 provides an example of a grade III CEP. These projections can affect plaque removal, can complicate scaling and root planing, and may be a local factor in the development of gingivitis and periodontitis. CEPs should be removed to facilitate maintenance.

Box 64.1

Classification of Cervical Enamel Projections

Grade I: The enamel projection extends from the cementoenamel junction of the tooth toward the furcation entrance.
Grade II: The enamel projection approaches the entrance to the furcation. It does not enter the furcation, and therefore no horizontal component is present.
Grade III: The enamel projection extends horizontally into the furcation.

From Masters DH, Hoskins SW: Projection of cervical enamel into molar furcations. *J Periodontol* 35:49, 1964.

FIG. 64.4 **Furcation involvement by grade III cervical enamel projections.**

Anatomy of the Bony Lesions

Pattern of Attachment Loss

The form of the bony lesions associated with the furcation can vary significantly. Horizontal bone loss can expose the furcation as thin

facial or lingual plates of bone that may be totally lost during resorption. Alternatively, areas with thickened bony ledges may persist and predispose to the development of furcations with deep vertical components. The pattern of bone loss on other surfaces of the affected tooth and adjacent teeth must also be considered during treatment planning. The treatment response in deep, multiwalled bony defects is different from that in areas of horizontal bone loss. Complex multiwalled defects with deep, interradicular vertical components may be candidates for regenerative therapies. Alternatively, molars with advanced attachment loss on only one root may be treated by resective procedures.

Other Dental Findings

The dental and periodontal condition of the adjacent teeth must be considered during treatment planning for furcation involvement. The combination of furcation involvement and root approximation with an adjacent tooth represents the same problem that exists in furcations without adequate root separation. Such a finding may dictate the removal of the most severely affected tooth or the removal of a root or roots (Fig. 64.5).

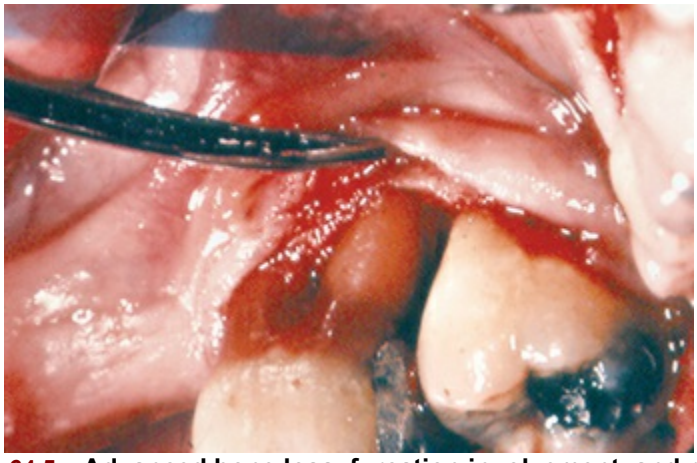

FIG. 64.5 **Advanced bone loss, furcation involvement, and root approximation. Note the buccal furcation, which communicates with the distal furcation of a maxillary first molar that also displays advanced attachment loss on the distal root and approximation with the mesial root of the maxillary second molar. The patient with such teeth may benefit from root resection of the distobuccal root of the first molar or extraction of the molar.**

The presence of an adequate band of gingiva and a moderate to deep vestibule will facilitate the performance of a surgical procedure, if indicated.

Indices of Furcation Involvement

The extent and configuration of the furcation defect are factors in both diagnosis and treatment planning. This has led to the development of a number of indices to record furcation involvement. These indices are based on the horizontal measurement of attachment loss in the furcation,[14,17] on a combination of horizontal and vertical measurements,[37] or a combination of these findings with the localized configuration of the bony deformity.[10] Glickman[14] classified furcation involvement into four grades (Fig. 64.6).

FIG. 64.6 Glickman's classification of furcation involvement. (A) Grade I furcation involvement. Although a space is visible at the entrance to the furcation, no horizontal component of the furcation is evident on probing. (B) Grade II furcation in a dried skull. Note both the horizontal and the vertical components of this cul-de-sac. (C) Grade III furcations on maxillary molars. Probing confirms that the buccal furcation connects with the distal furcation of both these molars, yet the furcation is filled with soft tissue. (D) Grade IV furcation. The soft tissues have receded sufficiently to allow direct vision into the

furcation of this maxillary molar.

Grade I

A grade I furcation involvement is the incipient or early stage of furcation involvement (see Fig. 64.6A). The pocket is suprabony and primarily affects the soft tissues. Early bone loss may have occurred with an increase in probing depth, but radiographic changes are not usually found.

Grade II

A grade II furcation can affect one or more of the furcations of the same tooth. The furcation lesion is essentially a cul-de-sac (see Fig. 64.6B) with a definite horizontal component. If multiple defects are present, they do not communicate with each other because a portion of the alveolar bone remains attached to the tooth. The extent of the horizontal probing of the furcation determines whether the defect is early or advanced. Vertical bone loss may be present and represents a therapeutic complication. Radiographs may or may not depict the furcation involvement, particularly with maxillary molars because of the radiographic overlap of the roots. In some views, however, the presence of furcation "arrows" indicates possible furcation involvement (see Chapter 33).

Grade III

In grade III furcations, the bone is not attached to the dome of the furcation. In early grade III involvement, the opening may be filled with soft tissue and may not be visible. The clinician may not even be able to pass a periodontal probe completely through the furcation because of interference with the bifurcational ridges or facial-lingual bony margins. However, if the clinician adds the buccal and lingual probing dimensions and obtains a cumulative probing measurement that is equal to or greater than the buccal-lingual dimension of the tooth at the furcation orifice, the clinician must conclude that a grade III furcation exists (see Fig. 64.6C). Properly exposed and angled radiographs of early class III

furcations display the defect as a radiolucent area in the crotch of the tooth (see Chapter 33).

Grade IV

In grade IV furcations, the interdental bone is destroyed, and the soft tissues have receded apically so that the furcation opening is clinically visible. A tunnel therefore exists between the roots of such an affected tooth. Thus the periodontal probe passes readily from one aspect of the tooth to another (see Fig. 64.6D).

Key Fact

Despite the valuable information found in the clinical examination, radiographs are essential for a complete and thorough diagnosis of furcation involvement.

Other Classification Indices

Hamp and associates[17] modified a three-stage classification system by attaching a millimeter measurement to separate the extent of horizontal involvement. Easley and Drennan[10] and Tarnow and Fletcher[37] have described classification systems that consider both horizontal and vertical attachment loss in classifying the extent of furcation involvement. The Tarnow and Fletcher article uses a subclassification that measures the probeable vertical depth from the roof of the furca apically. The subclasses being proposed are: A, B, and C. "A" indicates a probeable vertical depth of 1 to 3 mm, "B" indicates 4 to 6 mm, and "C" indicates 7 or more mm of probeable depth from the roof of the furca apically. Furcations would thus be classified as IA, IB, and IC; IIA, IIB, and IIC; and IIIA, IIIB, and IIIC.

Consideration of defect configuration and the vertical component of the defect provides additional information that is useful in planning therapy.

Key Fact

The functions of classification systems are to assist in communication among therapists and to provide a framework for treatment.

Treatment

The objectives of furcation therapy are to (1) facilitate maintenance, (2) prevent further attachment loss, and (3) obliterate the furcation defects as a periodontal maintenance problem. The selection of therapeutic mode varies with the class of furcation involvement, the extent and configuration of bone loss, and other anatomic factors.

Therapeutic Classes of Furcation Defects

Class I: Early Defects

Incipient or early furcation defects (class I) are amenable to conservative periodontal therapy.[15] Because the pocket is suprabony and has not entered the furcation, oral hygiene, scaling, and root planing are effective.[16] Any thick overhanging margins of restorations, facial grooves, or CEPs should be eliminated by odontoplasty, recontouring, or replacement. The resolution of inflammation and subsequent repair of the periodontal ligament and bone are usually sufficient to restore periodontal health.

Class II

Once a horizontal component to the furcation has developed (class II), therapy becomes more complicated. Shallow horizontal involvement without significant vertical bone loss usually responds favorably to localized flap procedures with odontoplasty, osteoplasty, and ostectomy. Isolated deep class II furcations may respond to flap procedures with osteoplasty and odontoplasty (Fig. 64.7). This treatment reduces the dome of the furcation and alters gingival contours to facilitate the patient's plaque removal.

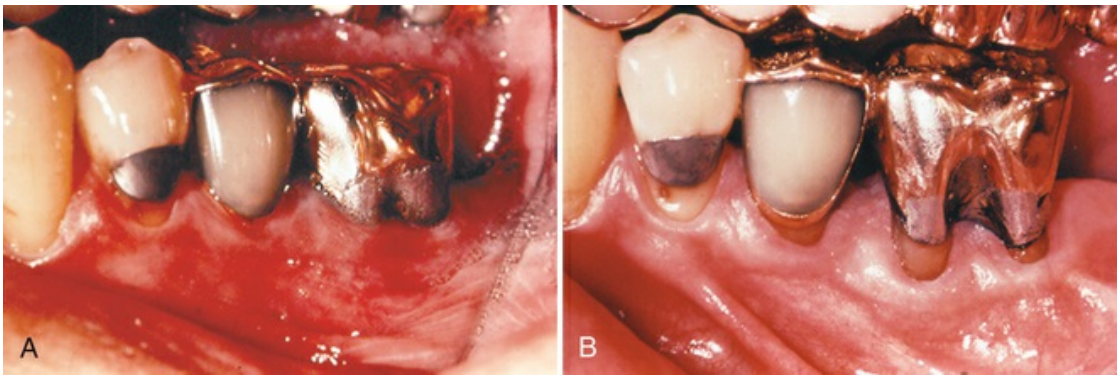

FIG. 64.7 **Treatment of a grade II furcation by osteoplasty and odontoplasty. (A) This mandibular first molar has been treated endodontically and an area of caries in the furcation has been repaired. A class II furcation is present. (B) Results of flap debridement, osteoplasty, and severe odontoplasty 5 years postoperatively. Note the adaptation of the gingiva into the furcation area.** (Courtesy Dr. Ronald Rott, Sacramento, CA.)

Classes II to IV: Advanced Defects

The development of a significant horizontal component to one or more furcations of a multirooted tooth (late class II, class III, or class IV[12]) or the development of a deep vertical component to the furca poses additional problems. Nonsurgical treatment is usually ineffective because the ability to instrument the tooth surfaces adequately is compromised.[31,40] Periodontal surgery, endodontic therapy, and restoration of the tooth may be required to retain the tooth.

Nonsurgical Therapy

Oral Hygiene Procedures

Furcal management is difficult at best. Therapeutic modalities for the treatment and maintenance of furcations have long been a dilemma for periodontists and restorative dentists. Nonsurgical therapy is a very effective way of producing a satisfactory stable result. Ideal results with furcations are impossible to obtain. Once furcation breakdown has begun, the clinical result is always somewhat compromised. Both surgical and nonsurgical therapies have been shown to work effectively over time. Nonsurgical therapy, a combination of oral hygiene instruction and scaling and

root planing, has provided excellent results in some patients. The earlier the furcation is detected and treated, the more likely it will be that a good long-term result can be obtained. Nonetheless, even advanced furcation lesions can have successful long-term treatment.[34] Several oral hygiene procedures have been used over time. All include access to the furcation. Obtaining access to the furcation requires a combination of the awareness of the furcation by the patient and an oral hygiene tool that facilitates that access. Many tools, including rubber tips, periodontal aids, both specific and general toothbrushes, and other aids have been used over time for access to the patient (Fig. 64.8).

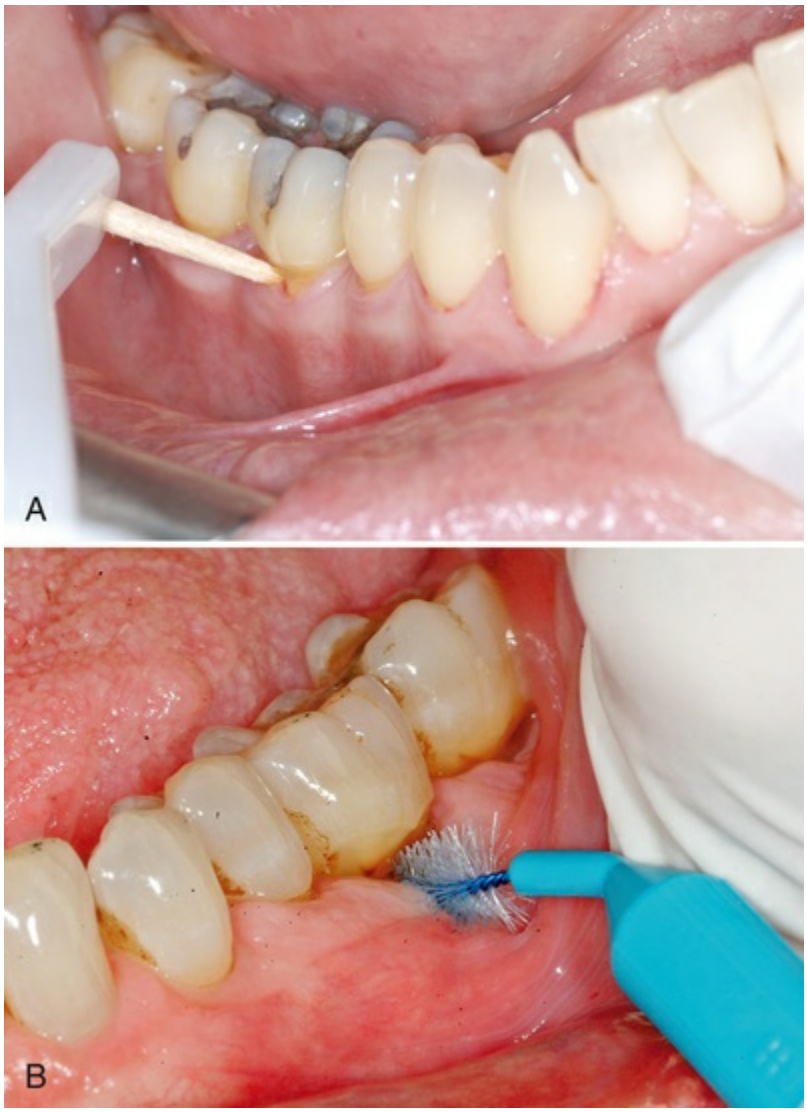

FIG. 64.8 (A) The utilization of a Perio-Aid into the furcation for plaque removal. (B) Proxy brush is used

for plaque removal into the furcation lesion. (Courtesy Karen DeYoung, RDH, and Janet Shigekawa, RDH.)

Scaling and Root Planing

Nonsurgical maintenance by the clinician has also improved over time as instrumentation has improved. In recent decades, instruments beyond simple curettes have been used to instrument the furcation. The frustration of instrumenting the furcation was illustrated beautifully by Bower in 1979 in his articles[5,6] showing that only 58% of furcations could be entered by typically using curettes (see Chapter 35). Subsequently, other instrumentation has evolved, including DeMarco curettes, diamond files, Quétin furcation curettes, and Mini Five Gracey Curettes. See Chapter 50 for a detailed discussion on this subject.

Svärdström and Wennström[34] illustrated that in the long term, furcations could be maintained using nonaggressive techniques over a 10-year period in patients who were participants in consistent maintenance. Other studies also illustrate that maintenance therapy is useful for patients to facilitate furcation cleanliness. Chemotherapy has proven disappointing. Ribeiro and colleagues[32] found that nonsurgical therapy can effectively treat class II furcation involvements, but using povidone-iodine did not provide additional benefits to subgingival instrumentation.

Key Fact

The maintenance of a furcation-involved tooth is difficult and requires special attention and care. This is especially true for Class III and IV cases.

The area most critical in furcation management is maintaining a relatively plaque-free status to the furcation. Attaining access is a problem in this regard, but with the previously mentioned instruments and an effective nonsurgical approach, much can be accomplished. The most critical component of multirooted tooth maintenance is always the successful reduction or elimination of

plaque retention areas from the furcation area; meticulous oral hygiene by the patient and effective nonsurgical therapy can play a major role in attaining this goal.[21,33]

Surgical Therapy

Osseous Resection

Osseous surgical therapy can be divided into resective and regenerative therapy. This also applies to the furcation areas when surgical therapy is contemplated. For many years, osteoplasty and ostectomy have been used to make the furcation areas cleansable. In advanced cases, techniques were used to open the furcation into a class IV from a severe class II or III case. This would allow easier hygiene into the furcation area for the patient. These techniques have limited usefulness today, but in the compromised individual whose teeth cannot be extracted or in whom conservative therapy has failed, these surgical techniques have been used. The immediate goal with these surgical approaches is to create access for the patient to maintain good hygiene.

Regeneration

In furcal lesions, bone regeneration is often thought to be relatively futile. The periodontal literature has well-documented therapeutic efforts designed to induce new attachment and reconstruction on molars with furcation defects. Many surgical procedures using a variety of grafting materials have been tested on teeth with different classes of furcation involvement. Some investigators have reported clinical success,[24] whereas others have suggested that the use of these materials in class II, III, or IV furcations offers little advantage compared with surgical controls.[3,9,30]

Furcation defects with deep two-walled or three-walled components may be suitable for reconstruction procedures. These vertical bony deformities respond favorably to a variety of surgical procedures, including debridement with or without membranes and bone grafts. Chapter 63 addresses therapies designed to induce new attachment or reattachment.

Tsao and associates[39] have shown that the furcation defect is a graftable lesion. They found that lesions that were grafted had greater vertical fill than areas treated with open flap debridement alone. Bowers and colleagues[7] have shown that furcation bone grafting using various membranes can improve the clinical status of these lesions. Nonetheless, bone grafting remains an elusive goal with variable results in furcation lesions.

Another area of interest has been barrier membrane technology. Analysis of published studies demonstrated a great variability in the clinical outcomes in mandibular grade II furcations treated with different types of nonbioabsorbable and bioabsorbable barrier membranes. Although many barrier membrane studies show a slight clinical improvement after treatment in both maxillary and mandibular furcations, the results are generally inconsistent.

Root Resection

Root resection may be indicated in multirooted teeth with grades II to IV furcation involvement. Root resection may be performed on vital teeth[19] or endodontically treated teeth. It is preferable, however, to have endodontic therapy completed before resection of a root or roots.[18] If this is not possible, the pulp should be removed, the patency of the canals determined, and the pulp chamber medicated before resection. It is distressing for both patient and clinician to perform a vital root resection and subsequently have an unfavorable event occur, such as perforation, fracture of the root, or an inability to instrument the canal.

The indications and contraindications for root resection were well summarized by Bassaraba.[1] In general, teeth planned for root resection include the following:

1. Teeth that are critically important to the overall dental treatment plan.[4] Examples are teeth serving as abutments for fixed or removable restorations for which loss of the tooth would result in loss of the prosthesis and entail major prosthetic retreatment.
2. Teeth that have sufficient attachment remaining for function. Molars with advanced bone loss in the interproximal and

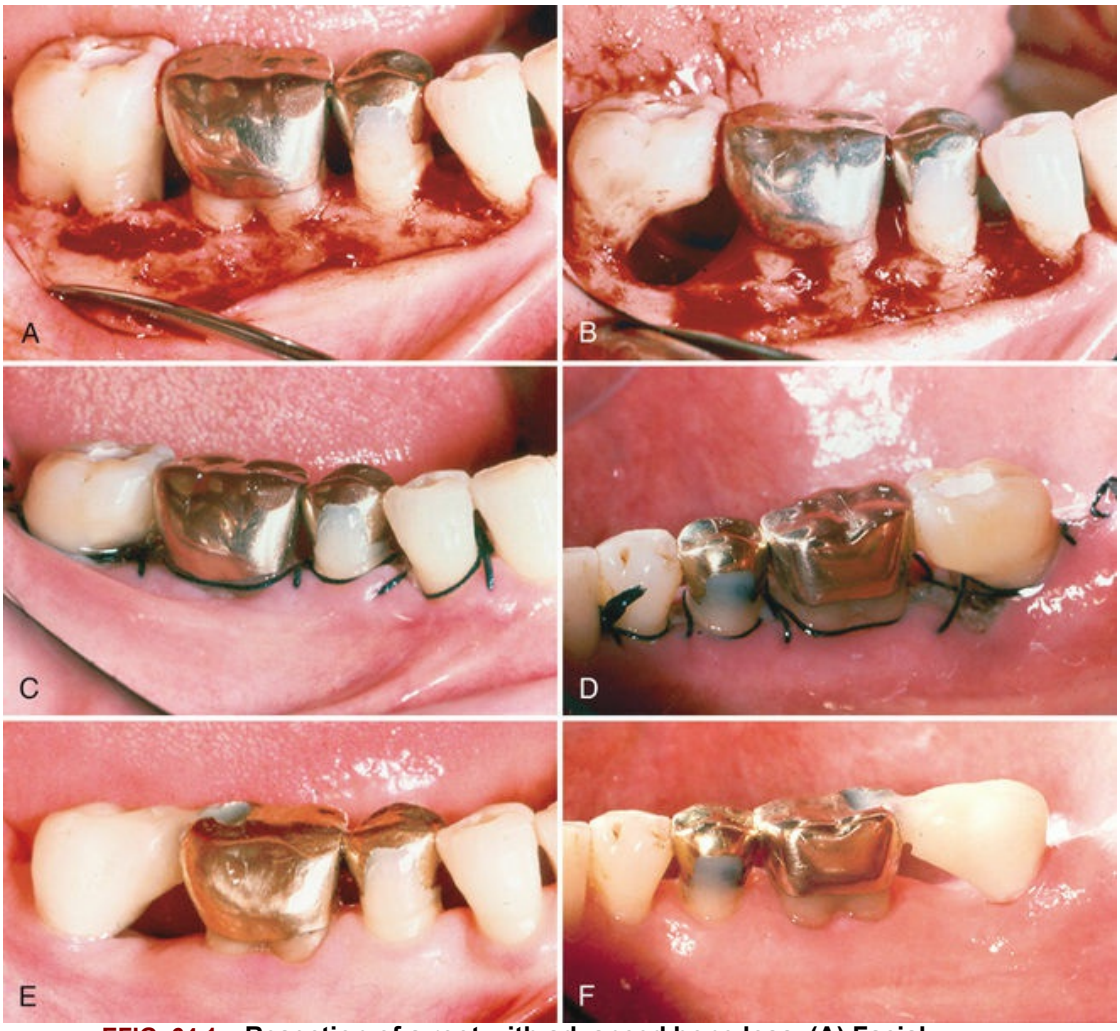
interradicular zones, unless the lesions have three bony walls, are not candidates for root amputation.

3. Teeth for which a more predictable or cost-effective method of therapy is not available. Examples are teeth with furcation defects that have been treated successfully with endodontics but now have a vertical root fracture, advanced bone loss, or caries on the root.
4. Teeth in patients with good oral hygiene and low activity for caries are suitable for root resection. Patients unable or unwilling to perform good oral hygiene and preventive measures are not suitable candidates for root resection or hemisection. Root-resected teeth require endodontic treatment[18] and usually cast restorations.

These therapies can represent a sizable financial investment by the patient in an effort to save the tooth. Alternative therapies and their impact on the overall treatment plan should always be considered and presented to the patient.

Which Root to Remove

A tooth with an isolated furcation defect in an otherwise intact dental segment may present few diagnostic problems. However, the existence of multiple furcation defects of varying severity combined with generalized advanced periodontitis can be a challenge to treatment planning. Careful diagnosis usually allows the therapist to determine the feasibility of root resection and the identification of which root to remove before surgery (eFig. 64.1). Every attempt should be made to determine this before surgical exposure.



EFIG. 64.1 Resection of a root with advanced bone loss. (A) Facial osseous contours. An early grade II furcation is present on the facial aspect of the mandibular first molar, and a class III furcation is present on the mandibular second molar. (B) Resection of the mesial root. The mesial portion of the crown was retained to prevent mesial drift of the distal root during healing. The grade II furcations were treated by osteoplasty. (C) Buccal flaps adapted and sutured. (D) Lingual flaps adapted and sutured. (E) Three-month postoperative view of the buccal aspect of this resection. New restorations were subsequently placed. (F) Three-month postoperative view of the lingual aspect of this resection.

The following is a guide to determining which root should be removed in these cases:

1. Remove the root or roots that will eliminate the furcation and allow the production of a maintainable architecture on the remaining roots.
2. Remove the root with the greatest amount of bone and attachment loss. Sufficient periodontal attachment must remain after surgery for the tooth to withstand the

functional demands placed on it such as bridge abutments and in bruxers. Teeth with uniform advanced horizontal bone loss are not suitable for root resection.

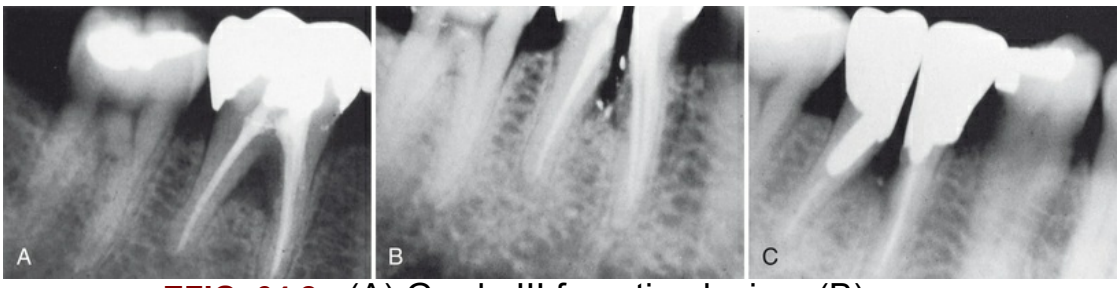
3. Remove the root that best contributes to the elimination of periodontal problems on adjacent teeth. For example, a maxillary first molar with a class III buccal-to-distal furcation is adjacent to a maxillary second molar with a two-walled intrabony defect between the molars and an early class II furcation on the mesial furcation of the second molar. Local anatomic factors affecting the teeth may or may not be present. The removal of the distobuccal root of the first molar allows the elimination of the furcation and management of the two-wall intrabony lesion and also facilitates access for instrumentation and maintenance of the second molar.
4. Remove the root with the greatest number of anatomic problems such as severe curvature, developmental grooves, root flutings, or accessory and multiple root canals.
5. Remove the root that least complicates future periodontal maintenance.

Hemisection

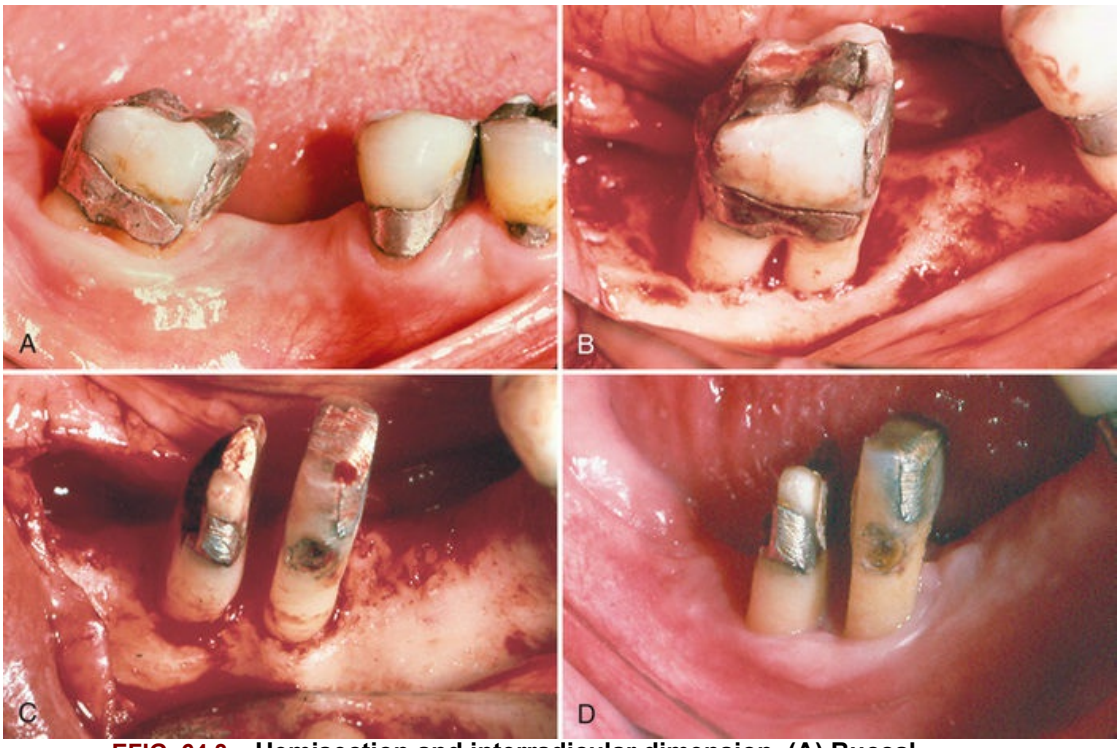
Hemisection is the splitting of a two-rooted tooth into two separate portions. This process has been called bicuspidization or separation because it changes the molar into two separate roots. Hemisection is most likely to be performed on mandibular molars with buccal and lingual class II or III furcation involvements. As with root resection, molars with advanced bone loss in the interproximal and interradicular zones are not good candidates for hemisection. After sectioning of the teeth, one or both roots can be retained. This decision is based on the extent and pattern of bony loss, root trunk and root length, ability to eliminate the osseous defect, and endodontic and restorative considerations. The anatomy of the mesial roots of mandibular molars often leads to their extraction and the retention of the distal root to facilitate both endodontic and restorative therapy.

The interradicular dimension between the two roots of a tooth to

be hemisected is also important. Narrow interradicular zones can complicate the surgical procedure. The retention of both molar roots can complicate the restoration of the tooth because it may be virtually impossible to finish margins or to provide an adequate embrasure between the two roots for effective oral hygiene and maintenance (eFig. 64.2). Therefore, orthodontic separation of the roots is often required to allow restoration with adequate embrasure form (eFig. 64.3). The result can be the need for multiple procedures and extensive interdisciplinary therapy. In these patients the availability of other treatment alternatives should be considered, such as guided tissue or guided bone regeneration or replacement by osseointegrated dental implants.



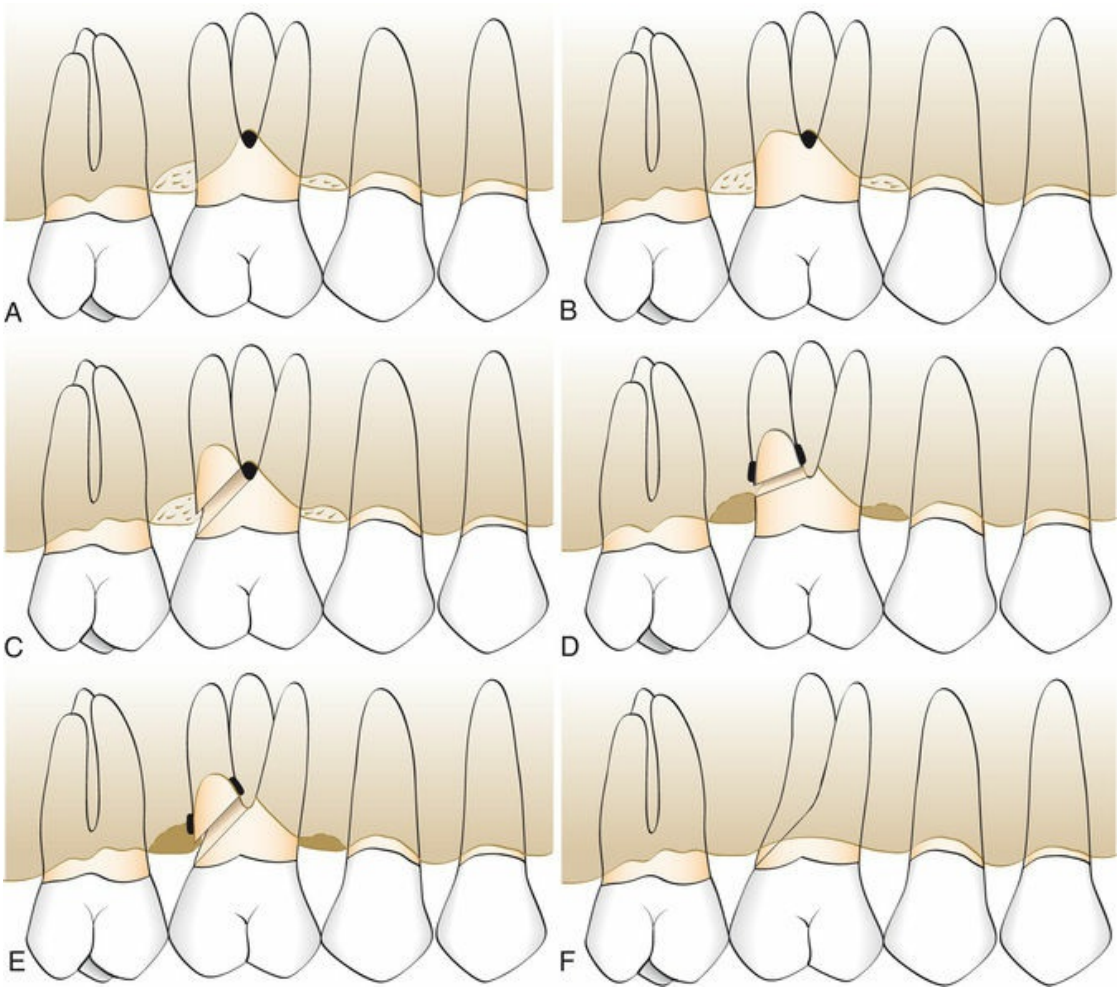
EFIG. 64.2 (A) Grade III furcation lesion. (B) Hemisection to divide the tooth into mesial and distal portions. (C) Postoperative view of a hemisected mandibular molar with new crowns for both roots.



EFIG. 64.3 **Hemisection and interradicular dimension. (A) Buccal preoperative view of a mandibular right second molar with a deep grade II buccal furcation and root approximation. (B) Buccal view of bony lesions with flaps. Note the mesial and distal one-wall bony defects. The lingual furcation was similarly affected. (C) The molar has been hemisected and partially prepared for temporary crowns. Observe the minimal dimension between the two roots. (D) Buccal view 3 weeks postoperatively. Because the embrasure space is minimal, these roots will be separated with orthodontic therapy to facilitate restoration.** (Courtesy Dr. Louis Cuccia, Roseville, CA.)

Root Resection or Hemisection Procedure

The most common root resection involves the distobuccal root of the maxillary first molar,[2,26] as diagrammed in eFig. 64.4. After appropriate local anesthesia, a full-thickness mucoperiosteal flap is elevated. Root resection or hemisection of teeth with advanced attachment loss usually requires opening both facial and lingual-palatal flaps (see Chapter 60). Typically, a root cannot be resected without elevating a flap. The flap should provide adequate access for visualization and instrumentation and minimize surgical trauma.



EFIG. 64.4 **Diagrams of distobuccal root resection of maxillary first molar. (A) Preoperative bony contours with grade II buccal furcation and a crater between the first and second molars. (B) Removal of bone from the facial side of the distobuccal root and exposure of the furcation for instrumentation. (C) Oblique section that separates the distal root from the mesial and palatal roots of the molar. (D) More horizontal section that may be used on a vital root amputation because it exposes less of the pulp of the tooth. (E) Areas of application of instruments to elevate the sectioned root. (F) Final contours of the resection.**

After debridement, resection of the root begins with the exposure of the furcation on the root to be removed (see eFig. 64.4A). The removal of a small amount of facial or palatal bone may be required to provide access for elevation and facilitate root removal (see eFig. 64.4B). A cut is then directed from just apical to the contact point of the tooth, through the tooth, and to the facial and distal orifices of the furcation (see eFig. 64.4C). This cut is made with a high-speed, surgical-length fissure or crosscut fissure carbide bur. The placement of a curved periodontal probe into or through the furcation aids in orienting the angle of the resection. For

hemisection, a vertically oriented cut is made faciolingually through the buccal and lingual developmental grooves of the tooth, through the pulp chamber, and through the furcation. If the sectioning cut passes through a metallic restoration, the metallic portion of the cut should be made before flap elevation. This prevents contamination of the surgical field with metallic particles.

If a vital root resection is to be performed, a more horizontal cut through the root is advisable (see eFig. 64.4D). An oblique cut exposes a large surface area of the radicular pulp and/or dental pulp chamber. This can lead to postoperative pain and can complicate endodontic therapy. A horizontal cut, although it may complicate root removal, has fewer postoperative complications. This root stump can be removed by odontoplasty after the completion of endodontic therapy or at the time of tooth preparation.

After sectioning, the root is elevated from its socket (see eFig. 64.4E). Care should be taken not to traumatize bone on the remaining roots or to damage an adjacent tooth. Removal of the root provides visibility to the furcation aspects of the remaining roots and simplifies the debridement of the furcation with hand, rotary, or ultrasonic instruments. If necessary, odontoplasty is performed to remove portions of the developmental ridges and prepare a furcation that is free of any deformity that would enhance plaque retention or adversely affect plaque removal (see eFig. 64.4F).

Patients with advanced periodontitis often have root resection performed in conjunction with other surgical procedures. eFig. 64.5 provides an example of combining root resection and periodontal osseous surgery. The bony lesions that may be present on adjacent teeth are then treated using resective or regenerative therapies. After resection, the flaps are then approximated to cover any grafted tissues or slightly cover the bony margins around the tooth. Sutures are then placed to maintain the position of the flaps. The area may or may not be covered with a surgical dressing.

EFIG. 64.5 **Hemisection combined with osseous surgery to treat furcation defects. (A) Buccal preoperative view with provisional bridge. (B) Lingual view with provisional bridge in place. (C) Radiograph of bony defects. Note the deep mesial bony defect, largely of one wall, and the radiolucent area in the furcation of the first molar, indicating a grade II defect. (D) Buccal view before osseous surgery. In addition to the furcation involvement, a root separation problem exists between the two roots of the first molar. Class II furcations are present on the second molar. (E) Buccal view after osseous surgery. Mesial root hemisected and removed. The other defects were treated by osteoplasty and ostectomy. (F) Lingual preoperative view. Note the heavy bony ledging at the lingual surface of these first and second molars. (G) Lingual postoperative view. The mesial root has been resected, the bony ledging recontoured, and the grade II furcations treated by osteoplasty. (H) Buccal view 10 years after treatment. (I) Lingual view 10 years after treatment.** (Courtesy Dr. Louis Cuccia, Roseville, CA.)

The removal of a root alters the distribution of occlusal forces on the remaining roots. Therefore, it is wise to evaluate the occlusion of teeth from which roots have been resected and, if necessary, adjust the occlusion. Centric holds should be maintained, but eccentric forces should be eliminated from the area over the root that was removed. Patients with advanced attachment loss may benefit from temporary stabilization of the resected tooth to prevent movement (eFig. 64.6).

EFIG. 64.6 **Mesial root resection in the presence of advanced bone loss. (A) and (B) Buccal and lingual preoperative views. Note the soft tissue contours that are predictive of the bony defects. (C) Radiograph of extent of furcation involvement of the first and second molars. (D) and (E) Buccal preoperative and postoperative views. The mesial root of the second molar was resected and the interproximal craters treated by osteoplasty and minor ostectomy. (F) and (G) Lingual preresection and postresection views. The heavy ledges and horizontal bone loss on the lingual surface were managed by osteoplasty. (H) and (I) Buccal and lingual views 6 weeks postoperatively. A temporary wire splint has been bonded to the molars to prevent tipping of the distal root of the mandibular second molar.** (Courtesy Dr. Louis Cuccia, Roseville, CA.)

Extraction

The extraction of teeth with through-and-through furcation defects (classes III and IV) and advanced attachment loss may be the most appropriate therapy for some patients. This is particularly true for individuals who cannot or will not perform adequate plaque control, who have a high level of caries activity, who will not commit to a suitable maintenance program, or who have socioeconomic factors that may preclude more complex therapies. Some patients are reluctant to accept periodontal surgery or even allow the removal of a tooth with advanced furcation involvement, even though the long-term prognosis is poor. The patient may elect to forego therapy, opt to treat the area with scaling and root planing or site-specific antibacterial therapies, and delay extraction until the

tooth becomes symptomatic. Although additional attachment loss may occur, such teeth may survive a significant number of years.[21,33]

Dental Implants

The advent of osseointegrated dental implants as an alternative abutment source has had a major impact on the retention of teeth with advanced furcation problems. The high level of predictability of osseointegration may motivate the therapist and patient to consider removal of teeth with a guarded or poor prognosis and to seek an implant-supported prosthetic treatment plan. Therefore careful evaluation of the long-term periodontal, endodontic, and restorative prognosis must be considered before invasive surgical therapy is undertaken to save a tooth with an advanced furcated lesion (Fig. 64.9).

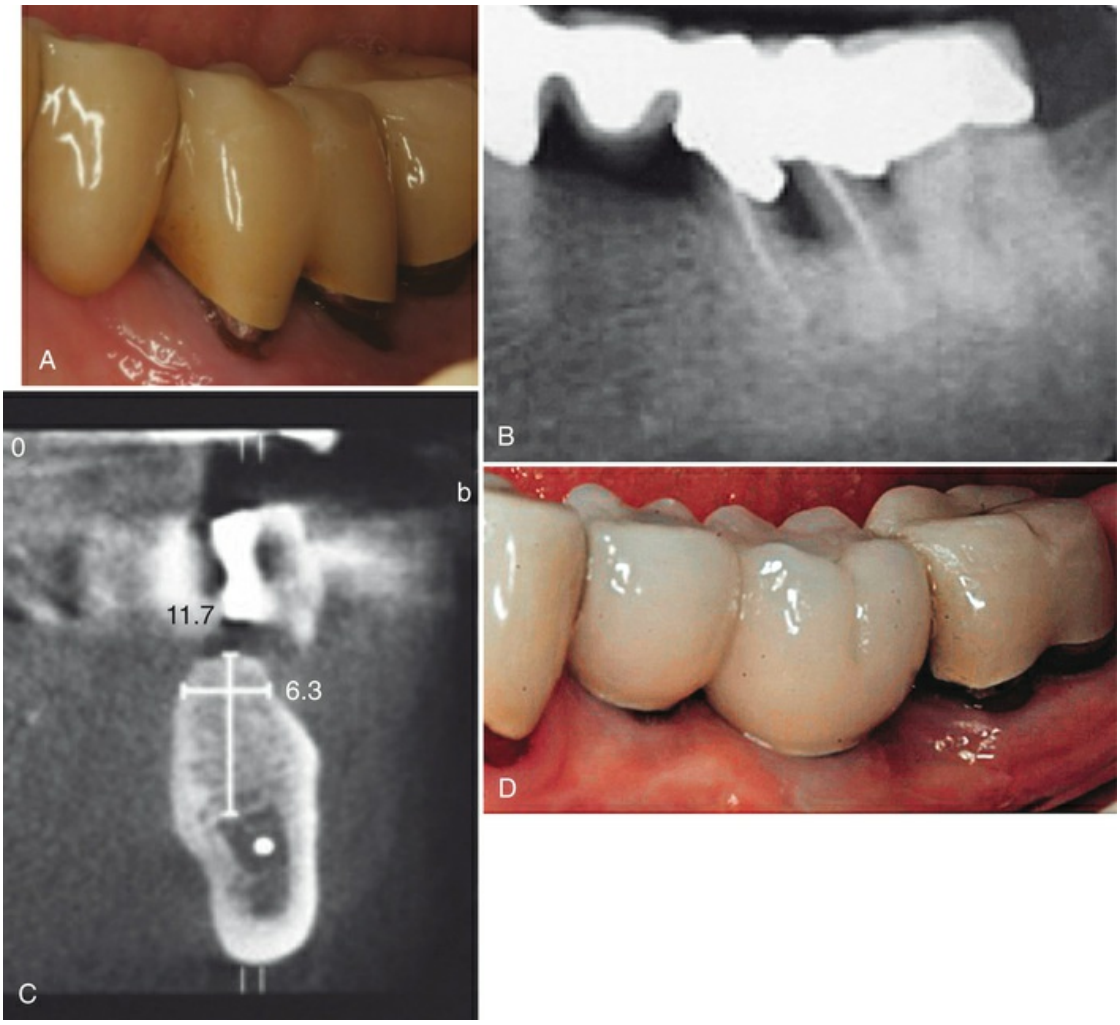


FIG. 64.9 (A) Clinical picture of a class III furcation involvement. (B) Radiographic appearance is far more grave than the clinical appearance. (C) After the tooth is removed, a computed tomography image is taken to plan treatment for implant replacement. (D) The implant restored. (Courtesy Dr. Sarvenaz Angha, Los Angeles, CA.)

Prognosis

For many years the presence of significant furcation involvement meant a hopeless long-term prognosis for the tooth. Clinical research, however, has indicated that furcation problems are not as severe a complication as originally suspected if one can prevent the development of caries in the furcation. Relatively simple periodontal therapy is sufficient to maintain these teeth in function for long periods.[21,33] Other investigators have defined the reasons for clinical failure of root-resected or hemisected teeth.[2,25] Their data indicate that recurrent periodontal disease is not a major cause of the failure of these teeth. Investigations of root-resected or hemisected teeth have shown that such teeth can function successfully for long periods.[2,8,25] The keys to long-term success appear to be (1) thorough diagnosis, (2) selection of patients with good oral hygiene, (3) excellence in nonsurgical therapy, and (4) careful surgical and restorative management.

Case Scenario 64.1

Question: The typical maxillary molar has three furcations. Despite differences in trunk length, which one is typically the most coronal?

A. The mesial
B. The distal
C. The buccal
D. They are all at the same relative position.

Answer: A

Case Scenario 64.2

In Fig. 64.2, the mandibular first molar is hemisected with separate crowns placed on the mesial and distal roots. Both roots have been treated endodontically with posts.

Question: The long-term prognosis for this tooth is questionable and may be lost for the following reason(s):

A. Recurrent periodontal disease
B. Root fracture
C. Root caries
D. Recurrent endodontic failure
E. All of the above

Answer: E

Cause of Marginal Tissue Recession
Factors That Affect Surgical Outcome
Techniques to Increase Attached Gingiva *(e-only)*
Techniques to Deepen the Vestibule *(e-only)*
Techniques to Remove the Frenum *(e-only)*
Techniques to Improve Aesthetics *(e-only)*
Tissue Engineering *(e-only)*
Criteria for Selection of Techniques
Conclusions

Terminology

The term *mucogingival surgery* was initially introduced in the literature by Friedman[38] to describe surgical procedures for the correction of relationships between the gingiva and the oral mucous membrane, with special reference to three problem areas: attached gingiva, shallow vestibules, and a frenum interfering with the marginal gingiva. With the advancement of periodontal surgical techniques, the scope of nonpocket surgical procedures has increased and now encompasses a multitude of areas that were not addressed in the past. Recognizing this, the 1996 World Workshop in Clinical Periodontics renamed mucogingival surgery as *periodontal plastic surgery*,[4] a term originally proposed by Miller in 1993 and broadened to include the following areas[3,4]:

- Periodontal-prosthetic corrections
- Crown lengthening
- Ridge augmentation
- Aesthetic surgical corrections
- Coverage of the denuded root surface
- Reconstruction of papillae
- Aesthetic surgical correction around implants
- Surgical exposure of unerupted teeth for orthodontics

Periodontal plastic surgery is defined as the surgical procedures performed to correct or eliminate anatomic, developmental, or traumatic deformities of the gingiva or alveolar mucosa.[3,4] Mucogingival therapy is a broader term that includes non-surgical procedures such as papilla reconstruction by means of orthodontic or restorative therapy. Periodontal plastic surgery includes only the surgical procedures of mucogingival therapy (Video 65.1).

The periodontal plastic surgical techniques included in the traditional definition of mucogingival surgery are (1) widening of attached gingiva, (2) deepening of shallow vestibules, and (3) resection of the aberrant frena. Aesthetic surgical therapy for

natural dentition and tissue engineering (i.e., biologic mediators) also are addressed in this chapter. Other aspects of periodontal plastic surgery, such as periodontal-prosthetic surgery, aesthetic surgery around implants, and surgical exposure of teeth for orthodontic therapy, are covered in Chapters 56, 69, and 81.

A classification system for periodontal surgery is shown in Fig. 65.1. It indicates the category of periodontal plastic surgery in surgical procedures that are used in periodontal therapy.

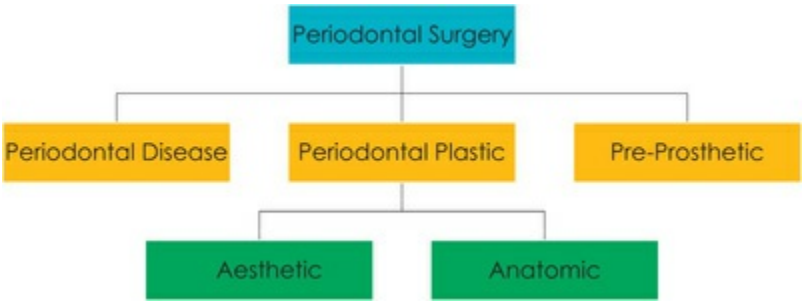

FIG. 65.1 Classification of periodontal surgery.

Objectives

Five objectives of periodontal plastic surgery are addressed in this chapter:

1. Problems associated with attached gingiva
2. Problems associated with a shallow vestibule
3. Problems associated with an aberrant frenum
4. Aesthetic surgical therapy
5. Tissue engineering

Problems Associated With Attached Gingiva

The ultimate goal of mucogingival surgical procedures is the creation or widening of attached gingiva around teeth and implants.[4] The width of the attached gingiva varies in different individuals and on different teeth of the same individual (see Chapter 3). Attached gingiva is not synonymous with keratinized gingiva because the latter also includes the free gingival margin.

The width of the attached gingiva is determined by subtracting the depth of the sulcus or pocket from the distance between the crest of the gingival margin and the mucogingival junction.

The original rationale for mucogingival surgery was predicated on the assumption that a minimal width of attached gingiva was required to maintain optimal gingival health. However, several studies have challenged the view that a wide, attached gingiva is more protective against the accumulation of biofilm than a narrow or a nonexistent zone. No minimal width of attached gingiva has been established as a standard necessary for gingival health. People who practice good, atraumatic oral hygiene can maintain excellent gingival health with almost no attached gingiva.

However, individuals whose oral hygiene practices are less than optimal can be helped by the presence of keratinized gingiva and vestibular depth. Vestibular depth provides space for easier placement of the toothbrush and prevents brushing on mucosal tissue. To improve aesthetics, the objective is the coverage of the denuded root surface. The maxillary anterior area, especially the facial aspect of the canine, often has extensive gingival recession. In these cases, the covering of the denuded root surface widens the zone of attached gingiva and creates an improved aesthetic result. Recession and the resultant denuded root surface have special aesthetic concerns for individuals with a high smile line. A wider zone of attached gingiva is also needed around teeth that serve as abutments for fixed or removable partial dentures and in the ridge areas bearing a denture. Teeth with subgingival restorations and narrow zones of keratinized gingiva have higher gingival inflammation scores than teeth with similar restorations and wide zones of attached gingiva.[96,97] In these cases, techniques for widening the attached gingiva are considered pre-prosthetic periodontal surgical procedures. Chapter 69 discusses this subject in detail.

Widening the attached gingiva accomplishes four objectives:

1. Enhances plaque removal around the gingival margin
2. Improves aesthetics
3. Reduces inflammation around restored teeth
4. Allows gingival margin to bind better around teeth and

implants with attached gingiva

Problems Associated With a Shallow Vestibule

Another objective of periodontal plastic surgery is the creation of vestibular depth when it is lacking. Gingival recession displaces the gingival margin apically, reducing vestibular depth, which is measured from the gingival margin to the bottom of the vestibule. With minimal vestibular depth, proper hygiene procedures are jeopardized. The sulcular brushing technique (i.e., Bass technique) requires placement of the toothbrush at the gingival margin, which may not be possible with reduced vestibular depth.

Minimal attached gingiva with adequate vestibular depth may not require surgical correction if proper atraumatic hygiene is practiced with a soft brush. Minimal amounts of keratinized attached gingiva with no vestibular depth benefit from mucogingival correction. Adequate vestibular depth is also necessary for the proper placement of removable prostheses.

Learning Box 65.1

Gingival recession can be a functional and aesthetic problem, and the biofilm is an oral hygiene problem because recession of the gingival margin reduces the vestibular depth. The proper position of the toothbrush (i.e., Bass technique) at the gingival margin becomes difficult or impossible without the space created by the vestibular depth.

Problems Associated With an Aberrant Frenum

An important objective of periodontal plastic surgery is correction of frenal or muscle attachments that may extend coronal to the mucogingival junction. If adequate keratinized, attached gingiva exists coronal to the frenum, it may not be necessary to remove the frenum. A frenum that encroaches on the margin of the gingiva can

interfere with biofilm removal, and the tension on the frenum tends to open the sulcus. In these cases, surgical removal of the frenum is indicated.

Aesthetic Surgical Therapy

Recession of the facial gingival margin alters the proper gingival symmetry and results in an aesthetic problem. The interdental papilla is also important to satisfy the aesthetic goals of the patient. A missing papilla creates a space that many call a *black hole*. Regeneration of the lost or reduced papilla is one of the most difficult goals in aesthetic periodontal plastic surgery.

Another area of concern is an excessive amount of gingiva in the visible area. This condition is often called as a *gummy smile,* and it can be corrected surgically by crown lengthening. Correction of these anatomic defects has become an important part of periodontal plastic surgery.

Tissue Engineering

The future of periodontal plastic surgery will encompass the use of tissue-engineered products at the recipient site to reduce donor site morbidity. Results of numerous experimental and clinical studies support the clinician's use of a minimally invasive approach to periodontal plastic surgery.

Cause of Marginal Tissue Recession

The most common cause of gingival recession and the loss of attached gingiva is abrasive and traumatic toothbrushing habits. The bone and soft tissue anatomy of the facial, radicular surface of the dentition is usually thin, especially around the anterior area. Teeth positioned facially may have an even thinner bone and gingiva. In many instances, the areas have a complete absence of bone beneath the thin overlying gingival tissue. This defect in the bone is called a *dehiscence.* This anatomic status combined with external trauma from overzealous brushing can lead to the loss of gingival tissue. Recession of the gingival tissue and bone exposes

the cemental surface of the root, which results in abrasion and ditching of the cemental surface apical to the cementoenamel junction (CEJ). The cementum is softer than enamel and is destroyed before the enamel surface of the crown.

Learning Box 65.2

Selection and daily use of the proper type of toothbrush are important. Daily use of a hard, improperly designed toothbrush is a poor instrument for biofilm removal and a principal cause of gingival recession.

Another cause of gingival recession is periodontal disease and chronic marginal inflammation. The loss of attachment caused by the inflammation is followed by the loss of bone and gingiva. Advanced periodontal involvement in areas of minimally attached gingiva results in the base of the pocket extending close to or apical to the mucogingival junction. Periodontal therapy for these areas results in gingival recession caused by the loss of gingiva and bone.

Frenal and muscle attachments that encroach on the marginal gingiva can distend the gingival sulcus, which creates an environment for biofilm accumulation. This condition increases the rate of periodontal recession and contributes to the recurrence of recession, even after treatment (Fig. 65.2). These problems are more common on facial surfaces, but they may also occur on the lingual surface.[11]

FIG. 65.2 **High frenum attachments. (A) Frenum between the maxillary central incisors. (B) Frenum attached to the facial surface of the maxillary lateral incisors. (C) Frenum attached to the facial surface of a mandibular incisor. (D) Frenum attached to the facial surface of an incisor.**

Orthodontic tooth movement through a thin buccal osseous plate may lead to a dehiscence beneath a thin gingiva. This situation can also lead to the recession of the gingival margin[46,117] (Fig. 65.3).

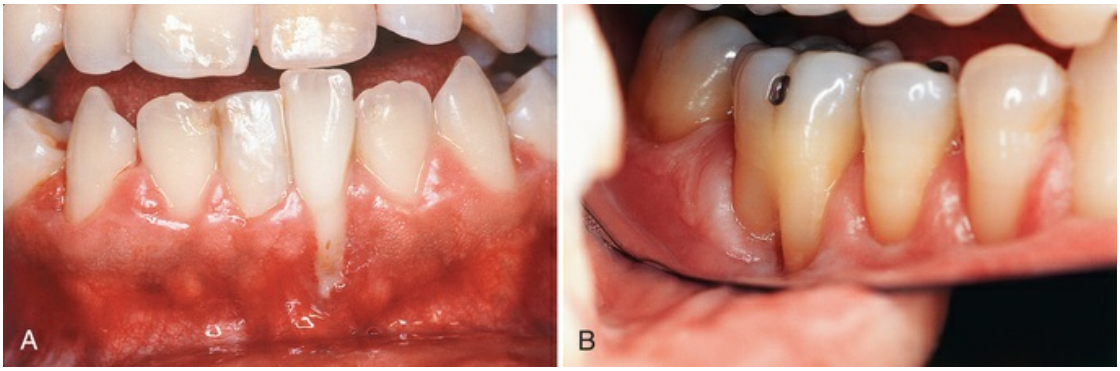

FIG. 65.3 (A) Gingival recession and extreme inflammation around a lower central incisor. (B) Advanced recession of the mesial root of a first lower molar.

Factors That Affect Surgical Outcome

Irregularity of Teeth

Abnormal tooth alignment is an important cause of gingival deformities that require corrective surgery and an important factor in determining the outcome of treatment. Location of the gingival margin, width of the attached gingiva, and alveolar bone height and thickness are affected by tooth alignment. On teeth that are tilted or rotated labially, the labial bony plate is thinner and located further apically than on the adjacent teeth. The gingival margin is recessed apically to follow the bone, which leads to the exposure of the root.[117] On the lingual surface of these teeth, the gingiva is bulbous, and the bone margins are closer to the CEJ. The level of gingival attachment on the root surfaces and the width of the attached gingiva after mucogingival surgery are affected as much by tooth alignment as by variations in treatment procedures.

Orthodontic correction is indicated when mucogingival surgery is performed on malposed teeth in an attempt to widen the attached gingiva or to restore the gingiva over denuded roots. If orthodontic treatment is not feasible, the prominent tooth should be reduced to within the borders of the alveolar bone, with special care taken to avoid pulp injury.

Roots covered with thin bony plates pose a hazard in mucogingival surgery. Even the most minimally invasive flap, such as the partial-thickness flap, creates the risk of bone resorption on the periosteal surface.[49] Resorption in amounts that ordinarily are not significant may cause loss of bone height when the bone plate is thin or tapered at the crest.

Learning Box 65.3

A facially malpositioned tooth and traumatic toothbrushing with a hard-bristled toothbrush are important factors in gingival recession.

Mucogingival Line

Normally, the mucogingival line (i.e., junction) in the incisor and canine areas is located approximately 3 mm apical to the crest of the alveolar bone on the radicular surfaces and 5 mm interdentally.[98] In periodontal disease and on malposed, disease-free teeth, the bone margin is located further apically and may extend beyond the mucogingival line. The distance between the mucogingival line and the CEJ before and after periodontal surgery is not necessarily constant. After inflammation is eliminated, the tissue tends to contract and draw the mucogingival line in the direction of the crown.[31]

Techniques to Increase Attached Gingiva

To simplify and better understand the techniques and the result of the surgery, the following classifications are presented:

- *Gingival augmentation apical to the area of recession.* The donor graft tissue (i.e., pedicle or free) is placed on a recipient bed apical to the recessed gingival margin. No attempt is made to cover the denuded root surface where there is gingival and bone recession.
- *Gingival augmentation coronal to the recession (i.e., root coverage).* The donor graft tissue (i.e., pedicle or free) is placed covering the denuded root surface. Apical and coronal widening of the attached gingiva enhances oral hygiene procedures, but only the latter can correct an aesthetic problem. For pre-prosthetic purposes, the combination of widening keratinized gingiva apical and coronal to the recession can satisfy this objective. Consideration of the objectives as apical

or coronal, or both, provides a better understanding of the techniques required to achieve the goals.

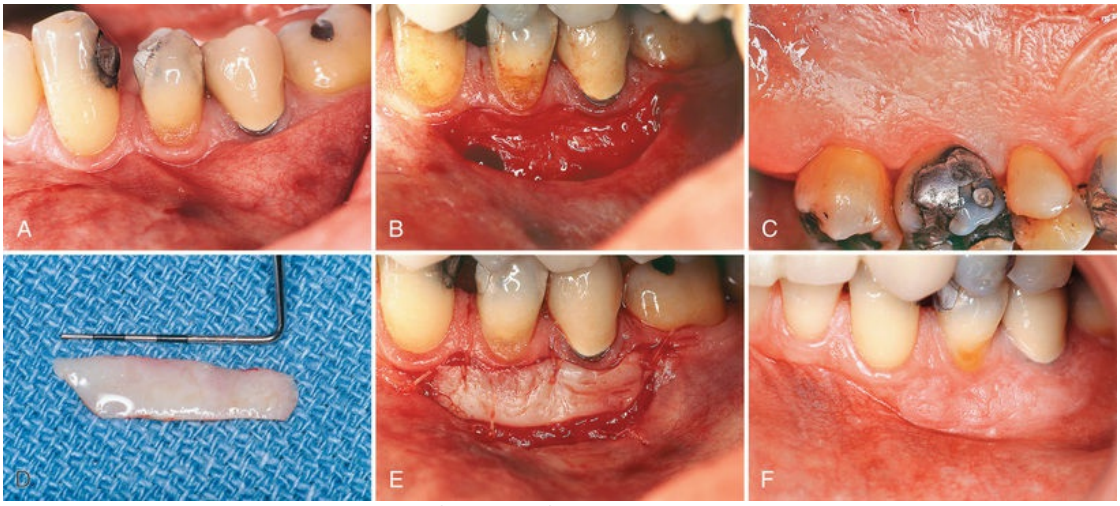
Widening of the keratinized attached gingiva (i.e., apical or coronal to the area of recession) can be accomplished by numerous techniques. The donor graft tissue can be a free gingival autograft, free connective tissue autograft, or a lateral pedicle flap, which can be used for either objective.

Gingival Augmentation Apical to Recession

Techniques for gingival augmentation apical to the area of recession place the free gingival autograft or the free connective tissue autograft in a recipient site created in a area apical to the recession.[10] Another technique is the apically positioned flap, which is possible if there is some keratinized gingiva that can be placed in a more apical position. This is essentially an apical pedicle flap, which is discussed in Chapter 60.

Free Gingival Autografts

Free gingival grafts are used to create a widened zone of attached gingiva. They were initially described by Bjorn[12] in 1963 and have been extensively used since that time (eFig. 65.1).[16]



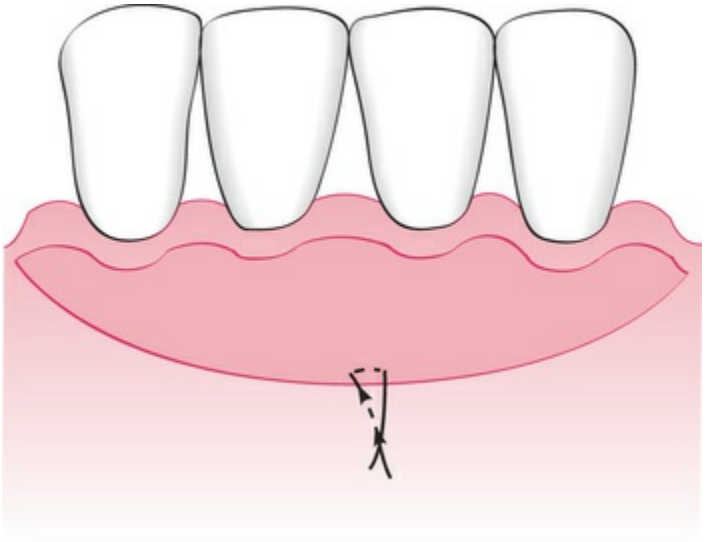
EFIG. 65.1 **Free gingival graft. (A) Before treatment, showing minimal**

keratinized gingiva. (B) Recipient site prepared for a free gingival graft. (C) The palate is the donor site. (D) Free graft. (E) Graft transferred to the recipient site. (F) At 6 months, showing widened zone of attached gingiva. (Courtesy Dr. Perry Klokkevold, Los Angeles, CA.)

The Classic Technique

Step 1: Prepare the recipient site. A firm connective tissue bed is prepared to receive the graft by incising at the existing mucogingival junction with a #15 blade to the desired depth, blending the incision on both ends with the existing mucogingival line. Periosteum should be left covering the bone. Another technique consists of outlining the recipient site with two vertical incisions from the incised gingival margin into the alveolar mucosa. Extend the incisions to approximately twice the desired width of the attached gingiva, allowing for 50% contraction of the graft when healing is complete. The amount of contraction depends on the extent to which the recipient site penetrates the muscle attachments. The deeper the recipient site, the greater is the tendency for the muscles to elevate the graft and reduce the final width of the attached gingiva. The periosteum along the apical border of the graft is sometimes penetrated in an effort to prevent postoperative narrowing of the attached gingiva.

- The #15 blade is used to incise along the gingival margin to separate a flap consisting of epithelium and underlying connective tissue without disturbing the periosteum. Extend the flap to the depth of the vertical incisions. Suture the flap where the apical portion of the free graft will be located. Three to four independent gut sutures are placed. The needle is first passed as a superficial mattress suture perpendicular to the incision and then on the periosteum parallel to the incision (eFig. 65.2).



EFIG. 65.2 Diagram of a graft bed suture.

- A sterile aluminum foil template of the recipient site can be made to be used as a pattern for procuring the graft from the palate.
- Grafts can also be placed directly on bone tissue. For this technique, the flap should be separated by blunt dissection with a periosteal elevator. The advantages of this variant are less postoperative mobility of the graft, less swelling, better hemostasis,[32] and 1.5 to 2 times less shrinkage.[52,53] However, a lag in the healing period is observed for the first 2 weeks.[19,22,36]

Step 2: Obtain the graft from the donor site. The classic or conventional free gingival graft technique consists of transferring a piece of keratinized gingiva approximately the size of the recipient site. To avoid the large wound that this procedure sometimes leaves in the donor site, some alternative methods have been proposed. The original technique is described first, followed by several of the most common variants.

- For the classic technique, a partial-thickness graft is used. The palate is the usual site from which the donor tissue is removed. The graft should consist of epithelium and a thin layer of underlying connective tissue. Place the template over the donor site, and make a shallow incision around it with a

#15 blade. Insert the blade to the desired thickness at one edge of the graft. Elevate the edge, and hold it with tissue forceps. Continue to separate the graft with the blade, lifting it gently as separation progresses to provide visibility. Placing sutures at the margins of the graft helps control it during separation and transfer and simplifies placement and suturing to the recipient site.[10]

- Proper thickness is important for survival of the graft. It should be thin enough to permit diffusion of fluid from the recipient site, which is essential in the immediate posttransplantation period. A graft that is too thin may necrose and expose the recipient site.[75,82] If the graft is too thick, its peripheral layer is jeopardized because of the excessive tissue that separates it from new circulation and nutrients. Thick grafts may also create a deeper wound at the donor site, with the possibility of injuring major palatal arteries.[112] The ideal thickness of a graft is between 1.0 and 1.5 mm.[75,82] After the graft is separated, remove the loose tissue tags from the undersurface. Thin the edge to avoid bulbous marginal and interdental contours. Special precautions must be taken with grafts from the palate.
- The submucosa in the posterior region is thick and fatty and should be trimmed so that it does not interfere with vascularization. Grafts tend to reestablish their original epithelial structure, and mucous glands may occur in grafts obtained from the palate.
- A thick graft can be thinned by holding it between two wet, sterile wooden tongue depressors and slicing it longitudinally with a sharp #15 blade.

Step 3: Transfer and immobilize the graft. Remove the sponge from the recipient site; reapply it with pressure if necessary until bleeding is controlled. Remove the excess clot. A thick clot interferes with vascularization of the graft.[76] Position the

graft, and adapt it firmly to the recipient site. A space between the graft and the underlying tissue (i.e., dead space) impairs vascularization and jeopardizes the graft. Suture the graft at the lateral borders and to the periosteum to secure it in position. The graft must be immobilized. Any movement interferes with healing. Avoid excessive tension, which can distort the graft from the underlying surface. Every precaution should be taken to avoid trauma to the graft. Tissue forceps should be used delicately, and a minimal number of sutures should be used to avoid unnecessary tissue perforation.

Step 4: Protect the donor site. Management of the donor site is important for the comfort of the patient and to properly handle postsurgical hemorrhage. The free gingival donor site is an open wound that cannot be sutured, preventing primary closure of the wound. If there is moderate or slight bleeding after pressure has been applied over the site at the completion of the surgery, several products can be placed over the wound, which can be covered with a periodontal dressing.

- Hemostasis can be achieved with hemostatic agents such as absorbable gelatin sponge (Gelfoam), oxidized cellulose (Oxycel), oxidized regenerated cellulose (Surgicel Absorbable Hemostat), and microfibrillar collagen hemostat (Avitene, CollaCote, CollaTape, or CollaPlug). All are useful hemostatic agents for the control of bleeding from capillaries and small blood vessels.
- A sterile aluminum foil is placed over the wound before the periodontal dressing is used to cover the wound for 1 week and is repeated if necessary. Retention of the dressing on the donor site can be a problem. The dressing can be retained by locking it through the interproximal spaces onto the palatal surface. If there are no open interdental spaces, the dressing can be covered by a plastic stent wired to the teeth. A modified Hawley retainer should be prepared if the donor site wound is expected to be

large. It is useful to cover the wound on the palate and over edentulous ridges. It is important that the patient is not dismissed from the office until the bleeding is completely under control.

Learning Box e65.1

The donor site for a free gingival graft is an open wound that cannot be sutured and for which primary closure is not possible. Primary closure of the donor site can be achieved with a connective tissue graft, making donor site wound management less traumatic for the patient.

Variant Techniques

The free gingival graft technique is a predictable procedure, but the donor site (i.e., palate) is left with an open wound that must heal by secondary intention. The following variant techniques attempt to minimize the donor site wound by removing the donor tissue in a different configuration and altering the shape to maximize coverage over the recipient site. The accordion technique, the strip technique, and the combination epithelial-connective tissue strip technique are modifications of the free gingival graft.

The accordion technique, described by Rateitschak and colleagues,[88] attains expansion of the graft by alternate incisions on opposite sides of the graft. This technique increases the donor graft by changing the configuration of the tissue.

The strip technique, developed by Han and associates,[48] consists of obtaining two or three strips of gingival donor tissue about 3 to 5 mm wide and long enough to cover the entire length of the recipient site (eFig. 65.3). These strips are placed side by side to form one donor tissue and sutured on the recipient site. The area is then covered with sterile aluminum foil and surgical dressing. The aluminum foil prevents the surgical dressing from sticking to the suture. The advantage of this technique is rapid healing of the donor site. The epithelial migration of the close wound edges (3 to 5 mm) allows rapid epithelialization of the open wound. The donor site usually does not require suturing and heals uneventfully in 1 to

2 weeks.

EFIG. 65.3 Strip technique for a free gingival graft:. (A through D) Mucosal tissue around the implants. (E and F) Recipient site is prepared. (G) Donor site with strips of free graft removed. Notice the good keratinized, attached gingiva. (Courtesy Dr. T. Han and Dr. P. Klokkevold, Los Angeles, CA.)

A variant of the strip technique is the combination graft. A deep strip graft is taken from the palate and is split into an epithelial donor graft and the undersurface portion of a connective tissue donor graft. The tissue is obtained by removing a strip of tissue from the palate that is about 3 to 4 mm thick. Place it between two wet tongue depressors, and split it longitudinally with a sharp #15 blade. Both are used as free grafts. The superficial portion consists of epithelium and connective tissue, and the deeper portion consists only of connective tissue. These donor tissues are placed on the

recipient site as in the strip technique. The minimal donor site wound obtained by two donor tissues from one site is the advantage of this technique.

Alternative Donor Tissue

Another technique to minimize the use of the palate as a donor site is the use of acellular dermal matrix (ADM) as a substitute for palatal donor tissue. The use of the palate as a donor site for gingival augmentation has numerous disadvantages. Many patients are fearful of palatal surgery for procurement of donor, and there is a limitation on the amount of tissue that can be removed.

Numerous clinicians advocate the use of ADM as a substitute for palatal donor tissue (see Tissue Engineering). This product is commercially available under the name AlloDerm, and it is derived from donated human skin.[1] Commercial preparation of this tissue includes a multistep process that removes the epidermis and the cells that can lead to tissue rejection and graft failure without damaging the matrix. The remaining ADM consists of a nondenatured, three-dimensional arrangement of intact collagen fibers, ground substance, and vascular channels.[29] Randomized, controlled clinical trials have demonstrated outcomes with ADM that are equivalent to those with palatal donor tissue in the treatment of gingival recession.[1,29,40,79,81,103] Equivalent root coverage has been demonstrated in four trials,[1,79,1,103] and an increase in marginal tissue thickness has been demonstrated at 6 and 12 months postoperatively by clinical assessment and by histometric analysis.[1,29,81] Equivalent attachment to the root surface has been found by histologic evaluation of human block sections at 6 months postoperatively.[29]

In addition to avoiding palatal donor surgery, ADM offers the advantage of availability of unlimited donor tissue for the treatment of multiple teeth in a single surgical appointment.

Surgical Techniques.

Two surgical techniques are suggested for the use of ADM in treating gingival recession. Each is a coronally positioned pouch method. The first is the alternate papilla tunnel (APT) method, and the second is the papilla retention pouch (PRP) method (eFig. 65.4).

A

F

EFIG. 65.4 (A) Preoperative view. (B) Intrasulcular incision. (C) AlloDerm on the surface before insertion into the pouch. (D) AlloDerm sutured in the pouch. (E) Pouch coronally positioned and sutured. (F) Postoperative view after 1 month. (G) Postoperative view after 1 year.

In the APT method, an incision is made in a papilla adjacent to a tooth with recession, and the adjacent papilla is tunneled. The next papilla is incised, and the following papilla is tunneled. Intrasulcular incisions are made facial to each tooth and interproximally at each tunneled papilla. The papilla in the anatomic midline is always tunneled to reduce tension and retraction of the recipient pouch. At each incised papilla, a V-shaped incision (or inverted V shape in the mandibular arch) is made to form a new surgical papilla tip approximately 3 mm from the anatomic papilla tip. The portion of the anatomic papilla coronal to the surgical papilla is denuded to expose a vascular recipient bed for the surgical papilla when coronally advanced. The initial dissection is performed with a microperiosteal elevator, extending apically past the mucogingival junction and laterally under the facial aspect of the tunneled papillae. The tunneling process is facilitated by the access provided at the incised papillae. The tunneled papillae are lifted from the interdental crest by blunt reflection with a curette. After blunt reflection, supraperiosteal sharp dissection is used to deepen and mobilize the recipient pouch.

On completion of the recipient site preparation, the length of

graft needed is measured and trimmed so that the graft will extend 3 mm past the last tooth with recession at each end of the prepared site. The vertical dimension of the graft should be 6 to 8 mm. The rehydrated and trimmed allograft is then placed into the surgical pouch, with the basement membrane surface facing outward, and secured coronally with 6-0 sling sutures. The graft should be well adapted to the root surface, extending to but not coronal to the CEJ and to the apical margin, but it should not be over the papillary recipient beds. The pouch is then coronally advanced to completely cover the allograft and secured with 6-0 or 7-0 sling sutures. The APT method combines the advantages of surgical access at the incised papillae with retraction resistance and wound stability at the tunneled papillae.

In the PRP method, all papillae are tunneled. Initially, intrasulcular incisions are made facial and proximal to all teeth to be treated plus an additional tooth at each end. The full-thickness elevation of the margin is initiated with a microperiosteal elevator extending apically past the mucogingival junction and laterally under the facial aspect of the papillae. The pouch is extended apically and mobilized by supraperiosteal sharp dissection, and the papillae are lifted from the interdental crest as in the APT method. The allograft is rehydrated, measured, and trimmed. Placement of the allograft within the pouch may be accomplished by drawing it in with a suture or placing it through the sulcus with a curette so that it is aligned within the pouch over the exposed roots.

The unique feature of the PRP method is suturing of the allograft with a continuous subgingival, double-back sling suture. Starting at the anterior end of the graft, the needle of a 6-0 suture is passed from the lingual side through the mesial embrasure and captured on the facial side. The allograft is engaged at the mesial line angle of the tooth; the needle is passed back through the mesial embrasure to the lingual side, around the lingual aspect toward the distal side, through the distal embrasure back to the facial aspect, and crosses under the papilla to engage the allograft at the mesial line angle of the next tooth. This process continues until the needle has engaged the graft at the mesial line angle of the most distal tooth. At this point, the needle is passed through the mesial embrasure, around the lingual aspect, and back to the facial aspect through the distal

embrasure, and the graft is engaged at the distal line angle. The needle is then passed back through the distal embrasure, around the lingual aspect, through the mesial embrasure to the facial, and under the papilla to engage the allograft at the distal line angle of the adjacent tooth. This process continues until passing through the distal embrasure of the initial tooth, in which the suture is tied with the knot on the lingual side. The entire suture resides subgingivally and draws the graft and the pouch coronally. The PRP procedure is completed by coronally advancing the pouch over the allograft with a series of interrupted 6-0 or 7-0 sling sutures.

Advantages of the PRP method include enhanced retraction resistance, graft containment, and wound stability. Postoperative care is similar for both methods and includes the following:

1. Systemic antibiotics for 10 days
2. Chlorhexidine mouthrinse for 2 to 3 weeks
3. Pain medication as needed
4. Inactivity for 24 hours
5. Ice applied to face for 24 hours
6. Cold liquids for the first three meals
7. No mastication or toothbrushing at the surgical site for 2 to 3 weeks
8. Removal of surface sutures at 2 to 4 weeks
9. Removal of the subgingival graft suture at 2 months

Developed 2 decades ago, ADM is a safe and effective biomaterial for use as a substitute for palatal connective tissue in root coverage grafting. There have been no reports of disease transmission in medical or dental applications during this period. ADM has proven equivalence to palatal connective tissue for root coverage procedures in randomized, controlled clinical trials. It produces a thicker marginal tissue and has a higher percentage of root coverage than a coronally advanced flap alone.[116] It provides advantages over palatal connective tissue in that it does not require a second surgical site to obtain donor tissue and provides an unlimited amount of tissue to treat multiple teeth in one appointment. The use of AlloDerm under a coronally advanced flap extends the application of the most aesthetic procedure in root

coverage. ADM and other techniques to avoid palatal donor site morbidity involve the use of biologic mediators, which are discussed later in this chapter.

Healing of the Graft

The success of the graft depends on survival of the connective tissue. Sloughing of the epithelium occurs in most cases, but the extent to which the connective tissue withstands the transfer to the new location determines the fate of the graft. Fibrous organization of the interface between the graft and the recipient bed occurs in 2 to several days.[95]

The graft is initially maintained by diffusion of fluid from the host bed, adjacent gingiva, and alveolar mucosa.[41] The fluid is a transudate from the host vessels and provides nutrition and hydration essential for the initial survival of the transplanted tissues. During the first day, the connective tissue becomes edematous and disorganized and undergoes degeneration and lysis of some of its elements. As healing progresses, the edema is resolved, and degenerated connective tissue is replaced by new granulation tissue.

Revascularization of the graft starts by the second[6] or third[44] day. Capillaries from the recipient bed proliferate into the graft to form a network of new capillaries and anastomose with preexisting vessels.[54] Many of the graft vessels degenerate and are replaced by new ones, and some of them participate in the new circulation. The central section of the surface is the last to vascularize, but it is complete by the tenth day.

The epithelium undergoes degeneration and sloughing, with complete necrosis occurring in some areas.[20,80] It is replaced by new epithelium from the borders of the recipient site. A thin layer of new epithelium is present by the fourth day, with rete pegs developing by the seventh day. Heterotopically placed grafts maintain their structure (i.e., keratinized epithelium), even after the grafted epithelium has become necrotic and has been replaced by neighboring areas of nonkeratinized epithelium. This suggests that a genetic predetermination of the specific character of the oral mucosa exists that depends on stimuli originating in the connective tissue.[55] This is the basis for the technique that uses grafts composed

only of connective tissue obtained from areas in which it is covered by keratinized epithelium.[17,30,36]

As seen microscopically, healing of a graft of intermediate thickness (0.75 mm) is complete by 10.5 weeks; thicker grafts (1.75 mm) may require 16 weeks or longer.[43] The gross appearance of the graft reflects the tissue changes within it. At transplantation, the graft vessels are empty, and the graft is pale. The pallor changes to an ischemic grayish white during the first 2 days, until vascularization begins, and a pink color appears. The plasmatic circulation accumulates and causes softening and swelling of the graft, which are reduced when the edema is removed from the recipient site by the new blood vessels. Loss of epithelium leaves the graft smooth and shiny. New epithelium creates a thin, gray, veil-like surface that develops normal features as the epithelium matures.

Functional integration of the graft occurs by the 17th day, but the graft is morphologically distinguishable from the surrounding tissue for months. The graft eventually blends with adjacent tissues. In some cases, it is somewhat bulbous although the tissue is pink, firm, and healthy. This usually does not present a problem, but if the graft traps biofilm or is aesthetically unacceptable, thinning of the graft may be necessary. Thinning the surface of the grafted tissue reduces the bulbous condition because the surface epithelium tends to proliferate again. The graft should be thinned by making the necessary incisions to elevate it from the periosteum, removing tissue from its undersurface, and suturing it back in place.

Accomplishments

Free gingival grafts effectively widen the attached gingiva. Several biometric studies have analyzed the width of the attached gingiva after the placement of a free gingival graft.[18,49,52] After 24 weeks, grafts placed on denuded bone shrink by 25%, whereas grafts placed on periosteum shrink by 50%.[62] The greatest amount of shrinkage occurs in the first 6 weeks.

Placement of a gingival graft does not improve the status of the gingiva.[34,35,108] The indication for a free gingival graft should be based on progressive gingival recession and inflammation. When recession continues to progress after a few months with good

biofilm control, a graft can be placed to prevent further recession and loss of attached gingiva.

Other materials have been used as a donor tissue to replace gingival tissue in gingival augmentation procedures. Attempts with lyophilized dura mater[93] and sclera have not been satisfactory. The use of irradiated free gingival allograft showed satisfactory results,[91] but further research is necessary before it can be considered for clinical use.

Free autogenous gingival grafts have been useful for covering nonpathologic dehiscences and fenestrations. *Nonpathologic* refers to openings of the bone through the tooth surface not previously exposed to the oral environment and found in the course of flap surgery.[33]

The use of free gingival autografts to cover denuded roots is described later in this chapter (see later discussion).

Free Connective Tissue Autografts

The connective tissue autograft technique was originally described by Edel[36] and is based on the fact that the connective tissue carries the genetic message for the overlying epithelium to become keratinized. Only connective tissue from beneath a keratinized zone can be used as a graft (eFig. 65.5).

EFIG. 65.5 **Free connective tissue graft. (A) Lack of keratinized, attached gingiva buccal to the central incisor. (B) Vertical incisions to prepare the recipient site. (C) Recipient site is prepared. (D) Palate from which connective tissue is removed for donor tissue. (E) Removal of connective tissue. (F) Donor site is sutured. (G) Connective tissue for the graft. (H) Free connective tissue is placed at the donor site. (I) Postoperative healing at 10 days. (J) Final healing at 3 months. Notice the wide, keratinized, attached gingiva.** (Courtesy Dr. M. Orisini, Italy.)

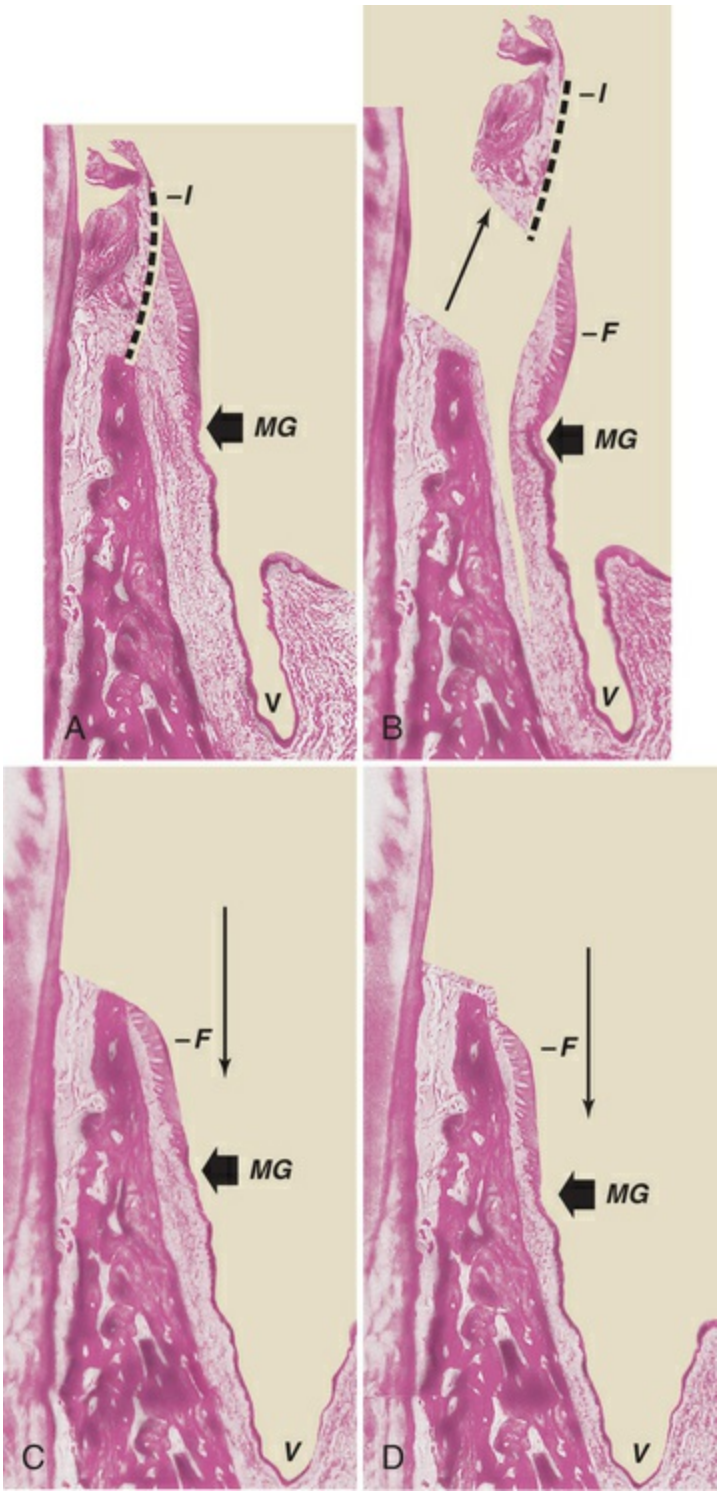
The advantage of this technique is that the donor tissue is obtained from the undersurface of the palatal flap, which is sutured back in primary closure. Healing is by first intention. The patient has less discomfort postoperatively at the donor site. Another advantage of the free connective tissue autograft is that improved aesthetics can be achieved because of a better color match of the grafted tissue to the adjacent areas.

Learning Box e65.2

The connective tissue autograft is unique because the connective tissue carries the genetic instructions for keratinization of the overlying epithelium. The autograft also allows the graft site to be sutured, enabling primary closure of the wound.

Apically Displaced Flap

This technique uses a partial-thickness or full-thickness, apically positioned flap to increase the zone of keratinized gingiva. Chapter 60 provides a step-by-step description of the surgical technique for apically displaced flaps, and eFig. 65.6 illustrates the procedure.



EFIG. 65.6 Apically displaced partial-thickness flap. (A) Internal bevel incision *(I)* separates the inner wall of the periodontal pocket. (B) Partial-thickness flap *(F)* is separated, leaving periosteum and a layer of connective tissue on the bone. The inner wall of the periodontal pocket *(I)* is removed, and the tooth is scaled and planed. (C) Partial-thickness flap *(F)* is displaced apically, with the edge of the flap at the crest

of the bone. The vestibular fornix is also moved apically. (D) Partial-thickness flap *(F)* is displaced apically, with the edge of the flap several millimeters below the crest of the bone. *MG,* Mucogingival junction; *V,* vestibular fornix.

Accomplishments

The apically displaced flap technique increases the width of the keratinized gingiva but cannot predictably deepen the vestibule with attached gingiva. Adequate vestibular depth must be present before the surgery to allow apical positioning of the flap. The edge of the flap may be located in three positions in relation to the bone:

1. *Slightly coronal to the crest of the bone.* This location attempts to preserve the attachment of supracrestal fibers; it may also result in thick gingival margins and interdental papillae with deep sulci and may create the risk of recurrent pockets.
2. *At the level of the crest* (see eFig. 65.6C). This results in a satisfactory gingival contour, provided that the flap is adequately thinned.
3. *Two millimeters short of the crest* (see eFig. 65.6D). This position produces the most desirable gingival contour and the same posttreatment level of gingival attachment as obtained by placing the flap at the crest of the bone.[39] New tissue covers the crest of the bone to produce a firm, tapered gingival margin.

Placing the flap short of the crest increases the risk of a slight reduction in bone height,[28] but the advantage of a well-formed gingival margin compensates for this.

Other Techniques

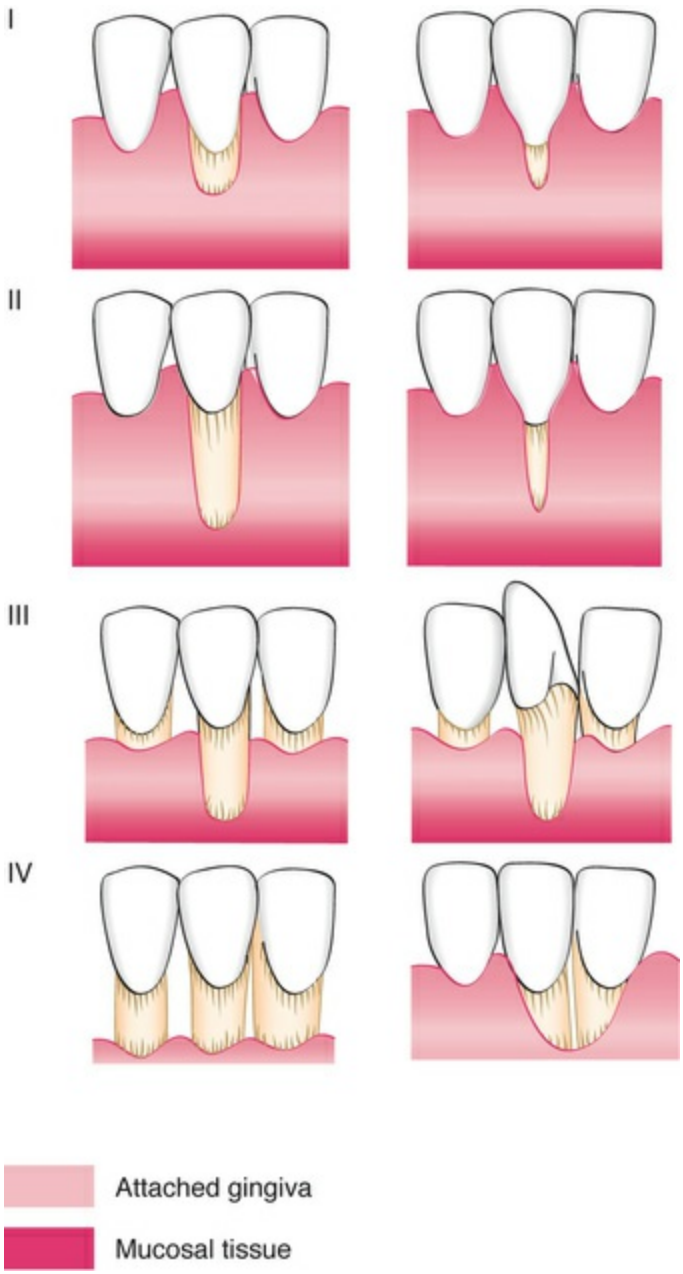
The vestibular extension technique, originally described by Edlan and Mejchar,[37] produced statistically significant widening of attached nonkeratinized tissue. The increase in width in the mandibular area reportedly persisted in patients observed for up to 5 years.[37,92,110] Currently, this technique is of historic interest only.

The fenestration operation was designed to widen the zone of attached gingiva with a minimal loss of bone height.[89,90] It has also been called the *periosteal separation technique*.[26] It uses a partial-thickness flap, except in a rectangular area at the base of the surgical field, where the periosteum is removed, exposing the bone. This is the area of fenestration. Its purpose is to create a scar that is firmly bound to the bone.[23] It prevents soft tissue separation from the bone and postsurgical narrowing of the attached zone. Results obtained with this technique are not as predictable as with the free gingival graft, and it is therefore not widely performed, except for small isolated areas.

Gingival Augmentation Coronal to Recession

Understanding the different stages and conditions of gingival recession is necessary for predictable root coverage. Several classifications of denuded roots have been proposed. In the 1960s, Sullivan and Atkins[100] classified gingival recession as four anatomic categories: (1) shallow-narrow, (2) shallow-wide, (3) deep-narrow, and (4) deep-wide. This early classification helped to categorize the lesion but did not enable the clinician to predict the outcome of therapy.

The predictability of root coverage can be enhanced by the presurgical examination and the correlation of the recession by using the classification proposed by Miller,[73] as follows (eFig. 65.7):



EFIG. 65.7 P.D. Miller's classification of denuded roots.

Class I. Marginal tissue recession does not extend to the mucogingival junction. There is no loss of bone or soft tissue in the interdental area. This type of recession can be narrow or wide.

Class II. Marginal tissue recession extends to or apical to the mucogingival junction. There is no loss of bone or soft tissue in the interdental area. This type of recession can be subclassified as wide and narrow.

Class III. Marginal tissue recession extends to or apical to the mucogingival junction. There is bone and soft tissue loss interdentally or malpositioning of the tooth facially.
Class IV. Marginal tissue recession extends to or apical to the mucogingival junction. There is severe bone and soft tissue loss interdentally or severe tooth malposition.

The prognoses for classes I and II are good to excellent; whereas for class III, only partial coverage can be expected. Class IV has a very poor prognosis with current techniques.

Several techniques are used for gingival augmentation coronal to recession (i.e., root coverage):

1. Free gingival autograft
2. Free connective tissue autograft
3. Pedicle autografts
    - Laterally (horizontally) positioned pedicle flap
    - Coronally positioned flap; includes semilunar pedicle (i.e., Tarnow method)
4. Subepithelial connective tissue graft (i.e., Langer method)
5. Guided tissue regeneration (GTR)
6. Pouch and tunnel technique (i.e., coronally advanced tunnel technique)

Some of the techniques used for widening the attached gingiva apical to the area of recession can also be used for root coverage. The free gingival graft and the connective tissue autograft used for apical widening can be used for coronal augmentation by incorporating some modifications. In using the free grafts for root coverage, the recipient bed surrounding the denuded root surface must be extended wider to allow for better blood supply to the donor free graft. This is necessary because a portion of the donor tissue overlies the root surface, which does not have blood supply.

Learning Box e65.3

The Miller classification allows the clinician to predict the outcome

of root coverage by evaluating the height of the interdental bone and gingiva adjacent to the tooth with recession.

Free Gingival Autograft

Successful and predictable root coverage has been reported using free gingival autografts.[72,74]

The Classic Technique

Miller[74] applied the classic free gingival autograft described previously with a few modifications:

Step 1: Root planing. Root planing is performed with the application of saturated citric acid for 5 minutes on the root surface. The application of citric acid has not been validated by some studies,[42] but numerous clinicians practice this technique.

Step 2: Recipient site preparation. Make a horizontal incision in the interdental papillae at right angles to create a margin against which the graft can have a butt joint with the incision. Vertical incisions are made at the proximal line angles of adjacent teeth, and the retracted tissue is excised. Maintain an intact periosteum in the apical area.

Steps 3 and 4. Follow the step-by-step technique described for the classic gingival graft earlier in this chapter. This technique results in predictable coverage of the denuded root surface but may cause aesthetic color discrepancies with the adjacent gingiva because of a lighter color.

Free Connective Tissue Autograft

The free connective tissue technique was described by Levine in 1991.[58] The difference between this technique and the free gingival autograft is that the donor tissue is connective tissue (see eFig. 65.5). The following is a step-by-step surgical description of the free connective tissue autograft technique:

Step 1: Divergent vertical incisions. Divergent vertical incisions are made at the line angles of the tooth to be covered,

creating a partial-thickness flap to at least 5 mm apical to the receded area.

Step 2: Suturing. The apical mucosal border is sutured to the periosteum using a gut suture.

Step 3: Scaling and root planing. Thoroughly scale and root plane the exposed root surface. The facial prominence on the root surface is also reduced, which is a favorable anatomy onto which the donor tissue is placed.

Step 4: Obtaining the graft. From the palate, obtain a connective tissue graft. The donor site is sutured after the graft is removed.

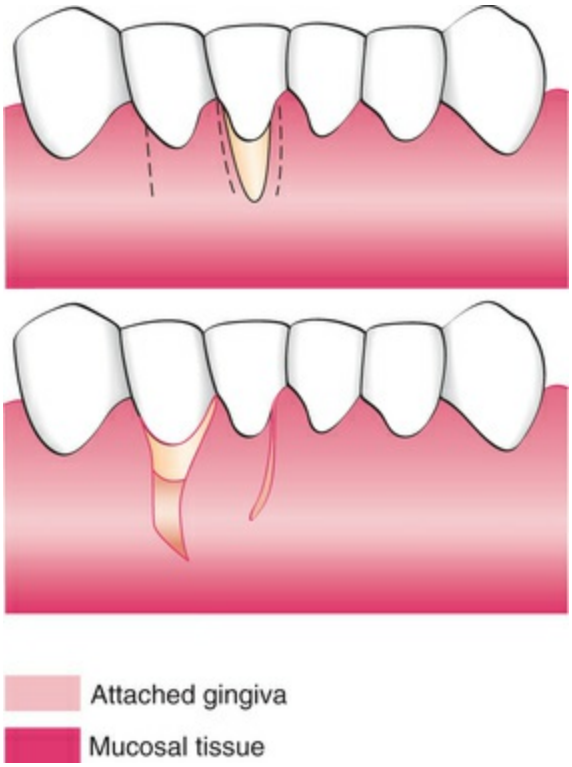
Step 5: Transferring the graft. Transfer the graft to the recipient site, and suture it to the periosteum with a gut suture. Good stability of the graft must be attained with the minimal number of sutures.

Step 6: Covering the graft. The grafted site should be covered with sterile foil before placing the dressing.

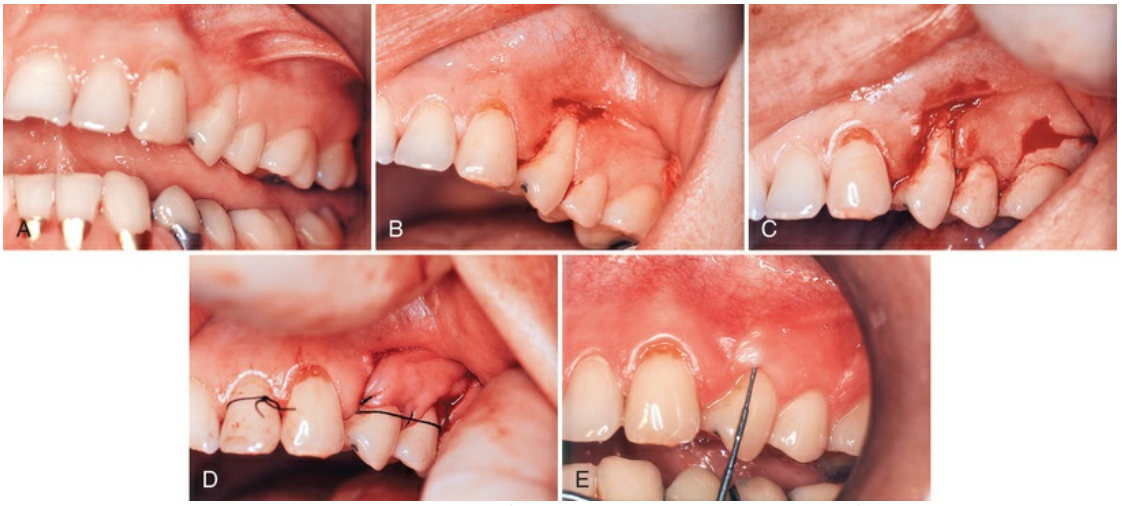
Pedicle Autograft

Laterally Displaced Pedicle Flap

The displaced pedicle flap technique, originally described by Grupe and Warren in 1956,[45] was the standard technique for many years and is still indicated in some cases. The laterally (horizontally) positioned flap can be used to cover the isolated, denuded root surfaces that have adequate donor tissue adjacent to the recipient site. The vestibular depth must exist to laterally move the pedicle. (eFigs. 65.8 and 65.9). The following is a step-by-step surgical description:



EFIG. 65.8 **Laterally displaced flap for coverage of denuded root. *Top,* Incisions *(dashed lines)* are indicated for removing the gingival margin around the exposed root and outlining the flap. *Bottom,* After the gingiva around the exposed root is removed, the flap is separated, transferred, and sutured.**



EFIG. 65.9 **Laterally displaced flap. (A) Preoperative view of the maxillary bicuspid. (B) Recipient site is prepared by exposing the connective tissue around the recession. (C) Incisions are made at the donor site in preparation of moving the tissue laterally. (D) The pedicle flap is sutured in position. (E) Postoperative result at 1 year.** (Courtesy Dr. E.B. Kenney, Los Angeles, CA.)

Step 1: Preparing the recipient site. Epithelium is removed around the denuded root surface. The exposed connective tissue will be the recipient site for the laterally displaced flap. The root surface is thoroughly scaled and root planed (see eFig. 65.9B).

Step 2: Preparing the flap. The periodontal tissue of the donor site should have a satisfactory width of attached gingiva without dehiscence or fenestration in the bone. A full-thickness or partial-thickness flap may be used, but the latter is preferable because it offers the advantage of rapid healing at the donor site and reduces the risk of loss of facial bone. This is especially important if the bone is thin or a dehiscence or fenestration is suspected. (see eFig. 65.9C).

- With a #15 blade, make a vertical incision from the gingival margin to outline a flap adjacent to the recipient site. Incise to the periosteum, and extend the incision into the oral mucosa to the level of the base of the recipient site. The flap should be sufficiently wider than the recipient site to cover the root and provide a broad margin for attachment to the connective tissue border around the root. The interdental papilla at the distal end of the flap or a major portion of it should be included to secure the flap in the interproximal space between the donor and the recipient teeth.
- Make a vertical incision along the gingival margin and interdental papilla, and separate a flap consisting of epithelium and a thin layer of connective tissue, leaving the periosteum on the bone.
- A releasing incision may be needed to avoid tension on the base of the flap, which can impair the blood supply when the flap is moved. A short, oblique incision is made into the alveolar mucosa at the distal corner of the flap.

Step 3: Transferring the flap. Slide the flap laterally onto the adjacent root. The flap should be placed flat and be firm without excess tension on the base. Stabilize the flap to the

adjacent gingiva and alveolar mucosa with interrupted sutures (see eFig. 65.9D). A suspensory suture may be used around the involved tooth to prevent the flap from slipping apically.

Step 4: Protecting the flap and donor site. Cover the surgical site with a sterile aluminum foil and periodontal dressing. Extend the dressing interdentally and onto the lingual surface to secure it. The dressing and sutures are usually removed after 1 week.

Variant Techniques

There are many variations in the incisions for the laterally displaced flap. A common alternative is the use of converging oblique incisions over the recipient site and a vertical or oblique incision at the distal end of the donor site to allow the flap to have a slightly wider base.

The lateral pedicle, partial-thickness grafts from neighboring edentulous areas[44] can be used to restore attached gingiva on teeth adjacent to edentulous spaces with denuded roots and minimal vestibular depth, which are often complicated by tension from an adjacent frenum. The *double-papilla flap* attempts to cover roots denuded by isolated gingival defects with a flap formed by joining the contiguous halves of the adjacent interdental papillae.[25,50] Results with this technique can be unpredictable because blood supply is impaired by suturing the two flaps over the root surface, which is devoid of blood supply.

Accomplishments of a Pedicle Autograft

Coverage of the exposed root surface with the sliding-flap technique has been successful in 60% of cases[41] in one study and 61% to 72%[88] in another. Histologic studies in animals have reported coverage in 50% of cases.[24,114]

The extent to which the flap establishes a new attachment to the root surface with the formation of new cementum and new connective tissue fibers has not been established. New attachment on artificially denuded roots in experimental animals[114] and in some clinical studies of humans has been reported,[99,101] but it does not occur consistently enough to be predictable. In the donor site, there

is uneventful repair and restoration of gingival health, with some loss of radicular bone (0.5 mm) and recession (1.5 mm) reported when full-thickness flaps are used as the donor tissue.

Coronally Displaced Flap

The purpose of the coronally displaced flap procedure is to create a split-thickness flap in the area apical to the denuded root surface. The flap is coronally positioned to cover the root. Two techniques are available for this purpose. The technique is essentially a coronally positioned pedicle flap.

First Technique

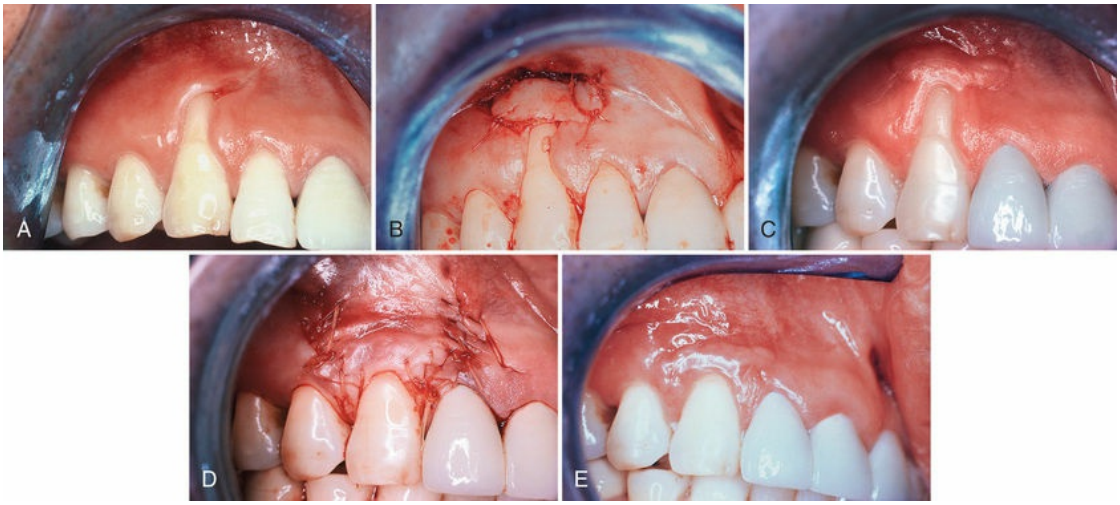
Step 1. With two vertical incisions, delineate the flap. These incisions should go beyond the mucogingival junction. An internal bevel incision is made from the gingival margin to the bottom of the pocket to eliminate the diseased pocket wall. Elevate a mucoperiosteal flap using a sharp dissection.

Step 2. Scale and plane the root surface.

Step 3. Return the flap, and suture it at a level coronal to the pretreatment position. Cover the area with a periodontal dressing. The postsurgical appointment is made after 1 week. The periodontal dressing is replaced for an additional week if necessary.

Variations of the First Technique

Results with the coronally displaced flap technique are often unfavorable[46] because of insufficient keratinized gingiva apical to the recession. To overcome this problem, a gingival augmentation procedure with a free autogenous graft can be performed before the coronally positioned graft as described earlier. This creates several millimeters of attached keratinized gingiva apical to the denuded root surface. (eFig. 65.10).



EFIG. 65.10 **Coronally displaced flap. (A) Preoperative view, showing the recession and the lack of attached gingiva. (B) After placement of a free gingival graft. (C) Three months after placement of the graft. (D) Flap, including the graft, positioned coronally and sutured. (E) Six months later, showing the root coverage and attached gingiva. Compare with A.** (Courtesy Dr. T.J. Han, Los Angeles, CA.)

Two months after this surgery, a second-stage procedure is performed to coronally position the flap, which includes the free autogenous graft. The use of citric acid with a pH of 1.0 for conditioning the root surface has been suggested by some clinicians.[51,59] A significant reduction in recession of the graft when the two-stage technique is used was reported after 2 years by Bernimoulin and colleagues[11] and confirmed by others.[21,61,62]

Second Technique

Tarnow described the semilunar, coronally repositioned flap to cover isolated denuded root surfaces[104] (eFig. 65.11).

EFIG. 65.11 **Semilunar coronally positioned flap. (A) Slight recession in the facial aspect of the upper left canine. (B–D) After thorough scaling and root planing of the area, a semilunar incision is made, and the tissue is separated from the underlying bone. The flap collapses, covering the recession. (E) Appearance after 7 weeks, showing coverage of the previous root denudation.** (Courtesy Dr. J.J. Elbaz, Beverly Hills, CA.)

Step 1. A semilunar incision is made following the curvature of the receded gingival margin and ending about 2 to 3 mm short of the tip of the papillae. This location is important because the flap derives its blood supply from the papillary areas. The incision should reach the alveolar mucosa if the attached gingiva is narrow.

Step 2. Perform a split-thickness dissection coronally from the incision, and connect it to an intrasulcular incision.

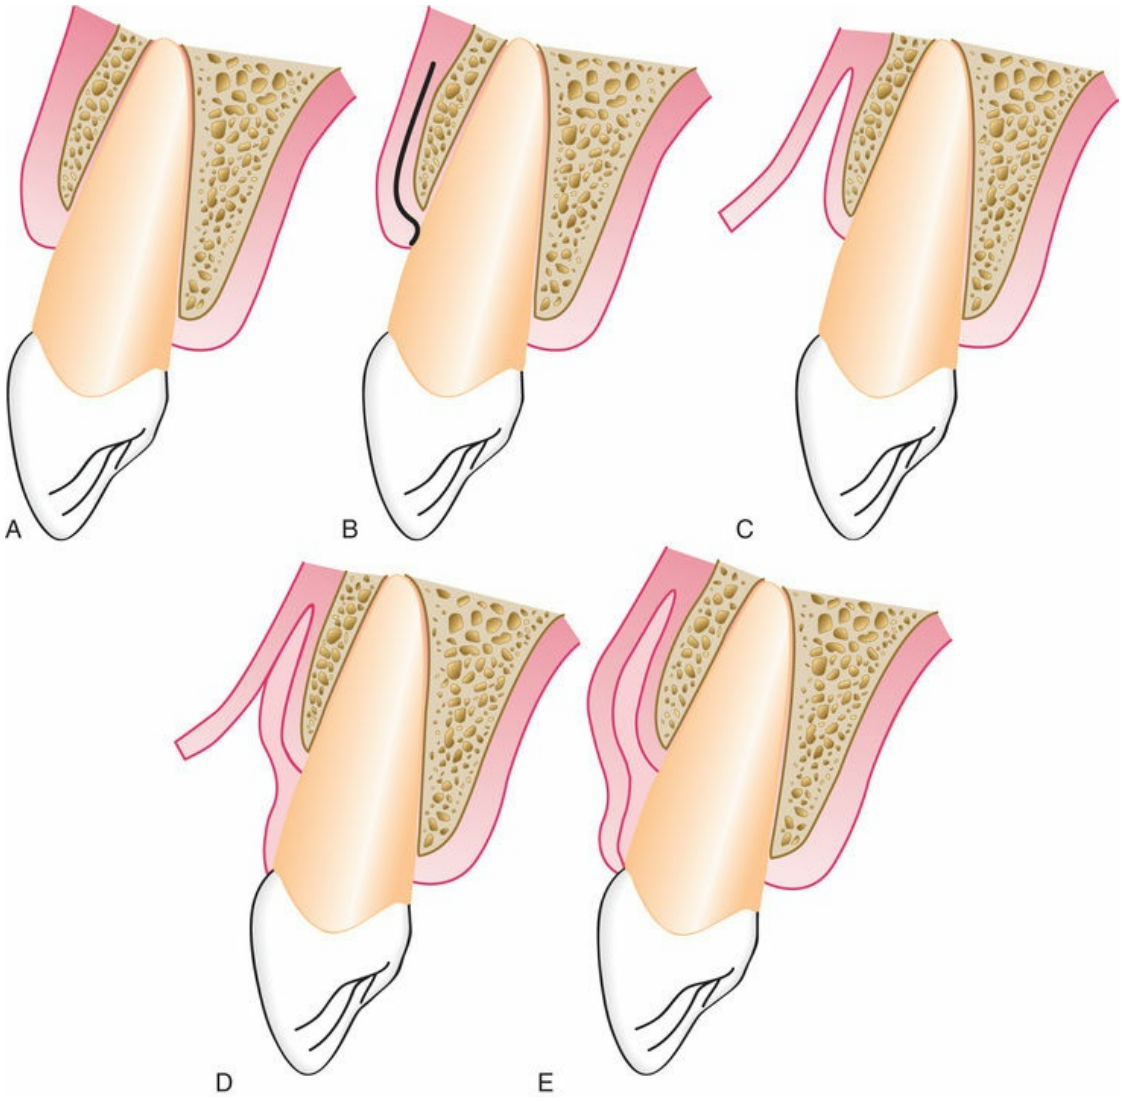
Step 3. The tissue collapses coronally, covering the denuded root. It is then held in its new position with a moist gauze. Many cases do not require sutures or periodontal dressing.

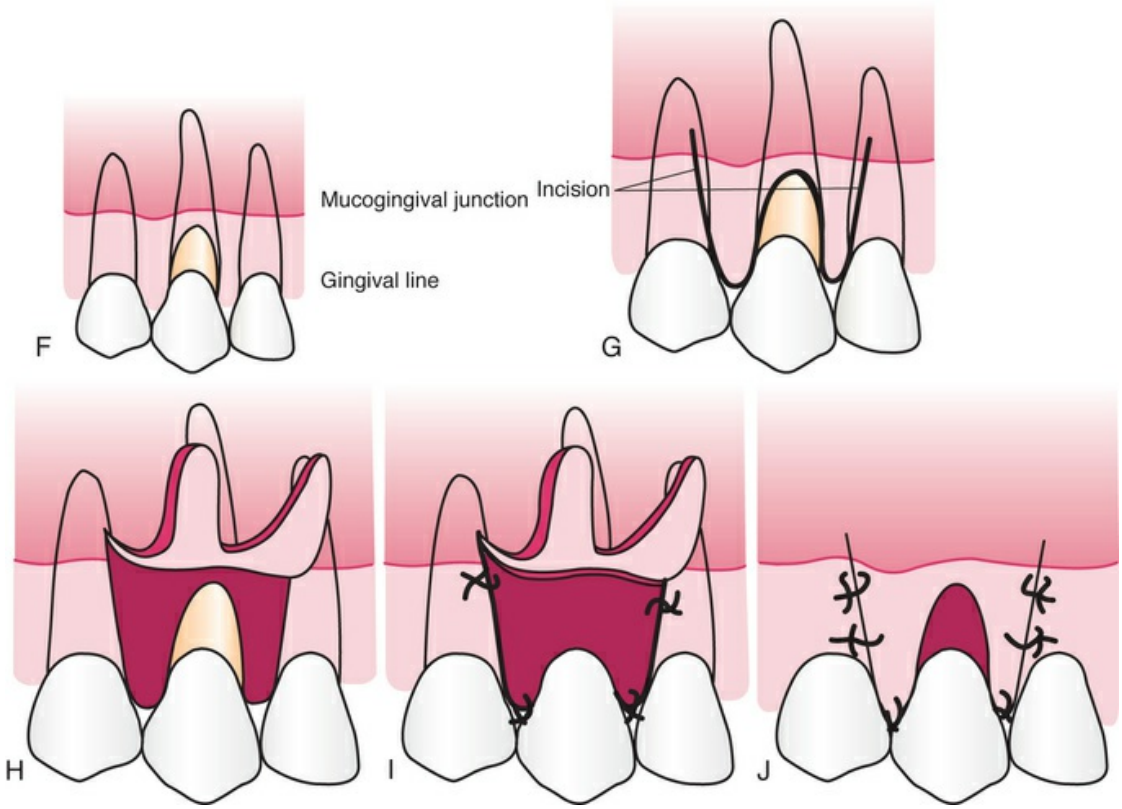
This technique is simple and predictably provides 2 to 3 mm of root coverage. It can be performed on several adjoining teeth. The technique is indicated for areas where the recession is not extensive (<3 mm) and the facial gingival biotype is thick. It is successful for the maxillary anterior area to cover root surfaces exposed at the crown margins.

Subepithelial Connective Tissue Graft

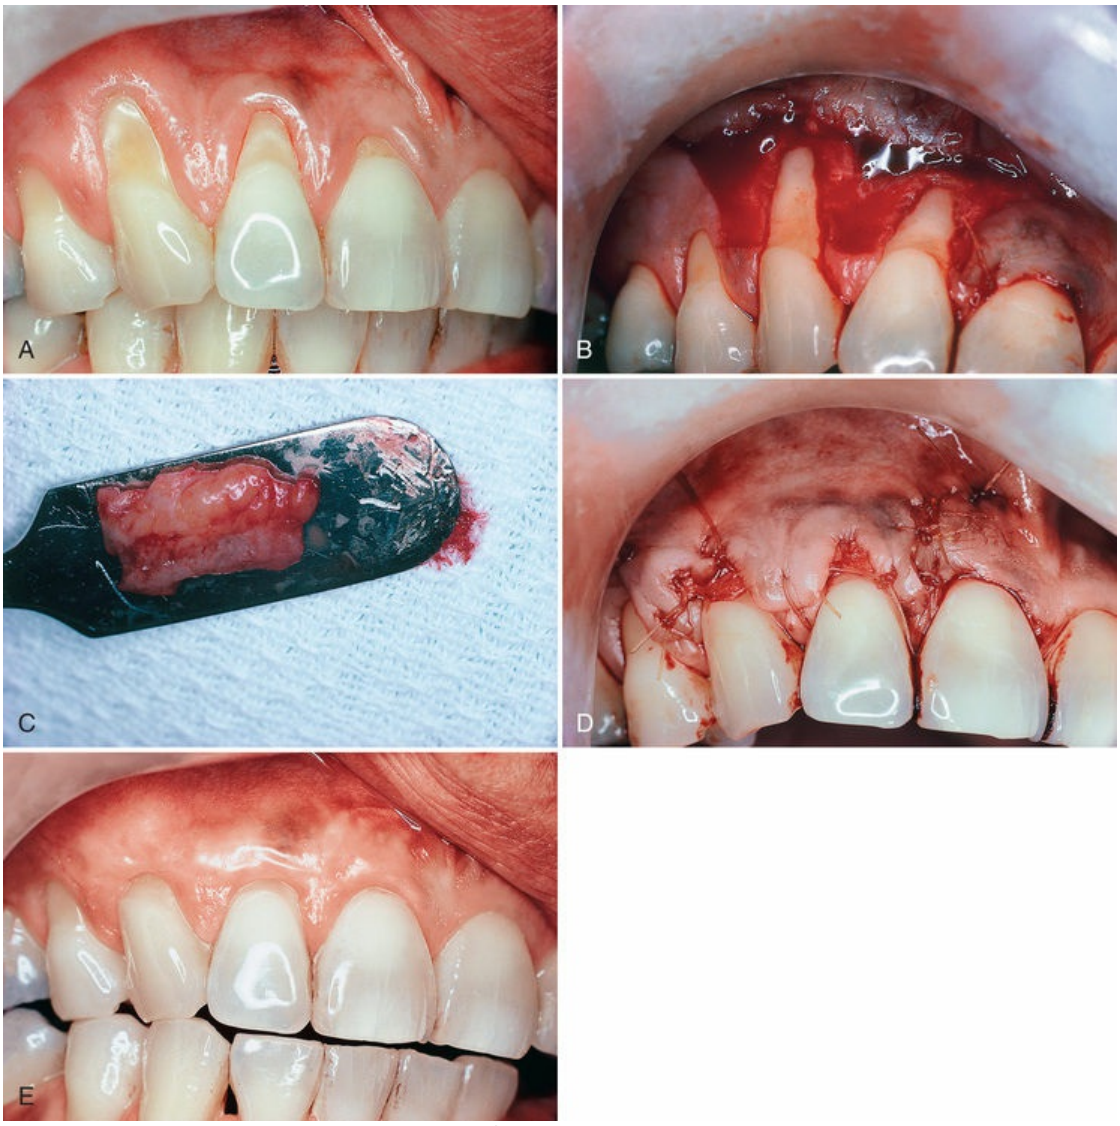
The subepithelial connective tissue graft (i.e., Langer procedure) is

indicated for larger and multiple defects with good vestibular depth and gingival thickness to allow a split-thickness flap to be elevated. Adjacent to the denuded root surface, the donor connective tissue is sandwiched between the split flaps (eFigs. 65.12 and 65.13). This technique was described by Langer and Langer in 1985.[57] Similar approaches had been previously reported by Perez-Fernandez[84] and Raetzke.[87]





EFIG. 65.12 **Subepithelial connective tissue graft for root coverage. (A through E) Sagittal views. (A) Preoperative view of facial recession on a maxillary central incisor. (B) Split-thickness incision for the recipient site. (C) Split-thickness flap is reflected. (D) Connective tissue is placed over the denuded root surface. The apical portion of the donor tissue is placed between the split-thickness flaps. (E) Recipient flap is closed. Subepithelial connective tissue graft is used for root coverage. (F) Gingival recession. (G) Vertical incisions to prepare the recipient site. (H) Split-thickness flap is reflected. (I) Connective tissue is sutured over the denuded root surface. (J) Split-thickness flap is sutured over the donor connective tissue.**



EFIG. 65.13 **Langer technique for root coverage. (A) Preoperative view, showing the recession on teeth #6 to #8. (B) Split-thickness flap is elevated on teeth #6 and #7. The interdental papillae are not included in the flap, nor is the gingival margin area of tooth #8, which was treated by means of a coronally displaced flap. (C) Connective tissue from the palate. (D) Graft placed under the flap and covering receded areas approximately to the cementoenamel junction. Sutures are in place. (E) Roots are covered after complete healing. Note the thickness of the tissue in the area covered and excellent color.** (Courtesy Dr. T.J. Han, Los Angeles, CA.)

The following is the step-by-step surgical description:

Step 1. A partial-thickness flap is reflected with a horizontal incision 2 mm away from the tip of the papilla, and two vertical incisions of 1 to 2 mm are made from the gingival margin of the adjoining teeth. These incisions should extend at least one tooth wider mesiodistally than the area of

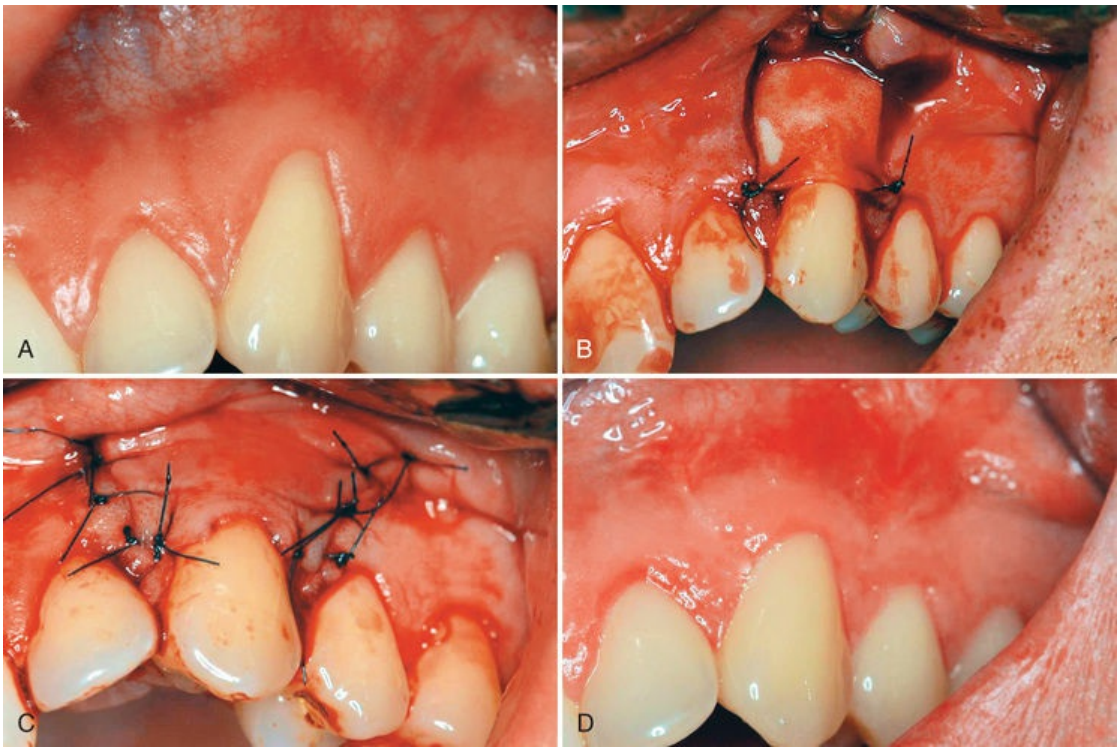
gingival recession. Extend the flap to the mucobuccal fold.
Step 2. The exposed root surface is scaled and planed, which cleans the root surface and reduces the facial convexity.
Step 3. Obtain a connective tissue graft from the palate by means of a horizontal incision 5 to 6 mm from the gingival margin of molars and premolars. The palatal wound is sutured in a primary closure.
Step 4. Place the connective tissue on the denuded root. Suture it with resorbable sutures to the periosteum.
Step 5. Cover the graft with the outer portion of the partial-thickness flap, and place the sutures interdentally.
Step 6. Cover the wound with a sterile foil and surgical dressing. After 7 days, the dressing and sutures are removed.

The aesthetic results are favorable with this technique because the donor tissue is connective tissue (see eFig. 65.13E). The donor site heals by primary intention.

A variant of the subepithelial connective tissue graft, called a *subpedicle (bilaminar) connective tissue graft*, was described by Nelson in 1987.[77] This technique uses a pedicle over the connective tissue that covers the denuded root surface. The blood supply is increased over the donor tissue, and the gingival margin is thickened for better marginal stability.

Guided Tissue Regeneration Technique for Root Coverage

Pini-Prato and coworkers[85] described a technique based on the principle of guided tissue regeneration (GTR) (see Chapter 63). Theoretically, GTR should result in reconstruction of the attachment apparatus, along with coverage of the denuded root surface (eFig. 65.14). The following is a step-by-step description of the surgery:



EFIG. 65.14 Guided tissue regeneration technique for root coverage. (A) Marked recession of the left maxillary cuspid. (B) Vertical incisions are made, and the membrane is placed over the recession. (C) Flap is sutured over the membrane. (D) Postoperative result, showing complete coverage of recession. (Courtesy Dr. Zoran Aleksic, Belgrade, Serbia.)

Step 1. A full-thickness flap is reflected to the mucogingival junction, continuing as a partial-thickness flap 8 mm apical to the mucogingival junction.

Step 2. A membrane is placed over the denuded root surface and adjacent tissue. It is trimmed and adapted to the root surface and covers at least 2 mm of marginal periosteum.

Step 3. A suture is passed through the portion of the membrane that will cover the bone. This suture is tied on the exterior and to bend the membrane, creating a space between the root and membrane. This space allows the growth of tissue beneath the membrane.

Step 4. The flap is then positioned coronally and sutured. Four weeks later, a small envelope flap is performed, and the membrane is carefully removed. The flap is then positioned coronally, to protect the growing tissue and sutured. One week later, the sutures are removed.

Tinti and Vincenzi[107] used titanium-reinforced membranes to create space beneath the membrane. Resorbable membranes have also been used to achieve root coverage. The inability to create space between the resorbable membrane and the denuded root may present a problem, even though a second surgery is not needed.

Clinical studies comparing this technique with the coronally displaced flap have shown that the GTR technique is better when the recession is greater than 4.98 mm apicocoronally.[85] Histologically, one case reported 3.66 mm of new connective tissue attachment associated with 2.48 mm of new cementum and 1.84 mm of bone growth.[27]

Pouch and Tunnel Technique

The pouch and tunnel technique is also referred to as the coronally advanced tunnel technique. To minimize incisions and the reflection of flaps and to provide abundant blood supply to the donor tissue, placement of the subepithelial donor connective tissue into pouches beneath papillary tunnels allows intimate contact of donor tissue with the recipient site.[118] Positioning of the graft in the pouch and through the tunnel and coronal placement of the recessed gingival margins completely covers the donor tissue. The aesthetic result is excellent. The technique is especially effective for the anterior maxillary area in which vestibular depth is adequate and there is good gingival thickness (eFig. 65.15).

EFIG. 65.15 **Pouch and tunnel technique for root coverage. (A) Preoperative view, showing gingival recession. (B) A sulcular incision is made from the mesial to the facial line angles. (C) A tunnel is made through the papilla using a blunt incision. (D) A connective tissue graft is taken from the palate. (E) The connective tissue is placed through the papillary tunnel and apically beneath the pouch. (F) The facial gingival margin covers the connective tissue using horizontal mattress sutures interdentally. (G) Postoperative view, showing complete root coverage and a thickened gingival margin at 3 months.** (Courtesy Dr. Robert R. Azzi, Paris, France.)

An advantage of this technique is thickening of the gingival margin after healing. The thicker gingival margin is stable, allowing for the possibility of creeping reattachment of the margin. The use of small, contoured blades enables the surgeon to incise and split the gingival tissues to create the recipient pouches and tunnels (eFig. 65.16). The work by Azzi and associates[8] in this area of surgery has contributed to a better understanding of the technique and outcome of this procedure.

EFIG. 65.16 Small, contoured blades are used for periodontal plastic surgery.

Learning Box e65.4

The successful outcome of the pouch and tunnel technique depends on several factors: (1) blood supply to the grafted donor tissue is abundant, (2) grafted donor tissue is stable inside the pouch, (3) donor tissue is protected from external trauma during healing, and (4) the gingival margin is thickened, which creates a favorable biotype for possible creeping reattachment.

The following steps describe the surgical procedure outlined by Azzi and colleagues[8] (see eFig. 65.15):

Step 1. Preparation of the patient includes biofilm control instructions and careful scaling and root planing several weeks before the surgical procedure. The patient is instructed to rinse for 30 seconds with a 0.12% chlorhexidine gluconate solution.
Step 2. After adequate anesthesia of the region, the surgical procedure is performed.
Step 3. Composite material is placed (temporarily) at the contact points to prevent collapse of the suspended sutures into the interproximal spaces before the surgery.
Step 4. Root planing of the exposed root surfaces is performed.
Step 5. Initial sulcular incisions are made using #15c and #12d

blades. Small, contoured blades (see Fig. 69.16) and minicurettes are used to create the recipient pouches and tunnels.

Step 6. On the buccal aspect, an intrasulcular incision is made around the necks of the teeth. The incision is extended to one adjacent tooth mesially and distally using a #15c blade. This incision maintains the full height and thickness of the gingival component and enables access beneath the buccal gingiva with curettes. The cutting edge is directed toward the bone to dissect the connective tissue beyond the mucogingival line and free the buccal flap from its insertions to the bone around each tooth.

Step 7. Muscle fibers and any remaining collagen fibers on the inner aspect of the flap, which prevent the buccal gingiva from being moved coronally, are incised .

Step 8. The papillae are kept intact and undermined to maintain their integrity and carefully released from the underlying bone, which allows coronal positioning of the papillae.

Step 9. An envelope, full-thickness pouch, and tunnel are created and extended apically beyond the mucogingival line by blunt dissection for insertion of the free connective tissue graft through the intrasulcular incision.

Step 10. The size of the pouch, which includes the area of the denuded root surface, is measured so that an equivalent-size donor connective tissue can be procured from the palate.

Step 11. A donor surgical site is created to obtain a connective tissue graft of adequate size and shape to be placed at the recipient site. The donor tissue connective tissue is contoured to fit into the recipient tunnel and pouch.

Step 12. A mattress suture placed at one end of the graft helps to guide the graft through the sulcus and beneath each interdental papilla. The border of the tissue is gently pushed into the pouch and tunnel using tissue forceps and a packing instrument. The graft is pushed from the adjacent tooth on one side of the surgical area to the adjacent tooth on the other side.

Step 13. A mattress suture placed on one end of the graft helps to maintain the graft in position while the buccal tissue

covers the connective tissue graft. This connective tissue graft is anchored to the inner aspect of the buccal flap in the interdental papilla area. A vertical mattress suture is used to hold the connective tissue in position beneath the gingiva. The connective tissue graft is completely submerged beneath the buccal flap and the papillae.

Step 14. The entire gingivopapillary complex (i.e., buccal gingiva with the underlying connective tissue graft and papillae) is coronally positioned using a horizontal mattress suture anchored at the incisal edge of the contact area. The contact areas are splinted preoperatively to close the interdental contact using a composite material to prevent the suture from sliding apically interdentally.

Step 15. Other holding sutures can be placed through the overlying gingival tissue and donor tissue to the underlying periosteum to secure and stabilize the donor tissue and the overlying gingiva in a coronal position.

The area is not covered with periodontal dressing. The patient is instructed to rinse daily with chlorhexidine gluconate and to avoid touching the sutures. Antibiotics can be administered (500 mg of amoxicillin three times each day) if deemed necessary.

Techniques to Deepen the Vestibule

Adequate vestibular depth is important for oral hygiene and retention of prosthetic appliances. Numerous surgical techniques have been proposed to accomplish deepening of the vestibule. The classic clinical studies in the early 1960s by Bohannan[13–15] indicated that deepening of the vestibule by non–free-graft procedures were not successful when evaluated years later. Predictable deepening of the vestibule can be accomplished only by the use of free autogenous graft techniques and their variants (discussed earlier).

The important clinical aspect in deepening the vestibule is proper preparation of the recipient site. The recipient site must be covered by immobile periosteal tissue. If there is a lack of periosteal connective tissue, donor tissue may be placed over the bone. The donor tissue can be free gingival or connective tissue, but it must be

placed over a nonmobile recipient site.

Techniques to Remove the Frenum

A frenum is a fold of mucous membrane, usually with enclosed muscle fibers, that attaches the lips and cheeks to the alveolar mucosa or gingiva and underlying periosteum. A frenum becomes a problem if the attachment is too close to the marginal gingiva. This anatomic situation can be a genetic condition or the result of recession of the gingival margin reaching the area of the frenum. Tension on the frenum can pull the gingival margin away from the tooth. This condition can be conducive to biofilm accumulation and inhibit proper placement of the toothbrush at the gingival margin. These hygiene problems are most often encountered in the anterior mandibular areas. The maxillary anterior vestibule is deep, and the frenum is usually located in the midline between the two central incisors. The aberrant frenum located between the maxillary central incisors may cause an aesthetic problem in a patient with a high lip line.

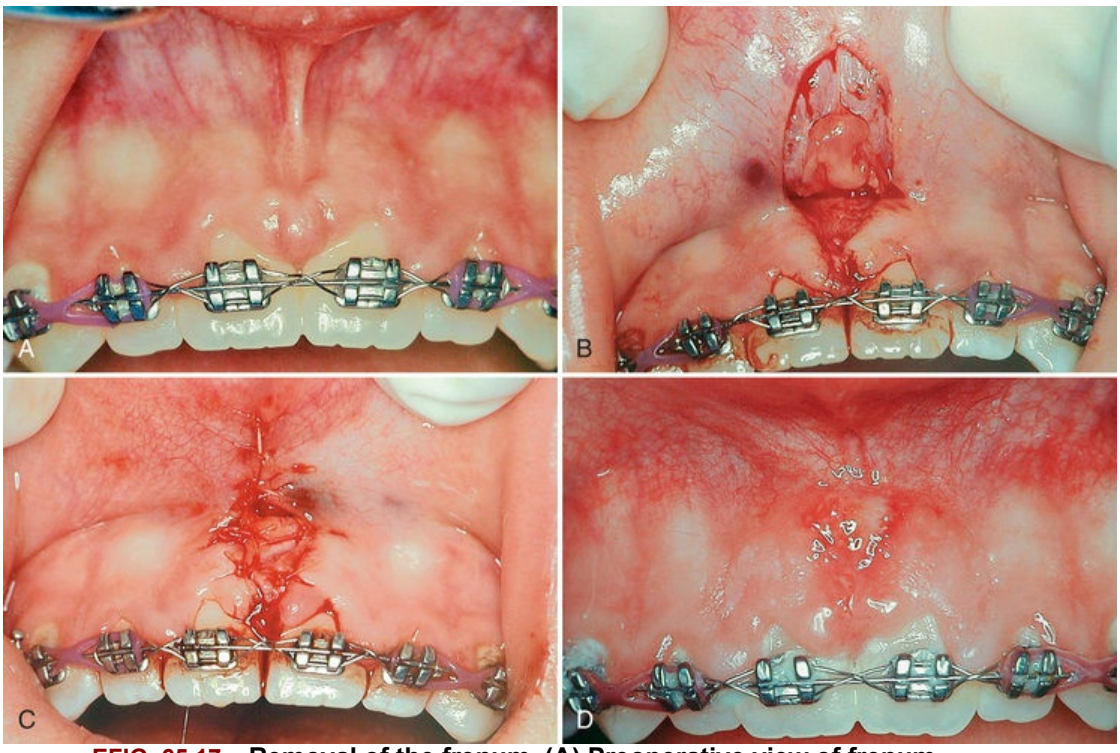
Frenectomy and Frenotomy

Frenectomy and *frenotomy* refer to surgical procedures that differ in degree. Frenectomy is complete removal of the frenum, including its attachment to underlying bone, and it may be required in the correction of an abnormal diastema between the maxillary central incisors. Frenotomy is relocation of the frenum, usually in a more apical position.

Frenectomy and frenotomy can be performed in conjunction with other periodontal treatment procedures, such as a free gingival graft procedure to deepen the vestibule in the mandibular anterior area. If the aberrant frenum is the only problem, the surgical procedure is accomplished separately. Frenal problems occur most often on the facial surface between the maxillary and mandibular central incisors and in the canine and premolar areas[113] (see Fig. 65.2D). They occur less often on the lingual surface of the mandible.

Procedure

If the vestibule is deep, the procedure is confined to the frenum. It is often necessary to deepen the vestibule to provide space for the repositioned frenum. This is accomplished as follows (eFig. 65.17):



EFIG. 65.17 Removal of the frenum. (A) Preoperative view of frenum between the two maxillary central incisors. (B) Removal of the frenum from the lip and gingiva. (C) The site is sutured after a connective tissue graft is placed over the wound. (D) Postoperative view at 2 weeks. (Courtesy Dr. J.J. Elbaz, Beverly Hills, California, CA.)

Step 1. After anesthetizing the area, engage the frenum with a hemostat inserted to the depth of the vestibule.
Step 2. Incise along the upper surface of the hemostat, extending beyond the tip.
Step 3. Make a similar incision along the undersurface of the hemostat.
Step 4. Remove the triangular resected portion of the frenum with the hemostat. This exposes the underlying fibrous attachment to the bone.
Step 5. Make a horizontal incision, separating the fibers, and bluntly dissect to the bone.
Step 6. If necessary, extend the incisions laterally, and suture

the labial mucosa to the apical periosteum. A gingival graft or connective tissue graft is placed over the wound.

Step 7. Clean the surgical field with gauze sponges, and apply pressure until the bleeding stops.

Step 8. Cover the area with dry, sterile aluminum foil, and apply the periodontal dressing.

Step 9. Remove the dressing after 2 weeks, and redress if necessary. One month is usually required for the formation of an intact mucosa with the frenum attached in its new position.

Techniques to Improve Aesthetics

The maxillary anterior area in a patient with a high lip line may cause concerns about the aesthetic appearance of gingival tissues. This area is called the *aesthetic zone*, and it requires special consideration in restorative, periodontal, and implant therapy. The symmetry of the facial gingival margin from canine to canine is altered with recession of the gingival margin, loss of the interdental papilla, or an excessive amount of gingival tissue creating a gummy smile. Therapy to correct these gingival conditions is discussed under the topics of root coverage, papilla reconstruction, and correction of excessive gingival display.

Root Coverage

The surgical correction of root coverage is discussed in detail in the section on Gingival Augmentation Coronal to Recession.

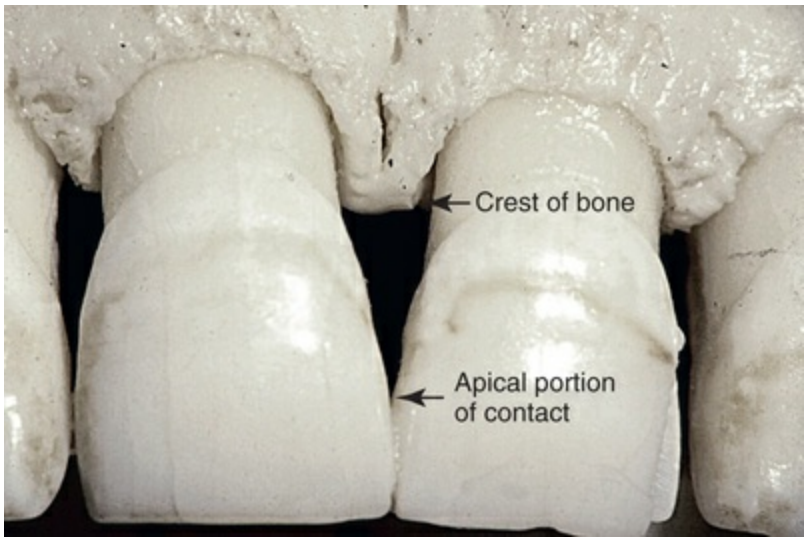
Papilla Reconstruction

Loss of the interdental papilla is a major aesthetic problem for many patients. It is often referred to as the *black triangle or hole* (eFig. 65.18). Reconstruction of the lost or reduced interdental papilla is the most difficult and unpredictable problem in aesthetic periodontal therapy. Interdental papilla is gingival tissue supported and created by two adjacent teeth in contact and the underlying bone beneath this tissue.[102] The loss of bone as the result of

periodontal disease or the loss of the contact alters the support of the interdental tissue, which can lead to the loss or reduced height of the papilla.

EFIG. 65.18 The loss of the interdental papilla creates an aesthetic problem. Notice the black triangles or holes.

Tarnow,[105] in his study of this area, stated the distance from the crest of the interdental bone to the apical portion of the contact above this bone determines whether the interdental papilla is absent or present (eFig. 65.19). The predictable reconstruction of the papilla is determined by augmentation of the gingival tissue, the presence or absence of the underlying bone, and contact of the two adjacent teeth.



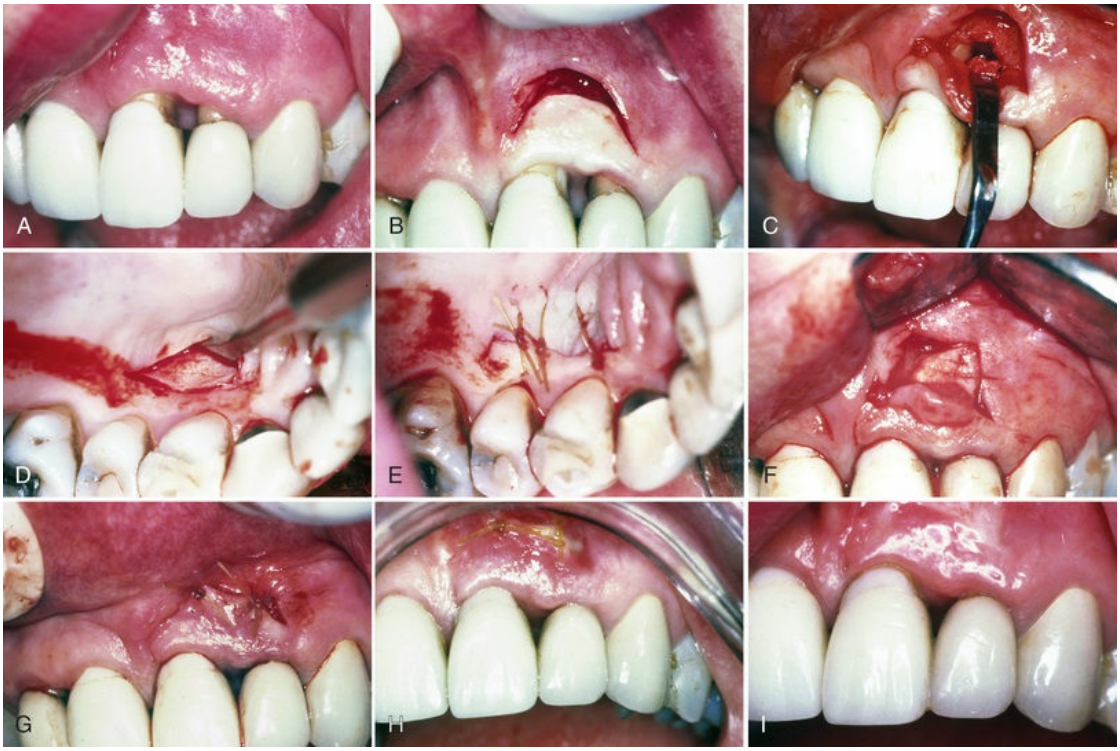
EFIG. 65.19 The distance from the crest of the interdental bone to the apical portion of the contact, above this bone determines whether the interdental papilla is absent, as indicated by Tarnow and colleagues.[105]

Orthodontics and restorative therapy also play important roles in the loss and reconstruction of the papilla because they can determine the location of the contact position in the dentition. We have also learned from experience that grafting bone or gingiva of minimal size to a small recipient site is unpredictable because of the lack of blood supply from the recipient site to the donor tissue, both of which have minimal contact due to their size. Bone grafting or free gingival grafting of interdental areas to reconstruct the papilla is not a predictable procedure.

There have been numerous case reports of different techniques to augment gingival tissue into the interdental area. All techniques must be based on the principle of adequate blood supply to the donor tissue. Of the many gingival grafting procedures used in periodontal therapy, the technique that offers the best blood supply to the donor tissue is the pedicle graft because it maintains a connection between the donor tissue and the origin of the graft. The pouch and tunnel surgical procedure also creates the ideal blood supply for the recipient site to accept the donor tissue.

Han and colleagues[47] reported a technique using a semilunar pedicle graft and pouch to gain papillary height, but without bone support this technique was only able to reduce the interdental space (eFig. 65.20). Azzi and coworkers[5–9] reported successful results in

numerous cases using different surgical techniques to regain the lost papilla. All of these cases employed different grafting techniques using connective tissue and bone and a surgical flap design that applied the principle of the pouch and tunnel to maximize the blood supply to the grafted tissue. The case shown in eFig. 65.21 incorporates several of the concepts indicated earlier for papilla reconstruction, including (1) semilunar pedicle design, (2) connective tissue and bone grafting into the interdental area, and (3) use of restorative dentistry to place the apical portion of the contact closer to the crestal bone.[9]



EFIG. 65.20 (A) Interdental crater between tooth 9 and tooth 10. Learning Box e65.5

Grafting bone or gingival tissue to reconstruct a papilla that has been lost is unpredictable because small amounts of bone or gingiva grafted to a small recipient site lack blood supply for both tissues. Bone grafting or free gingival grafting of interdental areas to reconstruct the papilla is not a predictable procedure.

The future of papilla reconstruction will involve techniques developed by tissue engineering using biologic mediators. In a study reported by McGuire and Scheyer,[68] autologous fibroblasts were injected into the interdental papilla to atraumatically augment the deficient interdental papilla. Further discussion of this topic is

presented in the Tissue Regeneration section of this chapter. The exciting field of tissue engineering will allow the clinician to use minimally invasive procedures to reconstruct lost papillae.

Therapy to Correct Excessive Gingival Display

Excessive gingival display (i.e., gummy smile) is an aesthetic concern for many patients. This appearance may be caused by a skeletal problem called *vertical maxillary excess,* by dentoalveolar extrusion, or by incomplete exposure of the anatomic crown, often referred to as *altered passive eruption.* It can be associated with a short upper lip or excessive lip translation. A combination of causative factors can require more than one treatment option.

In patients with excessive gingival display, the primary aesthetic feature may also be excessive appearance of the teeth. If the cause of the gummy appearance is incomplete exposure of the anatomic crown, the teeth will appear short and unattractive. This appearance is often noticed in adolescent patients during orthodontic treatment. If there is a need for aesthetic crown lengthening before orthodontic therapy, there will still be a need after orthodontic therapy, which may be 5 years later.[56] Although patients may complain about the gummy exposure, the real aesthetic issue is the altered tooth form. Surgical crown lengthening addresses both concerns, but its focus should be on the exposure of a properly proportioned tooth.

Ideally, the width-to-length ratio of a maxillary central incisor clinical crown should fall between 0.78 and 0.85.[60,96] A central incisor with a width of 8.5 mm should have a length between 10 and 11 mm. The length of the maxillary canine is equal to or slightly less than the central incisor, and its gingival margin should be aligned with the central incisor gingival margin. The gingival margin of the lateral incisor is usually about 1.0 mm coronal to the margins of the adjacent teeth, although in patients with a high lip line, it is usually more pleasing to have the lateral incisor gingival margin equal to that of the central incisors and canines.[2]

Surgical Techniques

Exposure of the full anatomic crown is necessary to achieve a smile with minimal gingival exposure. Measurements before surgery should include clinical crown width and length, anatomic crown length, and height of keratinized tissue.

Surgical crown lengthening can be accomplished by soft tissue excision alone or by flap surgery with or without osseous surgery. Determinates for choice of a surgical procedure are (1) the need to leave a minimum of 3.0 mm of keratinized marginal tissue and (2) the possible need for osseous surgery. If excision of soft tissue for full anatomic crown exposure would leave at least 3.0 mm of keratinized marginal tissue, there is no need for osseous surgery, and soft tissue excision alone is the treatment of choice. If less than 3.0 mm of keratinized marginal tissue would remain after the necessary excision, an apically positioned flap is required.

Osseous Surgery

The soft tissue level is determined by the thickness and level of the underlying alveolar bone. A thick bone margin or an alveolar crest at or near the CEJ causes the overlying gingiva to cover more of the anatomic crown than that seen when the alveolar crest is of normal thickness and positioned 2 mm apical to the CEJ. The facial soft tissue margin is located approximately 3 mm coronal to the osseous crest, allowing 2 mm for biologic attachment and 1 mm for sulcus depth.[42] Failure to adjust bone form and level to account for these dimensions leads to rebound of surgically reduced soft tissue to reform this biologic width.[83,86]

Precise osseous surgery is best accomplished after elevation of a full-thickness mucoperiosteal flap that provides good visibility and access for three-dimensional ostectomy and osteoplasty. In aesthetic crown lengthening, only a facial flap is raised to prevent loss of papillary fill. Initial gross osteoplasty is accomplished with a round bur to reduce excessive bone thickness, followed by alteration of the crestal level with hand chisels and curettes. It is important to reduce the osseous crest so that the new position parallels the CEJ at each tooth facially and proximally. However, the height of the interdental crest is not reduced in aesthetic crown lengthening. If full exposure of the anatomic crown is desired, the alveolar crest should be reduced to a position 3 mm apical to the CEJ. Excessive

bone thickness interdentally is reduced with a round bur to produce a slight prominence of the roots relative to the alveolar ridge. Care should be exercised to maintain adequate bone thickness over the root surfaces. Creation of an ideal osseous form leads to predictable and stable soft tissue position and ideal crown exposure.

Flap closure is accomplished with interrupted 7-0 sutures. Postoperative instructions are focused on biofilm control to prevent soft tissue rebound. eFig. 65.22 demonstrates a clinical case of aesthetic crown lengthening to correct the gummy appearance in the maxillary anterior aesthetic zone.

Tissue Engineering

Tissue engineering in periodontics and all of dentistry holds the future of wound repair and will continue to evolve into a valuable treatment option that the clinician can influence and up-regulate. It is important, however, to understand the limitations when it comes to influencing the complex wound healing scenario. The roles of inflammation, existing cytokines, growth factors, extracellular matrices, and collagen synthesis must be considered when evaluating tissue engineering methods. Having the correct factor at the appropriate time and at an effective concentration and for the proper duration are issues that need further investigation and clinical validation. Just as we strive to understand the host role in the pathogenesis of periodontal disease, we must also take into consideration positive and negative host influences on wound healing after regenerative procedures.

Tissue engineering and the use of biologic mediators in periodontal plastic surgery have become a reality as the result of research and the demand for noninvasive surgical procedures by patients and clinicians. Current periodontal plastic surgery is based on the use of the palatal site for donor tissue (i.e., subepithelial connective tissue graft [SECTG]), which entails a second surgical wound. Many patients are fearful of this donor wound and resist the surgery needed to correct a mucogingival problem. For those who desire to avoid the palatal donor site, morbidity associated with the SECTG and free gingival graft (FGG), tissue-engineering methods provide an excellent alternative.

Periodontal therapy has involved tissue engineering for decades, beginning with GTR, which is a form of passive tissue engineering that excluded certain cell types and created an engineered wound left to heal with the appropriate cell types (see Chapter 63).

Learning Box e65.6

Much of periodontal plastic surgery is based on using donor tissue from the palatal site for the subepithelial connective tissue graft (SECTG), which entails a second surgical wound. Due to the research and demand for noninvasive surgical procedures by

patients and clinicians, tissue engineering and the use of biologic mediators in periodontal plastic surgery has become a reality.

The passive and active categories recognize the roles cells play in tissue engineering. Passive engineering involves the following treatments and materials:

1. Therapies based on GTR-based therapies; barrier membranes
2. Biologically based acellular dermal matrix (ADM)

Active engineering involves the following treatments and materials:

1. Enamel matrix derivative (EMD)
2. Growth factors: recombinant human platelet-derived growth factor-BB (rhPDGF-BB) plus beta-tricalcium phosphate (β-TCP) plus collagen wound dressing
3. Cell therapy
    - Autologous fibroblast: Isolagen
    - Bilayered cell therapy (BLCT): Celltx
    - Human fibroblast-derived dermal substitute (HFDDS): Dermagraft

GTR (see Chapter 63) and ADM are considered passive cell manipulation in which the cells are not biologic mediators. Barrier membranes and ADM offer wonderful solutions with an unlimited source and positive outcomes reported in the literatures as a GTR technology or tissue replacement graft, respectively.[1,103,106,111] Barrier membranes allow certain cell types to proliferate but do not offer an active component. ADM used in periodontal plastic surgery holds no active component to influence wound healing and is considered a component in passive engineering. In GTR and ADM, the cells are not actively participating in the cellular changes. In active tissue engineering, the cells are biologically active in the regeneration process.

A large body of literature provides clinical and histologic evidence of periodontal regeneration from biologically active

materials for the intrabony lesion.[65,78,94,109] This evidence supports the exploration of these active materials for application in mucogingival surgery. Randomized, controlled clinical trials and human histologic evidence are needed to claim true regeneration and efficacy using the new technologies. The remainder of this chapter concentrates on the novel approaches and products used for active tissue engineering in periodontal mucogingival applications.

In 2003, McGuire and Nunn[64,66] published results of a single-center, randomized, controlled clinical trial comparing a coronally advanced flap using EMD with SECTG. The results showed no statistical difference in the percentage of root coverage between the test group and controls. It was concluded that within the limitations of the single-center trial, EMD with a coronally advanced flap was a valid alternative to the subepithelial connective tissue (eFig. 65.23).

(B) Application of EMD to the root surface before coronally advancing the flap with 5-0 plain gut sutures. (C) The 1-year follow-up reveals 100% root coverage and increased keratinized gingiva. (Courtesy Dr. Michael K. McGuire.)

In 2006, McGuire and Scheyer published a case series using a growth factor–mediated procedure, including rhPDGF, β-TCP, and

a collagen wound dressing, to obtain root coverage comparable to that of SECTG, which led to a randomized, controlled clinical trial. The clinical trial used the growth factor–mediated procedure to obtain clinical and histologic evidence of root coverage and regeneration compared with SECTG.[67,69,71] These studies provided proof of principle that in four of four human histology block sections, true periodontal regeneration (i.e., alveolar bone, periodontal ligament, and new cementum) was possible with rhPDGF plus β-TCP plus a collagen wound dressing. Histologic evidence of root coverage verifies that this tissue-engineering method offers true periodontal regeneration, which is not expected with SECTG (eFig. 65.24).

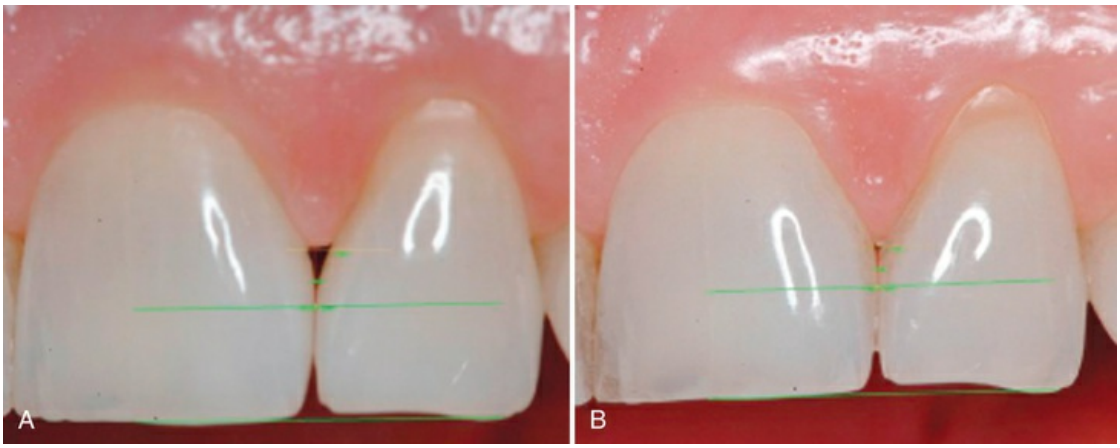
Reconstruction of the open interproximal space remains one of the greatest challenges in aesthetic periodontal therapy. In a landmark study by McGuire and Scheyer in 2007,[68] autologous fibroblasts were injected into the interdental papilla using a method to atraumatically augment the deficient gingival papilla. Although this method has not been thoroughly validated, treatment outcomes reduced open interproximal spaces and improved aesthetics in the maxillary arch (eFig. 65.25). No long-term evidence exists for tissue stability with this method, but the pilot study showed promise for an innovative study design for a tissue-engineering application in dentistry. For example, the technology allows for the concept of banking autologous fibroblasts for future clinical use or research.



EFIG. 65.25 (A) Preoperative view of the open interproximal space. (B) Four months after three injections into the papilla with the patient's own

expanded and concentrated fibroblasts, note the improved papillary form. Green horizontal lines are used for image analysis. In 2008, McGuire and Scheyer[70] published a pilot study comparing a tissue-engineered bilayered cell therapy (BLCT) (Apligraf, Organogenesis, Canton, MA) to FGG with promising enough results to warrant a multicenter, controlled clinical trial (eFig. 65.26). From the pilot study, there is evidence of de novo formation of attached and keratinized gingiva with the placement of a live cell therapy device without donor site surgery. In this randomized, controlled clinical trial, the test material was capable of generating up to 2.72 mm of keratinized gingiva, and in more than 75% of the subjects, more than 2 mm of keratinized tissue was developed after a 6-month follow-up visit. This pilot study supports further research of the BLCT to produce de novo keratinized gingiva without the use of a traditional autograft. More data are being analyzed to allow the commercial use of this material.

(M) The test site is stained with Schiller's iodine, showing the de novo formation of attached and keratinized gingiva. (Courtesy M.K. McGuire and E.T. Scheyer. Houston, TX.)

In 2005, McGuire and Nunn[63] published a pilot study evaluating the safety and efficacy of a living tissue-engineered human fibroblast–derived dermal substitute (HFDDS) (Dermagraft, Advanced Tissue Science, La Jolla, CA) compared with a gingival autograft. Although the autograft produced a larger band of

keratinized tissue, the test group represented the first attempt to use an off-the-shelf tissue-engineered material capable of generating attached and keratinized gingiva.[115]

In the quest for new technologies to reduce trauma during surgery, further research is needed to investigate treatment methods such as ADM, biologic factors, and materials that could carry growth factors to the surgical site and maintain their action. At some point, recombinant growth factors could eliminate the need for donor sites and the use of exogenous materials inserted into the human body. Future research should focus on obtaining additional evidence for using growth factors and live-cell technology during periodontal therapy to eliminate donor site morbidity.

Criteria for Selection of Techniques

Numerous techniques are used for solving the mucogingival problems outlined in this chapter. Proper selection of a technique must be based on the predictability of success, which is based on specific criteria.

The following criteria are used for selection of mucogingival techniques:

1. Surgical site free of biofilm, calculus, and inflammation
2. Adequate blood supply to the donor tissue
3. Anatomy of the recipient and donor sites
4. Stability of the grafted tissue to the recipient site
5. Minimal trauma to the surgical site

Surgical Site Free of Biofilm, Calculus, and Inflammation

Periodontal plastic surgical procedures should be undertaken in a biofilm-free and inflammation-free environment to enable the clinician to manage gingival tissue that is firm. Meticulous, precise incisions and flap reflection cannot be achieved when tissue is inflamed and edematous. Thorough scaling and root planing and meticulous biofilm removal by the patient must be accomplished

before any surgical procedure.

Adequate Blood Supply

To obtain the maximal amount of blood supply to the donor tissue, gingival augmentation apical to the area of recession provides a better blood supply than coronal augmentation because the recipient site is entirely periosteal tissue. Root coverage procedures involve a portion of the recipient site (i.e., denuded root surface) without blood supply. If aesthetics is not a factor, gingival augmentation apical to the recession may be more predictable. A pedicle-displaced flap has a better blood supply than a free graft, with the base of the flap intact. If the anatomy is favorable, the pedicle flap or any of its variants may be the best procedure for root coverage.

The Langer subepithelial connective tissue graft (SECTG) procedure and the pouch and tunnel techniques use a split flap with the connective tissue sandwiched between the flaps. This flap design maximizes the blood supply to the donor tissue. If large areas require root coverage, these sandwich-type recipient sites provide the best flap design for blood supply.

Anatomy of the Recipient and Donor Sites

The presence or absence of vestibular depth is an important anatomic criterion at the recipient site for gingival augmentation. If gingival augmentation is indicated apical to the area of recession, there must be adequate vestibular depth apical to the recessed gingival margin to provide space for a free or pedicle graft. If a vestibule is necessary, only a free graft can accomplish this objective apical to the recession.

Mucogingival techniques, such as free gingival grafts and free connective tissue grafts, can be used to create vestibular depth and widen the zone of attached gingiva. Other techniques require vestibular depth to exist before the surgery, including pedicle grafts (i.e., lateral and coronal), the Langer SECTG, and pouch and tunnel procedures.

Availability of donor tissue is another anatomic factor that must be considered. Pedicle displacement of tissue necessitates an

adjacent donor site that has gingival thickness and width. Palatal tissue thickness is also necessary for the connective tissue donor autograft. Gingival thickness is required at the recipient site for techniques using a split-thickness, sandwich-type flap or the pouch and tunnel techniques.

Stability of the Grafted Tissue to the Recipient Site

Good communication of the blood vessels from the grafted donor tissue to the recipient site requires a stable environment. This necessitates sutures that stabilize the donor tissue firmly against the recipient site. The least amount of sutures and maximal stability should be achieved.

Minimal Trauma to the Surgical Site

As with all surgical procedures, periodontal plastic surgery is based on the meticulous, delicate, and precise management of oral tissues. Unnecessary tissue trauma caused by poor incisions, flap perforations, tears, or traumatic and excessive placement of sutures can lead to tissue necrosis. The proper selection of instruments, needles, and sutures is mandatory to minimize tissue trauma. Sharp contoured blades (see eFig. 65.16), smaller-diameter needles, and resorbable monofilament sutures are important factors in achieving atraumatic surgery.

Conclusions

Periodontal plastic surgery refers to soft tissue relationships and manipulations. In all of these procedures, blood supply is the most significant concern and must be the underlying issue for all decisions regarding the individual surgical procedure. A major complicating factor is the avascular root surface, and many modifications to existing techniques are used to overcome this. Diffusion of fluids is short term and of limited benefit as tissue size increases. The formation of a circulation through anastomosis and angiogenesis is crucial to the survival of these therapeutic

procedures.

Formation of vascularity is based on growth molecules, such as vascular endothelial growth factor (VEGF), and on cellular migration, proliferation, and differentiation. As tissue-engineering techniques improve, the success and predictability of mucogingival surgery should dramatically increase. However, all advancements must have adequate circulation and blood supply as their basis.

New techniques are being developed and are slowly being incorporated into periodontal practice. The practitioner should be aware that new methods sometimes are published without adequate clinical research to ensure the predictability of the results and the extent to which the techniques may benefit the patient. Critical analysis of recently presented techniques should guide the evolution toward better clinical methods.

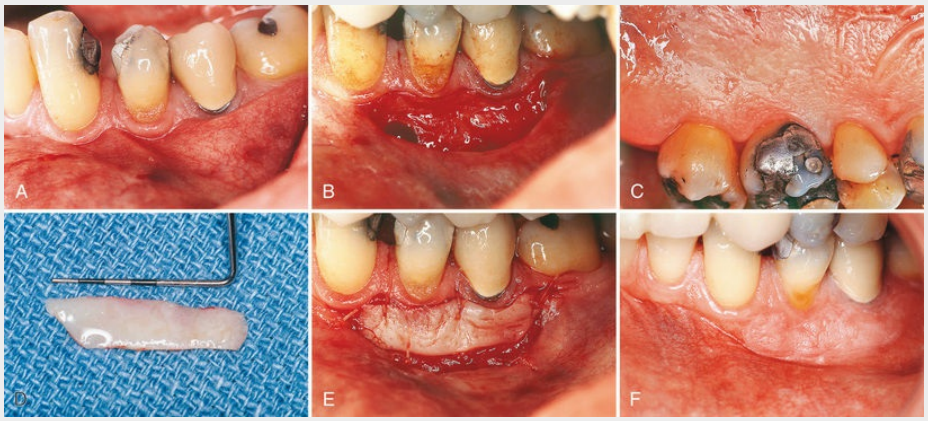
Case Scenario 65.1

Patient:
35-year-old male

Chief Complaint:
Gingival tissue facial to teeth 20, 21, and 22 is tender and sore during brushing due to a lack of keratinized, attached gingiva.

Background Information:
The mandibular left cuspid and first bicuspid have minimal keratinized tissue on the buccal gingival margin. The second bicuspid has a crown with no buccal keratinized gingiva.

Current Findings:
A free gingival graft is placed apical to the mucogingival junction on the cuspid and the first bicuspid and almost at the crown margin on the buccal gingiva of the second bicuspid.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What is gained anatomically with this surgery, and which foramen and nerve are near this area? A. Unattached keratinized gingiva is gained. The lingual foramen and nerve are near the area. B. Unattached keratinized gingiva is gained. The mental foramen and nerve are near the area. C. Attached keratinized gingiva and vestibular depth are created. The mental foramen and nerve are near the area. D. Attached nonkeratinized gingiva is gained. The greater palatine foramen and nerve are near the area.	**Answer: C** **Explanation:** All other answers are either unattached keratinized gingiva or attached nonkeratinized gingiva with no mention of vestibular depth. Also, answers A and D have indicated nerve foramens that are incorrect.

Initial Observations on the PRF-Block *(e-only)*
Conclusions

Introduction

Wound healing has been and remains an important topic in dentistry and other medical fields. Biomaterials proved to be beneficial in the process of wound healing.[10] They can be derived from nature or synthesized in the laboratory using a variety of chemical approaches. Countless efforts have been made to find new and specific bioactive additives that promote and accelerate healing, regulate inflammation, and improve regeneration. The impact of platelet concentrates to achieve these goals has been explored in sports medicine and orthopedics.[26] By facilitating recruitment, proliferation, and maturation of cells participating in regeneration, platelet concentrates clearly improve wound healing.[14]

Tissue adhesives (fibrin glues) were the precursors of platelet concentrates. Afterward, different types of platelet concentrates were developed. Based on the leukocyte content and fibrin structure, platelet concentrates can be classified into four main categories[26]:

- Pure platelet-rich plasma (P-PRP) without leukocytes and with a low-density fibrin network after activation
- Leukocyte- and platelet-rich plasma (L-PRP) with leukocytes and with a low-density fibrin network after activation
- Pure platelet-rich fibrin (P-PRF) without leukocytes and with a high-density fibrin network
- Leukocyte- and platelet-rich fibrin (L-PRF) with leukocytes and a high-density fibrin network

The literature is at times contradictory on the benefits of these platelet concentrates, and the data is often difficult to interpret. This chapter focuses on the use of L-PRF as a platelet concentrate for tissue regeneration.

From Fibrin Sealers to Platelet Concentrates

Fibrin sealers were one of the first biologic adjuvants in surgery. They were used in the 1970s to stimulate wound healing in rats.[65] It was the derivatives of human plasma that mimicked the last steps in the process of blood coagulation by the formation of a fibrin clot. Fibrin sealers are divided into two groups:

- Homologous fibrin sealers: products made from a combination of fibronectin, fibrinogen, factor VIII, and a thrombin concentrate in calcium chloride
- Autologous fibrin sealers: products of plasma in which the fibrin polymerization is started by the addition of thrombin of animal origin

The main action of these fibrin sealers is to stimulate local angiogenesis, minimize edema or hematoma formation, and reduce postoperative pain. The fibrin matrix is the main component of fibrin sealers. The properties of this matrix are determined by interactions among circulating fibrinogen, platelet aggregation, and molecules produced by the platelets.

Further research led to an upgraded version of the sealers, called platelet-derived wound healing factor (PDWHF). This group of sealers contains a significant concentration of platelets to strengthen the fibrin gel and simultaneously promote healing capacities. The addition of more components from blood forms a more natural product. The results in general surgery, neurosurgery, and ophthalmology are encouraging.

The First Generation of Platelet

Concentrates: Platelet-Rich Plasma

Whitman, Berry, and Green in 1997[90] and Marx and colleagues in 1998[63] were the first to promote the use of PRP in oral and maxillofacial surgery. In essence, PRP is an increased concentration of autologous platelets in a small amount of plasma that is obtained after centrifugation. The preparation is quite complex (Fig. 66.1). Briefly, 27 mL of blood is collected in a 30-mL syringe containing 3 mL of adenosine-citrate-dextrose acid (ACD-A) anticoagulant. The content of the syringe is transferred to the 30-mL separation tube and centrifuged at a relative centrifugal force (RCF) of 1900*g* for 15 min at room temperature. After removal of the plasma, the buffy coat is resuspended in the leftover plasma by shaking the tube for 30 seconds. A second syringe containing 1 mL of ACD-A is used to collect an additional 11 mL of blood, which is transferred into a Clotalyst disposable tube (Biomet Inc., Dietikon, Switzerland) containing 4 mL thrombin. After gentle mixing, the tube is placed into a Clotalyst disposable tube heater for 25 min. Subsequently, the mix is centrifuged for 5 min at 1900*g*. Coagulation is performed with the use of a double syringe (spray applicator) that allows uniform mixing of the two components, resulting in the formation of a clot. The time between centrifugation and clinical use is approximately 45 min.

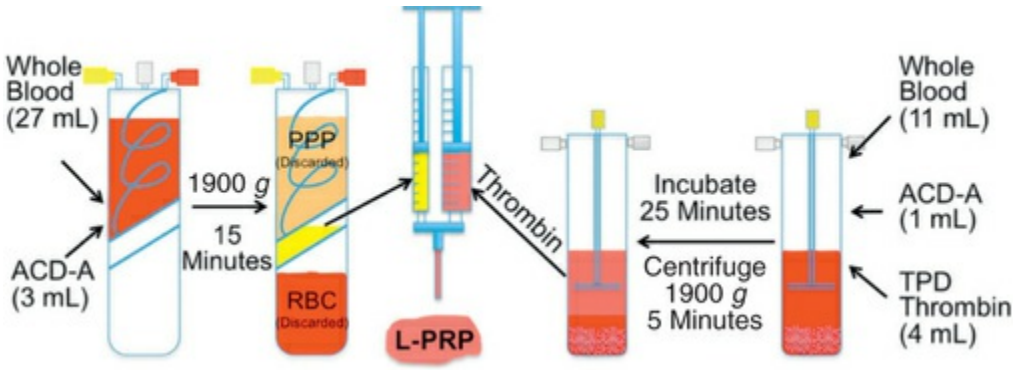

FIG. 66.1 Centrifugation protocol for L-PRP (leucocyte- and platelet rich plasma) according to the manufacturer's protocol (Biomet Inc., Dietikon, Switzerland). *ACD-A,* Adenosine-citrate-dextrose acid anticoagulant; *PPP,* plasma-poor platelets; *RBC,* red blood cells; *TPD,* thrombin processing device (Thermogenesis Corp., Rancho Cordova, CA). (From

Schär MO, Diaz-Romero J, Kohl S, Zumstein MA, Nesic D: Platelet-rich concentrates differentially release growth factors and induce cell migration in vitro. *Clin Orthop Relat Res* 473:1635–1643, 2015.)

The benefits of using PRP in medicine have been studied extensively. Most reviews are found within the field of orthopedics and sports medicine. According to a meta-analysis,[16] the intra-articular injection of PRP in patients with osteoarthritis of the knee is beneficial. However, results are not conclusive.[55] In oral and maxillofacial surgery, PRP is particularly used after extraction of third molars,[9] in the treatment of periodontal intrabony defects,[34,71] in sinus elevation techniques,[53] and for hard and soft tissue augmentation.[69] The purpose of using PRP in these types of surgeries was to accelerate the vascularization of the graft, improve soft tissue healing and bone regeneration, and reduce postoperative morbidity. However, results remained inconclusive.

To improve its efficacy, the preparation protocol for this platelet concentrate has been changed and adapted several times over the years. A well-known example is platelet-rich growth factor (PRGF), which was first described by Anitua and coworkers.[4] PRGF differs from other platelet concentrates in its versatility. Depending on the degree of coagulation and activation of the blood, four different types of preparations with different therapeutic potentials were obtained (e.g., PRGF structure as a liquid substance or a dense elastic fibrin). Research showed that PRGF may be used as a treatment modality for osteoarthritis, treatment of ulcers, tissue engineering, and oral surgery applications. However, the results should be interpreted with some caution.[5] Overall, we can say that there is a shortage of critical scientific data on the positive effects of PRP in clinical procedures. There is great variability in study designs (e.g., small groups of patients, no control groups) and also in preparation protocols (e.g., without clear classification), which makes comparisons difficult. Furthermore, the use of PRP has a number of significant disadvantages: the preparation protocol is expensive, complicated, and very operator dependent, and the need for animal thrombin as a coagulant raises legal issues in some countries.[51]

The Second Generation of Platelet Concentrates: Platelet-Rich Fibrin

New techniques were investigated to overcome the disadvantages of PRP (Table 66.1). This resulted in the introduction of PRF by Choukroun and coworkers in 2001.[22] PRF can be seen as an autologous biomaterial made of a fibrin matrix that contains the following[41]:

Table 66.1

Major Differences Between Platelet-Rich Plasma (PRP) and Leukocyte- and Platelet-Rich Fibrin (L-PRF)

Blood Products	PRF (2004)	PRP (1998)
Protocol	Easy	Very complex
Speed	Fast	Slow
Reproducibility	No bias	Possible bias
Use of anticoagulants	No	Yes
Amount obtainable	Good	Enough
Cost of the protocol	Low	Moderate
Amount of fibrin obtainable	High	Low
Speed of fibrin formation	Physiological	High
Fibrin morphology	Trimolecular	Tetramolecular
Leukocyte amount	65%	0–50%
Immunomodulatoy properties	Yes	Poor
Neoangiogenic potential	+++++	+
Osteoconductive potential (scaffolding)	High	Poor
Mechanical properties (sol-gel membrane)	Good	Enough
Presence of MSCs	Yes	Yes

MSCs, Mesenchymal stem cells.

From Giannini S, Cielo A, Bonanome L, et al: Comparison between PRP, PRGF and PRF: lights and shadows in three similar but different protocols. *Eur Rev Med Pharmacol Sci* 19:927–930, 2015.

- The highest concentration of platelets
- The highest concentration of growth factors, including platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and transforming growth factor (TGF)
- A representative concentration of fibrin, fibronectin, vitronectin, and thrombospondin

- An approximately 65% concentration of leukocytes

Nowadays, PRF can be regarded as the least expensive and most streamlined way to produce platelet concentrate. PRF is classified according to its leukocyte content as either L-PRF or P-PRF. L-PRF contains up to 90% of the platelets and at least 75% of the leukocytes present in the patient's blood. This chapter deals only with L-PRF.

Preparation of L-PRF

Blood samples (9–10 mL) are collected in sterile glass or plastic-coated tubes. The tubes are placed in pairs and centrifuged at 400*g* RCF for 12 min using the Intraspin centrifuge (Intra-Lock International, Boca Raton, FL); 400*g* RCF is equivalent to 2700 rpm. The Intraspin centrifuge is approved by the U.S. Food and Drug Administration and has a level 2 CE certificate. It is very important that the collection of blood and placement of the tubes in the centrifuge happen as rapidly as possible, before the spontaneous coagulation process occurs. Ideally, the tubes should be centrifuging within 60 seconds after the start of the venipuncture. This often requires loading the centrifuge with tubes two by two or one by one. In the latter case, a tube filled with the same amount of glycerine or saline should be considered to balance the centrifugation.

There is no manipulation of the blood; no anticoagulants are used in the tubes, and hence there is no need for animal thrombin and calcium chloride for fibrin polymerization. Plastic tubes are coated with silica and silicon to activate the coagulation. The absence of anticoagulants allows the activation of platelets in contact with the inner walls of the tube. After a few minutes, a coagulation cascade is initiated. Initially, the fibrinogen is positioned in the upper part of the tube. However, after centrifugation, due to the activation of autologous thrombin, it is converted to fibrin and a fibrin clot is created. After centrifugation, three distinct layers can be seen in the tube (Fig. 66.2): red blood cells (RBCs) at the bottom of the tube, platelet-poor plasma (PPP) at the top of the tube, and the fibrin clot

(containing most leukocytes and platelets) in the middle of the tube.

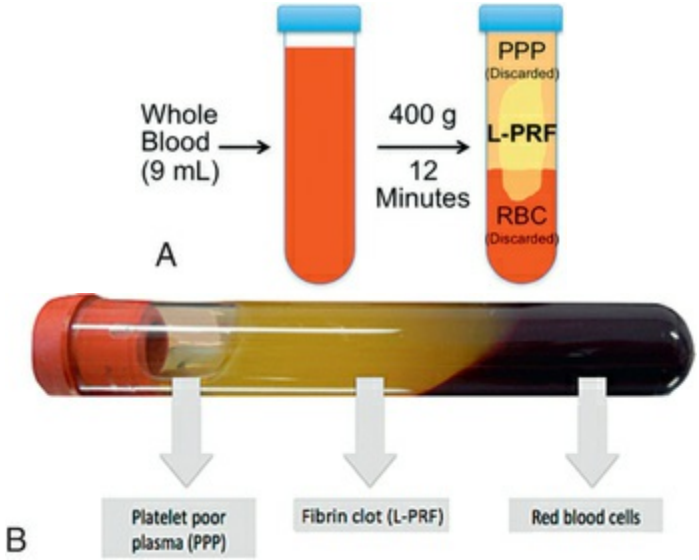

FIG. 66.2 (A) L-PRF tube after centrifugation, with its three compartments. (B) Photograph of a tube after the preparation of L-PRF. *PPP,* platelet-poor plasma; *RBC,* red blood cells. (A, from Schär MO, Diaz-Romero J, Kohl S, Zumstein MA, Nesic D: Platelet-rich concentrates differentially release growth factors and induce cell migration in vitro. *Clin Orthop Relat Res* 473:1635–1643, 2015.)

The L-PRF clot can be removed from the tube with surgical tweezers. With an instrument similar to a spatula, the RBC fraction can be gently separated from the fibrin clot. The clot by itself contains a great amount of exudate, which is rich in growth factors. This exudate can be expressed by gentle compression of the clot (about 5 min) in order to obtain stronger L-PRF membranes. For this compression, one can utilize a specially engineered box. The box contains a weighted press plate that is designed to express serum from the L-PRF clot in a controlled manner. It forms standard 1-mm-thick L-PRF membranes (Box 66.1 and Fig. 66.3). The membranes remain stable at room temperature for several hours.

Box 66.1

Step-by-Step Approach for the Preparation of L-PRF (Simple Chair-Side Procedure)

Protocol for Preparation of L-PRF Clots:

- Venipuncture: collect between four and eight 9-mL tubes of blood (see Fig. 66.3A,B).
- Tubes have to be in the centrifuge within 60 seconds. *(Often, the centrifuge is loaded step-wise with two tubes at a time; centrifugation is performed between collections of new tubes.)*
- Centrifuge at 400*g* RCF (2700 rpm) using the IntraSpin centrifuge (Intra-Lock International, Boca Raton, FL) for at least 12 min (see Fig. 66.3C). *(Start timing after the centrifuge has been loaded with the last two tubes.)*
- After at least 12 min of centrifugation (for patients taking anticoagulant medication, 15–18 min is recommended), the L-PRF clots are ready (see Fig. 66.3D).
- Take the clots out of the tubes and separate them from the red blood cells (see Fig. 66.3E,F).

Protocol for Preparation of L-PRF Membranes:

- Place clots in Xpression kit (Intra-Lock) for gentle compression by gravity (e.g., with light metal plate) (see Fig. 66.3G,H).
- Five minutes later, the L-PRF membranes are ready for use (see Fig. 66.3I).
- Membranes can be used during at least the next 2 hours but should be prevented from drying out.

Protocol for Preparation of L-PRF Plugs:

- Place clots in the small cylinder of the metal Xpression box.
- Use the piston to carefully compress the clot.
- Plugs can be used during at least the next 2 hours, but prevent them from drying out.

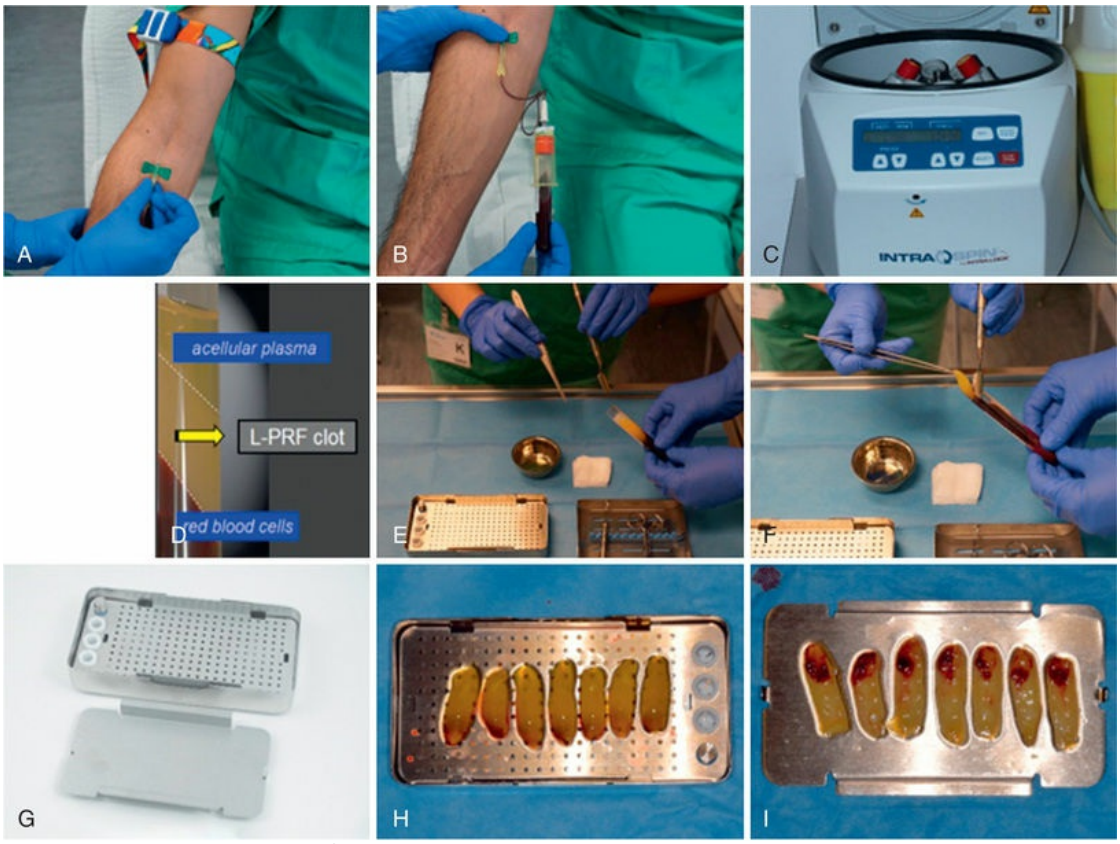

FIG. 66.3 **Process of preparing L-PRF clots and membranes. (A and B) Venipuncture and blood collection. (C) Centrifugation at 400*g* RCF (2700 rpm) with the IntraSpin centrifuge (Intra-Lock International, Boca Raton, FL). (D) L-PRF clot in tube, showing clear separation: red blood cells (RBCs) at the bottom, PPP (platelet-poor plasma) on the top, and L-PRF fibrin clot in the middle. (E and F) Removal of clot from tube and separation of clot from RBCs. (G) A specially designed kit (Xpression box; Intra-Lock International) is used to compress L-PRF clots into L-PRF membranes with a consistent thickness of 1 mm. A piston and cylinder assembly *(left side of kit)* can be used for the creation of L-PRF plugs, which are suitable for filling extraction sockets. (H) L-PRF clots before compression. (I) L-PRF membranes after gentle compression; the red area of the membrane represents the face side, where most leukocytes and platelets are concentrated.**

These autologous membranes, which have a dense fibrin network, are strong (one membrane can withstand a load of approximately 400 g before rupture) and have excellent biologic properties (rich in platelets, growth factors, and cytokines), opening many new clinical avenues. L-PRF provides a scaffold consisting of fibrin that promotes cellular migration, a fundamental aspect in the process of regeneration.[62] L-PRF membranes remain solid and intact in vitro and continuously release large quantities of growth factors for 7 to 14 days.

Key Fact

The blood tubes have to be in the centrifuge within 60 seconds after the start of the venipuncture and centrifuged at 400*g* RCF for at least 12 minutes.

General Characteristics of L-PRF Membranes

Platelets in L-PRF

After centrifugation, at least 90% of the platelets derived from the blood sample are present in the fibrin clot. The platelets are mainly present in the lower portion of the clot, at the border between the RBCs and the clot itself. As a result, the lower portion of the clot, also called the *face*, is considered to be the most biologically active. The platelet cytoplasm contains several granules. The content is released at the time of activation. These granules contain many cytokines and many active substances such as serotonin, von Willebrand factor, factor V, osteonectin, and antimicrobial proteins. When platelets come in contact with the collagen of a damaged blood vessel, they get activated. This activation is necessary for platelet aggregation and thus starts and maintains hemostasis. Activation of the platelets involves degranulation and the sequential release of various cytokines. They stimulate cell migration and proliferation into the fibrin matrix. The principal role of the platelets is the maintenance of homeostasis; however, they are capable of binding, aggregating, and internalizing microorganisms, which enhances the clearance of pathogens from the bloodstream. Platelets participate in antibody-dependent cell cytotoxicity functions to kill protozoal pathogens and to release an array of potent antimicrobial peptides.[12,83]

Key Fact

After centrifugation, at least 90% of the platelets derived from the

blood sample are present in the fibrin clot. The platelets are mainly present in the lower portion of the clot, at the border between the red blood cells and the clot itself. As a result, the lower portion of the clot, also called the face, is considered to be the most biologically active.

Leukocytes in L-PRF

Dohan and associates[32] analyzed the cellular content of L-PRF membranes and concluded that more than 50% of the leukocytes are concentrated in the fibrin matrix. A cell count performed at the KU Leuven (Periodontology and Oral Microbiology Laboratory) shows that more than 75% of the leukocytes remain within the L-PRF membrane (Table 66.2), whereas the concentration in the L-PRF exudate is very low. The latter, however, contains a high concentration of growth factors.

TABLE 66.2

Cellular Content of the L-PRF Membrane or L-PRF Exudate Based on the Analysis of 15 Patients

Cells	L-PRF Exudate (%)	L-PRF Membrane (%)
Red blood cells	1.1 ± 0.9	42.8 ± 17.7
Platelets	1.0 ± 0.8	96.9 ± 2.0
White blood cells (leukocytes)	3.5 ± 2.3	74.3 ± 8.9
Neutrophils	1.5 ± 2.2	62.9 ± 13.1
Lymphocytes	4.9 ± 3.9	82.1 ± 21.9
Monocytes	1.9 ± 2.5	93.3 ± 4.5
Eosinophils	1.6 ± 1.7	36.0 ± 29.9
Basophils	1.9 ± 2.8	84.4 ± 10.6

L-PRF, Leukocyte- and platelet-rich fibrin.

Adapted from Castro AB, Meschi N, Temmerman A, et al: Regenerative potential of leucocyte- and platelet-rich fibrin (L-PRF). Part B: sinus floor elevation, alveolar ridge preservation, and implant therapy. A systematic review. *J Clin Periodontol* 44:225–234, 2017b.

The presence of leukocytes in platelet concentrates is of great importance. Leukocytes have potential antibacterial characteristics but can also regulate cell proliferation and cell differentiation. In addition, they are the basic cells responsible for the wound healing process and the first cells to start neoangiogenesis. In fact, they contain VEGF, which acts as a potent vascular growth factor. The

leukocytes are also a source of production of the aforementioned growth factors.

Neutrophils are recruited to the site of injury within minutes after trauma and are the hallmark of acute inflammation. They migrate toward the damaged site and get embedded in the fibrin network, forming a dense barrier against pathogens and preventing infection. Their main function is the production of inflammatory cytokines and growth factors.[4]

Monocytes are the largest type of leukocyte and can differentiate into macrophages, playing a central role in healing. They have immunologic functions as antigen-presenting cells and phagocytes.

Macrophages have been implicated in inflammation processes. However, they also play an essential role in bone repair. The role of monocytes and macrophages in bone repair has become an area of increased interest. Macrophages apparently direct osteogenic cell signals and promote mineralization during in vitro studies.[20] During bone injury, monocytes and macrophages modulate the acute inflammatory response, produce growth factors such as bone morphogenetic protein 2 (BMP-2) and PDGF-BB, and induce osteogenesis in mesenchymal stem cells.[19,91,92,93] Macrophages secrete collagenase, which promotes the cleaning of the wound. Additionally, they are a source of growth factors such as TGF, which stimulates the keratinocytes, and PDGF, which plays an important role in angiogenesis. Granulocytes and macrophages promote the production of inflammatory mediators such as leukotriene B_4 and platelet-activating factor, which stimulate the expansion and increased permeability of blood vessels as well as the production of inflammatory cytokines and protolithic enzymes. These factors also act on the endothelial cells of blood vessels, stimulating the adhesion of neutrophils and lymphocytes and their migration out of blood vessels.[4]

Despite the release of activated oxygen species (free radicals) from leukocytes during phagocytosis activity and the ischemia reperfusion process, it seems that the inclusion of leukocytes in blood derivatives such as L-PRF may play a beneficial role.[38]

Key Fact

More than 75% of the leukocytes remain within the L-PRF membrane. The presence of leukocytes in platelet concentrates is important. They can regulate cell proliferation and cell differentiation. Leukocytes are the basic cells responsible for wound healing and the first cells to start neoangiogenesis. They contain vascular endothelial growth factor (VEGF), which acts as a potent vascular growth factor.

Growth Factors in L-PRF

Platelets have an important function in the release of growth factors. The alpha-granules in platelets contain PDGF, insulin-like growth factor-1 (IGF-1), epidermal growth factor (EGF), VEGF, and TGF-β, which initiate wound healing by attracting and activating macrophages, fibroblasts, and endothelial cells. L-PRF membranes continuously release (≥7 days) a large quantity of growth factors. A significant amount of them are produced by the platelets (Fig. 66.4). These growth factors are also present in PRP gel. However, their release occurs specifically in the first hours, and they are completely dissolved in the medium after 3 days due to the chemical activation of the platelet content. This difference can be explained by the differences in fibrin architecture between the PRF families. PRF has a natural polymerization with intrinsic growth factor enmeshment, whereas PRP gel families have an artificial provoked polymerization with extrinsic growth factor enmeshment, leading to their immediate release and use or destruction.[28,74]

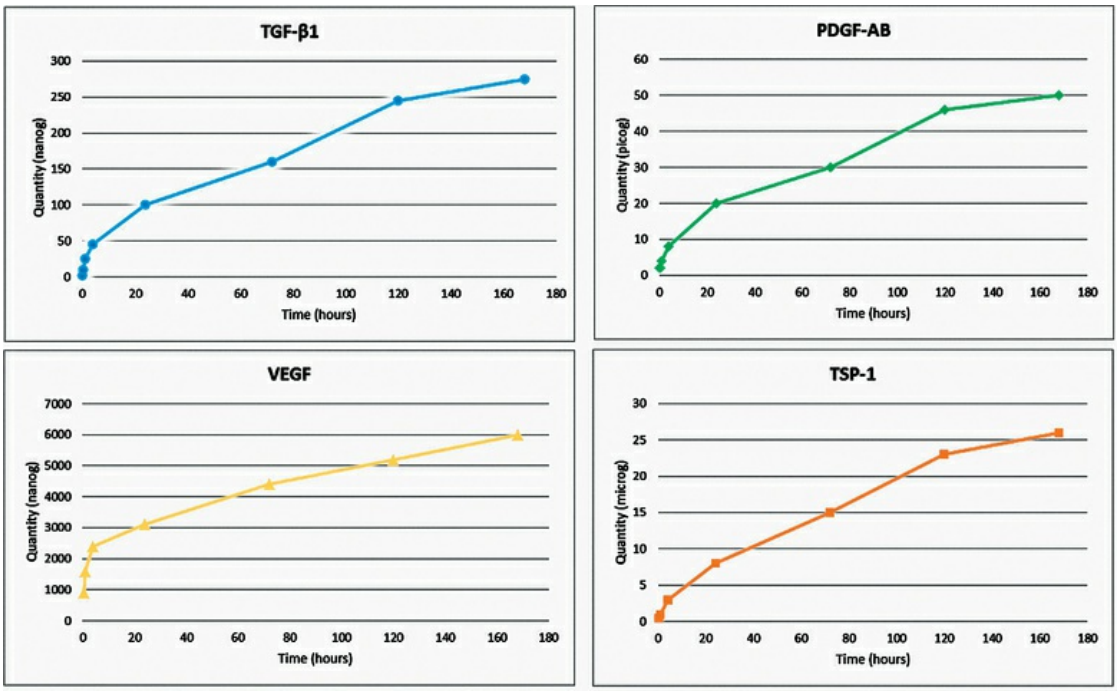

FIG. 66.4 Slow release of TGF-β1, PDGF-AB, VEGF, and thrombospondin-1 from an L-PRF membrane over 7 days. Values are expressed as the cumulative mean quantity of molecules at 20 min, 1h, 4h, 24h, 72h (3 days), 120h (5 days), and 168h (7 days). *PDGF,* Platelet-derived growth factor; *TGF,* transforming growth factor; *TSP,* thrombospondin; *VEGF,* vascular endothelial growth factor. (From Dohan DM, de Peppo GM, Doglioli P, Sammartino G: Slow release of growth factors and thrombospondin-1 in Choukroun's platelet-rich fibrin (PRF): a gold standard to achieve for all surgical platelet concentrates technologies. *Growth Factors* 27:63–69, 2009.)

Fibrin in L-PRF

Fibrin is an insoluble clotting protein that plays a major role in platelet aggregation during hemostasis and wound healing. Fibrinogen, the precursor of fibrin, is converted by thrombin into fibrin, which forms long, nonsoluble strands that bind to platelets. Present in physiologic concentrations, thrombin allows the formation of a fibrin matrix in a slow and physiologic manner. The fibrin wires tend to polymerize and form a biochemical structure with trimolecular or equilateral junctions, providing a fine and flexible fibrin network that favors the entrapment of cytokines and cell migration (Fig. 66.5). This three-dimensional network has an

important function as a matrix, promoting the invasion of various types of inflammatory, endothelial, and other cells. This matrix is also able to capture glycosaminoglycans (originating from the blood platelets). These glycosaminoglycans have a high affinity for circulating peptides (e.g., cytokines) and a large capacity to support cell migration and healing processes.[28]

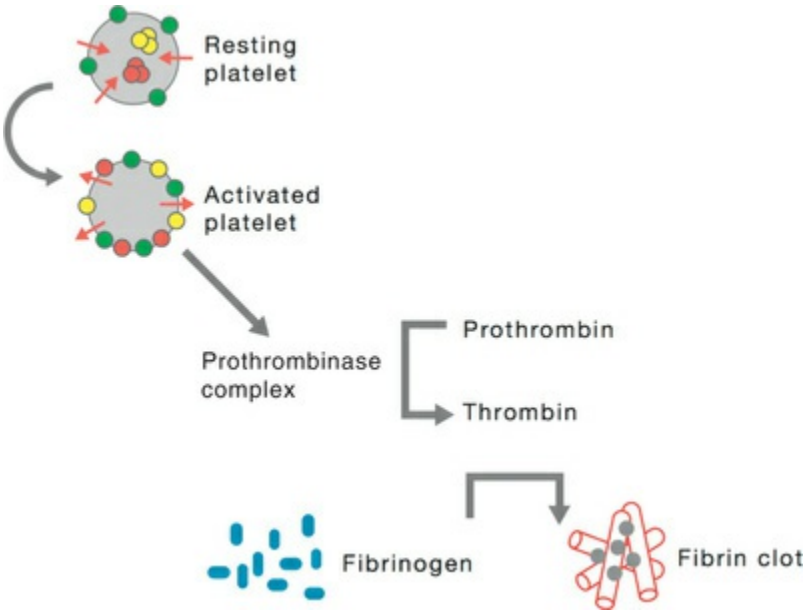

FIG. 66.5 Interaction between release of granules by activated platelets and conversion of prothrombin to thrombin, which by itself regulates the conversion of fibrinogen into a fibrin clot. This principle is also used in the preparation of an L-PRF block. The activation of the platelets occurs during centrifugation.

Stem Cells in L-PRF

Dohan and colleagues[33] showed a significant stimulation of human bone mesenchymal stem cells when in contact with L-PRF. This effect was dose-dependent during the first weeks in normal conditions and during the whole experiment in differentiation conditions. The cultures without L-PRF in differentiation conditions did not rise above the degree of differentiation of the cultures in normal conditions with L-PRF up to the 14th and 28th day, respectively. The scanning electron microscopy (SEM) culture

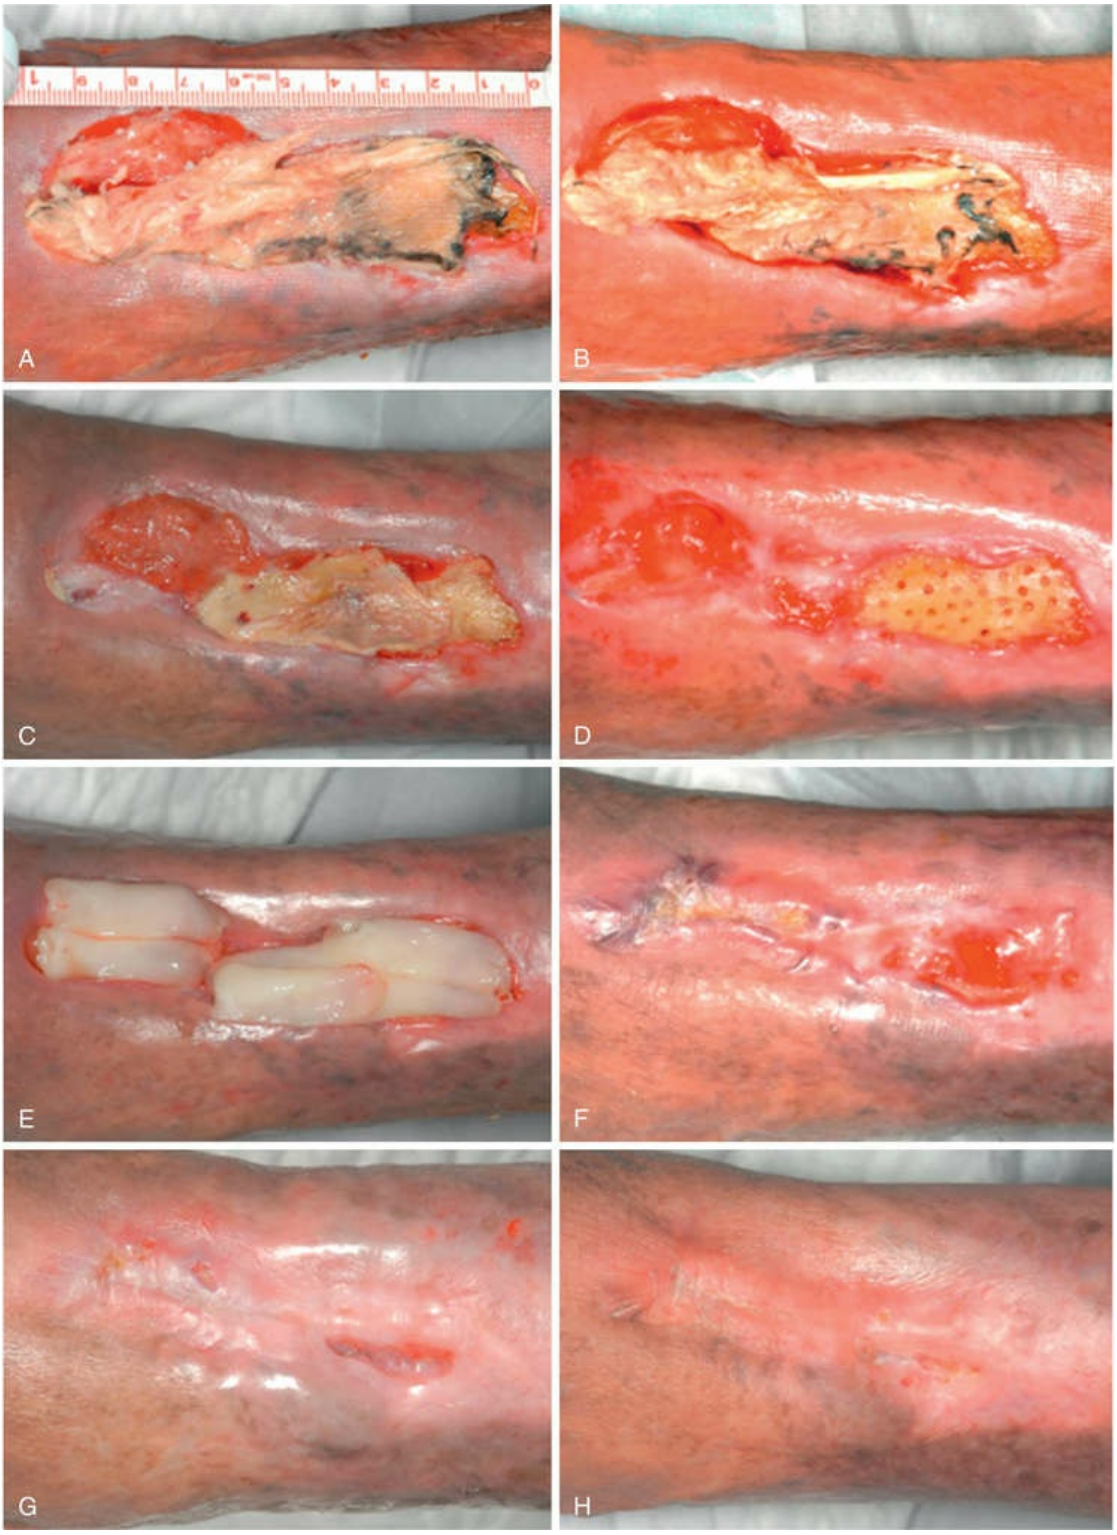
analysis at day 14 showed mineralization nodules more numerous and more structured in the groups with L-PRF compared to the control groups.

Extraoral Applications of L-PRF

In several countries, L-PRF is used for the treatment of nonresponding skin ulcers, including diabetic foot ulcers (DFUs), pressure ulcers (PUs), acute surgical wounds, and venous leg ulcers (VLUs). Such wounds, especially if recalcitrant despite appropriate wound care, have a dramatic impact on patients' quality of life. They are associated with high treatment costs and are a significant cause of morbidity. The standard treatment for chronic ulcers may include debridement of necrotic tissues, revascularization surgery, infection control, hyperbaric therapy, mechanical offloading, management of blood glucose, foot care education, mechanical compression, or limb elevation.[42,67] Full wound closure after standard VLU care can take months or even years in some patients. In as many as half of these patients, wound closure fails.[45,61] For DFUs, similar wound closure rates have been reported (24.2% and 30.9% at 12 and 20 weeks, respectively).[60] For PUs, there is no good evidence to support the use of any particular wound cleansing solution or technique. Furthermore, wound closure remains extremely difficult.[79] If such treatment fails, advanced wound care is recommended. During the last decade, a large array of advanced therapies have been proposed. However, their efficacy, comparative effectiveness, and eventual harms are not well established. Most of these advanced therapies are expensive, and they are not obviously superior to standard optimal wound care.[15,42,70,79]

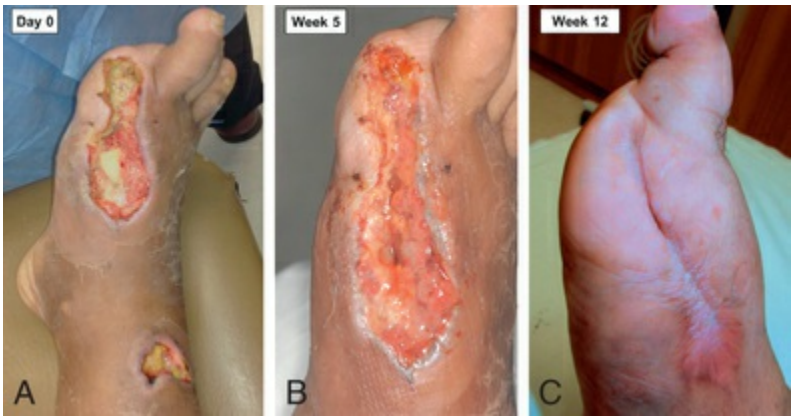
In an ongoing clinical research project, L-PRF application resulted in 100% wound closure for VLUs ≤10 cm^2, and at least 10 of the 15 large wounds could be closed (eFig. 66.1). For DFUs, again L-PRF seems superior, with a 100% wound closure in sites where standard wound care failed (eFig. 66.2). The beneficial effect of L-PRF membranes in the healing of chronic leg ulcers can be explained by its high concentration of platelets and leukocytes, together with the long-term release of growth factors. Especially the progressive release of growth factors (e.g., TGF-β1, TGF-β2, PDGF-

AB, VEGF, IGF), matrix glycoproteins (trombospondin-1, fibronectin, and vitronectin), proinflammatory cytokines (interleukin-1β [IL-1β], IL-6, tumor necrosis factor-α [TNF-α]), and an antiinflammatory cytokine (IL-4) for up to 7 days seems crucial.[11,25,27,28,29] This might also explain why L-PRF could be an immune regulation node with inflammation abilities and could lead to a reduction of postoperative infections when used as a surgical additive.[29,30]



EFIG. 66.1 Follow-up pictures of very large venous leg ulcer (VLU) recalcitrant to advanced treatment strategies, with visibility of tendons and exposed bone. (A and B) The initial wound. Treatment session at 6 weeks (C), at 10 weeks (D), at 12 weeks (E), and at 21 weeks with nearly complete wound closure (F). Follow-

up sessions at 12 months (G) and 3 years (H).



EFIG. 66.2 Follow-up pictures of a diabetic foot ulcer. (A) Initial wound. (B) Treatment session at 5 weeks and (C) 12 weeks of L-PRF application. At 12 weeks the wound was completely closed.

L-PRF in the Treatment of Periodontal Bony Defects

The use of L-PRF in the treatment of periodontal or bone defects can be described as natural tissue regeneration and natural bone regeneration, analogous to guided tissue regeneration and guided bone regeneration.[23] The defect is filled with L-PRF (optionally combined with a biomaterial to prevent collapse) and sealed with L-PRF membranes.

These membranes have a protective function (induction of the periosteum) and serve as a competitive barrier (Fig. 66.6 and Box 66.2). Epithelium and connective tissues are kept away from the intrabony crater, so that the cells from the periodontal ligament or periosteum have time to regenerate cementum, bone, and ligament. These cells can also migrate through the membranes, which results in fast neo-angiogenesis. L-PRF also promotes the proliferation and differentiation of osteoblasts and bone marrow stromal cells in vitro.[31] This stimulation appears to be dose dependent, with leukocytes playing a key role.

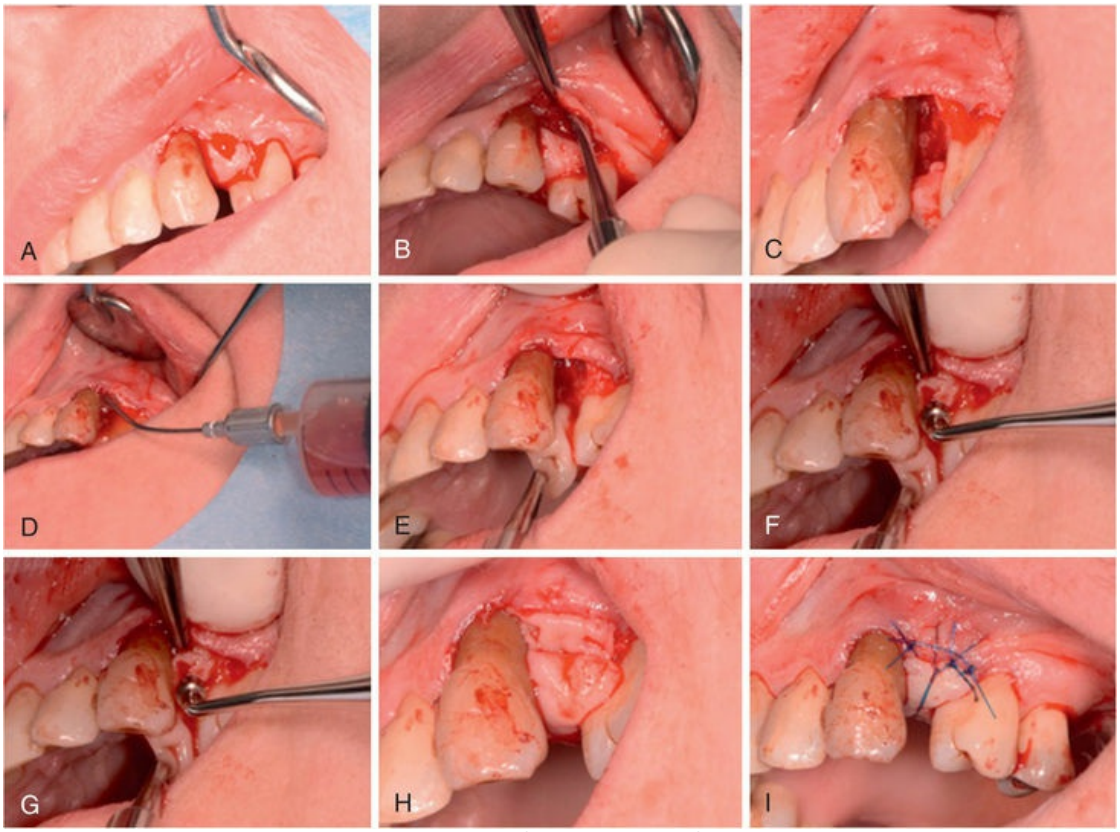


FIG. 66.6 **Regenerative treatment of intrabony defects with L-PRF. (A) Intrasulcular incision with papilla preservation. (B) Minimal flap elevation (palatally pediculated). (C) Defect after root planing. (D) Rinsing of the intrabony defect with L-PRF exudate. (E and F) Application of chopped L-PRF membrane in the defect (preferably face side). (G and H) Coverage of bony defect with at least two layers of L-PRF membranes. (I) Flap suturing, preferably with primary closure of the interdental papilla, in the absence of tension.**

Box 66.2

Step-by-Step Approach for the Use of L-PRF During Open Flap Debridement

Protocol for L-PRF as Sole Biomaterial for Intrabony Defect Regeneration During Open Flap Debridement (Fig. 66.9):

- Intrasulcular incision with maximal preservation of gingival complex (see Fig. 66.6A).
- Minimal flap elevation and degranulation of intrabony defects

(see Fig. 66.6B).

- Optimal root planing (see Fig. 66.6C).
- Rinse defect with L-PRF fluid (see Fig. 66.6D). *(The fluid is collected at the bottom of the* Xpression kit *[Intra-Lock International, Boca Raton, FL] after compression of the clots.)*
- Apply L-PRF membrane (or part of it) in the defect (preferably with the face part of the membrane toward bone) (see Fig. 66.6E,F).
- Cover bony defect with at least two layers of L-PRF membranes, running at least 2 mm over the bony borders underneath the periosteum, in order to seal the socket and to force the soft tissues to grow over instead of underneath the membranes (see Fig. 66.6G,H).
- Suture flap and try to provide primary closure of the interdental papilla in the absence of tension (see Fig. 66.6I).

Postoperative Care:

- Soft food intake; no biting in treated area; no mechanical cleaning of the treated area.
- Use of 0.12% chlorhexidine mouthwash twice daily for 1 min for at least 3 weeks.
- Painkillers.

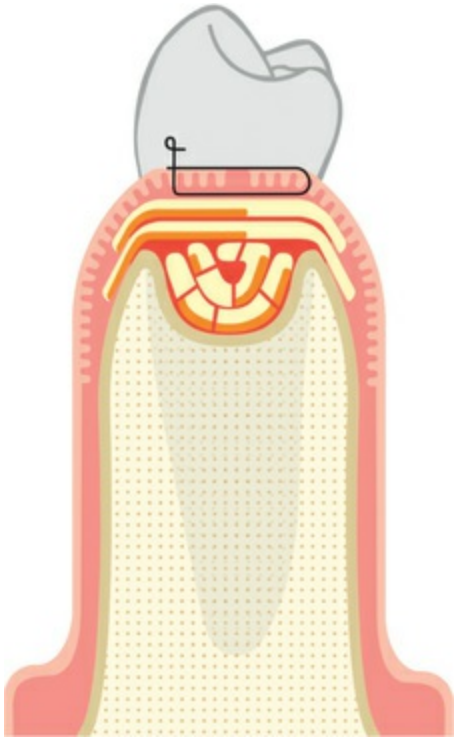

FIG. 66.9 Graphic representation of an intrabony defect filled with chopped L-PRF membrane parts (preferably the face part) and covered with L-PRF membranes (at least two layers with face side toward bony defect and running over the buccal and lingual bony borders). Primary closure is not mandatory.

« Flash Back

Guided tissue regeneration uses a barrier membrane to separate tissues. This allows slower-moving cells from the periodontal ligament and periosteum to occupy the wound, facilitating periodontal regeneration, while delaying the faster-moving cells of epithelium and connective tissue from entering the site.

A series of clinical studies evaluated the benefits of applying L-PRF alone during open flap debridement (Table 66.3). A systematic review and meta-analysis on the use of L-PRF in regenerative procedures reported an adjunctive improvement, when L-PRF was used, on parameters such as probing pocket depth reduction (1.1 ± 0.5 mm extra reduction), clinical attachment level (1.2 ± 0.6 mm extra gain), and bone defect fill (1.5 ± 0.3 mm or 46% ± 12.8% extra

bone fill).[17] In some studies, L-PRF was combined with a bone substitute, and even here an additional benefit could be observed. When L-PRF was compared to enamel matrix derivative, similar improvements were reported (see Table 66.3).

TABLE 66.3

Most Important and Most Relevant RCTs and CCTs on the Use of L-PRF in Periodontal Defects

Article	Type	Subjects	Groups	Conclusions
Thorat et al. 2011[86]	RCT	32 defects	test: L-PRF + OFD control: OFD	OFD + L-PRF: -More PPD reduction, CAL gain, and defect fill
Sharma & Pradeep, 2011b[77]	RCT	56 defects	test: L-PRF + OFD control: OFD	OFD + L-PRF: -More PPD reduction, CAL gain, and defect fill
Sharma & Pradeep, 2011a[76]	RCT split-mouth	36 furcation class 2 mandible	test: L-PRF + OFD control: OFD	OFD + L-PRF: -Significantly better clinical and radiologic parameters
Lekovic et al. 2012[57]	CCT split-mouth	17	test: L-PRF + DBBM control: L-PRF	L-PRF improved the clinical parameters L-PRF + DBBM: greater filling of the defect and greater PPD reduction
Pradeep et al. 2012[70]	RCT	57	test 1: L-PRF + OFD test 2: L-PRF + HA + OFD control: OFD	Both test conditions resulted in greater reduction of PPD, greater gain in CAL, and greater filling of the intrabony defects.
Rosamma Joseph et al. 2012[72]	RCT split-mouth	15	test: OFD + L-PRF control: OFD	OFD + L-PRF: -More effective than OFD alone in the treatment of intrabony periodontal defects
Bansal & Bharti, 2013[8]	RCT split-mouth	10	test: L-PRF + DFDBA control: DFDBA	OFD + L-PRF: -More PPD reduction and CAL gain
Gupta et al. 2014[44]	RCT	44 defects	test: L-PRF control:	Similar results in both groups; EMD was superior in filling defects.

			EMD	
Rosamma Joseph et al. 2014[73]	CCT split-mouth	15	t1: L-PRF gel + OFD t2: L-PRF + OFD control: OFD	L-PRF in any form was more effective in PPD reduction and CAL gain than OFD alone.
Agarwal et al. 2015[1]	RCT split-mouth	30	test: L-PRF + DFDBA control: DFDBA	DFDBA in combination with L-PRF gave significant advantages in PPD reduction and CAL gain and an increase in bone density.
Ajwani et al. 2015[2]	RCT split-mouth	20	test: L-PRF + OFD control: OFD	OFD + L-PRF: -More filling of the defect
Elgendy & Abo Shady, 2015[35]	RCT split-mouth	20	test: L-PRF + HA control: HA	HA in combination with L-PRF gave more PPD reduction and CAL gain and an increase in bone density.
Mathur et al. 2015[64]	RCT	38	test: OFD + L-PRF control: OFD + ABG	Both groups resulted in a reduction of PPD and gain in CAL and were effective in the treatment of intrabony defects.
Shah et al. 2015[75]	RCT split-mouth	20	test: L-PRF + OFD control: OFD + DFDBA	Similar results in both groups

ABG, Autologous bone graft; CAL, clinical attachment level; CCT, controlled clinical trial; DBBM, deproteinized bovine bone mineral; DFDBA, demineralized freeze-dried bone allograft; EMD, enamel matrix derivative; HA, hydroxyapatite; L-PRF, leukocyte- and platelet-rich fibrin; OFD, open flap debridement; PPD, probing pocket depth; RCT, randomized controlled trial.

L-PRF for Ridge Preservation

After tooth extraction and loss of the bundle bone, the alveolar ridge undergoes a remodeling process in both vertical and horizontal directions. This process often complicates the placement of implants in an ideal position. Many surgical techniques have been developed to prevent, or at least minimize, this bone resorption. Different bone grafts or bone substitutes have been

developed to be used in extraction sockets, with or without the addition of a soft tissue graft or soft tissue substitute to seal the alveolus. However, a systematic review[89] concluded that today there is no clear guideline on which technique to use for this purpose. Another approach suggests keeping the vestibular part of the tooth root in the extraction socket, with the implant inserted behind this dentine shield.[47] The use of L-PRF in an extraction socket could be a less costly, more simplified, and more effective treatment alternative (Fig. 66.7 and Box 66.3), but standardization of the protocol is required to obtain reproducible results. The use of enough L-PRF clots or membranes seems to be crucial to obtain an optimal effect.[18]

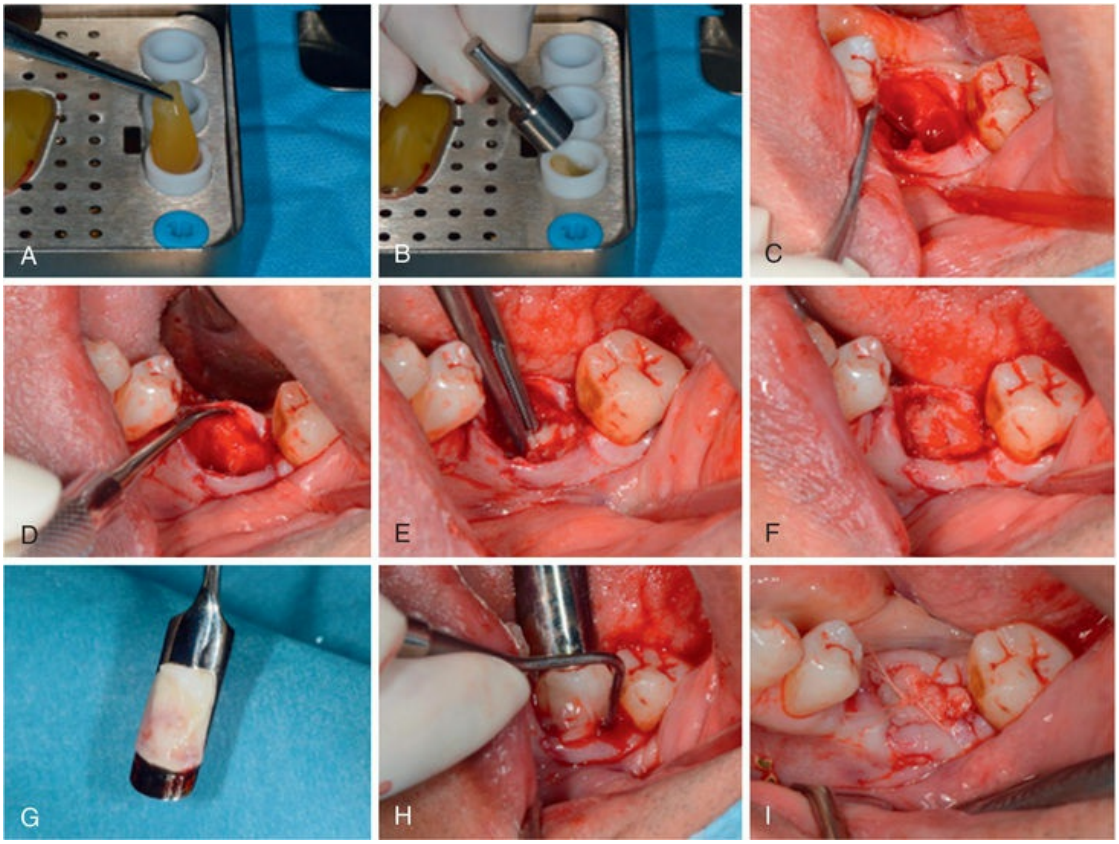

FIG. 66.7 **The use of L-PRF as a filling material for a tooth socket, with the aim of maintaining the alveolar bone dimensions. (A and B) Preparation of L-PRF plugs with the Xpression kit (Intra-Lock International, Boca Raton, FL). (C) Accurate removal of all inflammation and granulation tissue. (D) Preparation of envelope (approximately 2 mm in width) between the bony borders of the socket and surrounding soft tissues; this is needed to slide in the L-PRF membranes at the end, in order to prevent the fast ingrowth of connective tissue and to force the epithelium to grow over the membranes. (E and F) Placement, one by one, of three to five L-PRF**

plugs in the socket and vigorous compression. (G and H) Coverage of socket with at least a double layer of L-PRF membranes, sliding the borders of the membranes into the prepared envelope. (I) Tension-free suturing with, for example, a modified internal mattress or external mattress technique; primary closure is not necessary.

Box 66.3

Step-by-Step Approach for Ridge Preservation With L-PRF

Protocol for Ridge Preservation With L-PRF (Fig. 66.10):

- Atraumatic tooth extraction with maximal preservation of alveolar bone.
- Accurate removal of inflammation and granulation tissue (with bur, if needed) (see Fig. 66.7C).
- Preparation of envelope (approximately 2 mm in width) between the bony borders of the socket and surrounding soft tissues. This allows insertion of part of the L-PRF membranes between the periosteum and the flap, in order to seal the socket and force the soft tissues to grow over, instead of underneath, the membranes (see Fig. 66.7D).
- If applicable, use L-PRF exudate (aspirated in syringe), obtained after compression of clots, to irrigate and clean the socket.
- Place three to five L-PRF plugs, one by one, into the socket, compressing them vigorously with amalgam condenser and absorbing superfluous serum with gauze (see Fig. 66.7E,F).
- Cover the socket with at least a double layer of L-PRF membranes, and slide their margins between soft and hard tissues around the socket (envelope) to seal the socket and to prevent epithelial infiltration (see Fig. 66.7G,H).
- Suture with, for example, a modified internal mattress or external mattress technique, not with the intention to close the wound, but to keep the membranes in place without traction (see Fig. 66.7I).

Postoperative Care:

- No use of chlorhexidine during first 2 days, in order to not disturb initial soft tissue healing.

FIG. 66.10 Graphic representation of an extraction socket filled with L-PRF. Several L-PRF plugs or membranes (≥3) are condensed at the bottom (face toward bone), and the socket is sealed with at least two layers of L-PRF membranes. These membranes are slid under the periosteum at the bony socket borders (in the created envelope between the periosteum and the bony borders; 2 mm coverage is sufficient). Suturing is done without any attempt to close the wound (healing by secondary intention).

Hauser and coworkers[46] carried out a randomized controlled trial with a so-called split-mouth design in order to ascertain preservation of the alveolar ridge after tooth extraction. They concluded that L-PRF application resulted in better preservation of the width of the alveolar ridge and better intrinsic bone quality (measured by bone biopsies with micro-computed tomography). A split-mouth comparison[84] between natural healing of extraction sockets and sockets filled with L-PRF (comprising 22 patients) confirmed the above-mentioned benefits with significantly less

horizontal and vertical resorption, more socket fill, higher bone quality, and faster soft tissue and bone healing. This was reported even at sites with bone dehiscences. The observed reduction in bone resorption was comparable to the best-performing clinical procedures using bone substitutes in combination with connective tissue grafting and/or the placement of a membrane, similar to what was observed by Anwandter and coworkers.[6] These studies do, however, contradict a paper by Suttapreyasri and Leepong,[80] who did not record such significant differences (Table 66.4).

TABLE 66.4

Most Relevant RCTs and CCTs on the Use of L-PRF for Ridge Preservation

Article	Design	Subjects	Socket Fill	Conclusion
Hauser et al. 2013[46]	RCT	23 subjects	control: blood clot (8) test 1: L-PRF (9) test 2: L-PRF + flap (6)	L-PRF alone: -Improved bone healing with improved microarchitecture and quality -Better preservation of the alveolar bone L-PRF + flap: -Flap preparation negatively influenced benefits of L-PRF
Suttapreyasri & Leepong 2013[80]	RCT split-mouth	8 subjects	control: blood clot (10) test: L-PRF (10)	L-PRF: -Better preservation of the alveolar ridge -Less vestibular/lingual bone loss -No enhanced bone formation
Marenzi et al. 2015[59]	RCT split-mouth	26 subjects	2–8 sockets/patient control: blood clot test: L-PRF	L-PRF (up to 21 days): -Reduced postoperative pain -Improved healing of the soft tissues
Eshghpour et al. 2014[37]	RCT split-mouth	78 subjects	control: blood clot (78) test: L-PRF (7)8	L-PRF: -Decreased risk of alveolar osteitis after extraction of mandibular third molar
Anwandter et al. 2016[6]	prospective cohort	18 subjects	1 socket/patient test: L-PRF (18)	L-PRF: - Mean horizontal resorption of 1.2 ± 2.4 mm at the crest, 1.2 ± 2 mm and 0.8 ± 2.0 mm at 2 and 4 mm apically
Temmerman et al. 2016[84]	RCT split-mouth	22 subjects	2 sockets/patient control: blood clot (22) test: L-PRF (22)	L-PRF: -Less buccal bone resorption -Better preservation of the alveolar bone

CCT, Controlled clinical trial; L-PRF, leukocyte- and platelet-rich fibrin; RCT, randomized controlled trial.

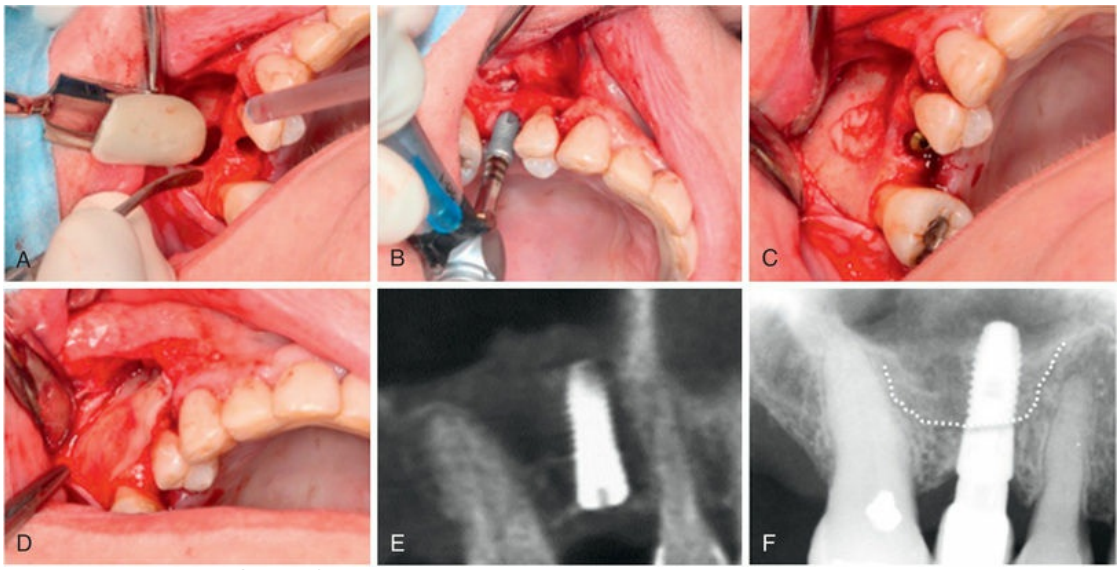
Several papers on third molar extractions indicated that L-PRF as a filling material has a beneficial effect on postoperative pain and soft tissue healing.[37,59]

The L-PRF clot enables fast neoangiogenesis and compensates for the bone trauma caused by the extraction with bone regeneration stimulated by growth factors.

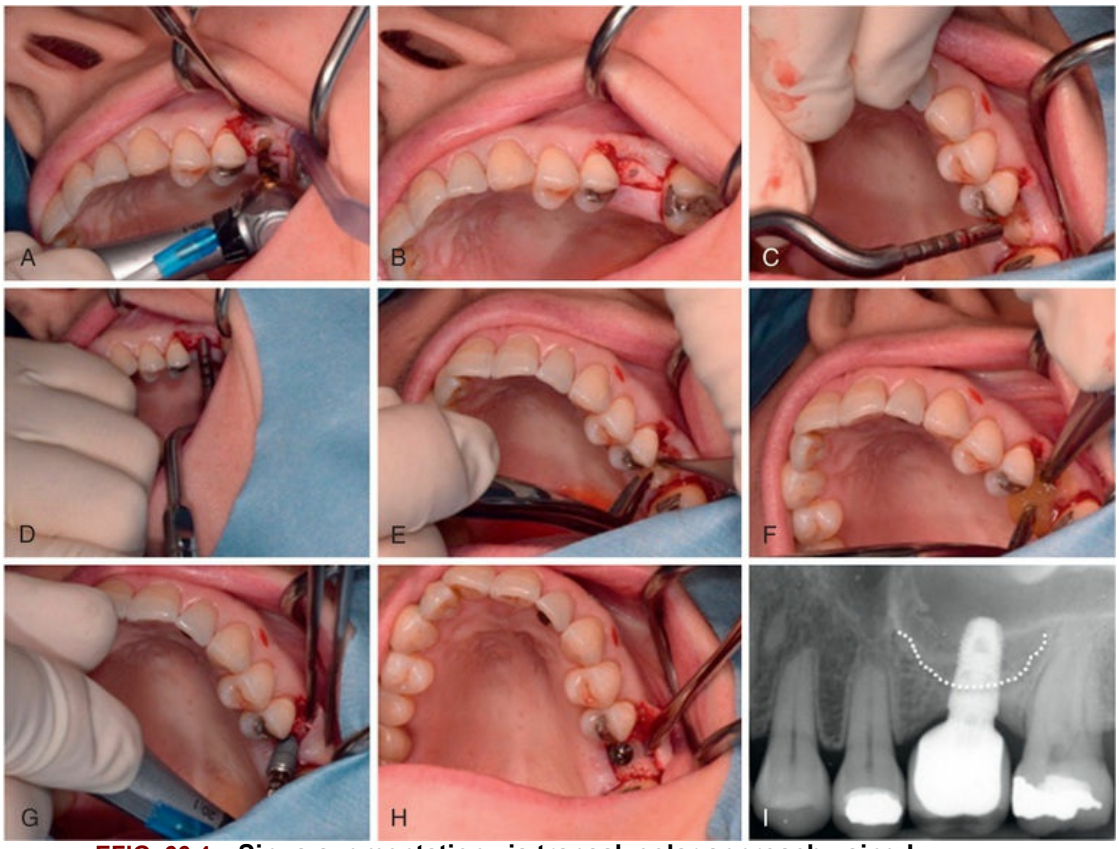
L-PRF and Sinus Floor Elevation

L-PRF can be used for the following indications: as a filling material for the sinus (either alone or in combination with a bone substitute), as a membrane to seal the lateral window, for protection of the schneiderian membrane after detachment from the underlying bone, or to close a membrane rupture.

L-PRF can be used successfully as the sole filling material during sinus augmentation, but only if it is used simultaneously with the placement of implants (which act like tent posts to preserve the space for bone regeneration). L-PRF can be applied by a lateral window technique[50,66,78,81] (eFig. 66.3 and eBox 66.1) or by a transalveolar approach[24,87] (eFig. 66.4 and eBox 66.2). Each of these studies concluded that when L-PRF was used as the sole filler material, natural bone regeneration occurred around the implants (approximately 10 mm vertical bone gain with the window technique, 3.5 to 4 mm with the transalveolar approach).[18] It is important to note that all gain in radiopaque areas in the sinus, observed on cone beam computed tomography (CBCT), is “vital” bone, with 0% substitute remnants.



EFIG. 66.3 **Sinus floor augmentation via a lateral window technique, with simultaneous implant placement using L-PRF as the sole substitute. (A) After careful preparation of the osteotomy, L-PRF membranes are placed covering the schneiderian membrane (at least two layers) and in the area to be augmented, especially palatally, because this area becomes difficult to reach after implant insertion. (B) Implant placement. (C) Additional L-PRF membranes placed around the implant. (D) Window coverage with at least two layers of L-PRF membranes. (E) Cone beam computed tomogram immediately after surgery. (F) Radiograph after 1 year (dotted line represents initial position of floor of the sinus).**



EFIG. 66.4 **Sinus augmentation via transalveolar approach using L-PRF as sole bone substitute. (A and B) Osteotomy preparation up to 1 mm away from the schneiderian membrane. (C) Placement of one L-PRF membrane in osteotomy (to act as a cushion for osteotomes). (D) Fracturing of remaining floor of the sinus with osteotomes. (E and F) Elevation of schneiderian membrane by insertion of several (≥3) L-PRF membranes. (G and H) Implant placement. (I) Radiography after 1 year.**

eBox 66.1

Step-by-Step Approach for Sinus Augmentation Using a Window Technique and L-PRF

Protocol for Lateral Window Technique and Simultaneous Implant Placement Using L-PRF as Sole Bone Substitute (Efig. 66.8):

EFIG. 66.8 Graphic representation of the final situation after a lateral window approach with immediate implant placement using L-PRF as the only substitute. Several L-PRF membrane layers (±3) cover the schneiderian membrane (face toward membrane) above the apex of the implant and fill the implant site. Also, the space between the implant and bony walls of the augmented sinus are filled with membranes (often ≥3). Finally, the window is sealed with at least two layers of L-PRF membranes.

- Crestal incision (and one or two releasing incisions).
- Reflection of the flap far enough apically and distally to have a clear view.
- Preparation of lateral window with piezo-ultrasonic instruments (or with a ball drill). *(Study the cone beam computed tomogram [CBCT] to look for potential arteries in the lateral sinus wall.)*
- Meticulous elevation of the schneiderian membrane, pushing the bone window inside (to prevent sharp edges).
- Once the membrane is elevated, the implant osteotomy site can be prepared.
- After careful preparation of the osteotomy but before implant placement, L-PRF membranes should be placed covering the schneiderian membrane; make sure that at least four layers of L-PRF (preferably two double-folded layers) are covering the

schneiderian membrane in the area where the apices of the future implants will be located (see eFig. 66.3A).
- Place some membranes against the palatal/mesial/distal walls of the uncovered sinus.
- Insert implants (see eFig. 66.3B).
- Add extra L-PRF membranes around the implants in the sinus and buccally (see eFig. 66.3C).
- Cover the window with at least two layers of L-PRF membranes (with the L-PRF face toward the sinus) (see eFig. 66.3D).
- Close flap without moving the L-PRF membranes.
- Suture with monofilament nonresorbing sutures.

Postoperative Care:

- No flying, diving, or use of air instruments for at least 6 weeks.
- Prevent forceful sneezing for at least 6 weeks.
- Prescribe sufficient painkillers, systemic antibiotics, and a nose spray and corticosteroids if needed.
- After 4–6 months of healing, the abutment can be placed and loaded if the implant is well integrated.

eBox 66.2

Step-by-Step Approach for Sinus Augmentation Using a Transalveolar Approach and L-PRF

Protocol for Transalveolar Sinus Floor Augmentation and Simultaneous Implant Placement Using L-PRF as Sole Bone Substitute (Efig. 66.9):

EFIG. 66.9 Graphic representation of the final situation after a transalveolar approach for sinus augmentation. Several L-PRF membranes (preferably three or more layers) separate the schneiderian membrane from the apex of the implant; fill the space between the implant and the augmented sinus, and fill the implant site (often four or more membranes are needed for a single implant).

- Crestal incision and one (or two) releasing incisions.
- Reflection of the flap to expose crestal bone.
- Osteotomy preparation up to 1 mm away from the schneiderian membrane (different techniques can be used, including piezo) (see eFig. 66.4A,B).
- Placement of L-PRF membrane in osteotomy (to act as a cushion for the next step (see eFig. 66.4C).
- Carefully fracture the remaining floor of the sinus with osteotomes (see eFig. 66.4D).
- Elevate the schneiderian membrane by carefully inserting several L-PRF membranes (one at a time) into the sinus via osteotomy with the use of osteotomes (see eFig. 66.4E).
- Make sure that at least four L-PRF membranes are placed in the sinus (see eFig. 66.4F).
- Insert implants (see eFig. 66.4G,H).
- Suture with monofilament nonresorbing sutures.

Postoperative Care:

- No flying, diving, or use of air instruments for at least 6 weeks.
- Prevent forceful sneezing for at least 6 weeks.
- Prescribe sufficient painkillers, systemic antibiotics, and a nose spray, and corticosteroids if needed.
- After 4–6 months of healing, the abutment can be placed and loaded if the implant is well integrated.

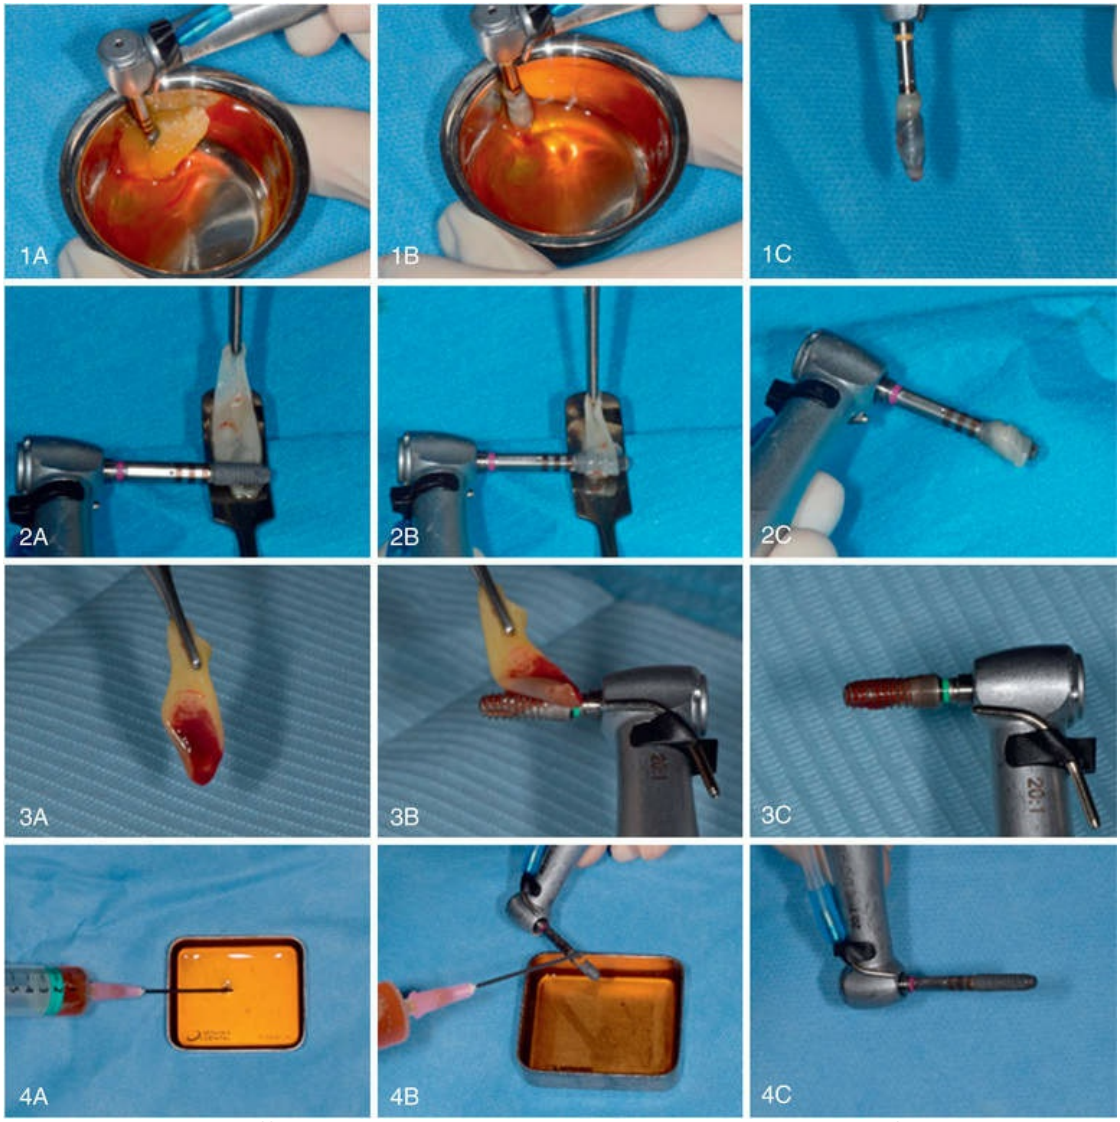
When implants have to be placed in a second stage (because of insufficient residual bone height), L-PRF can also be used, but it should be mixed with a bone substitute to delay its resorption. The bone substitute acts as a space maintainer and provides additional osteoinductive matrix. Which bone substitute is used in these procedures does not seem to be of great importance, although Lambert and coworkers[56] concluded that the use of pure autologous bone resulted in greater loss of the augmented volume after 5 weeks. A mixture of deproteinized bovine bone mineral (DBBM) and L-PRF resulted in more new bone formation than when DBBM was used exclusively.[82] As a result, the healing time after implant placement could be reduced. The concomitant use of L-PRF also reduced the amount of bone substitute, sped up the bone formation, and reduced the amount of remaining bone graft particles.

After an external lateral sinus lift, the window in the maxillary sinus is often sealed with a resorbable collagen membrane. This membrane reduces the proliferation of connective tissue and the ratio of reabsorption of graft material. Gassling and colleagues[40] conducted a randomized controlled trial with a split-mouth design in which a bilateral external sinus augmentation procedure was performed. The sinus was filled with a mixture of DBBM and autologous bone. On one side (control), the lateral window was sealed with a resorbable collagen membrane; on the other side (test), it was covered with L-PRF membranes. The authors concluded that there was no difference in rate of new bone formation and residual bone substitute between the two groups. From this we can conclude that an L-PRF membrane is a potential option for covering a lateral window in the maxillary sinus.

A perforation of the schneiderian membrane during preparation of the lateral window or during detachment and elevation of the membrane is one of the most frequent complications of external sinus augmentation. A few techniques have been described to deal with such intraoperative complications, including covering the perforation with a collagen membrane and suturing the perforation. A study in mongrel dogs[21] concluded that perforations of the schneiderian membrane treated with fibrin glue exhibited a newly formed epithelium identical to that present before the perforation. These results support the clinical use of L-PRF for the treatment of perforations of the schneiderian membrane, especially because the L-PRF membranes are resilient, pliable, easy to manipulate, and have an adhesive nature. They have the capacity to seal the connection to the sinus in minutes.

L-PRF and Implant Surgery

A study by Öncu and Alaaddinoglu[68] concluded that implants coated with L-PRF (the membrane or its exudate; eFig. 66.5 and eBox 66.3) and placed in osteotomies treated with L-PRF showed a statistically higher Implant Stability Quotient (ISQ; Osstell, Sweden) value compared with the control group, in particular up to 4 weeks of healing (difference of 15 ISQ units). Furthermore, when L-PRF is used during one-stage implant placement, the amount of initial bone remodeling (first 3 months after implant placement) can be reduced significantly.[13]



EFIG. 66.5 **Different techniques to coat an implant with L-PRF before insertion. (1A) Placement of implant against an L-PRF clot in a small Ti-dish. (1B and 1C) After slow rotation of the implant in contact with the clot while adding a little pressure against the wall of the Ti-dish, the implant is wrapped in L-PRF. (2A) Placement of the L-PRF membrane (carried by a Ti-spatula) in contact with the implant. (2B and 2C) L-PRF membrane wrapped around the implant (via slow rotation) with the L-PRF face at the outside part. (3A) Placement of the L-PRF membrane in contact with the implant. (3B and 3C) Slow rotation of the implant in contact with the membrane. (4A) Collecting L-PRF exudate. (4B and 4C) Rinsing the implant surface with the L-PRF exudate just before insertion.**

eBox 66.3

Step-by-Step Approaches for Implant Coating With L-PRF

Implant Coating With L-PRF:

- Prepare implant osteotomy following the implant protocol.
- Use L-PRF exudate, obtained after compression of L-PRF clots, to irrigate and clean the osteotomy.
- Position the implant on the implant driver.

Option 1:

- Place an L-PRF clot in a small Ti-dish (see eFig. 66.5, image 1A).
- Let the implant slowly rotate in the clot while putting a little pressure against the wall of the Ti-dish until the L-PRF is fully around the implant (see eFig. 66.5, images 1B and 1C).
- Insert implant in osteotomy.

Option 2:

- Place the implant in contact with the L-PRF membrane (see eFig. 6.5, image 2A).
- Let the implant slowly rotate and wrap the L-PRF membrane around it with the L-PRF face at the outside part (see eFig. 66.5, images 2B and 2C).
- Insert implant in osteotomy.

Option 3:

- Place the L-PRF membrane in contact with the implant (see eFig. 66.5, image 3A).
- Let the implant slowly rotate until the implant surface has been in contact with the membrane; remnants of the L-PRF membrane become visible on the implant surface (see eFig. 66.5, images 3B and 3C).
- Insert implant in osteotomy.

Option 4:

- Collect the L-PRF exudate with a plastic Monoject syringe (Medtronic, Minneapolis, MN) after compression of the clots (see eFig. 66.5, image 4A).
- Rinse the implant surface with the L-PRF exudate before insertion (see eFig. 66.5, images 4B and 4C).
- Insert implant in osteotomy.

L-PRF for Periodontal Mucogingival Surgery

Several procedures have been introduced to successfully cover an exposed root surface. These procedures resolve the hypersensitivity and aesthetic problems but biologically lead to an important clinical attachment level, an increase in the amount of keratinized mucosa, and an increase in gingival thickness. One can divide the treatment options into the following: a free gingival graft, a coronally advanced flap (CAF), a modified CAF, a coronally advanced tunnel technique, and combinations of these techniques using an autologous graft (often a connective tissue graft) or nonautologous graft between flap and root surface. Optionally, even enamel matrix derivative can be used.

L-PRF can be helpful in mucogingival surgery because of its strong three-dimensional fibrin network, which provides the possibility of its use as a membrane but also as a soft tissue graft. It slowly releases growth factors and matrix proteins that stimulate healing for more than 7 days. This release promotes two biologic mechanisms:

- *Impregnation:* The root surface is impregnated with blood proteins, which are the first biologic link between the surface and the new attachment.
- *Induction:* The release of growth factors lasts long enough to trigger cell induction—the growth factors stimulate periosteal cell proliferation, new blood vessels develop within the fibrin matrix,

gingival fibroblasts migrate within the fibrin matrix and provide slow remodeling, and the membrane surface induces epithelialization.

These processes allow rapid wound closure and healing and, in the longer term, could result in more stable recession coverage and thicker gingiva. The potential advantages of this technique triggered research (Table 66.5) in which L-PRF was added during periodontal plastic surgery or L-PRF membranes were used to replace connective tissue grafts (Fig. 66.8 and Box 66.4). To date, most studies have examined the use of L-PRF in combination with a CAF technique.

TABLE 66.5

Most Relevant RCTs and CCTs on the Use of L-PRF in Mucogingival Surgery

Article	Design	Subjects	Groups	Conclusion
Aroca et al. 2009[7]	CCT	20	test: CAF + L-PRF control: CAF	CAF + L-PRF: -More GTH after 6 mo
Aleksic et al. 2010[3]	RCT split-mouth	19	test: CAF + L-PRF control: CAF + CTG	No difference between groups Better healing and less postoperative pain in CAF + L-PRF group
Jankovic et al. 2010[48]	RCT split-mouth	20	test: CAF + L-PRF control: CAF + EMD	No difference between groups More GTH with CAF + L-PRF
Jankovic et al. 2012[49]	RCT	15	test: CAF + L-PRF control: CAF + CTG	Greater KM width with CAF + CTG Improved wound healing in the CAF + L-PRF group
Eren & Atilla 2014[36]	RCT split-mouth	22	test: CAF + L-PRF control: CAF + CTG	No difference in % coverage, GTH, or KM between groups L-PRF is easier and requires no donor site
Gupta et al. 2015[43]	RCT	23	test: CAF + L-PRF control: CAF	No difference between groups GTH greater in CAF + L-PRF group
Keceli et al.	RCT	40	test: CAF +	No difference between groups; more

2015[52]			CTG + L-PRF control: CAF + CTG	GTH with CAF + L-PRF
Thamaraiselvan et al. 2015[85]	RCT	20	test: CAF + L-PRF control: CAF	No difference between groups More GTH in CAF + L-PRF group
Tunali et al. 2015[88]	RCT	44 recessions	test: CAF + L-PRF control: CAF + CTG	No difference between groups after 12 months

CAF, Coronally advanced flap; CAL, clinical attachment level; CCT, controlled clinical trial; CTG, connective tissue graft; GTH, gingival thickness; KM, keratinized mucosa; L-PRF, leukocyte- and platelet-rich fibrin; RCT, randomized controlled trial.

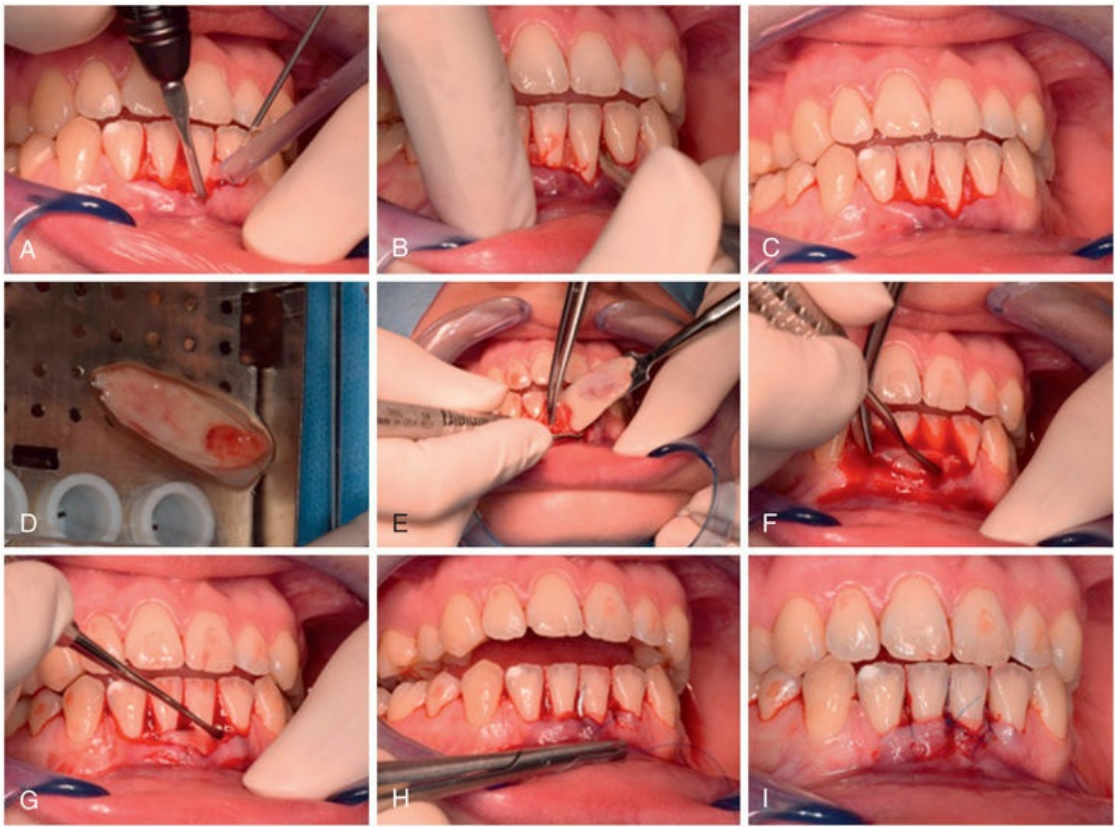


FIG. 66.8 Gingival recession coverage with the coronally advanced flap (CAF) procedure and L-PRF membranes. (A) Split-thickness preparation of receptor site. (B and C) Deepithelialization of papillae. (D) Fix (glue together) three or more L-PRF membranes with dimensions of receptor bed. (E through G) Place L-PRF graft on exposed connective tissue (receptor bed) and over the recession. (H and I) Suture with a coronal advancement of the flap for coverage of the graft.

Box 66.4

Step-by-Step Approach for Gingival Recession Coverage

Protocol for Gingival Recession Coverage With Coronally Advanced Flap (CAF) Procedure Using L-PRF as Graft Material (**Fig. 66.11**)

- Create incision (following surgical technique protocol) and prepare full-split, full-thickness receptor bed (see Fig. 66.8A).
- Perform de-epithelialization of papilla (see Fig. 66.8B,C).
- Fix at least three L-PRF membranes (with correct dimensions) together with resorbable 6-0 sutures (see Fig. 66.8D).
- Place L-PRF graft on exposed connective tissue (receptor bed) and over the recession, and fix it to the periosteum (see Fig. 66.8E,F,G).
- Suture with a coronal advancement of the flap for coverage of the graft (see Fig. 66.8H,I).

Postoperative Care

- No pressure or applied forces on the graft site for at least 6 months.
- Soft food intake; no biting in treated area. No mechanical cleaning of the treated area. Moderate use of the mouth.
- Chlorhexidine 0.12% (from day 3) three times per day for 1 min for at least 3 weeks.
- Prescribe sufficient painkillers.

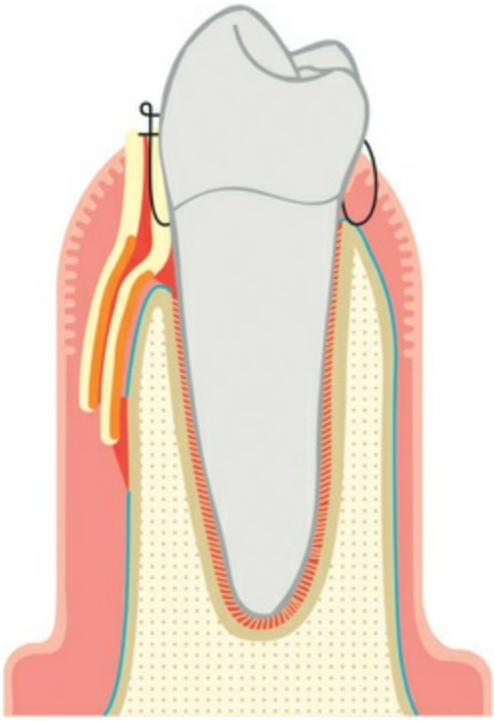

FIG. 66.11 Graphic representation of the final situation after gingival recession coverage with a coronally advanced flap (CAF) and L-PRF membranes. Several L-PRF membranes (≥3) are placed on the receptor bed and over the recession. Suturing is done to advance the flap coronally over the recession. (The periosteum [blue line] has been cut to enable coronal advancement of the flap.)

In general, one can conclude that L-PRF might successfully replace connective tissue graft, with, of course, less morbidity for patients owing to the absence of a donor site (see Table 66.5). However, long-term studies are needed to verify the stability of the outcomes. When CAF is applied with the use of L-PRF, additional advantages have been reported, compared to CAF without L-PRF.[17]

One study examined the benefits of L-PRF in the coverage of the donor site after harvesting of a free gingival graft.[39] The results were faster healing at the donor site and less postoperative pain with the use of L-PRF compared to spontaneous healing.

Clinical Correlation

L-PRF can be helpful in mucogingival surgery because of its strong three-dimensional fibrin network, which provides the possibility of

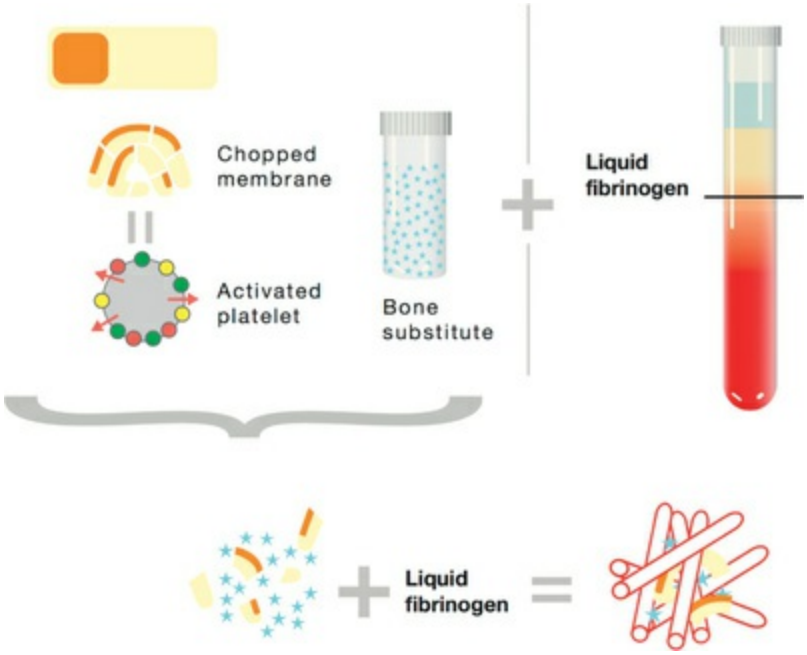
its use as a membrane but allows its use (alone) as a soft tissue graft. It slowly releases growth factors and matrix proteins that stimulate healing for more than 7 days.

L-PRF and Medication-Related Osteonecrosis of the Jawbone

Bisphosphonates are inhibitors of osteoclastic bone resorption. They are used in the treatment of osteoporosis (mostly in the oral form) and also in oncology (usually in the intravenous form). Patients who have been treated with bisphosphonates have a risk of delayed bone and tissue healing, and after extraction or oral surgery, medication-related osteonecrosis of the jawbone (MRONJ) may occur. The literature indicates that the use of platelet concentrate at the surgical site may reduce this risk. L-PRF membranes can also be used to stimulate the healing of MRONJ lesions.[54,58]

Initial Observations on the PRF-Block

With the use of a special procedure, one can create relatively strong bone substitute blocks that can resist some pressure. By combining (1) chopped L-PRF membrane parts (with activated platelets), (2) fibrinogen-rich liquid obtained via 3 min of centrifugation of blood at the same speed as for L-PRF membranes but using plastic tubes without coating on the inside, and (3) a bone substitute (eFig. 66.6), a fibrin network will be created around the bone substitute particles. A kind of bone block (with the strength of a gummy candy and an intrinsic memory shape) will be formed within minutes. The initial observations with PRF-Block (Intra-Lock), both in horizontal bone regeneration and in sinus augmentation, are extremely promising but need to be confirmed by well-designed clinical trials. One important advantage is the ease of handling. This approach might reduce the need for reinforced membranes or more expensive tools to maintain the space under the flaps for bone regeneration (eFig. 66.7 and eBox 66.4).



EFIG. 66.6 Schematic illustration of L-PRF block formation. The chopped L-PRF membranes contain a large number of activated platelets. After mixing the chopped L-PRF membrane(s) with a bone substitute and adding liquid fibrinogen (white-cap tubes, and only 3 min of centrifugation) a clotting process will start, creating quite strong "bone blocks" with an intrinsic memory.

eBox 66.4

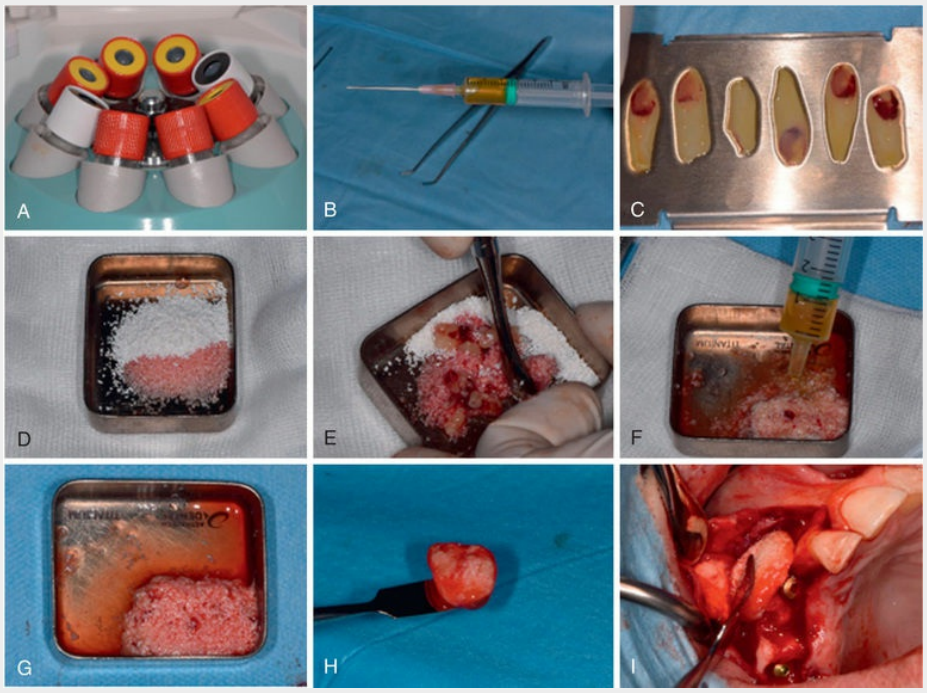
Step-by-Step Approach for Preparation of L-PRF-Block

Protocol for Preparation of PRF-Block (Intra-Lock International, Boca Raton, FL) Using 0.5 g of Geistlich Bio-Oss Biomaterial (Geistlich Bio-Oss; Geistlich Pharma North America, Inc., Princeton, NJ):

- Venipuncture: Following standard protocol, collect six tubes (red cap, glass coating) and two tubes (white cap, plastic coating) of blood; the white-cap tubes are drawn last and are placed last in the centrifuge (2700 rpm/400*g* RCF) (see eFig.

66.7A).

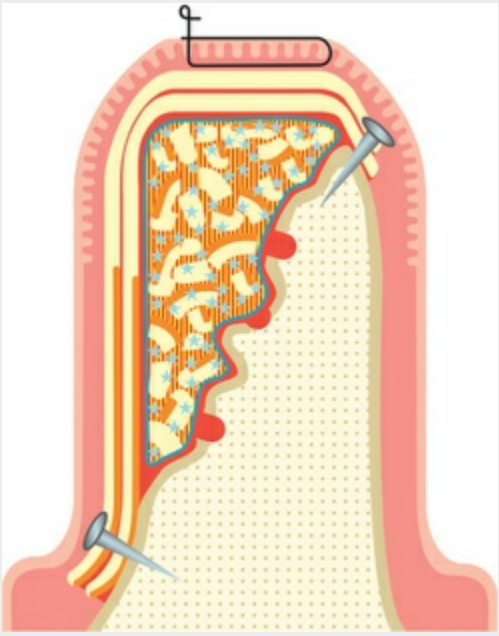
- After 3 min, interrupt centrifugation and remove both white-cap tubes.
- Immediately restart centrifuge with remaining red-cap tubes for another 9 min.
- Immediately aspirate the yellow fluid (liquid fibrinogen) in the white-cap tubes with a syringe; get as close as possible to the red blood cells, but do not aspirate them. Use a plastic Monoject syringe (Medtronic, Minneapolis, MN), and keep the liquid in that syringe (see Fig. 66.7B).
- After full centrifugation of the remaining tubes, remove L-PRF clots and compress gently into membranes in the Xpression kit (Intra-Lock) (see Fig. 66.7C).



EFIG. 66.7 Clinical preparation of PRF-Block (Intra-Lock International, Boca Raton, FL) using 0.5 g of biomaterial. (A) Collect six tubes (red cap, glass coated) of blood following standard protocol, and at least two tubes for liquid fibrinogen (white cap, plastic coating). (B) After 3 min of centrifugation, collect white-cap tubes, close the centrifuge, and restart for the remaining 9 min with the red-cap tubes. Collect the liquid fibrinogen (yellow part at top of tubes) with a

plastic Monoject syringe (Medtronic, Minneapolis, MN) and keep it. (C) Gently compress the clots into membranes in the Xpression kit (Intra-Lock). (D and E) Mix chopped membranes and bone substitute in Ti-dish. (F and G) Spray liquid fibrinogen over the homogeneous mix and stir gently while shaping it to the desired form. (H) L-PRF block is ready to use in approximately 5 min. (I) Placement of L-PRF block over implant with buccal dehiscence.

Preparation of Block (eFig. 66.10)



EFIG. 66.10 Graphic representation of L-PRF block for horizontal bone augmentation. The small holes in cortical bone guarantee optimal blood supply. The L-PRF block is quite well adapted to the bony defect, and the liquid fibrinogen is slowly transformed into fibrin. At least two membranes (face toward bone defect) are used to cover the block; they are fixed via membrane tacks. Primary closure while suturing is preferred.

- Chop two membranes into very small pieces.
- Mix chopped membranes and bone substitute in Ti-dish (ratio is approximately 2 membranes to 0.5 g biomaterial). If the mix

is too dry, add some L-PRF exudate from the Xpression kit. Get a uniform mix (see Fig. 66.7D,E).

- Spray 1 mL of liquid fibrinogen over the homogeneous mix, and stir gently for approximately 5 seconds while shaping it to the desired form (see Fig. 66.7F,G).
- Fibrinogen will clot into fibrin within some minutes and trap the biomaterial to form a PRF block (see Fig. 66.7H,I).
- *(A variation would consist of molding the mix of biomaterial and L-PRF membranes into the surgical defect and squirting the fibrinogen-rich liquid onto it. The block will form in situ, but the liquid can penetrate only about 5 mm deep into the mix.)*

Conclusions

The benefits of using the first-generation platelet concentrates were very controversial; however, the second-generation platelet concentrate (L-PRF) seems to produce more consistent and predictable results. The advantages of using L-PRF are its autologous nature, simple collection, ease of chair-side preparation, and simple clinical application without the risks associated with allogeneic products. Therefore, it seems suitable to be used in either a specialized or general practice. The special texture of L-PRF allows its clinical use in the amorphous form (clot) but mainly in the membranous form (obtained after slight compression). The membranes can be used to cover and protect wounds like a tissue graft. The biologic properties of L-PRF clearly show interesting surgical versatility and all the characteristics that can support faster tissue regeneration and high-quality clinical outcomes. L-PRF is able to stimulate osteogenesis in addition to angiogenesis, and it provides a scaffold that allows cellular migration. These are certainly the fundamental aspects of the process of bone regeneration. All of these features support the conclusion that L-PRF has numerous advantages compared with other similar blood products, and L-PRF has demonstrated the capability to enhance the natural healing of soft and hard tissue.

The use of L-PRF has already been investigated in many periodontal treatments, including the placement of implants.

However, some areas are still unexplored, and well-designed clinical studies are needed. Clearly, the arrival of L-PRF does not mean that the whole way of thinking and acting in oral surgery should be changed. Nonetheless, for many indications, L-PRF can replace bone substitutes or membranes. Also very relevant is the fact that its autogenous origin makes it 100% safe.

Case Scenario 66.1

Patient:
53-year-old female

Chief Complaint:
"I was in a bicycle accident and broke my tooth. It is very painful."

Background Information:
Patient is a nonsmoker and reported the use of aspirin because of a history of arterial thrombosis. Patient is currently taking ibuprofen for the pain. She reports brushing twice a day. She goes once a year to the dentist and has a few restorations. She fell from a bicycle and hit the ground with her face.

Current Findings:
Fracture of maxillary right cuspid. Tooth is deemed nonrestorable and needs to be extracted. Oral hygiene is fair.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. How long do we need to centrifuge the blood	**Answer: C** **Explanation:** Normal centrifugation time is 12 min; for

tubes to make L-PRF? A. 12 min B. Less then 8 min C. At least 15 min	patients taking anticoagulant medication, 15 to 18 min is recommended because of the slower aggregation.
2. At what time do we need to add thrombin or anticoagulants or calcium chloride? A. Before centrifugation B. During centrifugation C. After centrifugation D. Never	**Answer: D** **Explanation:** There is no manipulation of the blood and there are no anticoagulants in the tubes. Hence, there is no need for animal thrombin and calcium chloride for fibrin polymerization.
3. Do we need to raise a flap to achieve primary closure? A. Yes B. No	**Answer: B** **Explanation:** A double layer of L-PRF membrane is placed between the bony wall and the flap to cover the socket. Raising a flap may give unfavorable results.

CHAPTER OUTLINE

Philosophy of Periodontal Microsurgery
Advantages of Microsurgery
Magnification Systems
Microsurgical Sutures
Aesthetic Periodontal Microsurgery *(e-only)*
Microsurgical Knots *(e-only)*
Conclusions

Microsurgery is surgery performed under a magnification of ×10 or more, which is possible only by using a surgical microscope.[5] The hallmarks of microsurgery are increased visual acuity and improved manual dexterity.[17] When visibility is increased 10-fold, motor movement precision is increased 1 mm to 10 μm.[3] This is the approximate size of an epithelial cell.[12] Large incisions for visibility are therefore unnecessary.

Small surgical instruments are used to advantage in the reduced surgical field (Fig. 67.1). This minimally invasive philosophy results in less injury, diminished morbidity, and rapid healing.[9,12] Sharp microsurgical blades are used to create incisions at a virtually cellular level (Fig. 67.2). These incisions are closed with meticulous apposition to eliminate wound edge gaps and dislocations, allowing healing by primary intention to begin within hours of microsurgical closure. This circumvents the need for an extensive secondary mitotic stage of wound healing to bridge wound gaps and fill surgical voids.

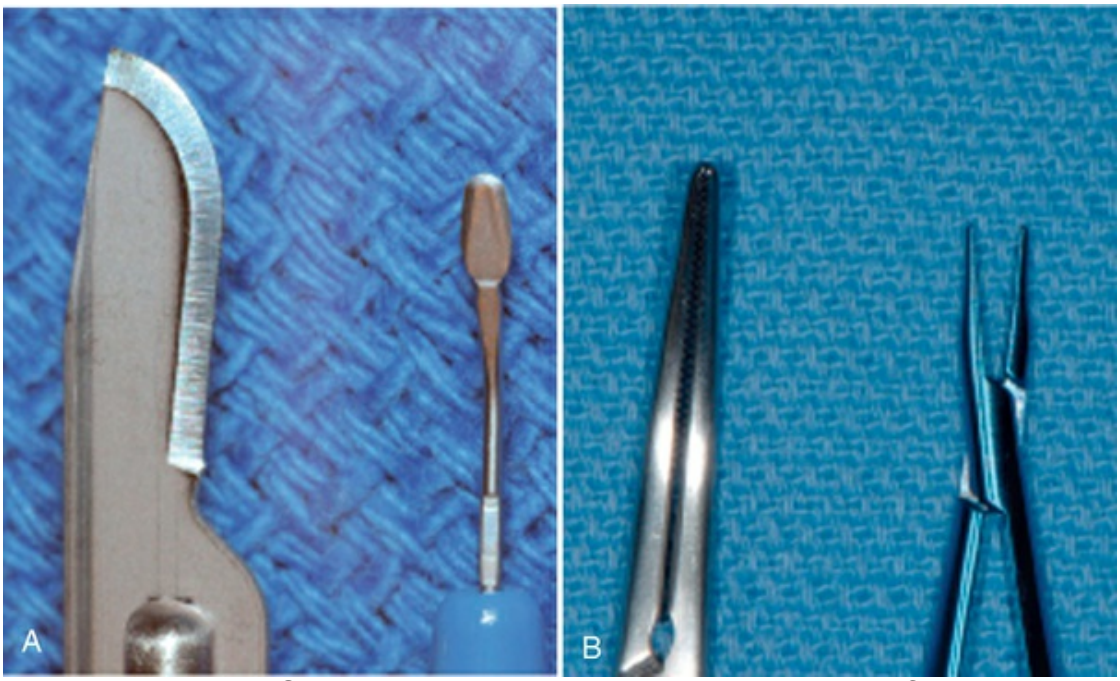

FIG. 67.1 Side-by-side dimensional comparison of commonly used conventional versus microsurgical instruments. (A) A #15 blade versus an ophthalmic blade. (B) Working tip of a conventional needle holder versus a McGregor microsuturing forceps.

FIG. 67.2 Scanning electron microscopy (SEM) comparison of the incisions made with a #15 blade *(upper left)* and an ophthalmic microsurgical "feather" blade *(upper right and lower right).* The *red circle* in the upper right image shows the area magnified in the lower right image. The *green circle* shows the disruption of only one epithelial cell. (SEM photographs courtesy Masana Susuki, DDS, Tokyo, Japan.)

Philosophy of Periodontal Microsurgery

The philosophy of microsurgery embraces three core values. The first is enhanced motor skill for better surgical performance. This is accomplished through improved visual acuity and the use of a precise hand grip to increase accuracy and reduce tremor (Fig. 67.3). The second is minimal tissue trauma, which is accomplished through smaller incisions and reduced surgical fields (Fig. 67.4). The third value is primary passive wound closure.[18] This is accomplished by microsuturing to eliminate gaps and dead spaces at the wound edge (Fig. 67.5).

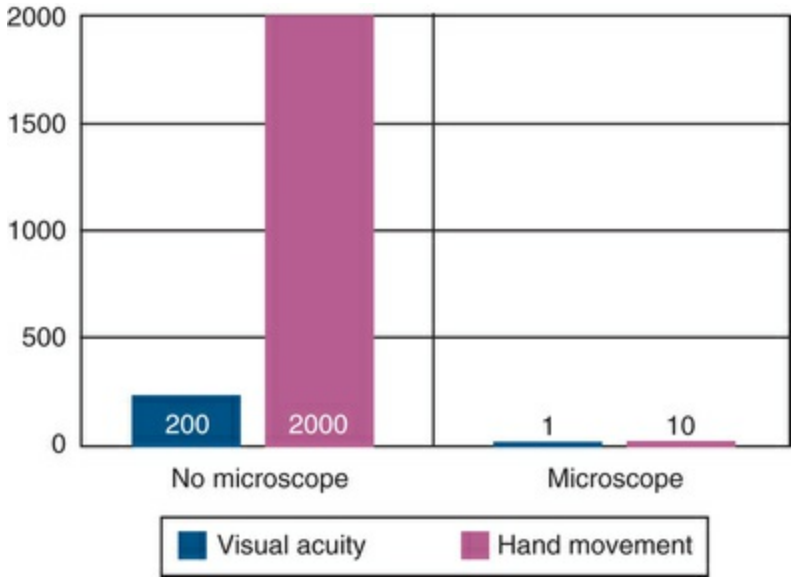

FIG. 67.3 Chart shows the correlation between enhanced visual acuity through magnification and a dramatic reduction in minimal hand movement. (From Shanelec DA: Periodontal microsurgery. *Esthet Restor Dent* 15:402–407, 2003.)

FIG. 67.4 (A through E) For a microsurgical connective tissue graft, minimal tissue trauma during incisions, surgical manipulation, and suturing is accomplished by following microsurgical principles.

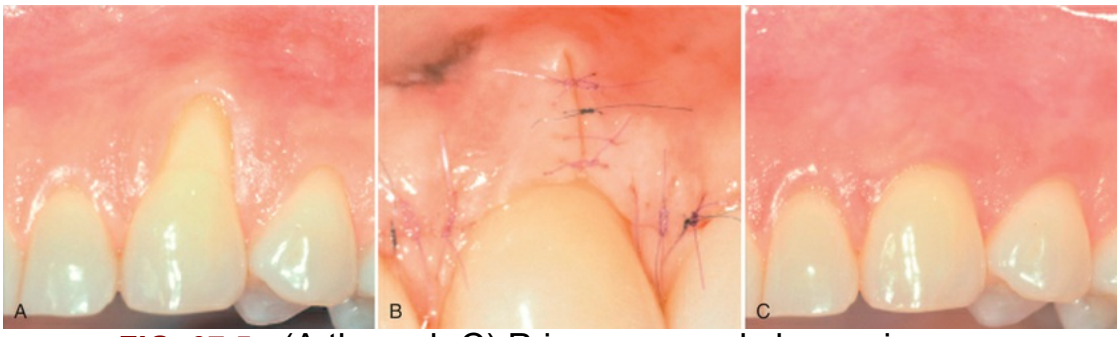

FIG. 67.5 (A through C) Primary wound closure is achieved using microsurgical principles.

Advanced periodontics has an increasing need for clinical procedures that require intricate surgical skills. Regenerative procedures, periodontal plastic surgery, and dental implants are a few of the surgical procedures that demand clinical performance that frequently challenge the skills of periodontal surgeons beyond the range of possibility with ordinary vision. Microsurgery establishes a minimally invasive surgical approach to periodontics exemplified by fewer vertical incisions and smaller surgical sites. Every field of microsurgery has recognized the extent to which reduced incision size and less retraction directly correlates with reduced postoperative morbidity and rapid healing[2] (Fig. 67.6).

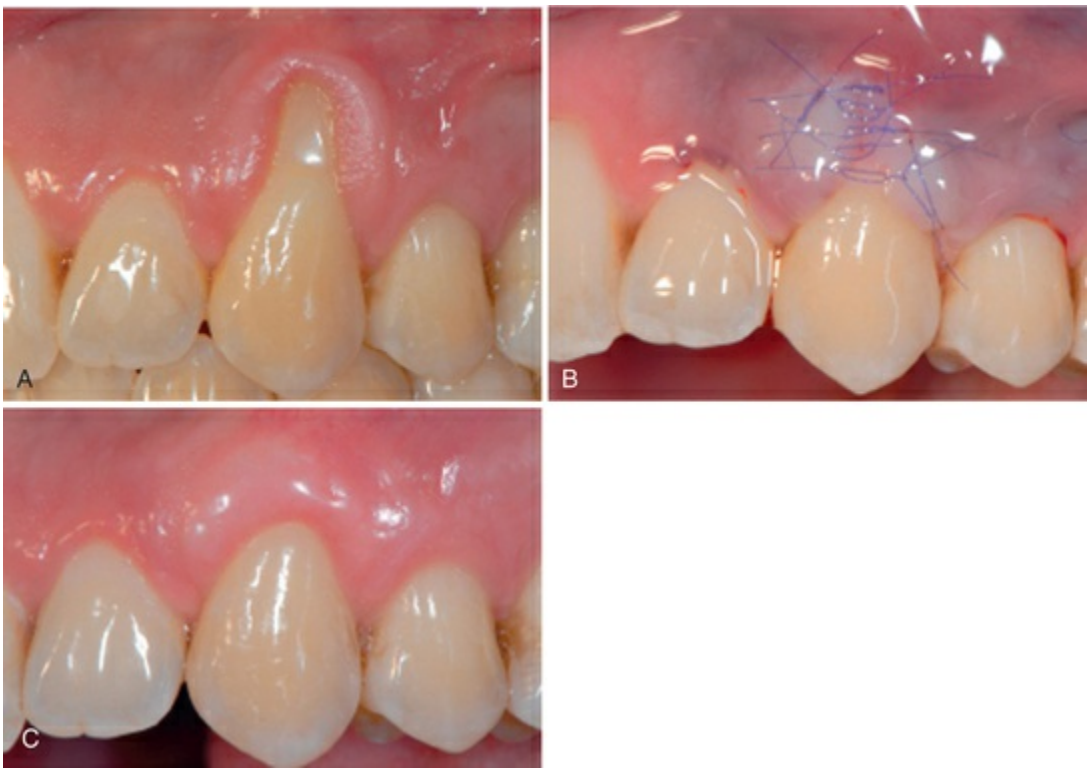

FIG. 67.6 Before (A), during (B), and 8 weeks after (C) healing of a microsurgical connective tissue graft.

In addition to the use of magnification and reliance on atraumatic technique, microsurgery requires specially constructed instruments designed specifically to minimize trauma. An important characteristic of microsurgical instruments is their ability to create clean incisions that prepare wounds for healing by primary intention. Microsurgical incisions are established at a 90-degree angle to the surface using ophthalmic microsurgical scalpels (Fig. 67.7).

FIG. 67.7 Castroviejo microsurgical scalpel.

Microscopy permits easy identification of ragged wound edges for trimming and freshening. For primary wound closure, microsutures in the range of 6-0 to 9-0 are needed to approximate the wound edges accurately (Fig. 67.8). Microsurgical wound apposition minimizes gaps or voids at the wound edges and encourages rapid healing with less postoperative inflammation and less pain. Figs. 67.9 and 67.10 illustrate periodontal surgery cases using microsurgical techniques.

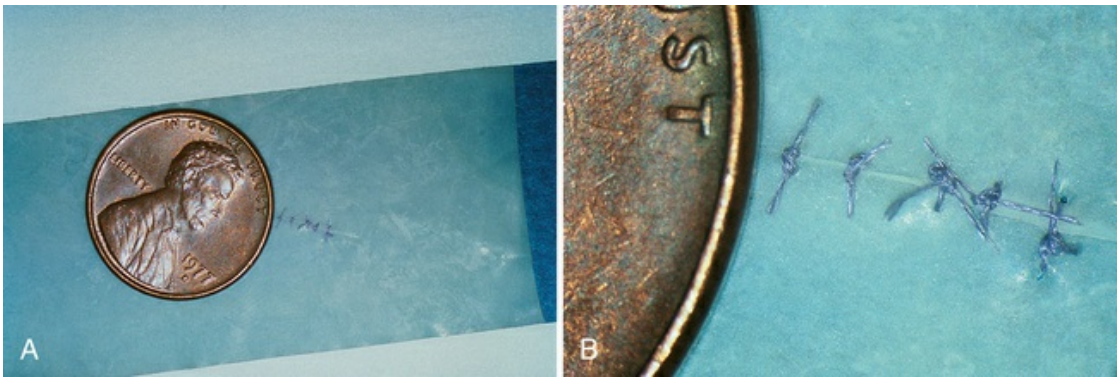

FIG. 67.8 (A and B) Microsurgical suturing.

FIG. 67.9 Microsurgical extraction. (A) Before surgery. (B) Microsurgical view. (C) One week after surgery.

FIG. 67.10 Papilla reconstruction. (A) Before surgery. (B) Microsurgical view. (C) After surgery.

Advantages of Microsurgery

Periodontal microsurgery raises the treatment bar in many ways. Surgical decision making is enhanced because the quality and quantity of visual data reaching the cerebral cortex is increased by a square of the magnification level. Ergonomic and body posture advantages also occur when using the surgical microscope[1] (Fig.

67.11). Issues such as neuromuscular fatigue and occupational skeletal pathology are reduced. Sitting comfort, good body posture, arm support, and controlled breathing are inherent to proper microscope use. Motor skills are enhanced through instruments designed for a precision grip of the hand. Titanium instruments are used for strength and lightness and are made with round handles to permit precise rotation (Fig. 67.12). This reduces hand fatigue and tremor for precise surgical movement. Ergonomic benefit is a significant aspect of microscope use in periodontics.

FIG. 67.11 Muscle strain and potential career-ending injuries can be prevented through a more ergonomic position facilitated by the proper use of a microscope.

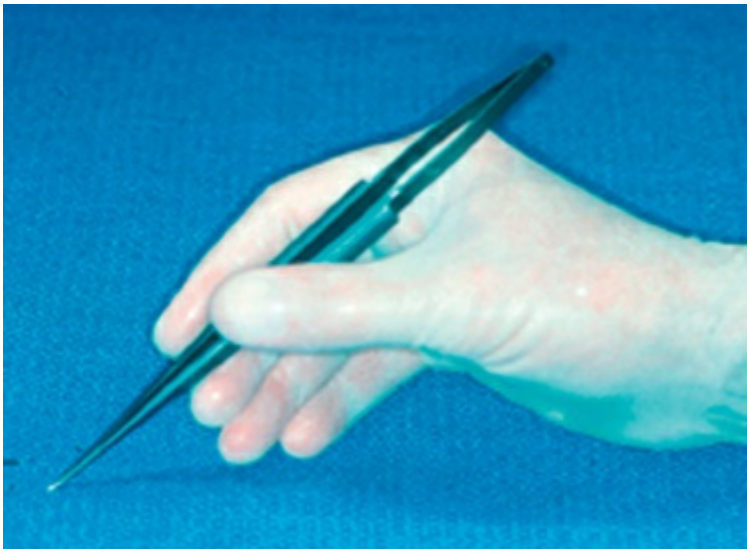

FIG. 67.12 Rounded, titanium microsurgical instruments, ideally 9 mm in diameter, reduce muscle fatigue and facilitate precise, rotational hand movements.

An important aspect of periodontal microsurgery is technical improvement in surgical performance. Higher skill levels have been shown in many surgical disciplines and can be fully appreciated when a surgeon tries his or her hand under the microscope. Viewing surgery under the microscope impresses a surgeon with the coarseness of conventional surgical manipulation (Fig. 67.13). What appears to the unaided eye as gentle surgery is revealed under the microscope as gross crushing and tearing of delicate tissues. Periodontics has long advocated atraumatic surgery, but the limits of normal vision have made this goal unattainable.

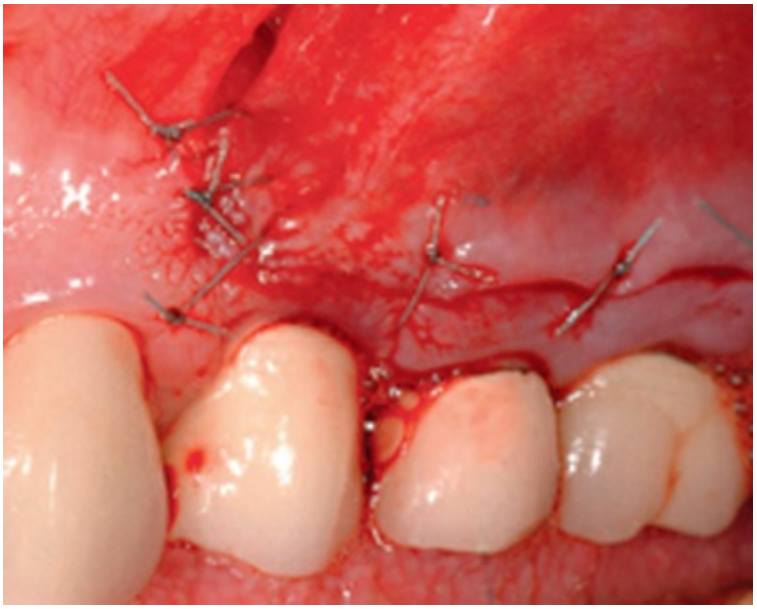

FIG. 67.13 The coarseness of conventional periodontal surgery is readily apparent under microscopic magnification.

Proprioceptive guidance is of little value at the microsurgical level. Visual guidance is used for midcourse correction of scalpels and instruments to achieve the finest degrees of skill and dexterity.[4,9] Incisions can be accurately mapped, flaps elevated with minimal damage, and wounds closed accurately without tension (Fig. 67.14). Periodontal microsurgery is a natural progression from conventional surgical principles to a surgical ethic in which the surgical microscope is employed for the most accurate and atraumatic handling of tissue (Fig. 67.15).

FIG. 67.14 Tension-free wound closure is one of the goals of a microsurgical approach.

FIG. 67.15 Atraumatic microsurgical tissue manipulation during a microsurgical crown-lengthening procedure.

The resulting appearance of microsurgery is superior to that of conventional surgery. The difference is often startling (Figs. 67.16 to 67.18). As much as judgment and knowledge play a role in surgery, in the end, surgery is a craft. Surgeons appreciate this, especially when microsurgery raises their work to levels of artistic expression.

Personal gratification in performing better surgery leads to acceptance of periodontal microsurgery by surgeons motivated to improve the quality of their work.

FIG. 67.16 (A) Suppurating gingival fenestration. (B) After careful root planing, a connective tissue graft (CTG) was carefully sutured under the envelope flap. (C) Postoperative healing at 3 weeks. (D) Postoperative follow-up at 1 year.

FIG. 67.17 Microsurgical correction of a macrosurgical unsatisfactory outcome. (A) Improper placement caused an unaesthetic result. (B) Microsurgical grafting procedure. (C) Final surgical result after fabrication of new crowns.

FIG. 67.18 Microsurgical crown-lengthening procedure.

(A) Altered passive eruption covering teeth crowns. (B) Immediate microsurgical postoperative result. (C) Postoperative healing at 3 weeks.

Microsurgery offers another advantage in the area of root preparation. The importance of root debridement is recognized universally as an essential component of periodontal therapy.[10,17] Research in clinical dentistry has shown that microscope-enhanced vision more readily accomplishes the established clinical goals of endodontic and restorative dentistry. In periodontics, studies demonstrated that root debridement performed without magnification was incomplete. When debrided roots were examined with the aid of a microscope, substantial deposits remained. Even in the absence of clinical studies, it may be inferred that microscope-enhanced vision in periodontics permits more definitive root debridement.

The primary goals of periodontal surgery include visual access to the root surface for plaque and calculus removal and for removing pathologically altered tooth structures. Magnification greatly improves the surgeon's ability to create a clean, smooth root surface (Fig. 67.19). The root surface represents one opposing edge of the periodontal wound. Root planing is therefore analogous to establishing a clean soft tissue incision. Magnification permits preparation of hard and soft tissue wound surfaces so that they can be joined together according to the accepted microsurgical principle of butt-joint wound approximation. This encourages primary wound healing and enhanced periodontal reconstruction. Studies of wound healing show epithelial anastomosis of microsurgically joined surgical wounds in animals within 48 hours.[4,16] With training, the average periodontal microsurgeon can consistently produce better-crafted work than the most talented conventional surgeon (Fig. 67.20).

FIG. 67.19 Magnified root planing.

FIG. 67.20 Procedure accessibility is enhanced through microsurgery. (A) Connective tissue graft (CTG) on a maxillary molar. (B) Before surgery. (C) During surgery. (D) Seven weeks postoperatively.

Magnification Systems

Simple and complex magnification systems are available to dentists. They range from simple loupes to prism telescopic loupes and surgical microscopes. Each magnification system has specific advantages and limitations. Although magnification improves the accuracy of clinical and diagnostic skills, it requires an understanding of optical principles that govern all magnification systems. The assumption that "more magnification is better" must always be weighed against the decrease in field of view and depth of focus that can occur as magnification increases, which is a problem more common with dental loupes than operating microscopes.

Magnifying Loupes

Dental loupes are the most common system of optical magnification used in periodontics. Loupes are fundamentally dual monocular telescopes with side-by-side lenses convergent to focus on the operative field. The magnified image formed has stereoscopic properties by virtue of their convergence. A convergent lens optical system is called a *Keplerian optical system.*

Although dental loupes are widely used, they have disadvantages compared with the microscope. The clinician's eyes must converge to view the operative field. This can result in eyestrain, fatigue, and pathologic vision changes, especially after prolonged use.

Three types of Keplerian loupes are typically used in periodontics: simple or single-element loupes, compound loupes, and prism telescopic loupes. Each type can differ widely in optical sophistication and individual design.

Simple Loupes

Simple loupes consist of a pair of single meniscus lenses (Fig. 67.21). Simple loupes are primitive magnifiers with limited capabilities. Each lens is limited to only two refracting surfaces. Their magnification can increase only by increasing lens diameter and thickness. Size and weight constraints make simple loupes

impractical for magnification beyond ×1.5. Another disadvantage of simple loupes is that they are greatly affected by spherical and chromatic aberration. This distorts the image shape and color of objects being viewed.

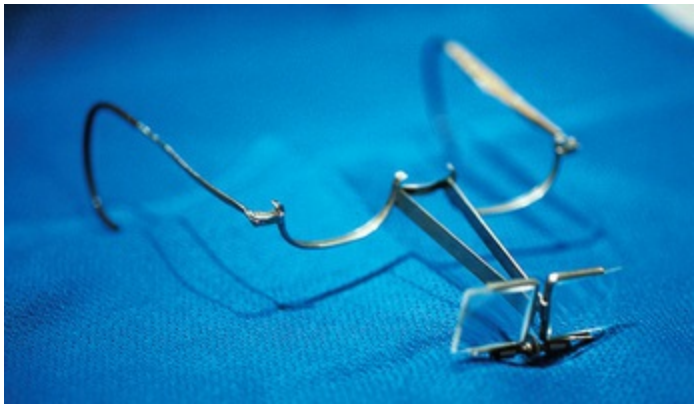

FIG. 67.21 Simple loupes.

Compound Loupes

Compound loupes use multielement lenses with intervening air spaces to gain additional refracting surfaces (Fig. 67.22). This allows increased magnification with more favorable working distance and depth of field. Magnification of compound loupes can be increased by lengthening the distance between lenses, thereby avoiding excessive size and weight.

FIG. 67.22 Compound loupes.

In addition to offering improved optical performance, compound

lenses can be *achromatic,* which is an optical feature that clinicians should always choose when selecting magnifying loupes. Achromatic lenses consist of two glass lenses joined together with clear resin. The specific density of each lens counteracts the chromatic aberration of its paired lens to produce a color-correct image. However, multielement compound loupes become optically inefficient at magnifications above ×3.

Prism Telescopic Loupes

The most advanced loupe optical magnification currently available is the prism telescopic loupe. These loupes employ Schmidt or rooftop prisms to lengthen the light path through a series of switchback mirrors between the lenses. This arrangement folds the light so that the barrel of the loupes can be shortened. Prism loupes produce better magnification, wider depths of field, longer working distances, and larger fields of view than other types of loupes. The barrels of prism loupes are short enough to be mounted on eyeglass frames (Fig. 67.23) or headbands. However, increased weight of prism telescopic loupes with magnification above ×4 makes headband mounting more comfortable and stable than eyeglass frame mounting. Innovations in prism telescopic loupes include coaxial fiberoptic lighting incorporated in the lens elements to improve illumination (Fig. 67.24).

FIG. 67.23 Eyeglass-mounted prism loupes.

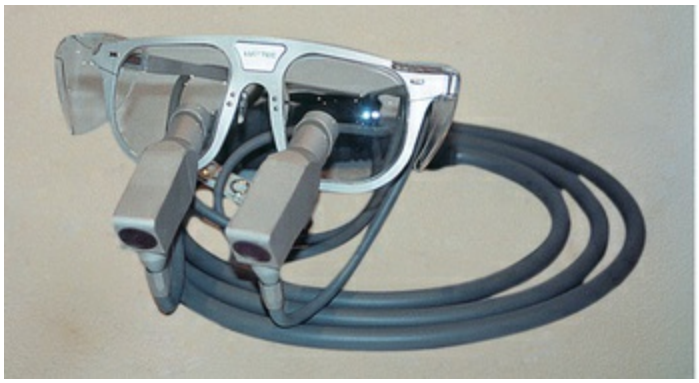

FIG. 67.24 Coaxial lighted prism loupes.

Magnification Range of Surgical Loupes

Dental loupes provide a limited range of magnification (×1.5 to ×6). Loupes delivering magnification of less than ×3 are usually inadequate for the visual acuity necessary for clinical periodontics. Surgical loupes providing magnification of more than ×4 are impractical because of their small field of view, shallow depth of focus, and excessive weight. Excessively heavy loupes can make it difficult to maintain a stable visual field.

For some periodontal procedures, prism telescopic loupes with magnification of ×4 provide an adequate combination of magnification, field of view, and depth of focus. However, the surgical microscope offers much higher magnification and superior optics compared with any of the loupe optical systems mentioned.

The Surgical Microscope

The surgical microscope offers greater versatility than dental loupes by providing a range of magnification with superior optical performance. A surgical microscope can last an entire career, making its long-term expense practical. Proficient use of the microscope requires training and practice. Surgical microscopes designed for dentistry employ galilean optics, which have binocular eyepieces joined by offset prisms to establish a parallel optical axis and permit stereoscopic vision without eye convergence or eyestrain. An additional binocular eyepiece can aid the microsurgical assistant (Fig. 67.25).

FIG. 67.25 Accessory binocular module allows the assistant to better support the operator during the procedure.

Surgical microscopes have coated achromatic lenses, high optical resolution, and a rotating magnification element that allows the microsurgeon to easily change magnification to a value appropriate for the surgical task at hand (Fig. 67.26). Because the optical elements of surgical microscopes are more advanced than those in loupes, depth-of-focus and field-of-view characteristics are greatly enhanced. Surgical microscopes have objective lenses with various working distances. A useful range in dentistry is 250 to 350 mm.

FIG. 67.26 Rotating magnification element with a field of view ranging from the full mouth to approximately 3

cm when using a 250-mm objective lens.

For practical use, a surgical microscope must have maneuverability and stability. Mountings are available for the ceiling, wall, or floor. Adjustable inclining eyepieces enhance postural flexibility for various procedures (Fig. 67.27). This maneuverability provides visual access to every area of the mouth and is an important factor in choosing to use a surgical microscope.

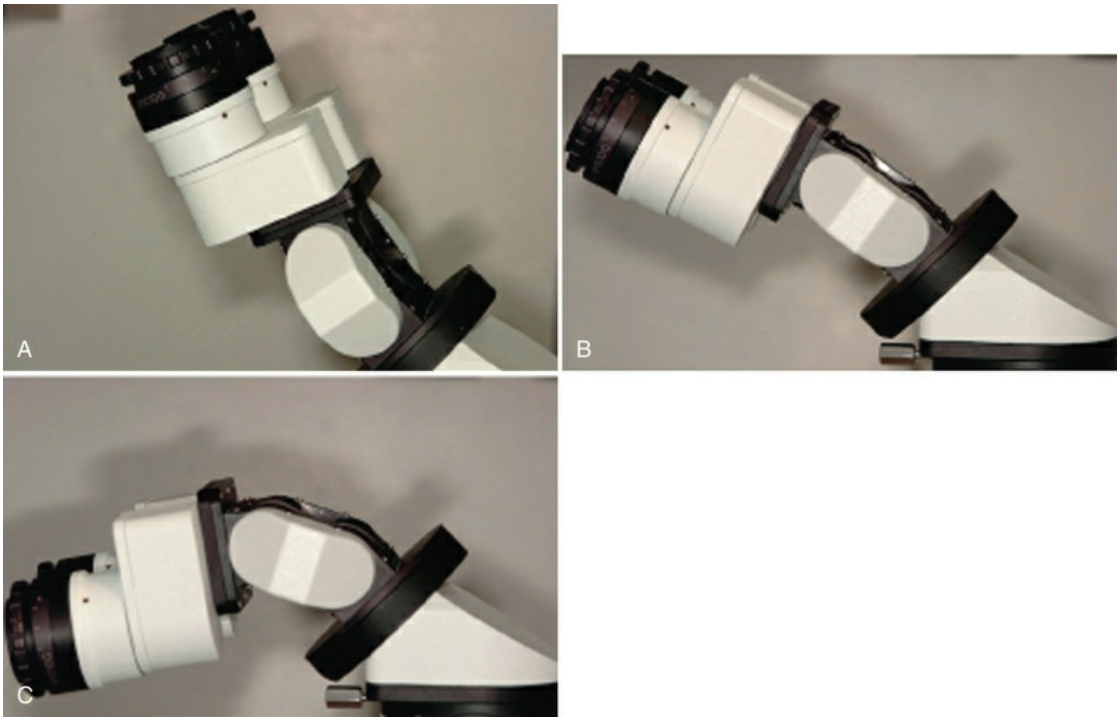

FIG. 67.27 (A through C) The inclinable adjustable eyepieces have a wide range of motion.

Illumination of the microsurgical field is also an important consideration. Dentists are accustomed to working with lateral illumination from side-mounted dental lights or headlamps. Fiberoptic coaxial illumination is a major advantage because it focuses light parallel to the microscope's optical axis, which eliminates shadows. Surgeons can visualize the deepest reaches of the oral cavity, including subgingival pockets and angular bony defects. Definitive visualization of root surface to detect deposits and irregularities is possible. Surgeons can view anatomy to make clinical decisions based on accurate assessment of pathology rather than blind, educated guesses.

Documentation is important for patient and professional education and for dental-legal reasons. The surgical operating microscope is an ideal platform for documenting periodontal pathology and clinical procedures. Digital images can be captured using a beam splitter and camera attachment. A foot-controlled switch permits a surgeon to record as the procedure unfolds without interrupting surgery. These images represent the surgical field exactly as the surgeon sees it, as opposed to a camera view over the surgeon's shoulder. High-definition video cameras capture still and video images simultaneously to permit documentation of periodontal procedures for educational purposes (Fig. 67.28).

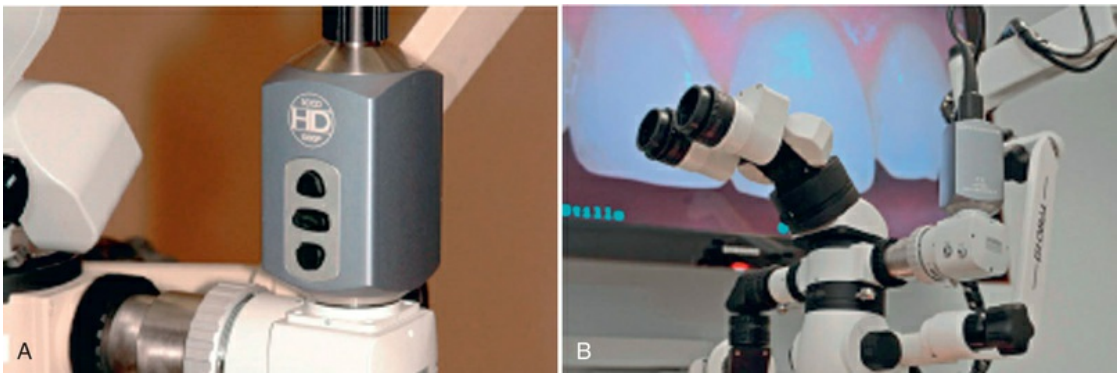

FIG. 67.28 (A) High-definition (HD) video and still capture camera mounts conveniently fit into the microscope and (B) can be viewed in real time on an HD monitor. (Courtesy Optronics Microcast HD Studio, Optronics Medical Grade HD Microimaging Systems, Goleta, CA.)

Microsurgical Sutures

To achieve ideal microsurgical wound closure, a surgeon depends on how the incisions were planned and executed, how the surgery was performed, and the suturing technique. Selection of proper suture needles and materials is essential for successful microsurgical wound closure. The choice of suture and needle size is critical for atraumatic tissue passage. Suture material must maintain wound closure until healing is sufficiently advanced to withstand functional stress.

Sutures are classified according to structure as monofilament or braided, according to surface as coated or uncoated, and according to biologic properties as absorbable or nonabsorbable.[2] The suture of choice in microsurgery is a monofilament suture material such as polypropylene or polydioxanone. These materials are bacteriostatic and noninflammatory, hold a knot extremely well, and are easily removed. The purpose of sutures is to provide initial wound support. They are chosen to appropriate wounds based on the fragility of the tissue. The smallest suture capable of supporting the wound produces the least tissue trauma and the least interruption of the blood supply.

In periodontal microsurgery, the suture size ranges from 6-0 (i.e., diameter of a human hair) to 9-0 (Fig. 67.29). The size and shape of the needle used is essential for the atraumatic passage of the suture. The needle diameter is ideally slightly larger than the suture size. Sutures used in microsurgery are swaged, making the needle and the suture continuous[1] (Fig. 67.30). Penetration and passage of the needle depends on the angle of entry of the needle point. Cutting needles pass through gingival tissue easily but can tear tissue. Tapered needles are less traumatic and less likely to tear tissue.

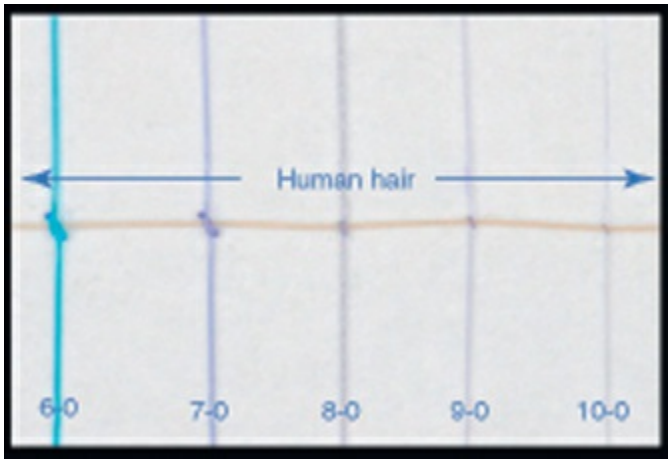

FIG. 67.29 Size comparison of microsutures in relation to the dimension of a human hair.

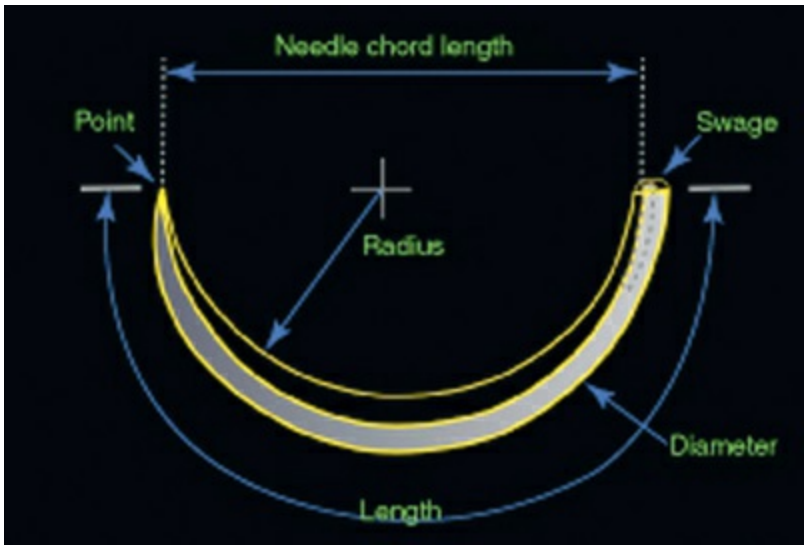

FIG. 67.30 Anatomy of a needle. Microsutures are hand-inserted into the laser-drilled swaged end of the needle, forming a seamless, contiguous unit.

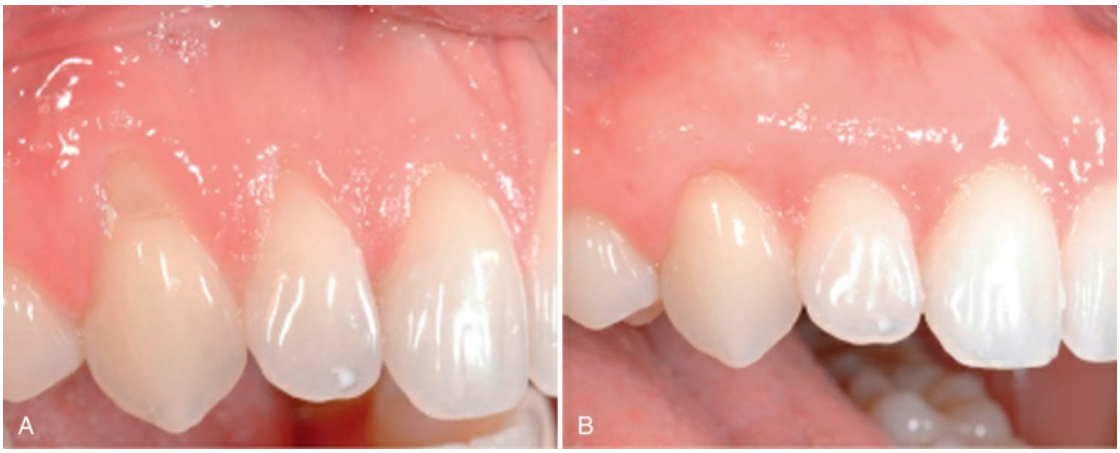
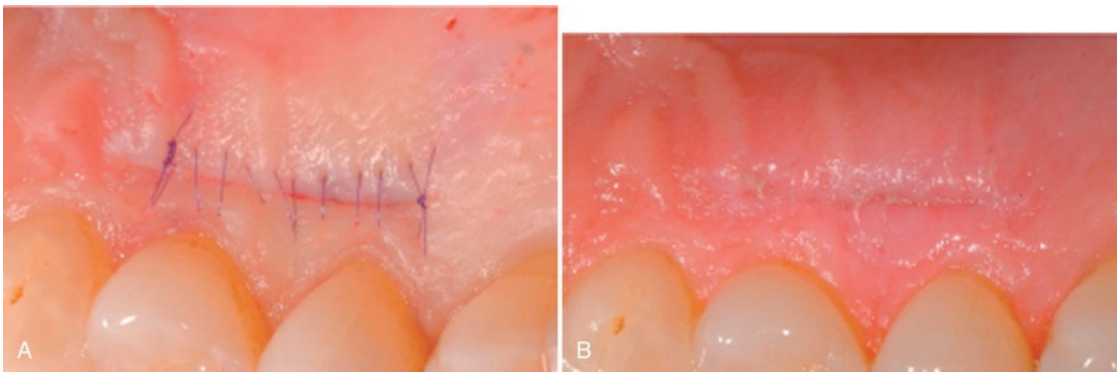
An important component of needle design is the chord distance (see Fig. 67.30). The chord of a needle is the length of a line drawn between the cutting point and the swaged end.[1] The radius of a needle is the arc of its circumference. A half-round needle has an arc of 180 degrees. The chord determines the ease in passing a suture between adjacent teeth. The arc determines the bite size and angle of entry taken by the needle. These needle dimensions are important when selecting sutures for periodontal microsurgery.[4]

Aesthetic Periodontal Microsurgery

Aesthetic periodontal microsurgery to reconstruct gingival tissue over denuded roots is routine and predictable using subepithelial connective tissue grafting (eFig. 67.1). The color match, aesthetic appearance, and lack of scarring of these grafts are ideal. Microsurgical closure of the palatal donor site allows healing by primary intention without a painful period of open granulation (eFig. 67.2). This greatly reduces postoperative pain.



EFIG. 67.1 (A) Preoperative and (B) postoperative views of the recession area treated microsurgically with a connective tissue graft.

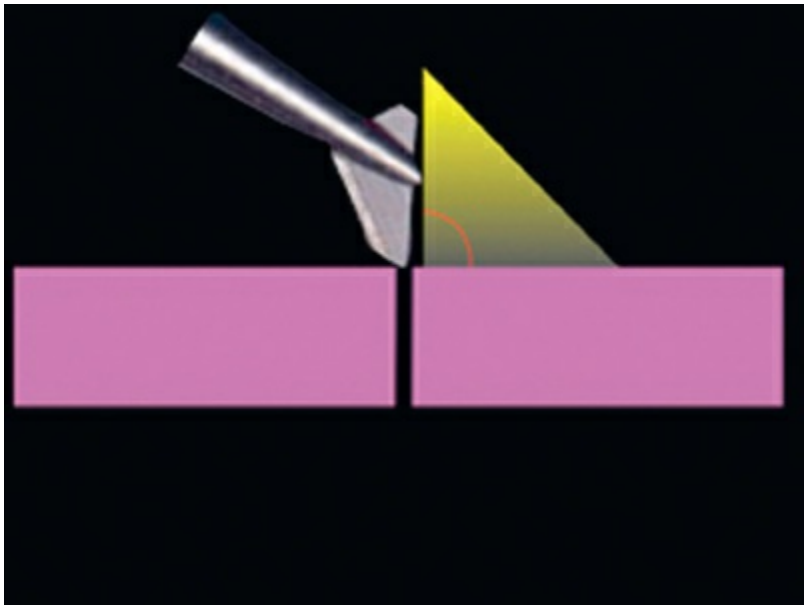


EFIG. 67.2 (A) Microsuturing of the palatal donor site after harvesting the connective tissue graft. (B) One-week postoperative healing of the donor site.

To achieve optimal wound healing, three basic microsurgical principles are needed: (1) precision tailoring, (2) delicate tissue manipulation, and (3) passive primary wound closure.[8]

Precise Tailoring

An important feature of microsurgery is the ability to create clean incisions. The design of incisions has significant impact on how the wound edges fit together. A fundamental principle of microsurgery is making incisions perpendicular to the tissue surface, creating butt joint edges that easily approximate for wound edge stability and maintain blood supply patency (eFig. 67.3).



EFIG. 67.3 Cross-sectional representation of a microsurgical blade making an incision line at 90 degrees to the tissue surface.

Delicate Tissue Manipulation

The microsurgical philosophy is based on minimal invasiveness and minimal trauma. This premise extends to the manipulation gingival tissues during surgery.[10] Gentle handling is necessary to reduce cellular injury and subsequent necrosis and inflammation. It is also necessary to maintain tissue hydration and color to maximize healing.[7]

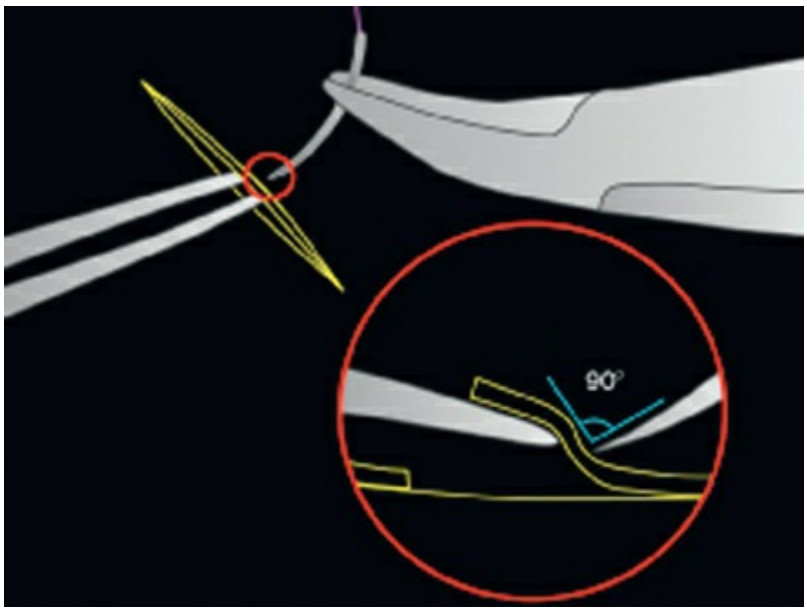
Passive Primary Wound Closure

After precision tailoring and gentle tissue manipulation, the final and critical element of microsurgery is achieving passive primary wound closure. A specific geometry of suturing is required, with the following six well-defined components[13]:

1. *Angle of entry and angle of exit*. The needle should penetrate the tissue at a 90-degree angle, perpendicular to the tissue surface. Passing the needle at an oblique angle causes tearing when the knot is tied (eFig. 67.4).
2. *Bite size*. Proper bite size is between 1 and 1.5 times the tissue

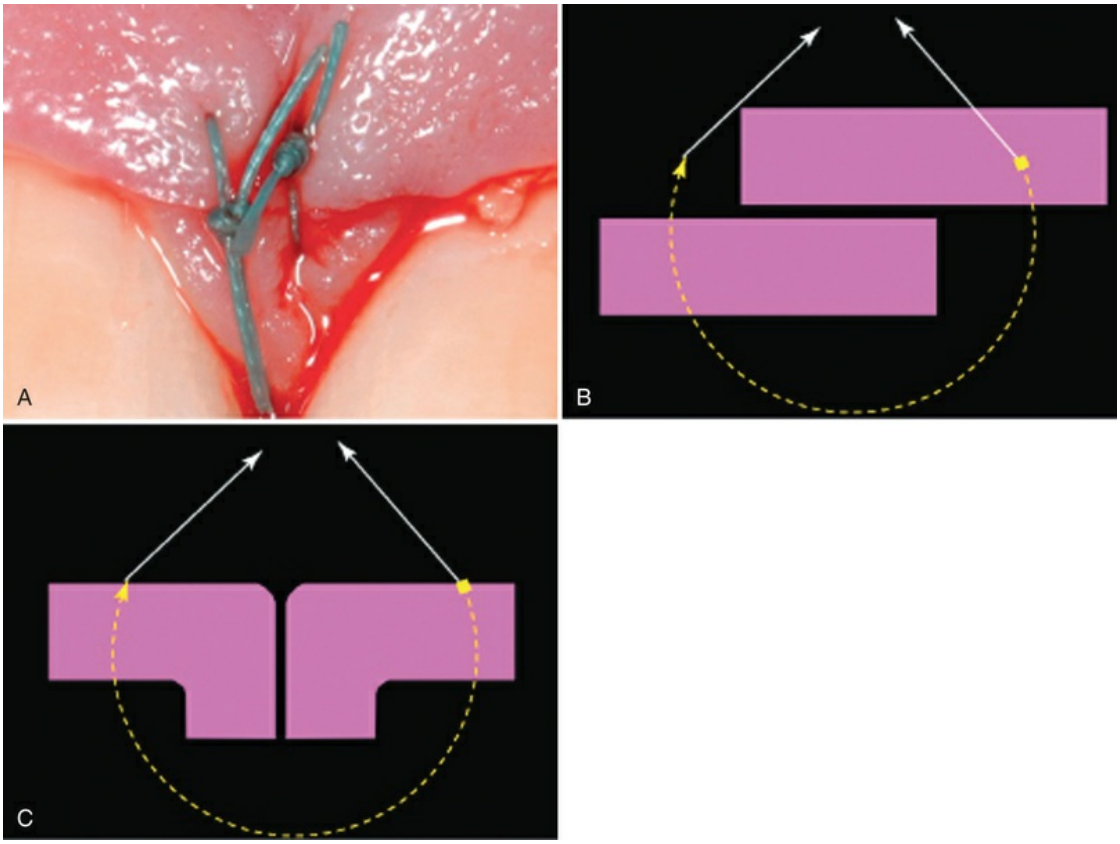
thickness. Too small a bite size can tear the wound edges. Too large a bite size can cause underriding or overriding of wound edges (eFig. 67.5). Both outcomes result in impaired healing and unsightly scarring (eFig. 67.6).

3. *Direction of passage*. After the needle has penetrated one edge of the wound, it must exit the opposing side of the wound with a direction of passage perpendicular to the incision line. This directs the suture force vectors at 90 degrees and prevents lateral dislocation at the wound edge (eFig. 67.7).
4. *Tension*. Suturing should be accomplished with minimal tension. Gentle passage of the suture in a perpendicular direction of passage sets the stage for a microsurgical knot that does not cause tissue strangulation through ligation. Good suturing, however, can never save poor tailoring (eFig. 67.8).
5. *Symmetry*. The distance between the bite sizes on either side of the wound edge should be symmetric, as should the distance between sutures (eFig. 67.9).
6. *Frequency*. Smaller suture material and smaller bite size makes it necessary to place more microsutures at frequent intervals along the wound edge. This supports wound closure and avoids stress breakage of sutures or tissue tearing (eFig. 67.10).

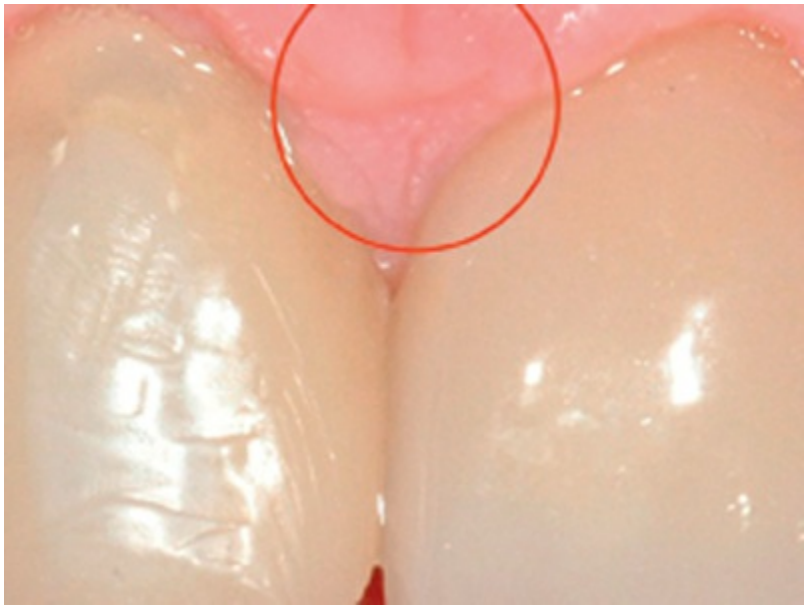


EFIG. 67.4 Suture needle penetrates the gingiva at a

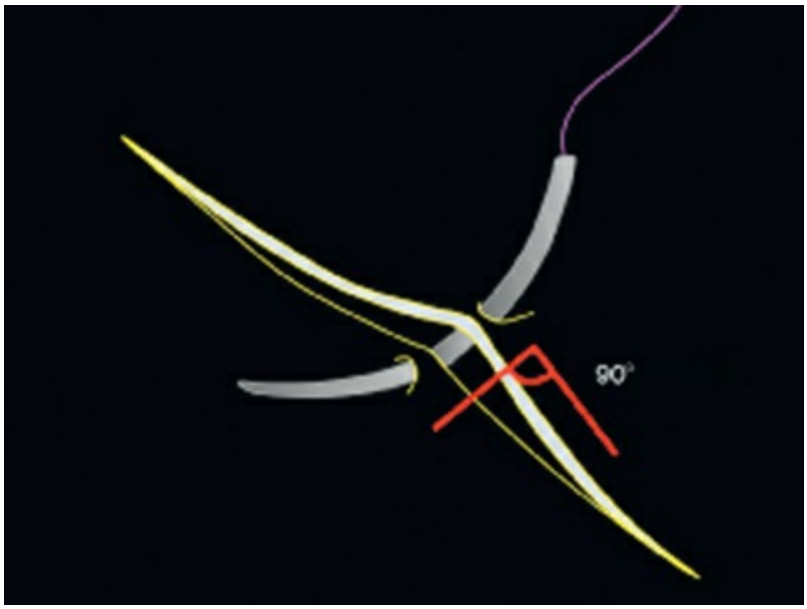
90-degree angle of entry by elevating and supporting the soft tissue with a microsurgical tissue forceps.



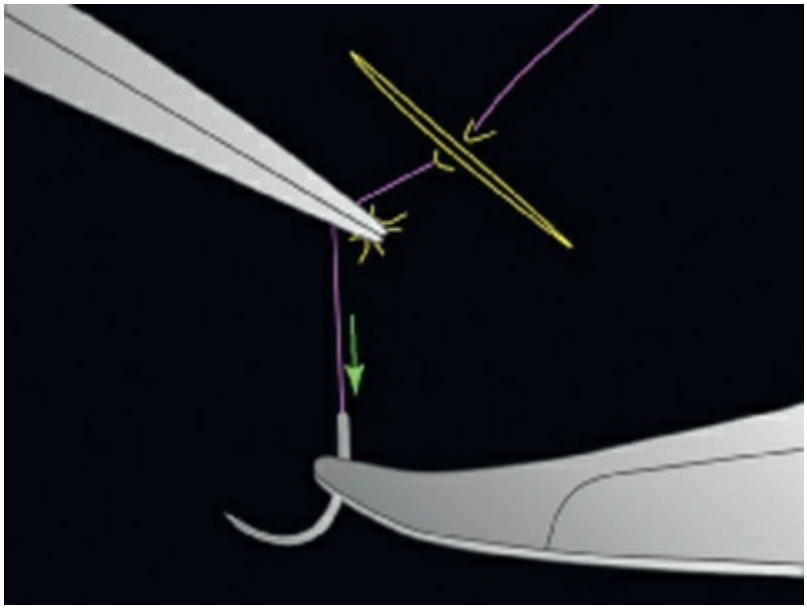
EFIG. 67.5 (A) Incorrect bite size. The tissue margin overlap is caused by a bite size larger than the 1 : 1.5 tissue thickness ratio. (B and C) Cross-sectional representation of tissue overlap and invagination caused by an improper bite size.



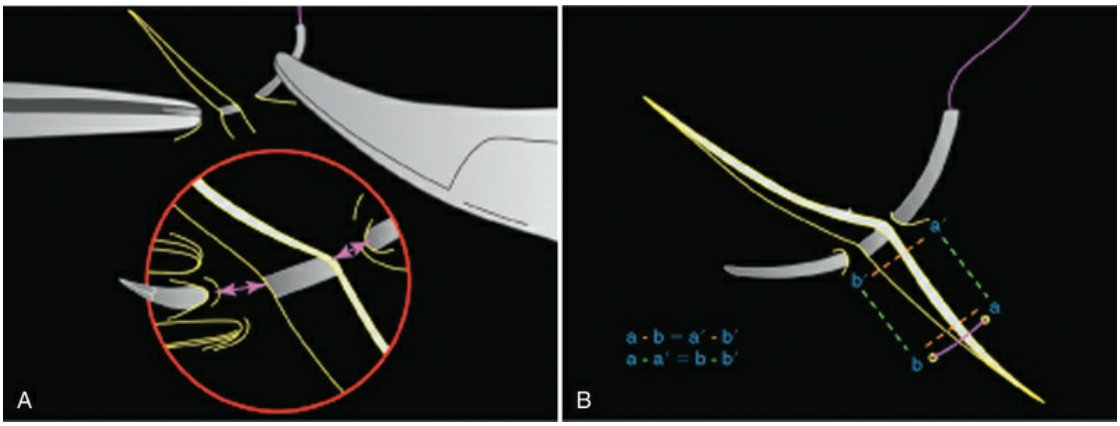
EFIG. 67.6 Unaesthetic healing of an incision caused by tissue margin invagination during suturing.



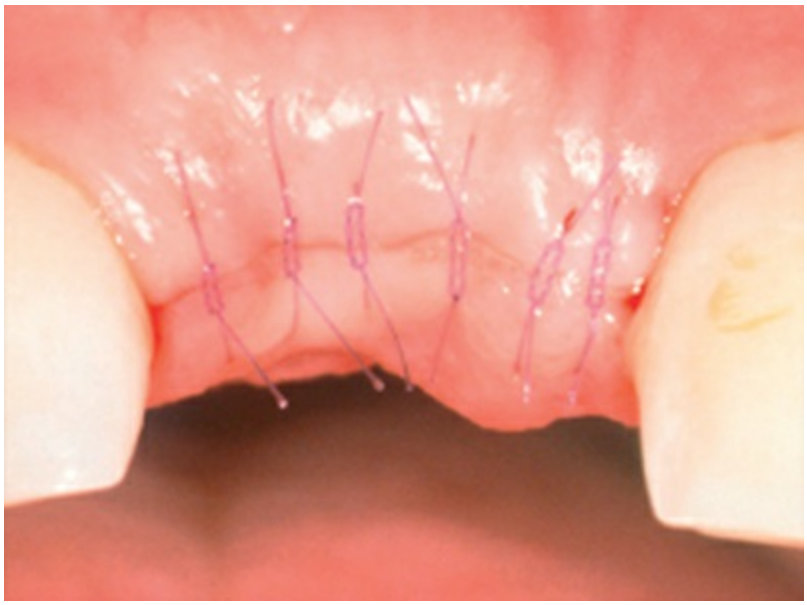
EFIG. 67.7 Direction of passage is demonstrated by the needle penetrating and exiting tissue perpendicular to the incision line.



EFIG. 67.8 Using tissue forceps to guide the perpendicular direction of the suture tread breaks the surface tension while pulling the exiting needle away from the incision, thereby avoiding tissue tearing.



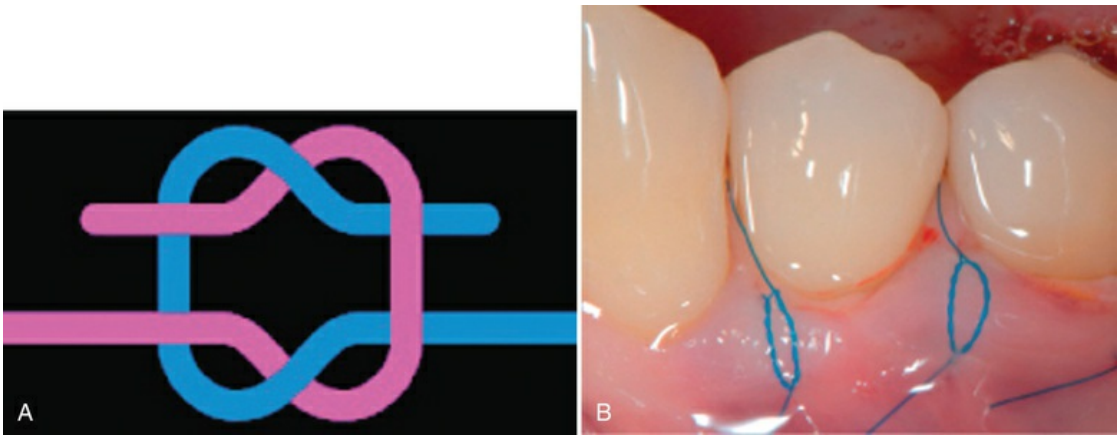
EFIG. 67.9 (A) Symmetry of the distance between the entrance and exit points of the needle across an incision line. (B) Symmetry of the bite size and distance between suture #1 *(a–b)* and suture #2 *(a′–b′).*



EFIG. 67.10 Excellent tissue approximation and coadaptation result from properly following the principles of the geometry of suturing.

Microsurgical Knots

Two basic knots are employed in microsurgery. The square knot, or reef knot, is composed of two single loops thrown in opposite directions. The reef knot has more internal stability than any other knot. For this reason, it has been employed for centuries in nautical applications. It lies flat when tied well and is ideal for passive wound closure. As postsurgical edema occurs, the reef knot opens slightly and then becomes self-locking. It maintains wound edge support without ligation caused by excessive tension (eFig. 67.11). If, in tying a knot, both loops are thrown in opposite directions, it becomes the granny knot and unties easily.



EFIG. 67.11 (A and B) English surgeon's knot has a hollow center that allows for tissue expansion without producing tissue ligation during the edema healing phase.

The English surgeon's knot is composed of two double loops thrown in opposite directions. The first double throw is less likely to loosen when performing the second throw, making it is easier to control tissue apposition. The English surgeon's knot requires a larger bite size. Both knots are tied with instruments.

Conclusions

As medicine and dentistry continue the pursuit of minimally invasive treatment, periodontal microsurgery and its principles will emerge as the methodology to meet professional and public demand.[14] The microscope provides a tremendous platform from which the microsurgical clinician can gather and observe detailed and precise amounts of information for the diagnosis and treatment of patients with skill and accuracy.[6] Microsurgery leads to improved aesthetics, rapid healing, reduced morbidity, and enhanced patient acceptance.[3,15,16]

CHAPTER 68

Lasers in Periodontal and Peri-implant Therapy

Perry R. Klokkevold, Bobby Butler, Richard T. Kao

CHAPTER OUTLINE

Laser Physics and Biologic Interactions
Laser Applications in Periodontics
Lasers in the Management of Periodontitis *(e-only)*
Lasers in the Management of Peri-implantitis *(e-only)*
Complications and Risks of Laser Therapy
Conclusion

The first working laser was made in 1960 by Theodore H. Maiman at Hughes Research Laboratories, a subdivision of Hughes Aircraft in Malibu, California.[68] Maiman created the laser by pumping very high energy from a flashtube into a solid state ruby medium, which emitted a monochromatic beam of deep red visible light with a

wavelength of 694.3 nm. Almost immediately thereafter researchers began investigating the use of lasers for dental applications.[47,76,94,115] Early uses focused on removal of hard tissues and caries, but these lasers offered little benefit over standard rotary instruments. Consequently, interest in the use of lasers for dentistry faded. Laser activity for dental applications remained nominal until the 1990s when advances in new wavelengths, delivery units, and power maximums refocused the use of lasers for soft tissue as well as hard tissue procedures (Table 68.1).[39,66] More recently, there has been an increased interest in the use of lasers for periodontal therapy including both surgical and nonsurgical applications. In addition to their application as a cutting device, lasers have been advocated in antimicrobial photodynamic therapy mode for biofilm disruption to reduce or eliminate pathogens from the periodontal pocket. Yet another potential laser application in periodontics is the use of low-level laser therapy (LLLT) to stimulate cellular activity for enhanced wound healing and tissue regeneration.

TABLE 68.1

Types of Lasers Currently Used in Dentistry

Laser Medium	Wavelength (nm)	Dental Uses
Argon	488–514	Tooth bleaching and advanced curing lights
Diode	655–980	Gingivectomy/gingivoplasty, oral medicine uses (aphthous ulcer therapy, biopsies, dentinal desensitizing), second-stage implant exposure, periodontal curettage (advocated but not evidence based)
Neodymium:yttrium-aluminum-garnet (Nd:YAG)	1064	Gingivectomy/gingivoplasty, oral medicine uses (aphthous ulcer therapy, biopsies, dentinal desensitizing), second-stage implant exposure, periodontal curettage (advocated but not evidence based)
Erbium, chromium:yttrium-scandium-gallium-garnet (Er,Cr:YSGG)	2780	Gingivectomy/gingivoplasty, oral medicine uses (aphthous ulcer therapy, biopsies, dentinal desensitizing), second-stage implant exposure, periodontal curettage (advocated but not evidence based), hard tissue cutting (dentin and osseous)
Erbium:yttrium-aluminum-garnet (Er:YAG)	2940	Gingivectomy/gingivoplasty, oral medicine uses (aphthous ulcer therapy, biopsies, dentinal desensitizing), second-stage implant exposure, periodontal curettage (advocated but not evidence based), hard tissue cutting (dentin and osseous)
Carbon dioxide (CO_2)	10,600	Gingivectomy/gingivoplasty, second-stage implant exposure, periodontal curettage (advocated but not evidence based)

As with the introduction of most new technologies, advocates of laser therapy for periodontics hope it will be able to replace or enhance traditional therapies. It is important to recognize that making the determination of whether a new technology should be incorporated into practice requires evidence from clinical studies to demonstrate equivalence or superiority to accepted therapies. The sample size required to statistically test superiority versus equivalence is generally much larger than what has been tested in clinical trials evaluating lasers to date. Hence, the only reasonable conclusions will state that lasers are equivalent, at best, as compared with conventional therapies. The limited number of longitudinal clinical trials and cohort studies for each laser type along with the fact that different exposure settings and various protocols are used in these studies make justification to implement this new technology for periodontal applications difficult. Published studies to date are too small and heterogeneous to make definitive conclusions. Nonetheless, if a new therapy is found to be equivalent, albeit not superior to a conventional therapy, there may be other reasons such as safety, cost, or ease of use that warrant utilization of the new technology.[48] Systematic reviews and meta-analyses of available reports have attempted to define whether lasers provide additional benefits for periodontal applications.[111–113,115] Unfortunately, there is a lack of well-designed randomized controlled clinical trials (RCTs), which is the optimal type of study needed for meta-analyses, and those studies that exist are often heterogeneous with regard to laser type, settings, and exposure. As such, the conclusions should be interpreted with caution. This chapter describes some of the clinical applications of lasers for periodontal therapy and discusses the currently available literature.

Clinical Correlation

Laser energy delivered to target tissues will vary depending on laser type (wavelength), settings (power), and exposure (time). It is difficult to compare the results of multiple studies unless the same laser is used with identical settings and exposure time.

Laser Physics and Biologic Interactions

Laser is an acronym for "*L*ight *A*mplification by *S*timulated *E*mission of *R*adiation." Lasers function by stimulating the emission of light energy from a given medium in a collimated, focused monochromatic ray of light. The energy beam reacts with a target tissue by being absorbed, reflected, or scattered depending on wavelength and absorption characteristics (Fig. 68.1). Some lasers (e.g., Nd:YAG lasers) may be transmitted through surface tissues to interact with deeper tissues. When the laser is well absorbed, the energy explodes the target tissue cells and extracellular matrix in a process called *ablation*.[93] The efficiency of ablation is related to the wavelength and the affinity of the laser beam for the target tissue. Laser beams may also be reflected or bounced off the target (e.g., reflected off a metal surface) without interaction. This is typically an undesirable effect because there is no effect on the target tissue and the reflected beam can interact with unintended targets. If the wavelength is not well absorbed, there can be scattering and a thermal reaction in the adjacent tissues with carbonization, charring, and melting. Clinicians must understand and appreciate not only how this energy is affecting the target tissues but also how it affects the adjacent tissues as well.

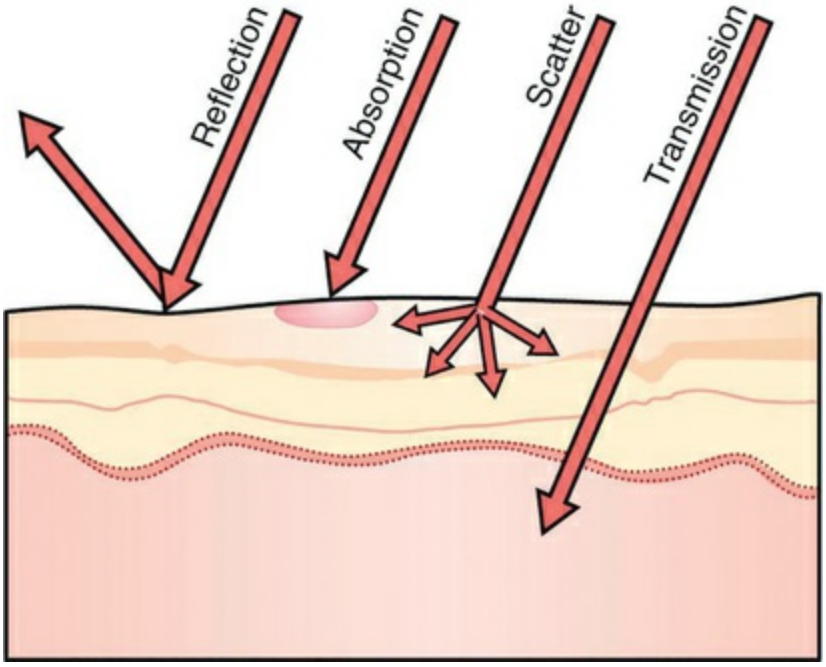

FIG. 68.1 Four potential laser-tissue interactions. The laser beam may be reflected, absorbed, scattered or transmitted. (From Convissar RA: *Principles and practice of laser dentistry,* ed 2, St. Louis, 2016, Mosby.)

Production of a laser requires a medium, an optical chamber or laser tube, and an externally applied energy source to create an emitted monochromatic energy beam (Fig. 68.2). When energy is applied to the medium, electrons are "excited" to a higher energy orbit. When they return to the normal orbit, a photon (particle of light) is emitted. Because the photons are all the same wavelength, the laser beam is "coherent." The medium, which can be a gas, a solid, or a semiconductor, determines the laser wavelength. Lasers are named in relationship to the active element(s) that, when stimulated, generates the energy beam. Typical lasers used in dentistry include argon, GaAs (diode), Nd:YAG, Er:YAG, Er,Cr:YSGG, and CO_2 lasers. Wavelengths are delivered either in a continuous, pulsed (gated) or in a running pulse waveform.[27] Argon lasers have wavelengths in the ultraviolet and visible light range with primary dental applications in composite resin placement, enamel and dentin bonding, preventive therapies, and endodontic procedures.[57] Reported periodontal applications for the other lasers include soft tissue incision, ablation, depigmentation, subgingival curettage, scaling of root surfaces, calculus removal, bacterial killing, osteoplasty, and ostectomy.

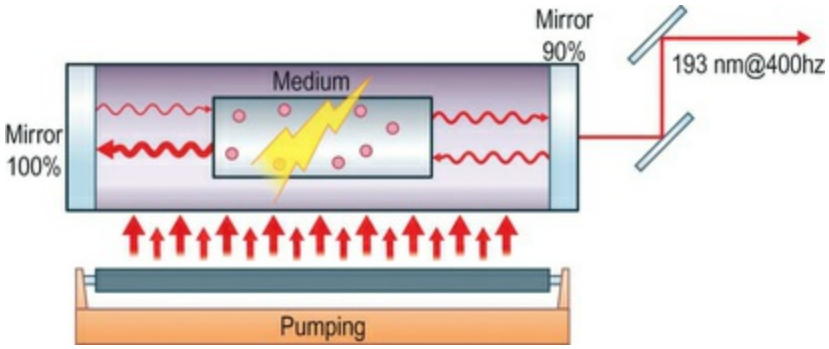

FIG. 68.2 Diagrammatic presentation of the main components of a laser device. Lasers require a medium, an optical chamber or laser tube, and an externally applied energy source to create an emitted monochromatic energy beam. (From Spaeth GL, Danesh-Meyer H, Goldberg I, et al: *Ophthalmic surgery: principles and practice*, ed 4, Edinburgh, 2012, Saunders.)

Key Fact

Lasers function by stimulating the emission of light energy from a given medium in a collimated, focused monochromatic ray of light. The energy beam reacts with a target tissue by being absorbed, reflected, or scattered depending on wavelength and absorption characteristics.

Each laser has a unique wavelength spectrum resulting in specific absorption characteristics that must be understood and appreciated for the desired purpose (Figs. 68.3 and 68.4). When applied to the various periodontal tissues such as the gingiva, periodontal ligament, cementum, dentin, and bone, the biologic interactions will be unique for that wavelength. Tissues are composite structures of inorganic and organic elements with various constituents. Gingiva is composed of fibrous connective tissue, extracellular matrix components (including melanin pigmentation), and 70% water. Bone is composed of 67% inorganic minerals (calcium hydroxyapatite) and 33% organic elements (collagen, noncollagenous proteins, and water). Other factors to consider are the textures, compositions, and densities of these structures. For example, the varying percentages of mineralized structures, blood

vessels, and fluid found in cortical bone versus cancellous bone will result in the laser energy beam encountering differing fluctuations in absorption and scattering, regardless of the wavelength, due to these differences. Blood contains 55% plasma (water) and 45% cells including red blood cells with hemoglobin, white blood cells, and platelets. Thus, when considering the use of lasers for a given clinical application, it is important to appreciate not only the type of laser being used and the target tissue but also the composition of that tissue.

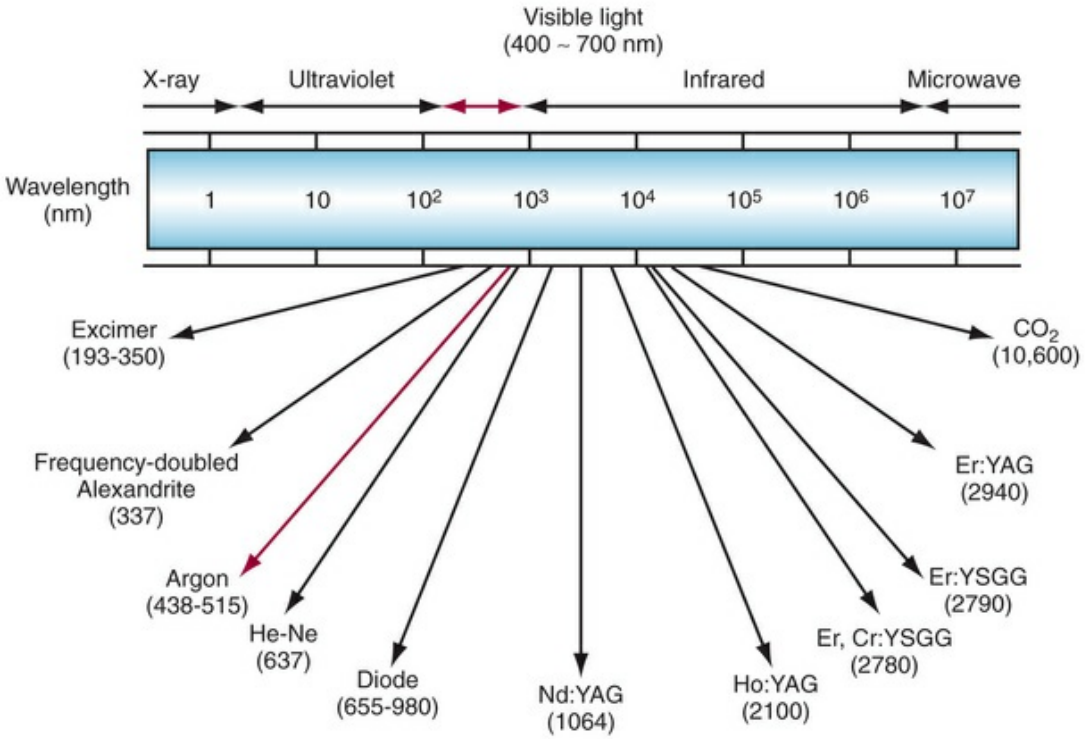

FIG. 68.3 Laser wavelengths. Each laser has a unique wavelength spectrum resulting in specific absorption characteristics. The wavelength of most of the lasers used in dentistry/periodontics is in the red and near-infrared spectrum.

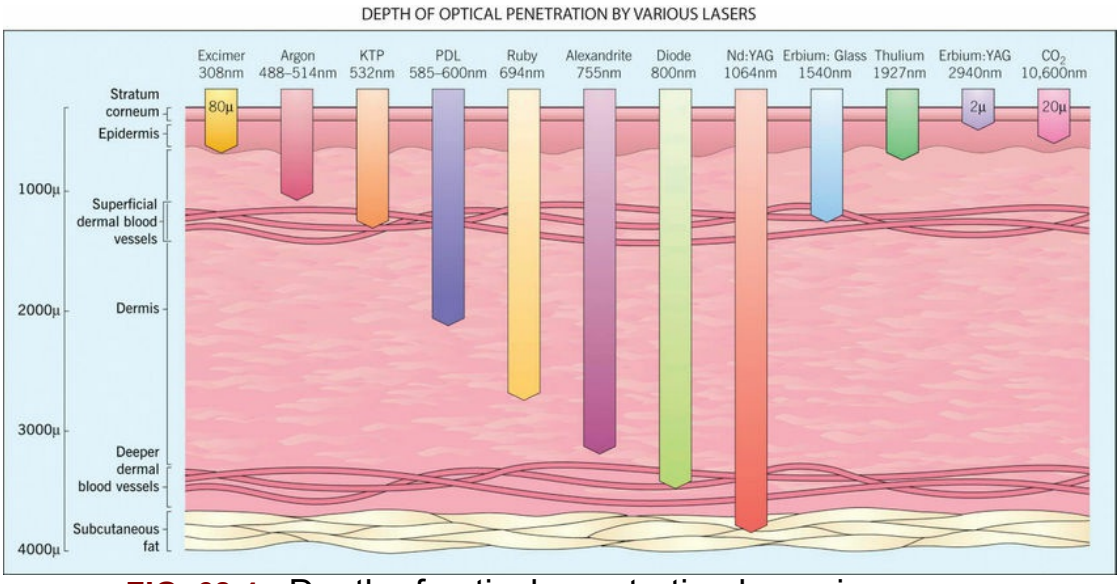

FIG. 68.4 Depth of optical penetration by various lasers. Tissue penetration is a function of laser wavelength and absorption characteristics. It should be noted that the treatment depth can greatly exceed the optical penetration depth for ablative lasers. On the face, the fat can be present at depth of 2 to 3 mm. For example, the depth of optical penetration for CO_2 lasers is only ~20 microns, but fractional CO_2 lasers can vaporize nearly full-thickness microchannels through the dermis. KTP, potassium titanyl phosphate; Nd, neodymium; PDL, pulsed dye laser; YAG, yttrium aluminum garnet. (From Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* two-volume set, ed 3, Philadelphia, 2012, Saunders.)

The affinity of a laser wavelength for the target tissue (absorption coefficient) is critical to its effectiveness for the procedure (Fig. 68.5). The relatively short wavelengths of the diode (655 to 980 nm) and Nd:YAG (1064 nm) are well absorbed by pigment and are better suited for soft tissue procedures than for hard tissue procedures. The CO_2 laser, which has a very long wavelength (10,600 nm), has an affinity for water and is best suited for soft tissue procedures. Diode and Nd:YAG wavelengths are not absorbed by hydroxyapatite and thus are not effective for hard tissues such as cementum, dentin, and bone. The wavelengths of Er:YAG (2940 nm) and Er,Cr:YSGG (2780 nm) lasers have a positive affinity for both water and hydroxyapatite. The specificity for hydroxyapatite allows erbium lasers to cut hard tissues including

bone, dentin, and enamel.[14,15,18–20] The selective absorption by water also makes erbium lasers effective for soft tissue procedures.

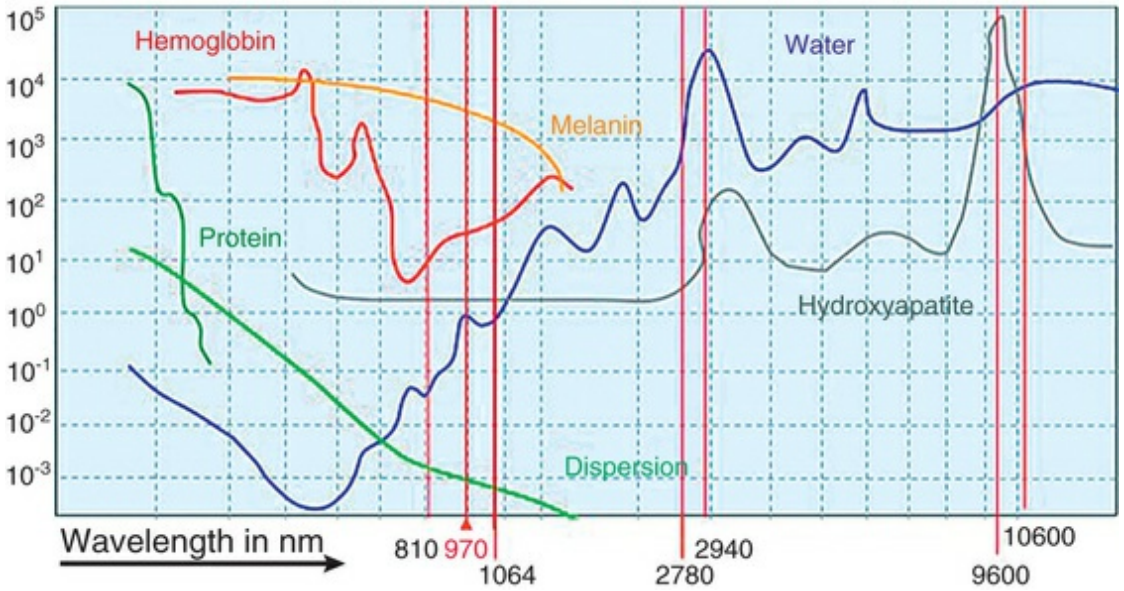

FIG. 68.5 Laser absorption coefficient of various tissue constituents as a function of wavelength.

Selection of the laser type is ultimately based on the amount of energy transmitted to the tissue during a procedure. Photothermal energy is measured in watts (W = joules/second) and hertz (Hz = cycles/second). The energy beam can be delivered in a continuous or pulsed manner. A continuous laser transmits more energy than a pulsed laser, as there are momentary breaks or cooling periods in the latter. When comparing outcomes of different laser therapies, it is imperative to consider the type of laser, the wavelength, *and* the amount of energy delivered to tissues including watts, hertz, and total time of exposure.

Care must be taken to avoid the transmission of excessive thermal energy to target and adjacent tissues. The amount of energy delivered to target tissues is critical to the desired outcome. Although the optimal energy delivered to tissues can be advantageous, excessive energy may completely negate the potential benefits. Consider a study that compared wound healing of incisions made with a scalpel versus Nd:YAG laser with two different power settings. Healing was best following the incision with the laser applied with settings of 1.75 W, 20 Hz. However,

healing was delayed when the energy was increased to 3 W, 20 Hz. Healing of the scalpel incision was better than that for the laser incision at the higher energy setting.[97] The study demonstrates that differences in energy level delivered to tissues from the same laser can have significantly different results. It also shows the dilemma faced when attempting to compare the results of one study to another unless both studies use the same laser with the same energy settings and the same quantity of energy delivered. Unfortunately, the literature is inundated with reports of various applications using different lasers, varied settings, and a wide range of protocols.

Key Fact

It is important for clinicians to recognize not only the type of tissue (e.g., hard vs. soft tissue) but also the quality of target tissue makeup when applying laser therapy. For example, the varying percentages of mineralized structures, blood vessels, and fluid found in cortical bone versus cancellous bone will result in the laser energy beam encountering differing fluctuations in absorption and scattering, regardless of the wavelength.

Specific Laser Types

Diode Laser

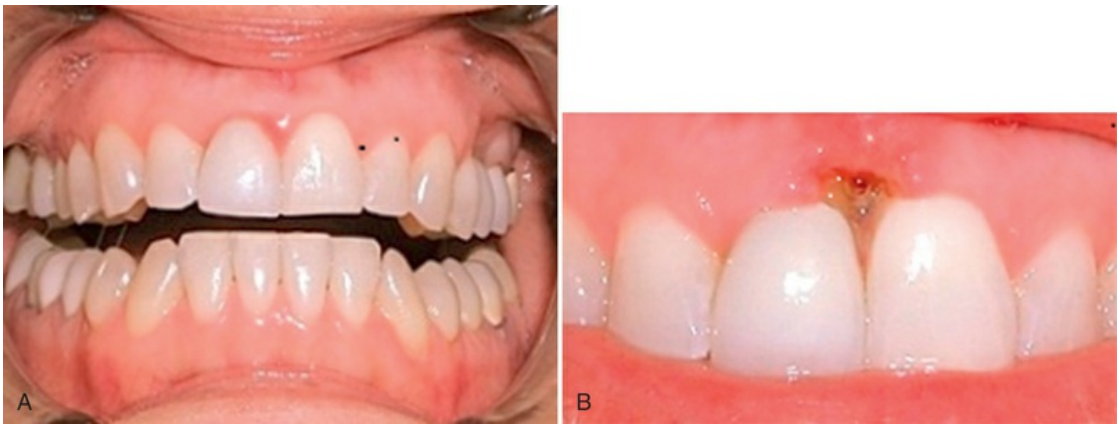
The diode laser uses an electrically pumped semiconductor to produce a laser beam with wavelengths in the range of 655 to 980 nm. Tissue penetration ranges from approximately 0.5 to 5 mm. The laser beam is delivered through a fiber tip. Tips may be preinitiated or require initiation prior to use. This laser is used in contact mode with target tissues. Air is used as a coolant. Water is not used. The wavelength characteristics are most highly absorbed by pigmented tissues, making this laser best suited for soft tissue applications.

Diode lasers are used in two clinical fashions. The first is used as an adjunct initial therapy to reduce the gingival inflammatory response. This is called low-level laser therapy (LLLT). Limited studies indicate that LLLT had no impact on inflammatory

response (as indicated by bleeding on probing and neovascularization) and plaque accumulation.[67,80] Contrary to these findings, LLLT has been demonstrated to be an effective adjunct to non-surgical and supportive periodontal therapy.[69,84]

The second use of diode laser therapy is as an adjunct to scaling and root planing (SRP). Studies of diode use in the treatment of chronic periodontitis reported no or minimal changes in photodynamic therapies (PDs)[91,128] and little to no effect on bacterial levels.[74,91,128] This finding of equivalence has been confirmed by a meta-analysis study that found the use of diode laser as adjunctive therapy to SRP did not achieve additional improvement in clinical parameters.[112] A study evaluating the effect of diode laser on root alteration reported little to no damage on the root surface at a power output of <1 W, whereas high-power selections produced varying levels of carbonization and heat-induced surface cracking.[61]

Diode lasers are relatively inexpensive by comparison to other lasers. Consequently, clinicians often purchase the diode laser for soft tissue management, especially as related to restorative dentistry. Diode lasers can be used to ablate soft tissues in procedures such as frenectomy, gingivectomy, aphthous ulcers, and more.[10,34,41,77] Unfortunately, misuse can often result in inappropriate energy density and duration resulting in tissue necrosis (eFig. 68.1).



EFIG. 68.1 In this case the patient had a diastema. It was closed restoratively, and the restorations violated the biologic width. The bleeding and gingival inflammation was misdiagnosed, and an 810-mm diode laser was used to “curettage” the gingiva. (A) Patient presented early postoperatively with tissue

highly inflamed and symptomatic complaints of pain (7 days postoperatively). (B) Necrotic interproximal and facial bone is present at 14 days post treatment.
(Courtesy Dr. Charles Cobb, University of Missouri, Kansas City.)

Neodymium:Yttrium-Aluminum-Garnet Laser

The Nd:YAG laser uses a neodymium doped yttrium-aluminum-garnet medium to produce a laser beam with a 1064-nm wavelength. Tissue penetration is approximately 2 to 5 mm or greater. The laser beam is delivered through a fiber tip that is used in close, noncontact mode with target tissues. The wavelength characteristics are most highly absorbed by pigment, making it best suited for soft tissue applications.

A limited number of clinical trials are using the Nd:YAG laser for the treatment of chronic periodontitis. A meta-analysis was conducted to investigate whether the use of the Nd:YAG laser as an adjunct to SRP could provide additional benefits compared with SRP alone in patients with chronic periodontitis.[113] Of the 438 articles available, only 3 articles met the inclusion criteria. The conclusion was that although the use of the Nd:YAG as an adjunct to conventional SRP could potentially provide additional benefits, the evidence is insufficient to support its effectiveness.

Although meta-analysis provides the most stringent criteria, some individual studies in the literature merit review. These studies provide conflicting results. Three studies reported little to no difference in PD reduction when comparing laser-treated sites with control sites (SRP only),[38,51,75] whereas two studies reported SRP sites had better resolution.[89,92] In this same series, reduction of the pathogenic bacteria is similarly conflicting. Three studies reported no difference,[51,78,115] one reported the SRP to be more effective,[93] and two reported a significant decrease of *Tannerella forsythia*, *Treponema denticola*, *Porphyromonas gingivalis*, and *Prevotella intermedia* in laser-treated sites.[15,80] These studies also reported the recolonization process to proceed similarly.[15,51] In vitro studies using the Nd:YAG at a low power setting (used in clinical situations) reported calculus ablation without resulting in cementum or dentinal changes.[121,123] However, it is important to recognize that if the energy is increased beyond that used clinically,

there is a linear increase in root surface alterations that included craters, charring, melting, and resolidification of the mineral phase.[6,122]

Erbium:Yttrium-Aluminum-Garnet Laser

The Er:YAG laser uses an erbium doped yttrium-aluminum-garnet medium to produce a laser beam with a 2940-nm wavelength. Because the primary target chromophore is water, tissue penetration is very shallow at approximately 1 micron. However, some reports have challenged this estimate, calculating the depth of penetration to be slightly greater, ranging from 1 to 20 microns.[16] Regardless, the depth of penetration for erbium lasers is shallow by comparison to other laser wavelengths. The laser beam is delivered through a variety of fiber tips that are used in close proximity to target tissues. Water is used along with air as a coolant. Adjustments to the air/water ratio change the laser dynamics and alter the tissue interaction. The wavelength characteristics are most highly absorbed by water and hydroxyapatite. Hence, the Er:YAG laser is effective for both soft and hard tissues.

Clinical trials with the Er:YAG laser in the treatment of chronic periodontitis have provided more consistent results because, in part, they have come from the same group of investigators.[105–110] The Er:YAG laser possesses characteristics most suitable for the nonsurgical treatment of chronic periodonitis.[5,64,100] Although most of these studies concluded that laser treatment was statistically superior in PD reduction, the improvement (ranging from no difference to 0.4 mm) may be of little clinical relevance.[12,14,33,62,106,109] Microbial studies reported no significant differences between treatments.[33,105,106] In vitro studies indicate that Er:YAG laser can effectively achieve bacterial ablation at energy levels that do not result in heat-associated damages to the root surface.[81,100] Despite these encouraging reports, a meta-analysis of 1282 potentially relevant titles and abstracts found only 5 randomized controlled trials included in the analysis.[111] The authors' conclusion was that there is no evidence of effectiveness over conventional SRP due to heterogeneity of the techniques, risks for bias, and methodical shortcomings. This conclusion of equivalence should be interpreted with caution, as the number of well-designed randomized clinical

trials was limited. Another meta-analysis that included 12 randomized clinical trials found no difference between the Er:YAG laser and SRP treatment at 3, 6, and 12 months.[131] The authors attributed the inconclusive results to the large heterogeneity across studies.

Er,Cr:YSGG Laser

The Er,Cr:YAG laser uses an erbium chromium doped yttrium-scandium-gallium-garnet medium to produce a laser beam with a 2780-nm wavelength. Similar to the Er:YAG laser, tissue penetration is very shallow, from 1 to several microns. The laser beam is delivered through a variety of fiber tips that are used in close proximity to target tissues. Water is used along with air as a coolant. Adjustments to the air/water ratio can change the laser dynamics and alter the tissue interaction. The wavelength characteristics are most highly absorbed by water and hydroxyapatite. Hence, the Er:YAG laser is effective for both soft and hard tissues.

CO_2 Laser

The CO_2 laser uses a carbon dioxide medium to produce a laser beam with a 10,600-nm wavelength. Tissue penetration is approximately 0.03 to 0.10 mm. The laser beam is delivered from a handpiece via mirrors that reflect the beam. It is used in noncontact mode with target tissues. Air is used as a coolant. Water is not used. Hollow tips are sometimes used to direct the laser beam into pockets or down canals. The wavelength characteristics are most highly absorbed by water, pigment, and hydroxyapatite. The CO_2 laser is most effective for soft tissues but also ablates hard tissues.

Laser Applications in Periodontics

Currently, lasers are used in periodontal therapy for (1) aesthetic surgical procedures such as gingivectomy, osseous crown lengthening, and depigmentation; (2) nonsurgical therapy; (3) decontamination and antimicrobial therapy; and (4) biomodulation.

Aesthetic and Pre-Prosthetic Surgical Applications

Several types of laser wavelengths have been used for soft tissue surgical procedures.[11,72,73] Appropriate use of lasers for procedures such as frenectomy, gingivectomy/gingivoplasty, reshaping of drug-induced gingival overgrowth, exposure of short crowns associated with altered passive/delayed eruption, and management of excess mucosal tissue such as pericoronitis situations distal of mandibular second molars have been well documented.[7,13,44,56] Some of the positive aspects of laser therapy are good visibility during the surgical procedure as a result of coagulation, hemostasis, and minimal tissue damage adjacent to the laser wound. Additionally, laser therapy can offer extreme precision and may be easier than using a scalpel.

Aesthetic applications for gingivectomy and gingivoplasty procedures allow delicate tissue reshaping. The laser is effective for the removal of pigmentation from the gingival tissues, which can significantly improve the aesthetics of highly pigmented areas. The CO_2, diode, Nd:YAG, Er:YAG, and Er,Cr:YSGG lasers have been used for depigmentation.[8,34,40,45,63,79]

Some clinicians advocate the use of lasers for crown-lengthening procedures. Whereas crown lengthening involving only soft tissue can be effectively performed with a wide variety of lasers, only lasers with wavelengths that have an affinity for hydroxyapatite are effective for crown-lengthening procedures that require osseous resection. Erbium lasers (e.g., Er:YAG and Er,Cr:YSGG), which have an affinity for water and hydroxyapatite, have been advocated for clinical crown lengthening without gingival flap reflection.[42,43,59,118,126–129] The Er,Cr:YSGG laser can safely cut bone without burning or altering the calcium-to-phosphate ratio of the irradiated bone.[59,127] This approach has been described in case reports and case series, but there are no controlled longitudinal or cohort studies supporting the use of lasers for clinical crown lengthening using the closed-flap technique. The use of lasers for flapless crown lengthening with osseous contouring remains controversial.

Decision making for the use of lasers in crown lengthening in an

open or closed approach is based on osseous biotypes.[60] In the closed approach, the Er,Cr:YSGG or Er:YAG laser is only feasible in medium biotype cases with an osseous crest that is approximately 1 mm in thickness and may be limited to situations where only 1 to 2 mm of osseous removal is required. In this technique, bone sounding with a probe is used after the external gingivectomy to determine the thickness of the osseous biotype and to determine the amount of bone removal required. The laser tip is aligned parallel to the root surface in contact with the bone and fired for 1 to 2 seconds. The tip is moved slowly around the tooth, firing intermittently while in contact with the bone until the desired osseous reduction is achieved. The osseous removal is verified by sounding, and detailing is performed with a small chisel (Fig. 68.6). This technique can be surgically conservative and result in symmetric gingival levels in the aesthetic zone.[11,65,72]

FIG. 68.6 Crown-lengthening procedure performed using a closed approach with a laser. (A) Periodontal sounding after the initial gingivectomy, which indicated the need for osseous contouring to achieve biologic width. (B) The osseous contouring was done via intrasulcular access. Sounding confirms 3 mm from the gingival to osseous crest. Final small fragments of bone are checked and removed with a small chisel. (C) Final surgical photograph shows minimal bleeding with no need for sutures. A frenectomy was also completed at the time of surgery. (D) Smile at 3 months postsurgery. (Case courtesy Dr. Bobby Butler, Seattle, Washington.)

Case selection based on osseous biotypes is critical for the success of this closed approach for crown lengthening. In a thick biotype, the laser will likely create a "trough" or an intrabony defect. Because inadequate bone removal is performed, the soft tissue will often rebound soon after the procedure. An open-flap approach with direct vision of bone is indicated for cases with a thick osseous biotype so definitive osseous contouring can be performed. Closed or flapless laser crown lengthening should absolutely be avoided in

all cases of thin biotype. Using laser therapy in an ablative mode for osseous removal in thin biotype cases poses a high risk for overheating tissues and adversely affecting the healing response, leading to unfavorable or possibly disastrous clinical outcomes.

Further issues of concern include the limited ability to assess the appropriateness of osseous recontouring and the inability to avoid or detect damage to root surfaces.[27] These concerns and the possible need for retreatment because of tissue rebound or poor healing suggest that this is not a superior or equivalent technique as compared with traditional functional crown lengthening that requires osseous contouring.

Nonsurgical Periodontal Therapy

One of the more prevalent applications of lasers in periodontics is the nonsurgical treatment of moderate to advanced chronic periodontitis. Lasers have been used as a monotherapy or as an adjunct to scaling and root planing. The purported benefits of lasers for nonsurgical periodontal therapy include subgingival curettage, minimally invasive access for scaling and root planning, and calculus removal, as well as detoxification and killing of subgingival periodontal pathogens.[49,102,114,131]

In the clinical situation, periodontal pathogenic bacteria exist within a protective biofilm in a periodontal pocket. Consequently, it is difficult for conventional periodontal therapies to completely eliminate them. Laser therapy is proposed to improve access to areas that are difficult for instruments to reach and to facilitate killing bacteria. Indeed, lasers with various wavelengths have been shown to effectively kill periodontal pathogens.[20,50] See the Photodynamic Therapy section.

When assessing the effectiveness of any particular laser type used for nonsurgical periodontal therapy, several questions need to be considered, as listed in Box 68.1.

Box 68.1

Questions to Consider When Evaluating the

Effectiveness of Laser Therapy

1. Do the in vivo studies demonstrate a reduction in pathogenic bacteria as compared with conventional therapy (e.g., scaling and root planing [SRP])?
2. Are positive microbial changes sustained, or do the periodontal pathogens return and recolonize the sites?
3. Are there any differences in clinical parameters following laser-assisted versus conventional therapy SRP? When evaluating nonsurgical periodontal therapy, gain in clinical attachment level (CAL) represents the gold standard. Pocket depth (PD) and levels of subgingival microbes are important because they correlate with changes in CAL.[26,99]
4. Are there changes in root surface condition based on in vitro or in vivo studies?

Clinical Correlation

Laser therapy used to treat moderate to advanced chronic periodontitis is one of the more prevalent applications of this technology. The purported benefits of lasers for nonsurgical periodontal therapy include minimally invasive access for scaling and root planing, calculus removal, and the detoxification and killing of subgingival periodontal pathogens. Laser therapy may reach difficult-to-access areas more effectively than conventional therapy.

Photodynamic Therapy

Photodynamic therapy (PDT) involves the use of a photosensitizer (photoactive dye) that is activated by exposure to a specific wavelength of light in the presence of oxygen. The activated photosensitizer transitions to an excited state and subsequently reacts with oxygen to create singlet oxygen and free radicals, which are damaging to proteins, lipids, nucleic acids, and other vital elements causing destruction of the target tissues. In the case of biofilm and periodontal pathogens, antimicrobial photodynamic therapy (aPDT) may *appear* to offer a magic bullet effect of target

killing bacteria. PDT may be an effective means of disrupting the biofilm.[96] Most studies evaluating photodynamic therapy have been conducted in Europe. The US Food and Drug Administration does not yet approve PDT.

The use of lasers for photodynamic therapy has been reviewed.[30,88,119] Antimicrobial PDT for periodontitis uses a photosensitizer dye that specifically targets microorganisms and is activated by low-level laser light. Photosensitizer activation can be achieved with low-level energy exposure from various laser light sources including but not limited to argon, Nd:YAG, and diode. The introduction of a photosensitizer can greatly increase the bactericidal ability of a laser.[19,20,22,29,92,117] This is supported by an in vitro study using methylene blue with a diode laser to destroy black-pigmented bacteria (*P. gingivalis* and *P. intermedia*)[117]; 99% to 100% of bacteria were eliminated. However, it is important to recognize that pathogenic bacteria within the protective biofilm that exists in vivo may not be killed to the same degree observed during in vitro studies. Laboratory analysis of laser bactericidal properties is not clinically relevant in that these bacteria do not exist as a suspension or monolayer in vivo.

Key Fact

Antimicrobial photodynamic therapy uses a photosensitizer (nontoxic dye), which specifically targets microorganisms and is activated by low-level laser light. The introduction of a photosensitizer can greatly increase the bactericidal ability of a laser.

To date, the results of clinical studies evaluating the effectiveness of aPDT are mixed and not convincing.[116] A systematic review including 17 clinical studies found that 4 studies demonstrated significantly reduced bacteria with laser photodynamic therapy, whereas 13 studies showed equivalent effectiveness as compared with conventional scaling root planing (SRP) alone.[2] The authors concluded that the bactericidal efficacy of aPDT as an adjunct to SRP against periodontal pathogens remains debatable. The incomplete elimination of periodontal pathogens and the protective

nature of the biofilm environment may be responsible for the observed persistence and recolonization of microbial pathogens in this microniche. Several individual clinical studies have been published on the use of aPDT as adjunct to SRP. A majority of these studies reported significant clinical and microbiologic improvements in the PDT + SRP combination as compared with SRP alone.[4,18,19,20,22,23,128] One study found the results to be comparable.[30] A clinical and microbiologic evaluation of the effectiveness of PDT in the nonsurgical treatment of aggressive periodontitis, using a split-mouth design (PDT + SRP versus SRP only), found no additional benefits from PDT as compared with SRP alone.[21] A meta-analysis evaluating the effectiveness of aPDT as an adjunct to nonsurgical periodontal therapy in patients with diabetes included four RCTs reporting clinical and metabolic parameters.[1] Although aPDT with SRP was shown to be effective in treating chronic periodontitis, no difference was observed between the test (aPDT + SRP) and control (SRP only) groups. The authors concluded that aPDT has no additional benefit. More clinical trials are required prior to clinical implementation.

Low-Level Laser Therapy

The use of low-level laser therapy (LLLT) for photobiomodulation is prevalent in medicine. Soon after the discovery of lasers in the 1960s, it was recognized that laser "light" therapy had the potential to reduce pain, inflammation, and swelling and to improve wound healing.[24,70,71] The term *low-level laser therapy* refers to the therapeutic application of light to tissues with the goal of reducing pain or stimulating healing. The wavelengths of light used for LLLT are in the red to near-infrared range (600–1070 nm). It is referred to as "low level" because the density of light energy is low compared with other lasers, which are used for ablation, cutting, and thermally heating tissue. The power of low-level light (energy) is typically in the range of 1 to 1000 mW.[24] LLLT is thought to promote wound healing by reducing inflammation, increasing the formation of granulation tissue, enhancing epithelialization, fibroblast proliferation, and matrix synthesis, as well as neovascularization.[28,124,125]

Although LLLT is widely used in medicine, it continues to be

controversial because the biologic mechanism(s) are not understood and the parameters of use (i.e., wavelength, power, pulse, and timing or exposure duration) are not defined. As with other laser investigations, there is heterogeneity of experimental protocols, parameters used, and results reported. Some published reports are positive, whereas others are negative. In the case of LLLT, perhaps more than other forms of laser therapy, the therapeutic effectiveness greatly depends on the optimal parameters being applied, and those details have yet to be defined.

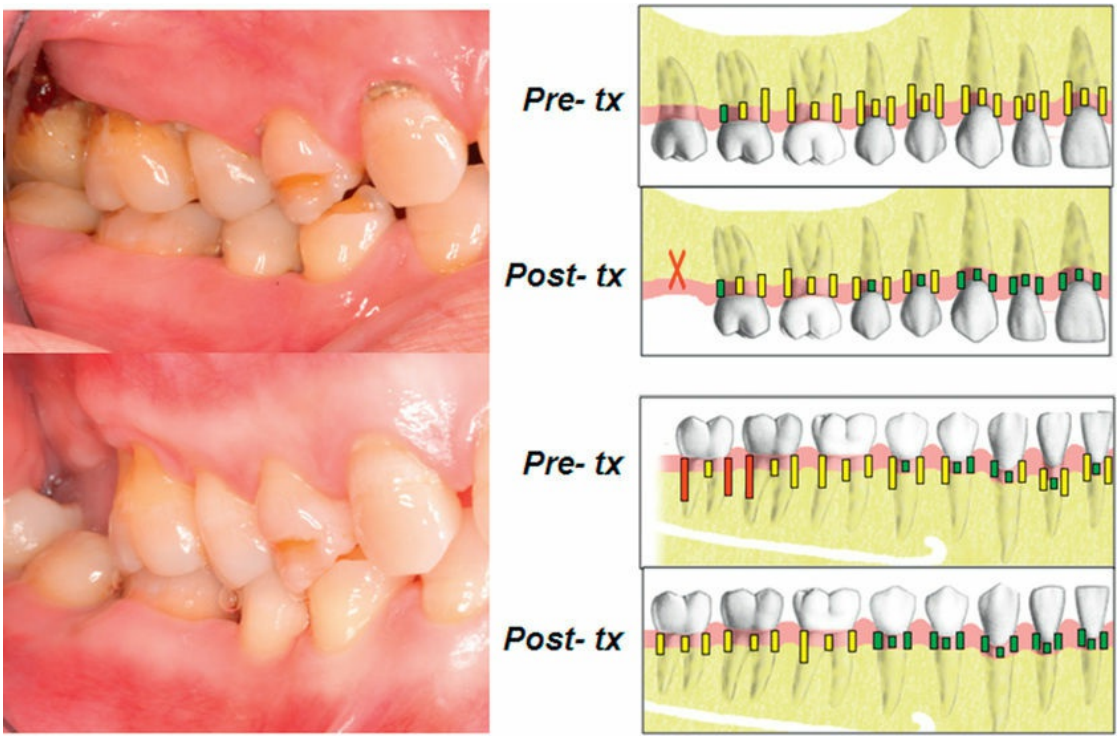
Low-level laser therapy has been shown to reduce inflammation and enhance nonsurgical periodontal treatment in healthy subjects as well as subjects with diabetes.[9,82] In a meta-analysis of eight publications (seven RCTs) evaluating the effectiveness of LLLT as an adjunct to nonsurgical periodontal therapy, short-term (1–2 months) improvements in probing pocket depth and crevicular fluid levels of IL-1ß were shown.[95] However, LLLT failed to show significant intermediate-term (3–6 months) effects in terms of clinical parameters.

Case reports and case controlled series have suggested that LLLT *may* improve the effects of periodontal regenerative procedures.[17,35,36] One clinical study evaluated the effectiveness of enamel matrix derivative (EMD, Emdogain) with or without the application of a low-level laser (diode) to treat intrabony defects in 22 periodontitis patients.[83] The EMD + LLLT sites healed with less gingival recession, less swelling, and less visual analog scale pain scores as compared with the EMD-only sites. More research, preferably well-designed, randomized controlled clinical trials, is needed to assess the effectiveness of LLLT on periodontal therapy.

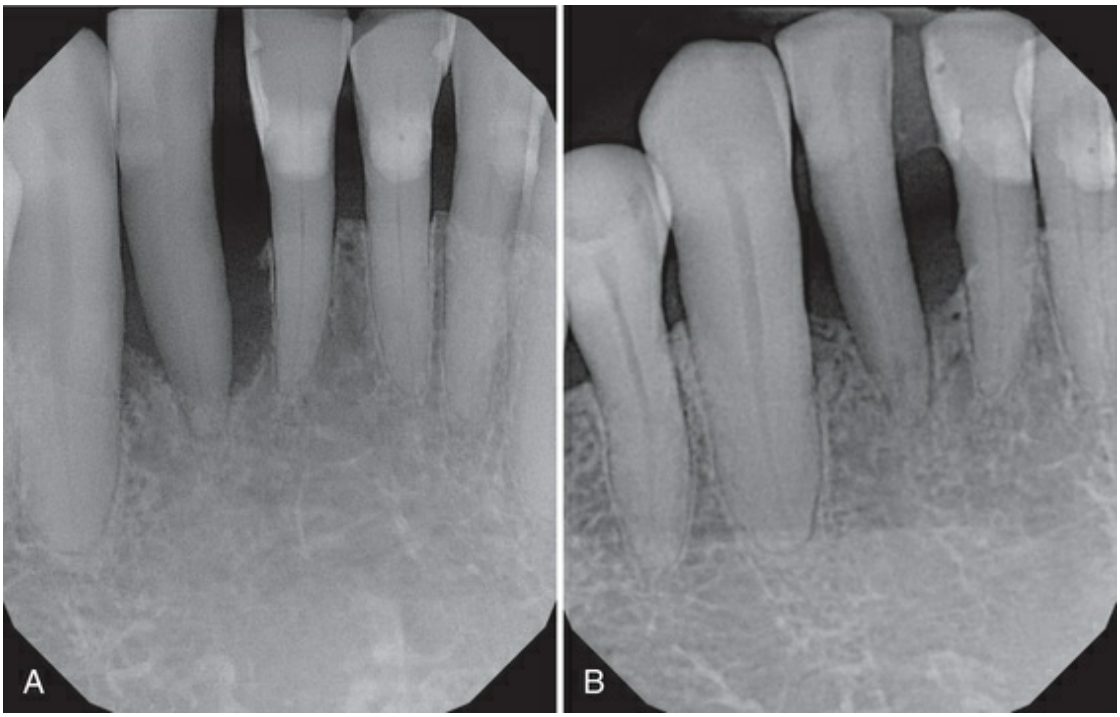
Lasers in the Management of Periodontitis

The role of laser therapy in the surgical management of periodontitis remains controversial. At the center of this controversy is the apparent potential for the Nd:YAG laser to result in new attachment and regeneration when used with the laser-assisted new attachment procedure (LANAP) protocol.[79,130] The

patented LANAP procedure consists of a first pass with the Nd:YAG laser at a setting of 4.0 W and energy density of 1965 mJ/mm^2, 100-μs pulse duration, and 20 Hz applied. The first pass is purported to de-epithelialize the sulcular/pocket epithelium while sparing the underlying connective tissue and killing pigmented bacteria. The teeth are then scaled and root planed with piezo ultrasonic instrumentation. A second pass is performed with similar output but with a 650-μs pulse duration and 20 Hz with the objective of creating a blood clot that presumably, if kept stable, acts as the foundation for periodontal wound healing (eFigs. 68.2 and 68.3).



EFIG. 68.2 The LANAP procedure in this case led to a good resolution, and results can be maintained with conventional periodontal supportive therapy. The resolution was comparable with conventional flap osseous surgery.



EFIG. 68.3 This lower anterior case was treated with LANAP, occlusal adjustment, and splinting. (A) Radiograph at pretreatment. (B) Radiograph at 7 months post treatment. (Case courtesy Dr. Braden Seamon, Kailua, Hawaii.)

Since the initial description of LANAP,[53] most evidence was based on case reports. Some publications suggest that this protocol may have merits. This is based on two histologic studies that report new attachment and periodontal regeneration (see Chapter 63) following treatment with the LANAP protocol.[79,130] More recently, the effectiveness of LANAP was examined in the treatment of 107 consecutive patients presenting with moderate-to-advanced chronic periodontitis.[122] The main criterion for determining treatment success over time was tooth loss. A significant criticism is that there were no controls in this study. Data were compared with published studies of tooth loss over time. Tooth loss per patient treated by LANAP was 0.43 of a tooth over an average of 6.2 years posttreatment. Although a direct comparison with classic studies is not possible due the shorter time frame for posttreatment evaluation, the trend suggests that LANAP compares favorably with conventional surgical treatment modalities and may be a less invasive treatment alternative.

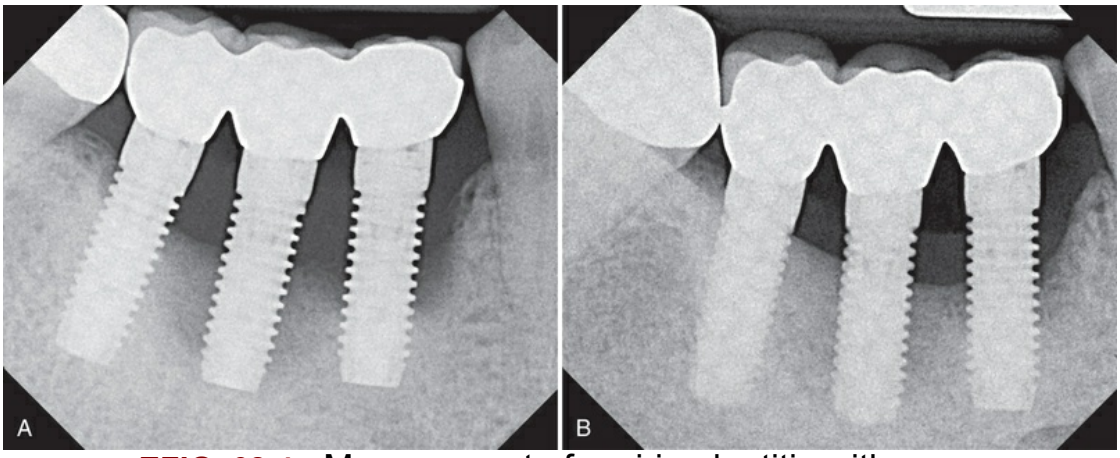
There are limited studies on the surgical management of chronic

periodontitis with other laser types. Given the positive histologic evidence of new attachment and regeneration associated with LANAP performed with the Nd:YAG, the question remains: Can the Er:YAG or the Er,Cr:YSGG laser produce similar results? If proved to be effective, erbium lasers may be advantageous due to the lower risk and greater versatility associated with this wavelength.[59,89,126,127] In a case report, periodontal regeneration (radiographic bone fill) of a maxillary intrabony defect following Er,Cr:YSGG treatment has been described.[85] In a case series that included 46 patients with 79 angular intrabony defects, Er,Cr:YSGG laser treatment resulted in significant pocket depth reduction and significant radiographic bone fill.[3] Although these results are promising, the difficulty is that there are no controls, and periodontal regeneration requires histologic evidence of new pulsed dye laser, cementum, and bone formation. Because this has not been demonstrated with this wavelength, one can only state that the finding is suggestive of radiographic bone fill of the intrabony defects that is consistent with *possible* periodontal regeneration. In a split-mouth design, the use of the ER,Cr:YSGG laser versus open-flap debridement was compared.[49] The laser-assisted pocket therapy was found to provide similar clinical attachment level gains with similar reduction in pocket depth, gingival index, and the sulcular bleeding index. These findings were similar to the findings that compared a split-mouth design with three closed approaches, which included SRP, diode laser curettage with SRP, and laser-assisted curettage with SRP and laser sealing, versus an open approach of papilla reflection with SRP and flap closure.[132] In comparing these open and closed protocols, all treatments resulted in a reduction in PD and bleeding on probing. Consistent with the previous study, closed protocols all resulted in less gingival recession. These authors concluded that if aesthetics is a concern, laser curettage is a viable option. Because this is an issue of concern in the maxillary anterior region, the caveat is that the clinician must be appropriately trained and familiar with the laser being used. There are clinical instances where mismanagement with laser resulted in irreversible hard and soft tissue damage (see eFig. 68.1 and Fig. 68.7).

Lasers in the Management of Peri-implantitis

There is increased interest in the use of laser to manage peri-implantitis. This is due to anecdotal reports of cession and reversal of radiographic changes associated with bone damages surrounding peri-implantitis cases (eFig. 68.4). This clinical phenomenology, although interesting, is not a consistent finding, and there is no clear biologic basis for when and why this phenomenology happens. In the Sixth European Workshop on Periodontology, the surgical treatment of peri-implantitis recognized the use of Er:YAG for implant surface decontamination.[25] In a dog study, surface decontamination of experimental peri-implantitis was compared with closed- and open-approach debridement using Er:YAG laser and an ultrasonic scaler or plastic curettes and local metronidazole gel application.[103] The authors found both open-flap submerged approaches (Er:YAG and ultrasonic scaling) resulted in higher clinical attachment gain (bone implant contact) with the laser therapy having a higher degree of reosseointegration (44.8%) as compared with ultrasonic (8.7%) and plastic curette/metronidazole gel debridement (14.8%). Similar but more modest results were found with the use of the CO_2 laser to decontaminate implant surfaces.[31,32] Subsequently, in a case series of 15 patients with failing implants, the CO_2 laser was used to decontaminate implant surfaces in conjunction with bone augmentation (autogenous bone or xenogenic bone covered with collagen membrane). Clinical and radiographic evaluation after 27 months revealed almost complete bone fill of peri-implant bony defects. Further in vitro investigation defined the optimal Er:YAG laser parameters for debridement of implant surfaces without damaging the implant surface.[120] Although the experimental findings of Er:YAG are encouraging, the use of this laser in two clinical trials found the healing response to be similar to controls, and the clinical improvements were limited.[86,104] This suggests that the long-term stability of clinical outcomes may be influenced by factors other than the method used for surface debridement and decontamination. In a case report, a soft laser was successfully used

to decontaminate the implant surface before regenerating the defect with autogenous bone and the use of an expanded polytetrafluoroethylene (ePTFE) membrane, but this approach has not been further investigated.[52] Finally, a laser-photodynamic approach for the management of peri-implantitis in 15 patients with IMZ implants (cylindrical titanium plasma sprayed) has been reported.[37] Although there was significant decrease in *Aggregatibacter actinomycetemcomitans*, *P. gingivalis*, and *P. intermedia*, complete elimination was not achieved.



EFIG. 68.4 Management of peri-implantitis with LANAP. (A) Radiographic bone loss with increasing probing depth and tissue inflammation was present at pretreatment. (B) After 11 months post LANAP treatment, there is increased radiopacity, suggestive of remineralization in addition to decreased probing depth and tissue inflammation. (Case courtesy Dr. Braden Seamon, Kailua, Hawaii.)

The biologic basis of peri-implant bone regeneration, reosseointegration, and reversal of peri-implantitis using laser therapy is being elucidated. Crevicular fluid analysis of patients and osteoblasts in cell culture treated with laser therapy demonstrate an increase in the levels of cytokines associated with tissue regeneration including platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF),[98,101] insulin-like growth factor 1 (IGF-1),[101] and bone morphogenic protein 2 (BMP-2).[58] These growth and differentiation factors are associated with tissue healing and regeneration. Conversely, proinflammatory

cytokines associated with inflammation and tissue destruction such as interleukin-1-β, tumor necrosis factor (TNF)-α, and metalloproteinases decreased.[46,87,90,98] The combination of an increase in reparative associated growth and differentiation factors and a decrease in proinflammatory cytokines suggests that the biologic mediators induced by lasers are of a profile that encourages tissue repair and regeneration. Although these studies provide early clues for a possible biologic basis, further research is needed.

Complications and Risks of Laser Therapy

The primary disadvantage of laser therapy is the potential for unintended tissue damage, as lasers can easily generate excessive temperatures. The exposure of bone to temperatures ≥47°C (116.6°F) can induce cellular damage and osseous resorption.[39] Extreme temperature levels of ≥60°C (140°F) result in tissue necrosis.[66]

Overexposure of laser energy has been the basis for complications, reports of tissue damage, and destruction of the periodontium. New, inexperienced operators as well as more seasoned, "cutting-edge" clinicians may encounter disastrous results from their initial treatments (Fig. 68.7). To avoid these negative outcomes, knowledge of the laser mechanics and technique is essential to minimize tissue damage. Once mastery of the information has been achieved, it is critical to identify the desired laser application and the fashion in which it will be used.

Photos in sequence: (A–B) One-month post laser treatment. (C) Sequestration of necrotic interproximal and facial bone at 2 months post treatment. (D) Healing at 3 months post treatment. (Courtesy Dr. Charles Cobb, University of Missouri, Kansas City.)

Conclusion

There are many potential advantages to using laser therapy, including better visualization of cutting, patient acceptance, wound detoxification, less invasive surgical access, and minimal wound contraction with less scarring.[11,54,72] Although these laser applications hold promise, many require more well-designed, controlled research to validate their effectiveness.[55]

The literature has numerous positive findings for the use of lasers in the management of periodontal and peri-implant disease. The

quality of the literature is largely dominated by case reports and case series. There are limited well-designed randomized controlled clinical trials. Further clouding the issue is the number of different lasers in use and the variety of settings and protocols being tested for each laser. The lack of consistency from one study to another has left the profession with no lasers that have been researched extensively enough to provide predictable parameters of use. Therefore laser use for the treatment of periodontal or peri-implant disease continues to have numerous unknowns.

As in all professions, technology is constantly advancing with new research to provide the clinician with better equipment, drugs, and techniques to improve the therapy rendered to patients. Lasers may become an integral part of periodontal therapy, but at the present time, further research as to the parameters for clinical efficacy and the biologic basis for laser therapy is required. Clinicians considering incorporating laser therapy should be familiar with what is known, understand the appropriate parameter for use, and receive adequate training to master the laser of interest.

Case Scenario 68.1

Patient:
56-year-old male

Chief Complaint:
"I don't like the way my gums look. They are swollen and now cover most of my teeth. I would like my teeth to be more visible and look normal."

Background Information
Patient reports a history of liver transplantation. He is currently taking cyclosporine, an immunosuppressant to prevent rejection. The patient is a nonsmoker and is allergic to penicillin. He sees his dentist regularly for periodontal recall maintenance, and he reports brushing two times a day and flossing once a day.

Clinical Findings:

Exam reveals severe gingival overgrowth that covers one-half to two-thirds of the crowns. Only the incisal/occlusal thirds of the patient's teeth are displayed. Oral hygiene (biofilm control) is inadequate. Clearly, the gingival overgrowth hinders his ability to perform good hygiene.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Patient needs surgical reduction of gingival overgrowth. What are the advantages of using laser to perform gingivectomy? A. Hemostatic control B. Precision of incision cutting C. Minimal wound contraction and scarring D. All of the above	**Answer: D** **Explanation:** These are all advantages of using laser therapy. Many of the concepts of laser therapy are positive; however, more research is needed.
2. What type of laser should NOT be used for this procedure? A. Nd:YAG B. Er:YAG C. Argon D. Diode	**Answer: C** **Explanation:** Each laser operates at a different wavelength suitable for different types of procedures. Argon is a type of laser only suitable for tooth bleaching and advanced curing lights.
3. All of the following are periodontal applications of lasers EXCEPT: A. Scaling of root surfaces B. Bacterial killing C. Osteoplasty and ostectomy D. None of the above	**Answer: D** **Explanation:** Depending on the type, specific lasers can be used to change scale root surfaces (remove calculus), reduce bacteria, and ablate osseous tissues. Soft tissue ablation is also a function of lasers.

CHAPTER OUTLINE

Rationale for Therapy
Sequence of Treatment
Control of Active Disease
Preprosthetic Surgery *(e-only)*
Conclusion

Editors' note: An animation (slide show) has been added by the editors as a supplement to the chapter. It was produced by My Dental Hub as a patient education tool and covers the basic elements in a conceptual manner. It is not intended to be a procedural guide for dental professionals.

Periodontal health is the *sine qua non*, a prerequisite, of successful comprehensive dentistry.[25] To achieve the long-term therapeutic targets of comfort, good function, treatment predictability, longevity, and ease of restorative and maintenance care, active periodontal infection must be treated and controlled before the initiation of restorative, aesthetic, and implant dentistry. In addition, the residual effects of periodontal disease or anatomic aberrations inconsistent with realizing and maintaining long-term stability must be addressed. This phase of treatment includes techniques performed in anticipation of aesthetic or implant dentistry, such as clinical crown lengthening, covering denuded roots, alveolar ridge retention or augmentation, and implant site development (Video 69.1: Effects of Single Tooth Loss).

Rationale for Therapy

The many reasons for establishing periodontal health before performing restorative dentistry include the following[52]:

1. Periodontal treatment is undertaken to ensure the establishment of stable gingival margins before tooth preparation. Noninflamed, healthy tissues are less likely to change (e.g., shrink) as a result of subgingival restorative treatment or postrestoration periodontal care.[28,29] In addition, tissues that do not bleed during restorative manipulation allow for a more predictable restorative and aesthetic result.[22,23]
2. Certain periodontal procedures are designed to provide for adequate tooth length for retention, access for tooth preparation, impression making, tooth preparation, and finishing of restorative margins in anticipation of restorative dentistry.[22,47] Failure to complete these procedures before restorative care can add to the complexity of treatment and introduce unnecessary risk for failure.[22]
3. Periodontal therapy should antecede restorative care because the resolution of inflammation may result in the repositioning of teeth[46] or in soft tissue and mucosal changes.[20,48] Failure to anticipate these changes may interfere

with prosthetic designs planned or constructed before periodontal treatment.

4. Traumatic forces placed on teeth with ongoing periodontitis may increase tooth mobility, discomfort, and possibly the rate of attachment loss.[9] Restorations constructed on teeth free of periodontal inflammation, synchronous with a functionally appropriate occlusion, are more compatible with long-term periodontal stability and comfort (see Chapters 18 and 55).
5. Quality, quantity, and topography of the periodontium may play important roles as structural defense factors in maintaining periodontal health. Orthodontic tooth movement and restorations completed without the benefit of periodontal treatment designed for this purpose may be subject to negative changes that complicate construction and future maintenance.[55]
6. Successful aesthetic and implant procedures may be difficult or impossible without the specialized periodontal procedures developed for this purpose.

Learning Box 69.1

Periodontal treatment is undertaken to ensure the establishment of stable gingival margins before tooth preparation. Noninflamed, healthy tissues are less likely to change (e.g., shrink) as a result of subgingival restorative treatment or postrestoration periodontal care. In addition, tissues that do not bleed during restorative manipulation allow for a more predictable restorative and aesthetic result.

Sequence of Treatment

Treatment sequencing should be based on logical and evidence-based methodologies, taking into account not only the disease state encountered but also the psychological and aesthetic concerns of the patient. Because periodontal and restorative therapy is situational and specific to each patient, a plan must be adaptable to

change depending on the variables encountered during the course of treatment. For example, teeth initially determined to be salvageable may be judged "hopeless," thus altering the established treatment scheme.[20,48]

Generally, the preparation of the periodontium for restorative dentistry can be divided into two phases: (1) control of periodontal inflammation with nonsurgical and surgical approaches and (2) preprosthetic periodontal surgery (Box 69.1).

Box 69.1

Sequence of Treatment in Preparing Periodontium for Restorative Dentistry

Control of Active Disease

Emergency treatment
Extraction of hopeless teeth
Oral hygiene instructions
Scaling and root planing
Reevaluation
Periodontal surgery
Adjunctive orthodontic therapy

Preprosthetic Surgery

Management of mucogingival problems
Preservation of ridge morphology after tooth extraction
Crown-lengthening procedures
Alveolar ridge reconstruction

Control of Active Disease

When the clinician is presented with a patient with different stages of periodontal involvement, this condition must be treated before one can contemplate any restorative dentistry. This step is the most important part of preparing the periodontium for restorative

dentistry. The inflammatory state of the supporting tissues must be eliminated or controlled with biofilm removal, scaling, root planing, and, if necessary, periodontal surgery.

The periodontal therapy is intended to control the active disease (see Chapters 47 to 57). In addition to the removal of biofilm and root surface accretions that are the primary etiologic agents, secondary local factors, such as plaque-retentive overhanging margins and untreated caries, must be addressed.[14,19]

Emergency Treatment

Emergency treatment is undertaken to alleviate symptoms and stabilize acute infection. This includes endodontic as well as periodontal conditions (see Chapters 45 and 46). To the patient, the control of acute pain, especially endodontic, is the most important reason for seeking dental therapy. Therefore this aspect of therapy must be properly addressed before any other therapy is instituted.

Extraction of Hopeless Teeth

Extraction of hopeless teeth is followed by provisionalization with fixed or removable prosthetics. Retention of hopeless teeth without periodontal treatment may result in bone loss around the adjacent teeth.[32] It is also important to consider the extraction of teeth with a poor prognosis when implant replacement has become a predictable alternative to keeping and attempting periodontal therapy.

Oral Hygiene Measures

As indicated earlier, oral hygiene measures, when properly applied, will reduce plaque biofilm scores and gingival inflammation[30,51] (see Chapter 48). However, in patients with deep periodontal pockets (>5 mm), plaque biofilm control measures alone are insufficient for resolving subgingival infection and inflammation.[5,30] Hygiene alone does not allow the brush to reach into the deep pocket area to remove nor disturb the plaque biofilm.

Scaling and Root Planing

Scaling and root planing combined with oral hygiene measures have been demonstrated to significantly reduce gingival inflammation and the rate of the progression of periodontitis[3,4,31] (see Chapter 50). This applies even to patients with deep periodontal pockets[5,15] (Fig. 69.1).

FIG. 69.1 Root planing has resolved the gingival inflammation of this patient.

Learning Box 69.2

When the clinician is presented with a patient with any stage of periodontal involvement, this condition must be treated before one can contemplate any restorative dentistry.

Reevaluation

After 4 weeks the gingival tissues are evaluated to determine oral hygiene adequacy, soft tissue response, and pocket depth (see Chapter 47). This permits sufficient time for healing, reduction in inflammation and pocket depths, and gain in clinical attachment levels. However, in deeper pockets (>5 mm), plaque biofilm and calculus removal are often incomplete[2,54] with risk of future breakdown[8,49] (Fig. 69.2). As a result, periodontal surgery to access the root surfaces for instrumentation and to reduce periodontal pocket depths must be considered before restorative care proceeds.

FIG. 69.2 (A) Before treatment. (B) After 4 weeks, oral hygiene instructions and scaling and root planing have improved this patient's periodontal status. However, inflammation associated with pockets deeper than 5 mm suggests a need for periodontal surgery.

Periodontal Surgery

Periodontal surgery may be required for some patients (see Chapters 60, 62, and 63). This should be undertaken with future restorative and implant dentistry in mind. Some procedures are intended to treat active periodontal disease successfully,[12,37] and others are aimed at preparing the mouth for restorative or prosthetic care.[55] Crown lengthening is an example of such surgery. Both types of surgery are for preparing the periodontium for restorative dentistry.

Adjunctive Orthodontic Therapy

Orthodontic treatment has been shown to be a useful adjunct to periodontal therapy[6,17,18,24,34] (see Chapter 56). It should be undertaken only after active periodontal disease has been controlled. If nonsurgical treatment is sufficient, definitive periodontal pocket therapy may be postponed until after the completion of orthodontic tooth movement. This allows for the advantage of the positive bone changes that orthodontic therapy can provide. However, deep pockets and furcation invasions may require surgical access for root instrumentation in advance of orthodontic tooth movement. Failure to control active periodontitis can result in acute exacerbations and bone loss during tooth movement.[10] As long as the periodontium is periodontally healthy, teeth with preexisting bone loss may be moved orthodontically without incurring additional attachment loss.[39,40]

If teeth that are to be orthdontically moved lack keratinized attached gingiva, soft tissue–grafting procedures are often indicated in anticipation of orthodontic therapy. The procedure is necessary to increase the dimension of attached tissue to prevent the possibility of gingival margin recession.[34,55]

Learning Box 69.3

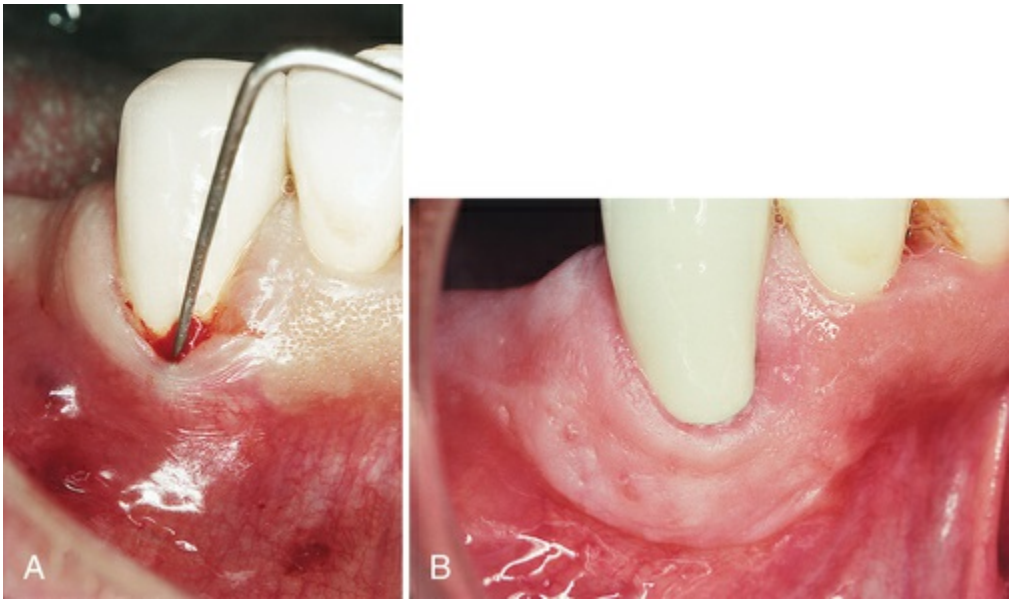
Periodontal surgery is performed for the treatment of active periodontal disease as well as for the preprosthetic preparation of the periodontium. Some procedures are intended to treat active disease successfully, and others are aimed at preparing the mouth for restorative or prosthetic care.

Preprosthetic Surgery

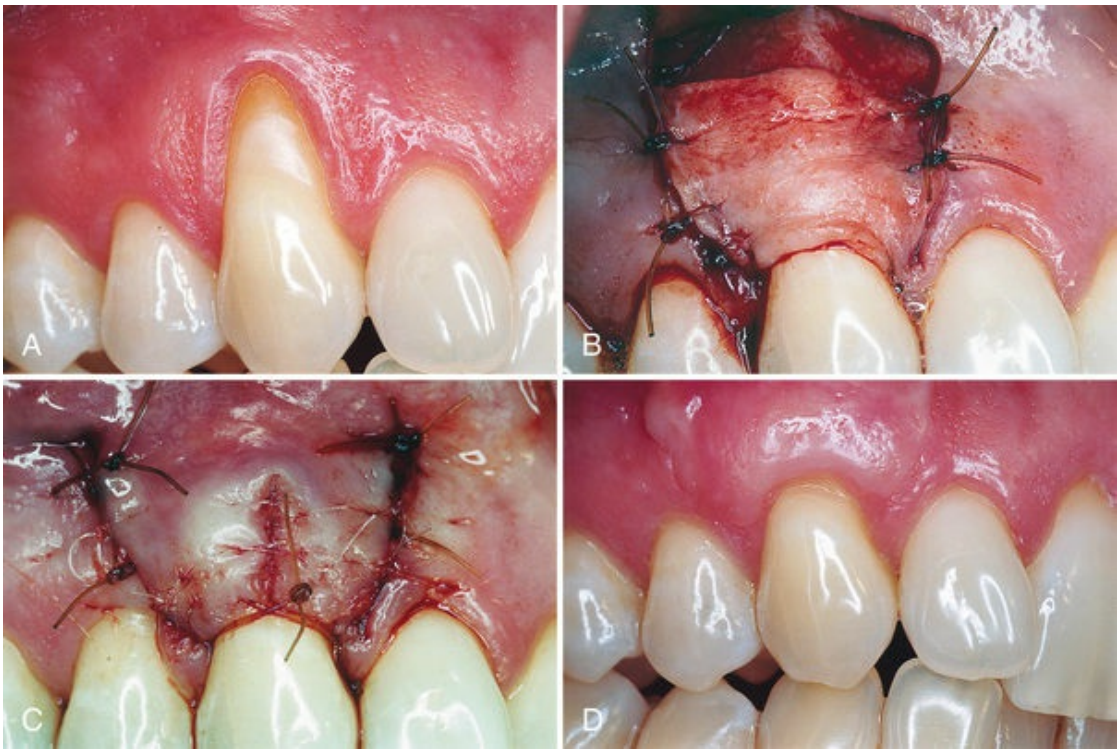
Management of Mucogingival Problems

Periodontal plastic surgical procedures may be undertaken for a variety of reasons.[7] The most common techniques include those that increase the gingival dimensions and achieve root coverage. These procedures are often indicated before restoration for prosthetic

reasons (eFig. 69.1) and in conjunction with orthodontic tooth movement.[34] Root coverage procedures may also be undertaken for purposes of comfort and aesthetics (eFig. 69.2).[7] At least 2 months of healing is recommended after soft tissue grafting procedures before initiating restorative dentistry[55] (see Chapter 65).



EFIG. 69.1 In preparation for a removable partial denture, this canine has received a gingival graft to increase attached gingiva and deepen the vestibule. (A) Before therapy. Note minimal attached gingiva. (B) After therapy, there is abundant attached gingiva and vestibular depth.



EFIG. 69.2 Connective tissue graft placed under a double-papilla flap has been used to provide root coverage for a maxillary right canine. (A) Maxillary canine before therapy. (B) Connective tissue graft placed over denuded root surface. (C) Papilla placed over connective tissue. (D) Final result.

Preservation of Ridge Morphology After Tooth Extraction

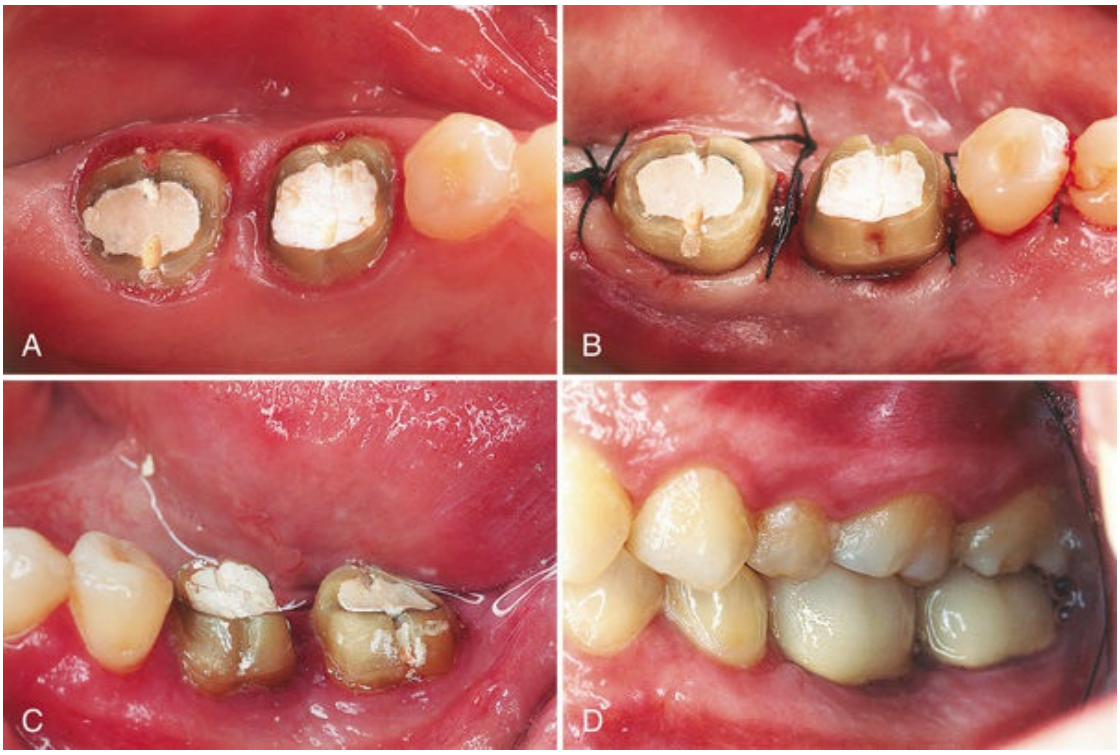
Alveolar ridge resorption is a common consequence of tooth loss.[1,2] Ridge preservation procedures have been shown to be useful in anticipation of the future placement of a dental implant or for pontics used for fixed bridges, as well as in cases where unaided healing would result in an unaesthetic deformity[16,26,27,33,36,42] (eFig. 69.3).

EFIG. 69.3 (A) The maxillary right lateral incisor has failed endodontically, with a fistulous tract noted exiting from the attached gingiva. (B) The tooth is atraumatically removed and the socket debrided while maintaining the surrounding anatomic integrity. (C) In an effort to reduce ridge collapse, the socket is grafted with a combination of deproteinized bovine bone and calcium sulfate. (D) Provisional fixed partial denture is placed, with an ovate pontic extending 2 mm into the socket and supporting the surrounding tissues. (E–F) After 8 weeks, the socket has healed, preserving the gingival and papillary architecture, in preparation for an aesthetic final prosthesis. (G) Final restoration.

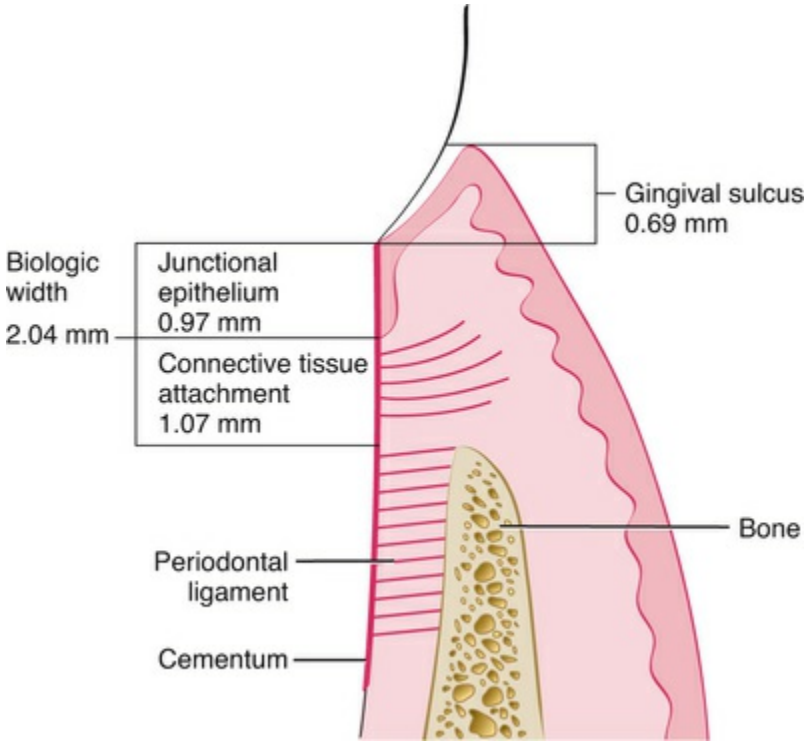
Crown-Lengthening Procedures

Surgical crown-lengthening procedures are performed to provide retention form to allow for proper tooth preparation, impression procedures,[23] and placement of restorative margins (eFig. 69.4),[23]

and to adjust gingival levels for aesthetics.[35,50] It is important that crown-lengthening surgery is done in such a manner that the biologic width is preserved. The *biologic width* is defined as the physiologic dimension of the junctional epithelium and connective tissue attachment (see Chapter 70). This measurement has been found to be relatively constant at approximately 2 mm (±30%).[11] The healthy gingival sulcus has an average depth of 0.69 mm (eFig. 69.5).[21] It has been theorized that infringement on the biologic width by the placement of a margin of a restoration within its zone may result in gingival inflammation,[21] pocket formation, and alveolar bone loss[38] (eFig. 69.6). Consequently, it is recommended that there be at least 3 mm between the gingival margin and bone crest.[13,41,44,47] This allows for adequate biologic width when the restoration is placed 0.5 mm within the gingival sulcus[44,47] (eFig. 69.7).

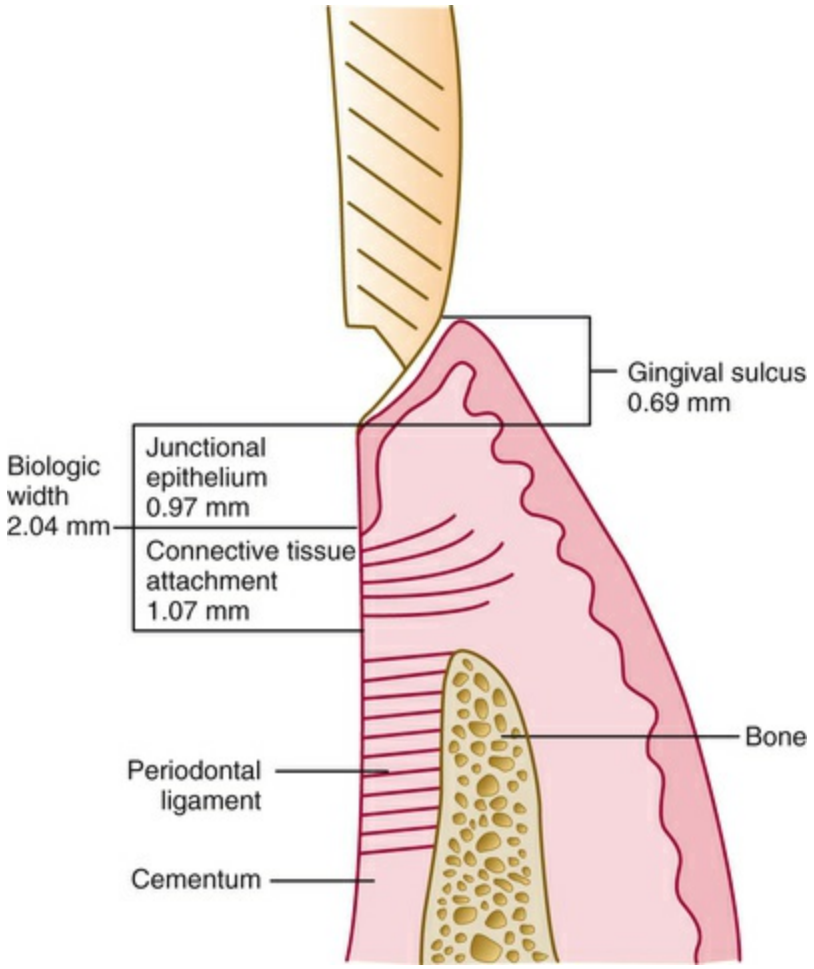


EFIG. 69.4 Surgical crown lengthening has provided these otherwise unrestorable mandibular molars with improved retention and restorative access for successful restorations. (A) Before crown lengthening. (B) Crown-lengthening surgery completed. Note increased clinical crown. (C) Buccal view after surgery. (D) Final restorations.



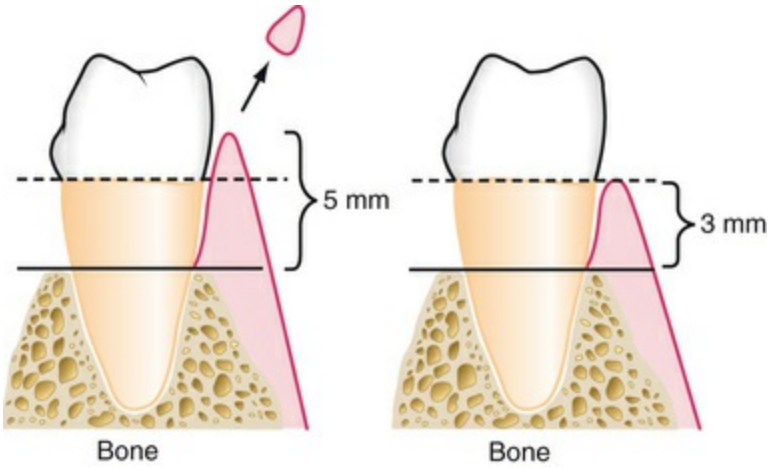
EFIG. 69.5 The biologic width has been estimated to be about 2 mm. Efforts should be made to preserve its integrity.

EFIG. 69.6 Although gingival inflammation around crowns may have a variety of causes, infringement of biologic width must be considered.

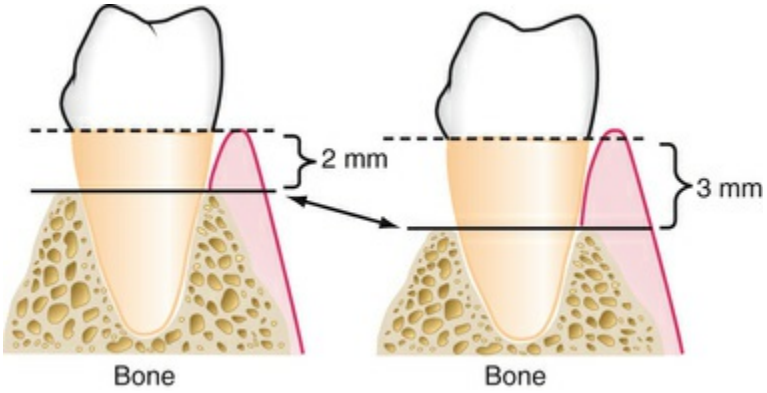


EFIG. 69.7 Placement of the restorative margin 0.5 mm into the sulcus allows for the maintenance of the biologic width.

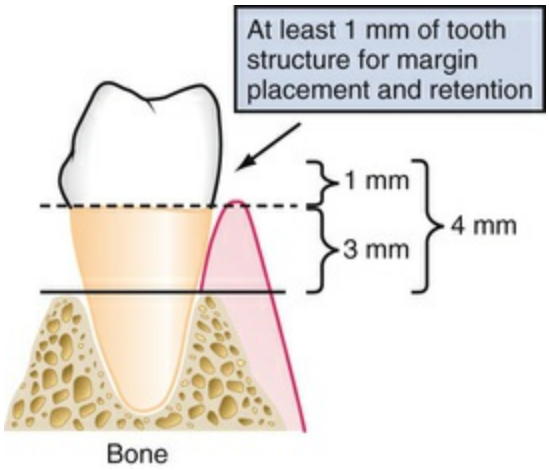
Surgical crown lengthening may include the removal of soft tissue or both soft tissue and alveolar bone. Reduction of soft tissue alone is indicated if there is adequate attached gingiva and more than 3 mm of tissue coronal to the bone crest (eFig. 69.8). This may be accomplished by either gingivectomy or flap technique (see Chapter 60). Inadequate attached gingiva and less than 3 mm of soft tissue require a flap procedure and bone recontouring (eFig. 69.9). In the case of caries or tooth fracture, to ensure margin placement on sound tooth structure and retention form, the surgery should provide at least 4 mm from the apical extent of the caries or fracture to the bone crest (eFig. 69.10).



EFIG. 69.8 Greater than 3 mm of soft tissue between the bone and gingival margin, with adequate attached gingiva, allows crown lengthening by gingivectomy.



EFIG. 69.9 With less than 3 mm of soft tissue between the bone and gingival margin, or less-than-adequate attached gingiva, a flap procedure and osseous recontouring are required for crown lengthening.



EFIG. 69.10 In the case of caries or fracture, at least 1 mm of sound tooth structure should be provided above the gingival margin for proper restoration.

With the advent of predictable implant dentistry, it is important to carefully evaluate the value of crown lengthening for restorative therapy as opposed to tooth removal and replacement with a dental implant (eBox 69.1).

eBox 69.1

Surgical Crown Lengthening

Indications

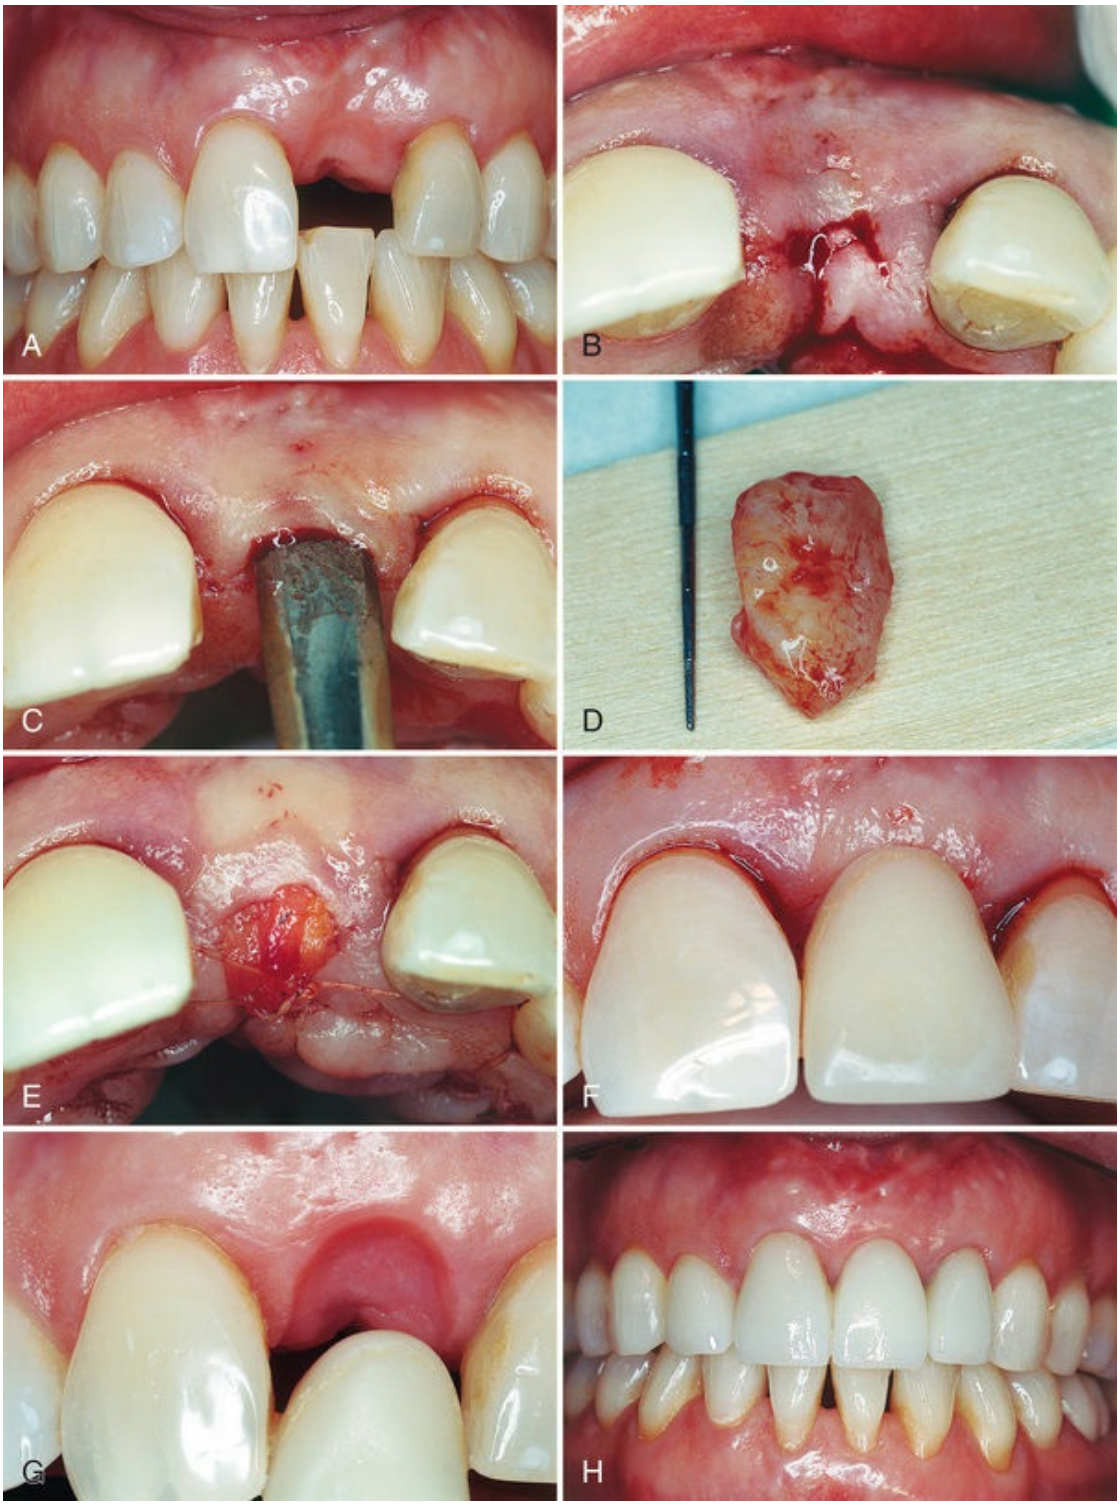
Subgingival caries or fracture.
Inadequate clinical crown length for retention.
Unequal or unaesthetic gingival heights.

Contraindications

Surgery would create an unaesthetic outcome.
Deep caries or fracture would require excessive bone removal on contiguous teeth.
The tooth is a poor restorative risk.

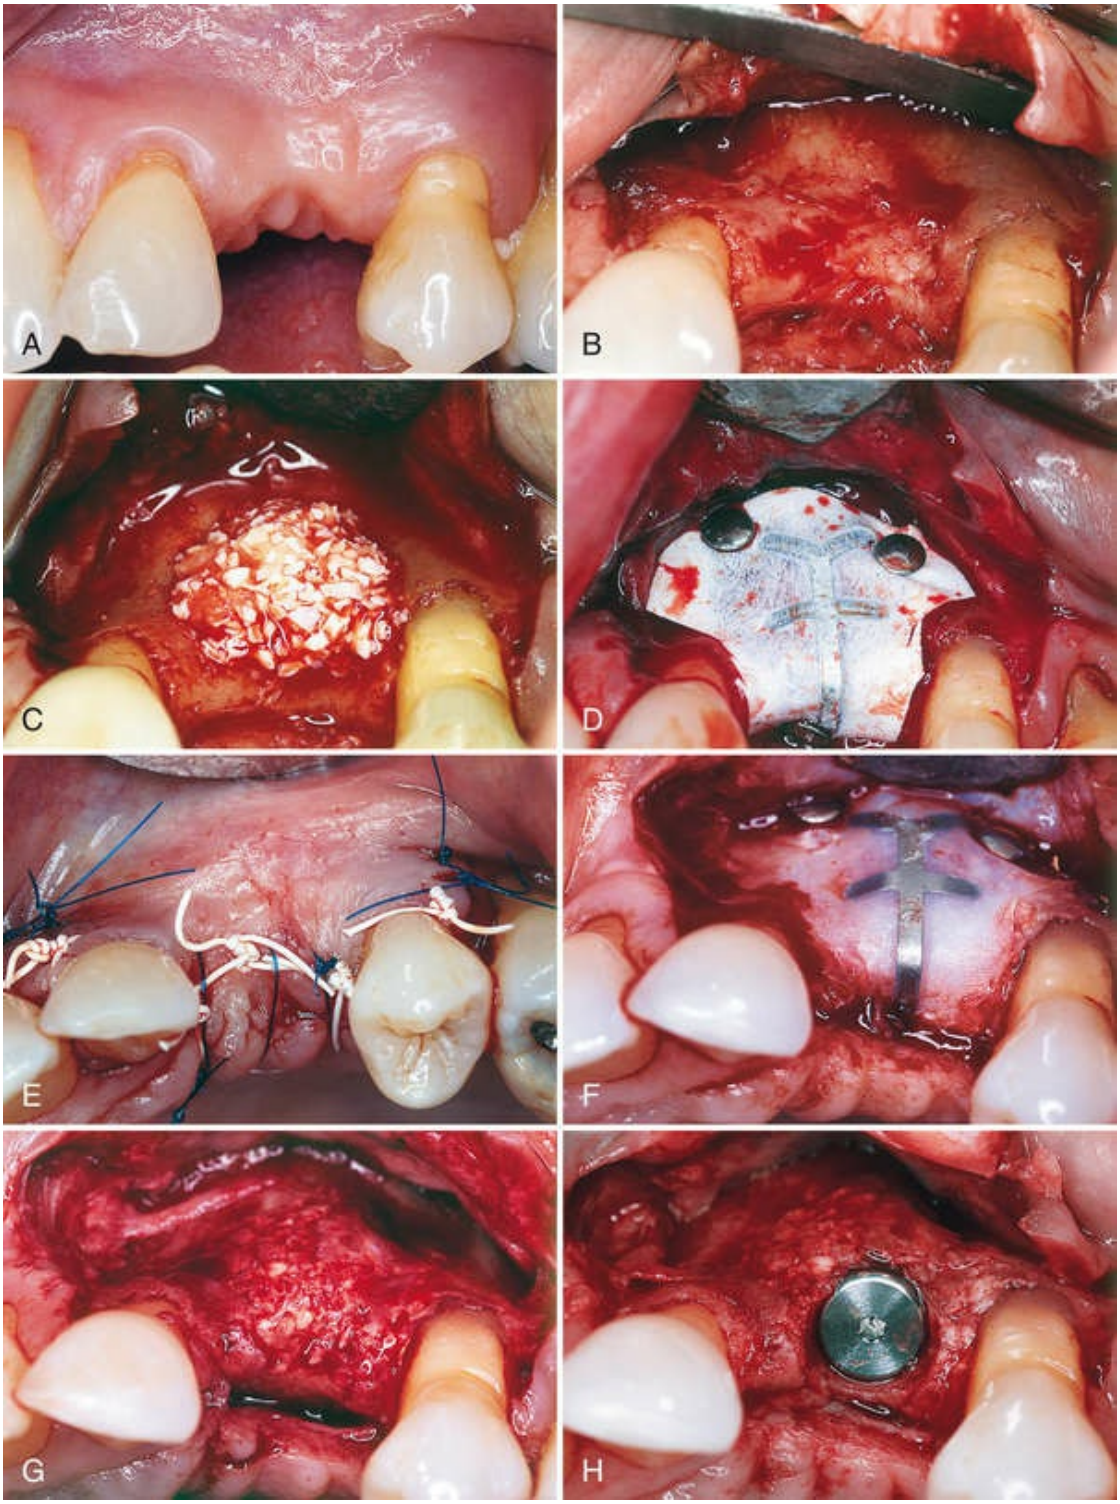
Alveolar Ridge Reconstruction

Patients are frequently seen with alveolar ridge resorption after tooth loss (see Chapter 75). To provide for adequate anatomic dimensions for the construction of an aesthetic pontic (see Chapter 70, or for a discussion on the placement of dental implants see Chapter 75), alveolar ridge reconstruction is undertaken.[42,43,45] In the case of aesthetic pontic construction, small defects may be treated with soft tissue ridge augmentation (eFig. 69.11). For larger defects and in those sites receiving dental implants, hard tissue modalities are used[43,45] (eFig. 69.12).



EFIG. 69.11 (A) Loss of the maxillary left central incisor has resulted in an unaesthetic alveolar ridge defect. (B–E) An incision is made at the ridge crest, a pouch is created, and a soft tissue graft harvested from the palate is placed into the pouch. (F–H) A removable appliance with an ovate pontic is placed in light contact with the grafted site. Swelling around the pontic apex results in a tissue concavity from which the more

natural-appearing final restoration emerges.



EFIG. 69.12 Postextraction ridge defect is grafted with a combination of autogenous and deproteinized bovine bone and contained by nonresorbable barrier

membrane.[53] After 8 months, the site is reopened and the membrane removed. A comparison of parts B and G shows significant reconstitution of hard tissue, in this case used for the installation of a dental implant. (A) Edentulous ridge before surgery. (B) Flap reflection to visualize defect. (C) Graft material placed over resorbed ridge. (D) Nonresorbable titanium-reinforced membrane placed over graft material. (E) Graft site sutured. (F) Surgical site reopened 8 months after surgery. (G) New bone over ridge. (H) Implant placed into augmented ridge.

Conclusion

As described in this and other sections of this textbook, the therapeutic goals of patient comfort, function, aesthetics, predictability, longevity, and ease of restorative and maintenance care are attainable only by a carefully constructed interdisciplinary approach with accurate diagnosis and comprehensive treatment planning serving as the cornerstones. The complex interaction between periodontal therapy and successful restorative dentistry only serves to underscore this premise.

Case Scenario 69.1

Patient:

31-year-old female

Background Information

The patient has a fractured crown on tooth #7. She is healthy and has no known drug allergies.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. To provide a full crown restoration in this case, a surgical crown lengthening should be performed. Why? A. To provide for retention, tooth preparation, and impressions B. To preserve "biologic width" C. To maintain aesthetic gingival levels D. All of the above	**Answer: D** **Explanation:** Teeth damaged by caries or fracture once certified as restorable can often be retained by performing a surgical crown-lengthening procedure. Teeth in the aesthetic zone require special consideration. Care should be taken not to increase the crown length at the expense of aesthetics. Efforts should be made to maintain a gingival level that is symmetrical to the contiguous teeth and the contralateral side. If it appears that a crown-lengthening surgery will result in an unaesthetic gingival level, an alternative treatment, such as orthodontic extrusion, should be considered.

Case Scenario 69.2

Patient:
44-year-old female

Chief Complaint:
My gums have receded and I am unhappy with my appearance.

Background Information
The patient is healthy and has no known drug allergies.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. This patient is preparing for orthodontics and restorative dentistry. Why should soft-tissue grafting be considered? A. To prevent future gingival recession B. To protect the exposed root C. To reduce dentinal sensitivity D. To provide for an aesthetic tooth length E. All of the above	**Answer: E** **Explanation:** Gingival recession is the result of a combination of an underlying bone dehiscence and gingival inflammation. The root exposure can result in dental sensitivity, root damage, and an unesthetic appearance. The treatment is soft tissue grafting.

Case Scenario 69.3

Patient:

64-year-old male

Chief Complaint:

"My gums are swollen."

Background Information

The patient has a history of infrequent dental care and developed asymptomatic gingival enlargement over several years. He also has hypertension and takes the antihypertensive medication amlodipine, a calcium channel blocker.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. What should this patient do to prepare for orthodontic treatment and restorative dentistry? A. Consult with his medical doctor before treatment to discuss a possible medication change, which may be in part responsible for the gingival overgrowth	**Answer: F** **Explanation:** It is important to complete periodontal treatment aimed at controlling an active disease before the commencement of orthodontics and restorative dentistry. This patient takes medication, which has led to drug-induced gingival overgrowth. This gingival enlargement is often related to a combination of plaque-associated inflammation and the effect of the calcium channel blocker, amlodipine. Resolution of the problem requires treating both the plaque-associated inflammation and the response to the medication. Once the medication has been discontinued, in conjunction with nonsurgical periodontal therapy, the result may be complete resolution of the hyperplasia. If not, surgical reduction may be indicated.

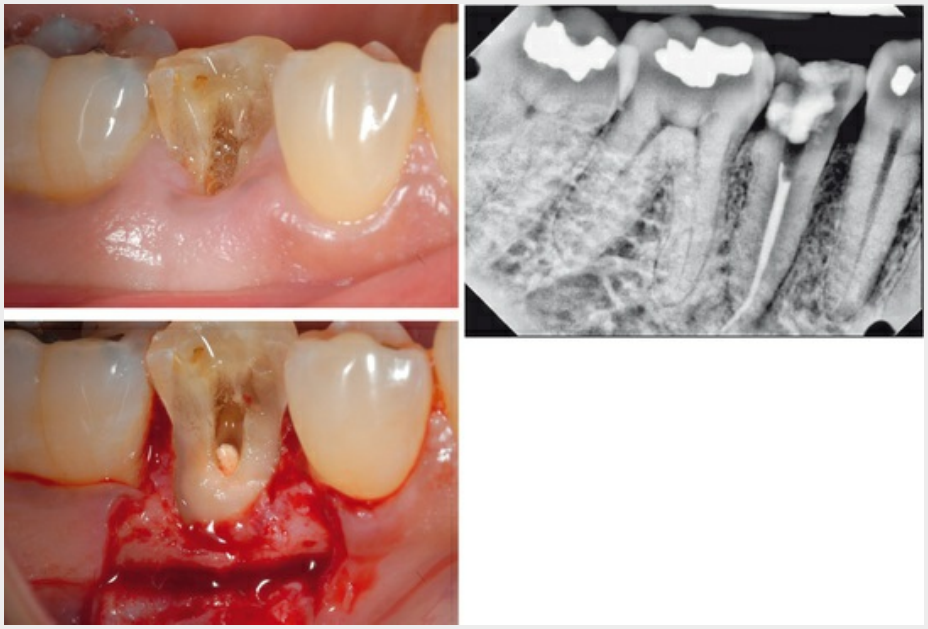
B. Complete scaling and root planing and oral hygiene education C. Reevaluate after a suitable period for the resolution of gingival enlargement D. Consider surgical treatment to reduce enlarged gingival tissues E. Enter into a well-planned prevention program F. All of the above	

Case Scenario 69.4

Patient:
55-year-old male

Chief Complaint:
"I fractured my tooth, but I would really like to retain it."

Background Information
The patient recently fractured tooth #29, close to bone crest. He has had previous endodontic treatment and is asymptomatic. The patient is healthy and has no known drug allergies.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Based on the photos presented, what treatment option is available to meet the patient's desire for tooth retention? A. Preparation of the tooth for a crown with the finish line approximating the bone crest. B. Surgical crown lengthening followed by a crown restoration. C. The tooth cannot be restored; extraction and replacement is the only option.	**Answer: B** **Explanation:** Tooth fracture is a common dental malady. Surgical crown lengthening provides the opportunity to retain structurally damaged teeth, once they have been judged to be salvageable. It allows access for restorative procedures and retention form. Care must be taken preserve space for supracrestal soft tissue growth to a physiologic dimension ("biologic width"). Failure to do so can result in chronic gingival inflammation and possible bone loss.

CHAPTER 70

Restorative Interrelationships

Frank M. Spear, Todd R. Schoenbaum, Joseph P. Cooney

CHAPTER OUTLINE

Biologic Considerations
Aesthetic Tissue Management
Occlusal Considerations in Restorative Therapy
Special Restorative Considerations *(e-only)*

Editors' note: An animation (slide show) has been added by the editors as a supplement to the chapter. It was produced by My Dental Hub as a patient education tool and covers the basic elements in a conceptual manner. It is not intended to be a procedural guide for dental professionals.

The relationship between periodontal health and the restoration of teeth is intimate and inseparable. For restorations to survive long term, the periodontium must remain healthy so that the teeth are

maintained. For the periodontium to remain healthy, restorations must be critically managed in several areas so that they are in harmony with their surrounding periodontal tissues. To maintain or enhance the patient's aesthetic appearance, the tooth–tissue interface must present a healthy natural appearance, with gingival tissues framing the restored teeth in a harmonious manner. This chapter reviews the key areas of restorative management necessary to optimize periodontal health, with a focus on the aesthetics and function of restorations.

Biologic Considerations

Margin Placement and Biologic Width

One of the most important aspects of understanding the periodontal–restorative relationship is the location of the restorative margin to the adjacent gingival tissue. Restorative clinicians must understand the role of biologic width in preserving healthy gingival tissues and controlling the gingival form around restorations. They must also apply this information in the positioning of restoration margins, especially in the aesthetic zone, where a primary treatment goal is to mask the junction of the margin with the tooth.

A clinician is presented with three options for margin placement: supragingival, equigingival (even with the tissue), and subgingival.[69] The *supragingival margin* has the least impact on the periodontium. Classically, this margin location has been applied in unaesthetic areas because of the marked contrast in color and opacity of traditional restorative materials against the tooth. With the advent of more translucent restorative materials, adhesive dentistry, and resin cements, the ability to place supragingival margins in aesthetic areas is now a reality (Figs. 70.1 and 70.2). Therefore whenever possible, these restorations should be chosen not only for their aesthetic advantages but also for their favorable periodontal impact.

FIG. 70.1 With the advent of adhesive dentistry and ultrathin ceramic veneers, it now is possible to prepare restorations equigingival without visible margins. The preparations for six porcelain veneers with the margins placed at the level of tissue are shown.

FIG. 70.2 The completed veneers from Fig. 70.1. Note the invisible gingival finish line, even though the margin has not been carried below tissue.

The use of *equigingival margins* traditionally was not desirable because they were thought to retain more plaque than supragingival or subgingival margins and therefore resulted in greater gingival inflammation. There was also the concern that any minor gingival recession would create an unsightly margin display. These concerns are not valid today, not only because the restoration

margins can be aesthetically blended with the tooth, but also because restorations can be finished easily to provide a smooth, polished interface at the gingival margin. From a periodontal viewpoint, both supragingival and equigingival margins are well tolerated.

The greatest biologic risk occurs when placing *subgingival margins.*[42] These margins are not as accessible as supragingival or equigingival margins for finishing procedures. In addition, if the margin is placed too far below the gingival tissue crest, it violates the gingival attachment apparatus.

As described in Chapter 3, the dimension of space that the healthy gingival tissues occupy between the base of the sulcus and the underlying alveolar bone is composed of the junctional epithelial attachment and the connective tissue attachment. The combined attachment width is now identified as the *biologic width.* Most authors credit Gargiulo, Wentz, and Orban's 1961 study[18] on cadavers with the initial research establishing the dimensions of space required by the gingival tissues. They found that, in the average human, the connective tissue attachment occupies 1.07 mm of space above the crest of the alveolar bone and that the junctional epithelial attachment below the base of the gingival sulcus occupies another 0.97 mm of space above the connective tissue attachment. The combination of these two measurements, averaging approximately 1 mm each, constitutes the biologic width (Fig. 70.3). Clinically, this information is applied to diagnose biologic width violations when the restoration margin is placed 2 mm or less away from the alveolar bone and the gingival tissues are inflamed with no other etiologic factors evident.

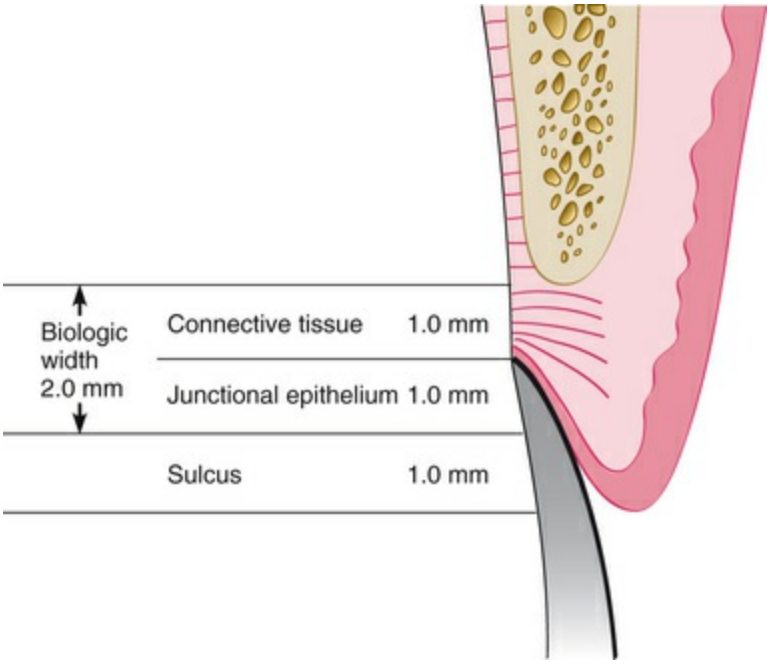

FIG. 70.3 Average human biologic width: connective tissue attachment 1 mm in height; junctional epithelial attachment 1 mm in height; sulcus depth of approximately 1 mm. The combined connective tissue attachment and junctional epithelial attachment, or biologic width, equals 2 mm.

Restorative considerations frequently dictate the placement of restoration margins beneath the gingival tissue crest. Restorations may need to be extended gingivally (1) to create adequate resistance and retentive form in the preparation, (2) to make significant contour alterations because of caries or other tooth deficiencies, (3) to mask the tooth–restoration interface by locating it subgingivally, or (4) to lengthen the tooth for aesthetic reasons. When the restoration margin is placed too far below the gingival tissue crest, it impinges on the gingival attachment apparatus and creates a violation of biologic width.[49] Two different responses can be observed from the involved gingival tissues (Fig. 70.4).

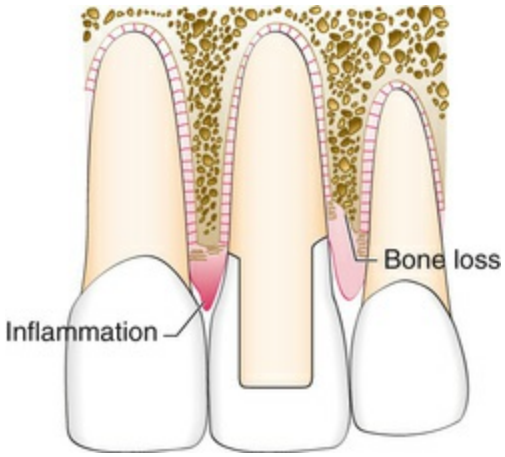

FIG. 70.4 Ramifications of a biologic width violation if a restorative margin is placed within the zone of the attachment. On the mesial surface of the left central incisor, bone has not been lost, but gingival inflammation occurs. On the distal surface of the left central incisor, bone loss has occurred, and a normal biologic width has been reestablished.

One possibility is that bone loss of an unpredictable nature and gingival tissue recession occurs as the body attempts to re-create room between the alveolar bone and the margin to allow space for tissue reattachment. This is more likely to occur in areas in which the alveolar bone surrounding the tooth is very thin in width. Trauma from restorative procedures can play a major role in causing this fragile tissue to recede. Other factors that may impact the likelihood of recession include (1) whether the gingiva is thick and fibrotic or thin and fragile and (2) whether the periodontium is highly scalloped or flat in its gingival form. It has been found that highly scalloped, thin gingiva is more prone to recession than a flat periodontium with thick fibrous tissue.[47]

Key Fact

Thin gingiva and highly scalloped papilla are more highly prone to recession after normal restorative procedures.

The more common finding with deep margin placement is that the bone level appears to remain unchanged, but gingival inflammation develops and persists. To restore gingival tissue

health, it is necessary to establish space clinically between the alveolar bone and the margin. This can be accomplished either by surgery to alter the bone level or by orthodontic extrusion to move the restoration margin farther away from the bone level.

Biologic Width Evaluation

Radiographic interpretation can identify interproximal violations of biologic width. However, with the more common locations on the mesiofacial and distofacial line angles of teeth, radiographs are not diagnostic because of tooth superimposition. If a patient experiences tissue discomfort when the restoration margin levels are being assessed with a periodontal probe, it is a good indication that the margin extends into the attachment and that a biologic width violation has occurred.

A more positive assessment can be made clinically by measuring the distance between the bone and the restoration margin using a sterile periodontal probe. The probe is pushed through the anesthetized attachment tissues from the sulcus to the underlying bone. If this distance is less than 2 mm at one or more locations, a diagnosis of biologic width violation can be confirmed. This assessment is completed circumferentially around the tooth to evaluate the extent of the problem. However, biologic width violations can occur in some patients in whom the margins are located more than 2 mm above the alveolar bone level.[22] In 1994 Vacek and colleagues[70] also investigated the biologic width phenomenon. Although their average width finding of 2 mm was the same as that previously presented by Gargiulo and associates,[18] they also reported a range of different biologic widths that were patient specific. They reported biologic widths as narrow as 0.75 mm in some individuals, whereas others had biologic widths as tall as 4.3 mm (Fig. 70.5).

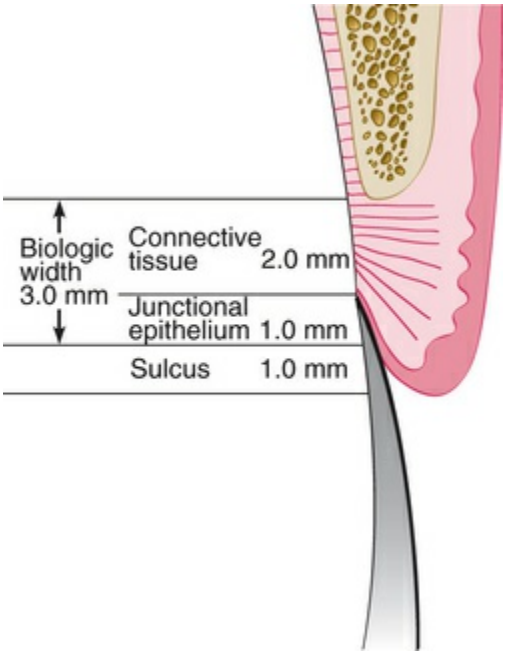

FIG. 70.5 Possible variations exist in biologic width. Connective tissue attachments and junctional epithelial attachments may be variable. In this example, the connective tissue attachment is 2 mm in height, the junctional epithelial attachment 1 mm in height, and the sulcus depth 1 mm, for a combined total tissue height above bone of 4 mm. However, the biologic width is 3 mm. This is just one variation that can occur from the average depicted in Fig. 70.3.

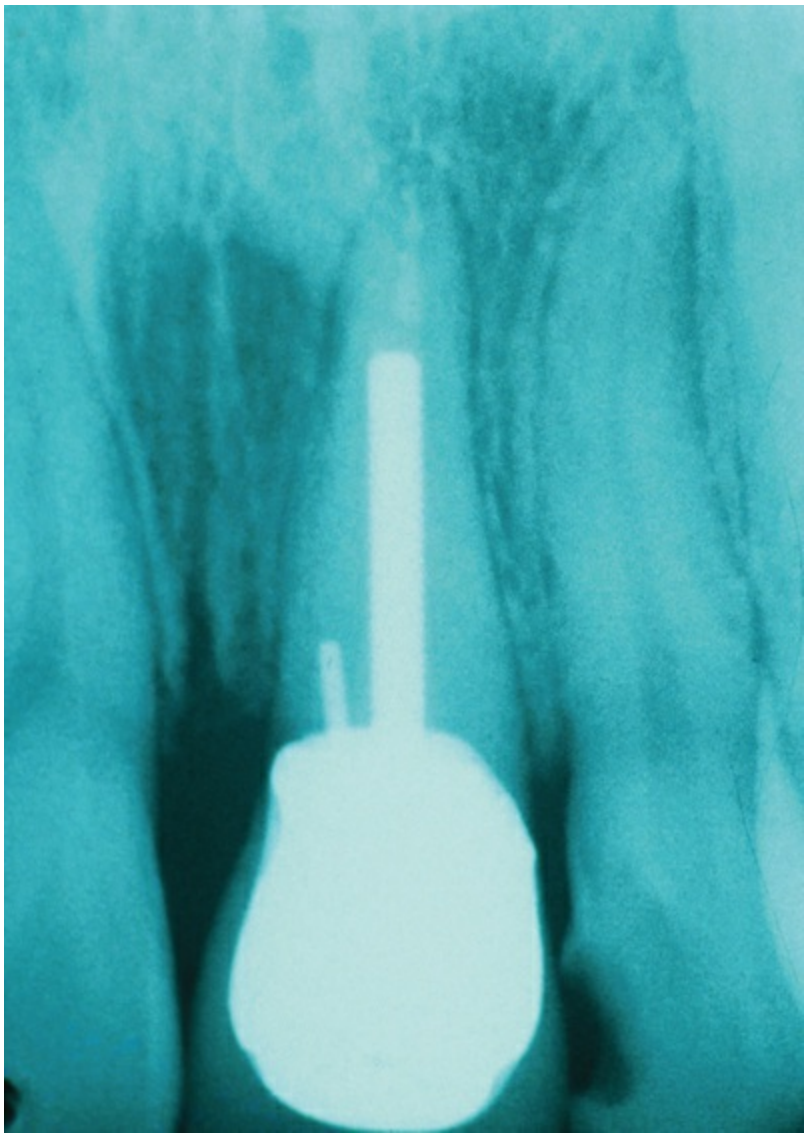
This information dictates that specific biologic width assessment should be performed for each patient to determine if the patient needs additional biologic width, in excess of 2 mm, for restorations to be in harmony with the gingival tissues. The biologic, or attachment, width can be identified for the individual patient by probing to the bone level (referred to as "sounding to bone") and subtracting the sulcus depth from the resulting measurement. This measurement must be done on teeth with healthy gingival tissues and should be repeated on more than one tooth to ensure an accurate assessment. The technique allows the variations in sulcus depths found in individual patients to be assessed and factored into the diagnostic evaluation. The information obtained is then used for definitive diagnosis of biologic width violations, the extent of correction needed, and the parameters for placement of future restorations.

Correcting Biologic Width Violations

Biologic width violations can be corrected either by surgically removing bone away from proximity to the restoration margin or by orthodontically extruding the tooth and thus moving the margin away from the bone. Surgery is the more rapid of the two treatment options.[57] It is also preferred if the resulting crown lengthening creates a more pleasing tooth length. Indications and contraindications for surgical crown lengthening are presented in Chapters 60 and 65 and illustrated with clinical examples. In these situations, the bone should be moved away from the margin by the measured distance of the ideal biologic width for that patient, with an additional 0.5 mm of bone removed as a safety zone.

There is a potential risk of gingival recession after removal of bone.[7] If interproximal bone is removed, there is a high likelihood of papillary recession and the creation of an unaesthetic triangle of space below the interproximal contacts. If the biologic width violation is on the interproximal side, or if the violation is across the facial surface and the gingival tissue level is correct, orthodontic extrusion is indicated[27] (eFigs. 70.1 to 70.4). The extrusion can be performed in two ways. By applying low orthodontic extrusion force, the tooth will erupt slowly, bringing the alveolar bone and gingival tissue with it. The tooth is extruded until the bone level has been carried coronal to the ideal level by the amount that needs to be removed surgically to correct the attachment violation. The tooth is stabilized in this new position and then is treated with surgery to correct the bone and gingival tissue levels. Another option is to perform rapid orthodontic extrusion where the tooth is erupted to the desired amount over several weeks.[31] During this period, a supracrestal fiberotomy is performed circumferentially around the tooth weekly in an effort to prevent the tissue and bone from following the tooth. The tooth is then stabilized for at least 12 weeks to confirm the position of the tissue and bone, and any coronal creep can be corrected surgically.

EFIG. 70.1 The left central incisor was fractured in an accident 12 months ago and restored at that time. The patient is unhappy with the appearance of the tissue surrounding the restoration (see eFigs. 70.2, 70.3, and 70.4).



EFIG. 70.2 Radiograph reveals a biologic width violation on the mesial surface interproximally. Removal of interproximal bone would create an aesthetic deformity. This patient is better treated with orthodontic extrusion (see eFigs.70.1 and 7.3).

EFIG. 70.3 After orthodontic eruption. The tooth has been erupted 3 mm to move the bone and gingiva coronally 3 mm on the left central incisor. It is now possible to reposition the bone surgically to the correct level and position the gingiva to the correct level, reestablishing normal biologic width.

EFIG. 70.4 One-year recall photograph after orthodontic extrusion, osseous surgery, and placement of a new restoration for the patient in eFig. 70.1. Note the excellent tissue health after the reestablishment of biologic width.

Margin Placement Guidelines

When determining where to place restorative margins relative to the periodontal attachment, it is recommended that the patient's existing sulcular depth be used as a guideline in assessing the biologic width requirement for that patient. The base of the sulcus can be viewed as the top of the attachment, and therefore the clinician accounts for variations in attachment height by ensuring that the margin is placed in the sulcus and not in the attachment.[4,36,37,56] The variations in sulcular probing depth are then used to predict how deep the margin can safely be placed below the gingival crest. With shallow probing depths (1 to 1.5 mm), extending the preparation more than 0.5 mm subgingivally risks violating the attachment. This assumes that the periodontal probe will penetrate into the junctional epithelial attachment in healthy gingiva an average of 0.5 mm. With shallow probing depths, future recession is unlikely because the free gingival margin is located close to the top of the attachment. Deeper sulcular probing depths provide more freedom in locating restoration margins farther below the gingival crest. In most circumstances, however, the deeper the gingival sulcus, the greater is the risk of gingival recession. Locating the restorative margin deep subgingivally should be avoided, as it increases the difficulty in making an accurate impression, finishing the restoration margins, and increases the likelihood of inflammation and recession.

Clinical Procedures in Margin Placement

The first step in using sulcus depth as a guide in margin placement is to manage gingival health. It should be noted that the use of reinforced all-ceramic restorations (i.e., layered zirconia, lithium disilicate) reduces the aesthetic rationale for subgingival margins. Once the tissue is healthy, the following three rules can be used to place intracrevicular margins:

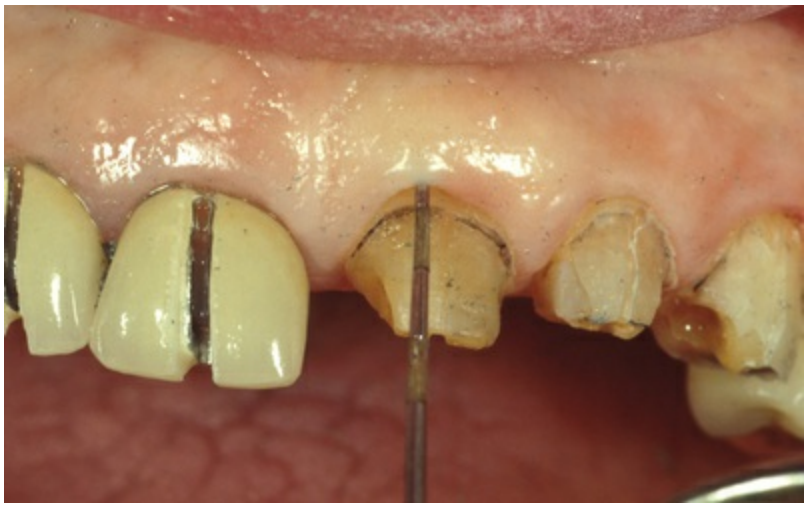
Rule 1: If the sulcus probes 1.5 mm or less, place the restoration margin no more than 0.5 mm below the gingival tissue crest. This is especially important on the facial aspect and will prevent a biologic width violation in a patient who is at high risk in that regard.

Rule 2: If the sulcus probes more than 1.5 mm, place the margin no more than half the depth of the sulcus below the tissue crest. This places the margin far enough below tissue so that it will still be covered if the patient is at higher risk of recession.

Rule 3: If a sulcus greater than 2 mm is found, especially on the facial aspect of the tooth, evaluate to see if a gingivectomy could be performed to lengthen the teeth and create a 1.5-mm sulcus. Then the patient can be treated using rule 1.

The rationale for rule 3 is that deep margin placement is more difficult and the stability of the free gingival margin is less predictable when a deep sulcus exists. Reducing the sulcus depth creates a more predictable situation in which to place an intracrevicular margin. The clinician cannot be sure that the tissue will remain at the corrected level, however, because some gingival rebound can occur after gingivectomy. However, sulcular depth reduction ensures that the restorative margins will not be exposed and visible in the patient's mouth (eFigs. 70.5 to 70.9).

EFIG. 70.5 A 78-year-old woman presents with the maxillary anterior restorations placed 6 months earlier. She is unhappy with the exposed margins and notes that the margins were covered the day the restorations were placed (see eFigs. 70.6 to 70.9).



EFIG. 70.6 Depth from the attachment to the level of the preparation margin is greater than 3 mm. The patient in eFig. 70.5 had an altered eruption pattern and a sulcus depth of more than 3 mm when these restorations were placed.

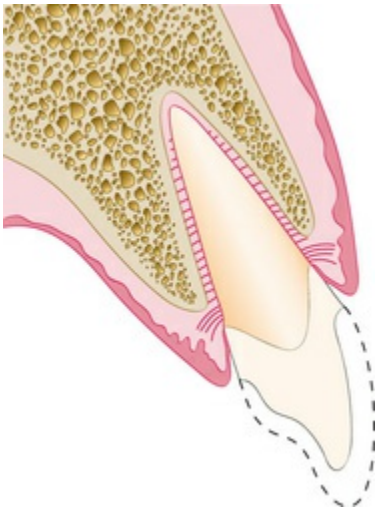
EFIG. 70.7 Two options were available to manage treatment appropriately: (1) place the original margins to half the depth of the sulcus, in which case the recession that occurred would not have exposed them, or (2) perform a gingivectomy, creating a 1- to 1.5-mm sulcus. The second option was chosen when the restorations were redone. The margins were then placed 0.5 mm below the tissue after the gingivectomy (see eFigs. 70.6 and 70.8).

EFIG. 70.8 At 6 weeks after the gingivectomy and preparation of the teeth. Note the tissue level and that the tissue is rebounding coronally over the margins. This is a common finding when a pure gingivectomy is done.

EFIG. 70.9 Four-year recall photograph after placement of the final restorations for the patient in eFig. 70.5. Note the tissue level has been maintained, with a sulcus depth of 2 mm on the facial surface.

The placement of supragingival or equigingival margins is simple because it requires no tissue manipulation. With regard to overall tooth preparation, the amount reduced incisally or occlusally, facially, lingually, and interproximally is dictated by the choice of restorative materials. Before extending subgingivally, the

preparation should be completed to the free gingival margin facially and interproximally. This allows the margin of the tooth preparation to be used as a reference for subgingival extension once the tissue is retracted (eFig. 70.10).



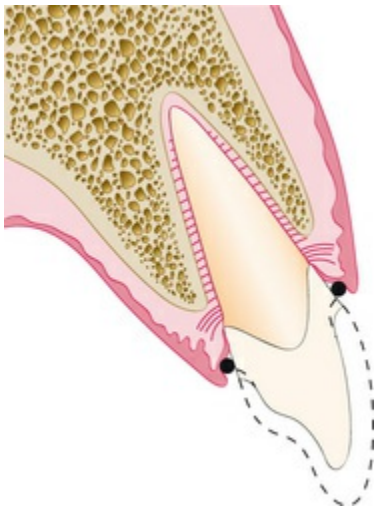
EFIG. 70.10 To provide a reference position for margin placement after tissue retraction, the margin of the tooth preparation is initially established level with the free gingival margin.

Tissue Retraction

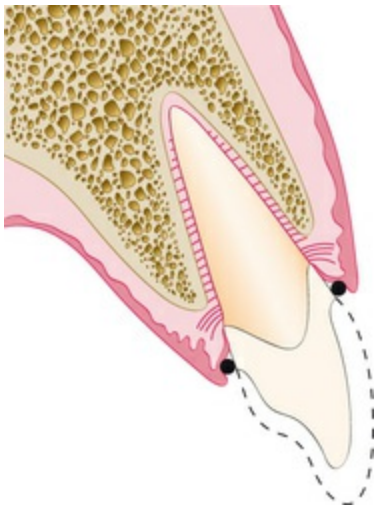
Once the supragingival portion of the preparation is completed, it is necessary to extend below the tissue.[6,23] The preparation margin must now be extended to the appropriate depth in the sulcus, applying the guidelines presented previously. In this process the tissue must be protected from abrasion, which will cause hemorrhage and can adversely affect the stability of the tissue level around the tooth. Access to the margin is also required for the final impression, with a clean, fluid-controlled environment. Tissue management is achieved with gingival retraction cords using the appropriate size to achieve the displacement required. Thin, fragile gingival tissues and shallow sulcus situations usually dictate that smaller diameter cords be chosen to achieve the desired tissue displacement.

For a rule 1 margin (sulcus depth 1.5 mm or less), the cord should

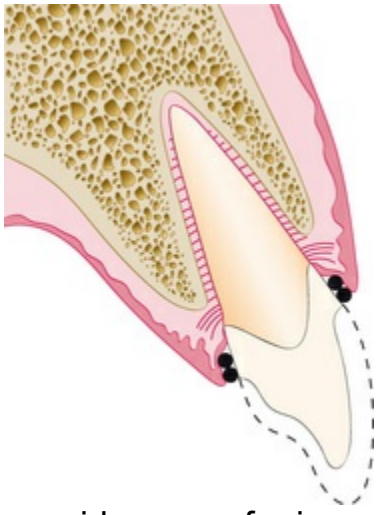
be placed so that the top of the cord is located in the sulcus at the level in which the final margin is to be established, which will be 0.5 mm below the previously prepared margin (eFig.70.11). On the interproximal aspects of the tooth, the cord is usually 1 to 1.5 mm below the tissue height because the interproximal sulcus is often 2.5 to 3 mm in depth. With this initial cord in place, the preparation is extended to the top of the cord, with the bur angled to the tooth so that it does not abrade the tissue (eFig. 70.12). This process protects the tissue, creates the correct axial reduction, and establishes the margin at the desired subgingival level. To create space and allow access for a final impression, it is now necessary to pack a second retraction cord. The second cord is pushed so that it displaces the first cord apically and sits between the margin and the tissue (eFig. 70.13). For the final impression, only the top cord is removed, leaving the margins visible and accessible to be recorded with the impression material (eFig. 70.14). The initial cord remains in place in the sulcus until the provisional restoration is completed.



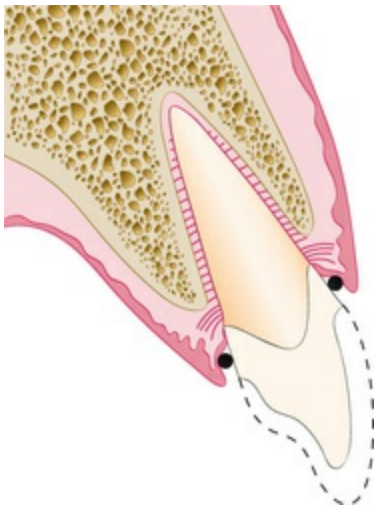
EFIG. 70.11 Second step in margin placement is to place a single layer of deflection cord below the previously prepared margin to the desired final margin level. Here, a single cord has been placed 0.5 mm below the previously prepared margin.



EFIG. 70.12 Margin of the preparation is now extended apically to the top of the retraction cord; this represents the correct placement of the margin below the previously nonreflected, free gingival margin.

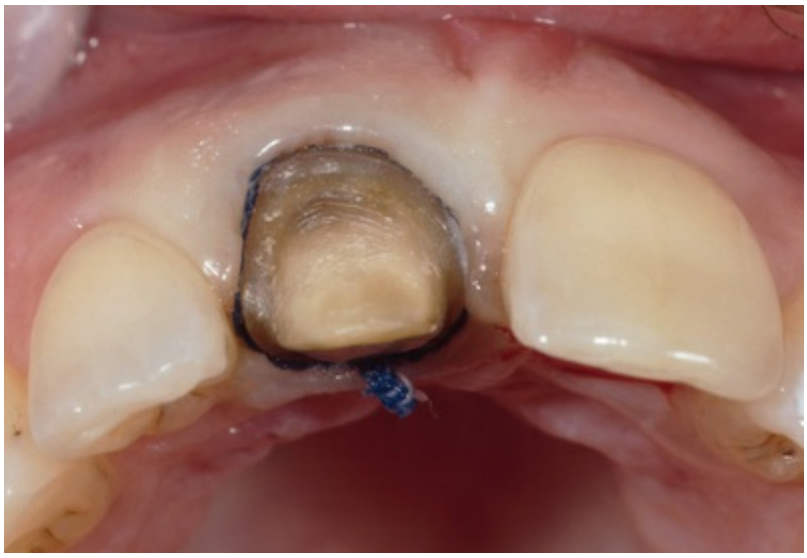


EFIG. 70.13 To provide space for impression material, a second impression cord is now placed on top of the first deflection cord. This impression cord is placed so that it is between the margin of the preparation and the gingiva to create adequate space for impression material after removal of the cord.



EFIG. 70.14 Ideal situation after removal of impression cord. The deflection cord is still in place maintaining the open sulcus but has been displaced apically another 0.5 mm by the placement of the impression cord, exposing tooth structure apical to the margin so that it can be captured in the impression.

As an alternative to additional retraction cords, electrosurgery can be used to remove any overlying tissue in the retraction process. A fine-wire electrode tip is held parallel to the tooth and against the margin in the sulcus and moved through the overhanging tissue, opening up the margin and the retraction cord to visual access (eFigs. 70.15 to 70.18). The electrosurgery tip sits on top of the retraction cord in place in the sulcus. This controls the vertical position of the tip and results in the removal of the least tissue needed for access.



EFIG. 70.15 Deflection cord and impression cord are in place. The soft tissue is falling over the margins of the preparation. In this situation, if the impression cord were removed, the impression would not capture the margins in the areas in which the tissue is overhanging.

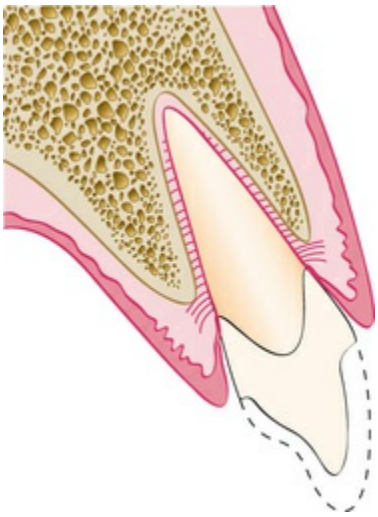
EFIG. 70.16 Overhanging tissue has been removed and space created for the impression material with electrosurgery. Note that the deflection cord and the impression cord are still in place. The impression cord is now visible completely around the tooth, allowing easy access for the impression material to the margin after removal of the impression cord.

EFIG. 70.17 Using electrosurgery, the fine-wire electrode tip is held parallel to the tooth preparation and rests on the cord as the tip is moved around the tooth.

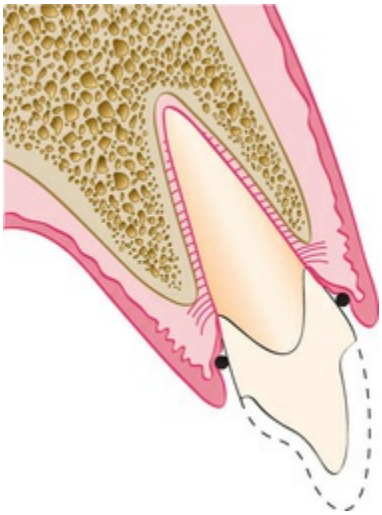
EFIG. 70.18 After removal of the impression cord, an adequate space is created for the impression material, with no soft tissue overhanging the margins to trap or tear the impression material. Note the first cord, or deflection cord, is still in place.

For rule 2 situations in which the sulcus is deeper, two larger-diameter cords are used to deflect the tissue before extending the margin apically (eFigs. 70.19 to 70.21). The top of the second cord is

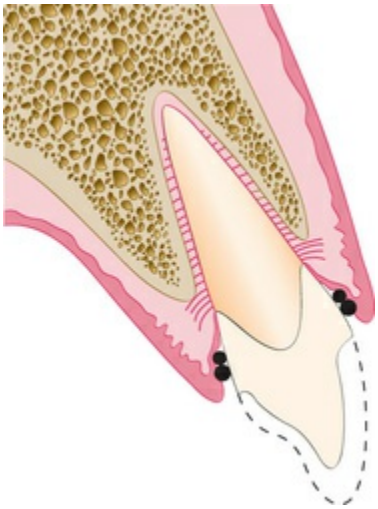
placed to identify the final margin location at the correct distance below the previously prepared margin, which was at the gingival tissue crest level. The margin is lowered to the top of the second cord (eFig. 70.22), then a third cord is placed in preparation for the impression (eFigs. 70.23 and 70.24). In the patient with a deep sulcus in which the margin may be 1.5 to 2 mm below the tissue crest, electrosurgery is often required to remove overhanging tissue. To avoid altering the gingival tissue height, it is important to hold the electrosurgery tip parallel to the preparation (eFig. 70.25).



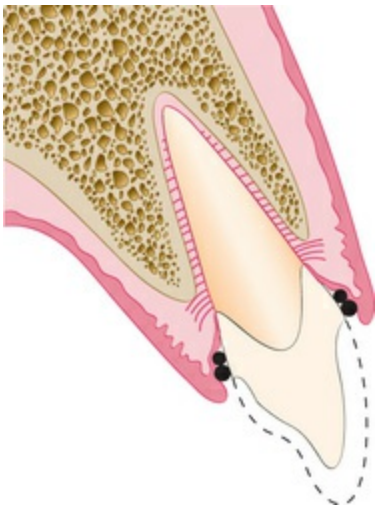
EFIG. 70.19 First step in margin placement for the patient with altered eruption or a deep sulcus is to prepare the existing free gingival margin, as in the “rule 1” patient (see text).



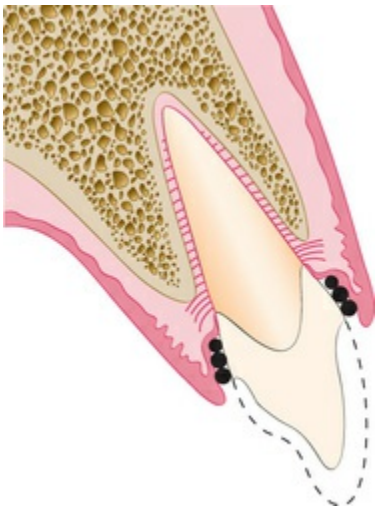
EFIG. 70.20 Second step for the patient with altered eruption is to place the deflection cord. Note that the placement of a single deflection cord does not provide adequate deflection of the tissue to allow the margin to be carried below tissue without abrading the gingiva with the bur.



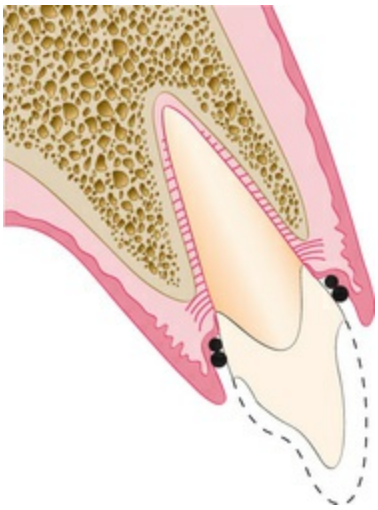
EFIG. 70.21 Third step for the patient with altered eruption and a deep sulcus is to place a second, larger-diameter deflection cord on top of the first deflection cord. Combined, these two cords allow adequate deflection to open up the sulcus so that the margin can be carried below tissue without abrading the gingiva.



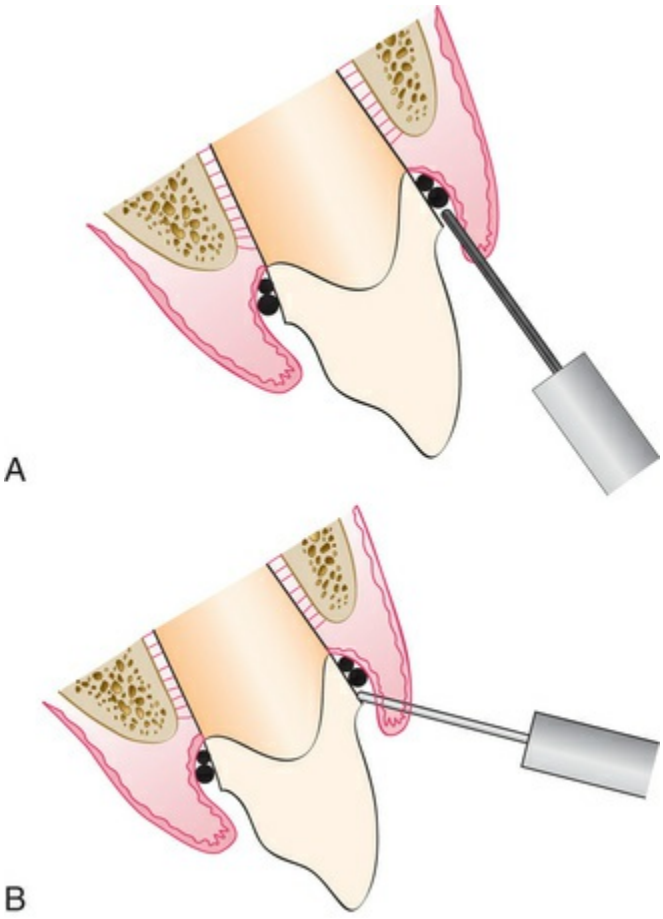
EFIG. 70.22 Preparation is now extended to the top of the second deflection cord, finalizing margin location.



EFIG. 70.23 After extension of the margin to the top of the deflection cord, a third layer of cord is applied that will act as the impression cord. This impression cord should be placed so that it fits between the free gingival margin and the margin of the preparation. Its placement will also apically displace the two previously positioned deflection cords.



EFIG. 70.24 Removal of the impression cord creates an adequate space for the impression material to capture the margin and 0.5 mm of tooth structure below the margin in which the impression cord had displaced the first two cords.



EFIG. 70.25 If it is necessary to use electrosurgery,

either in the normal or altered-eruption patient, the correct inclination of the electrosurgery tip is important. (A) Electrosurgery tip being held parallel to the preparation and resting on the previously placed retraction cord. This removes a minimal amount of tissue, and the presence of the retraction cord protects the attachment from the electrosurgery. (B) Incorrect inclination of electrosurgery tip. The tip is leaning away from the preparation. This inclination results in excess tissue removal.

Provisional Restorations

Three critical areas must be effectively managed to produce a favorable biologic response to provisional restorations.[3,74] The marginal fit, crown contour, and surface finish of the interim restorations must be appropriate to maintain the health and position of the gingival tissues during the interval until the final restorations are delivered. Provisional restorations that are poorly adapted at the margins, that are overcontoured or undercontoured, and that have rough or porous surfaces can cause inflammation, overgrowth, or recession of gingival tissues. The outcome can be unpredictable, and unfavorable changes in the tissue architecture can compromise the success of the final restoration.

Marginal Fit

Marginal fit has clearly been implicated in producing an inflammatory response in the periodontium. It has been shown that the level of gingival inflammation can increase corresponding with the level of marginal opening.[15] Margins that are significantly open (several tenths of a millimeter) are capable of harboring large numbers of bacteria and may be responsible for the inflammatory response seen. However, the quality of marginal finish and the margin location relative to the attachment are much more critical to the periodontium than the difference between a 20-μm fit and a 100-μm fit.[42,46,59]

Crown Contour

Restoration contour has been described as extremely important to the maintenance of periodontal health.[26,75] Ideal contour provides access for hygiene, has the fullness to create the desired gingival form, and has a pleasing visual tooth contour in aesthetic areas. Evidence from human and animal studies clearly demonstrates a relationship between overcontouring and gingival inflammation, whereas undercontouring produces no adverse periodontal effect.[48,51] The most frequent cause of overcontoured restorations is inadequate tooth preparation by the dentist, which forces the technician to produce a bulky restoration to provide room for the restorative material. In areas of the mouth in which aesthetic considerations are not critical, a flatter contour is always acceptable.

Subgingival Debris

Leaving debris below the tissue during restorative procedures can create an adverse periodontal response. The cause can be retraction cord, impression material, provisional material, or either temporary or permanent cement.[55] The diagnosis of debris as the cause of gingival inflammation can be confirmed by examining the sulcus surrounding the restoration with an explorer, removing any foreign bodies, and then monitoring the tissue response. It may be necessary to provide tissue anesthesia for patient comfort during the procedure.

Hypersensitivity to Dental Materials

Inflammatory gingival responses have been reported related to the use of nonprecious alloys in dental restorations.[52] Typically, the responses have occurred to alloys containing nickel, although the frequency of these occurrences is controversial.[50] Hypersensitivity responses to precious alloys are extremely rare, and these alloys provide an easy solution to the problems encountered with the nonprecious alloys. Importantly, tissues respond more to the differences in surface roughness of the material than they do to the composition of the material.[1,66] The rougher the surface of the restoration subgingivally, the greater are the plaque accumulation

and gingival inflammation. In clinical research, porcelain, highly polished gold, and highly polished resin all show similar plaque accumulation. Regardless of the restorative material selected, a smooth surface is essential on all materials subgingivally.

Aesthetic Tissue Management

Managing Interproximal Embrasures

Current restorative and periodontal therapy must consider a good aesthetic result, especially in the "aesthetic zone." As discussed in Chapters 58 and 65, the interproximal papilla is an important part in creating this aesthetic result. The interproximal embrasure created by restorations and the form of the interdental papilla have a unique and intimate relationship.[61,62] The ideal interproximal embrasure should house the gingival papilla without impinging on it and should also extend the interproximal tooth contact to the top of the papilla so that no excess space exists to trap food and to be aesthetically displeasing.

Papillary height is established by the level of the bone, the biologic width, and the form of the gingival embrasure. Changes in the shape of the embrasure can impact the height and form of the papilla. The tip of the papilla behaves differently than the free gingival margin on the facial aspect of the tooth. Whereas the free gingival margin averages 3 mm above the underlying facial bone, the tip of the papilla averages 4.5 to 5 mm above the interproximal bone (Fig. 70.6). This means that if the papilla is farther above the bone than the facial tissue but has the same biologic width, the interproximal area will have a sulcus 1 to 1.5 mm deeper than that found on the facial surface.

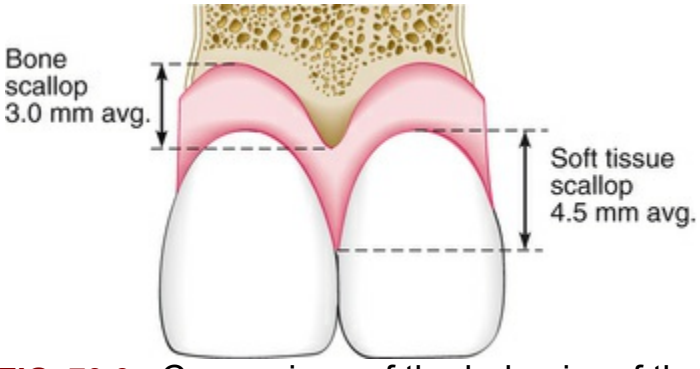


FIG. 70.6 Comparison of the behavior of the interproximal papilla relative to bone and the free gingival margin relative to bone in the average human. There is a 3-mm scallop from the facial bone to the interproximal bone. However, on average, a 4.5- to 5-mm gingival scallop exists between the facial tissue height and the interproximal papilla height. This extra scallop of 1.5 to 2 mm of gingiva compared with bone is the result of the extra soft-tissue height above the attachment interproximally.

Clinical Correlation

If you create restorations with no more than 5 mm from the contact to the bone, open gingival embrasures can be avoided. The downside to this approach is that the teeth will look square and blocky. However, some patients can support a 7-mm papilla. Well-made provisional restorations allow accurate determination of actual papilla length.

Van der Veldon[72] completely removed healthy papillae to the bone level and found that they routinely regenerated 4 to 4.5 mm of total tissue above bone, with an average sulcus depth of 2 to 2.5 mm. The height above bone that the papilla strives to maintain was indirectly confirmed by Tarnow and coworkers,[67] who studied the relationship of the papilla between the interproximal contact and the underlying bone. When the distance from the interproximal bone to the interproximal contact of the teeth measured 5 mm or less, 98% of these sites had complete papilla fill. When the distance was 6 mm, only 56% of the sites had complete papilla fill. When the

distance was 7 mm, only 27% of the sites had complete papilla fill (Fig. 70.7).

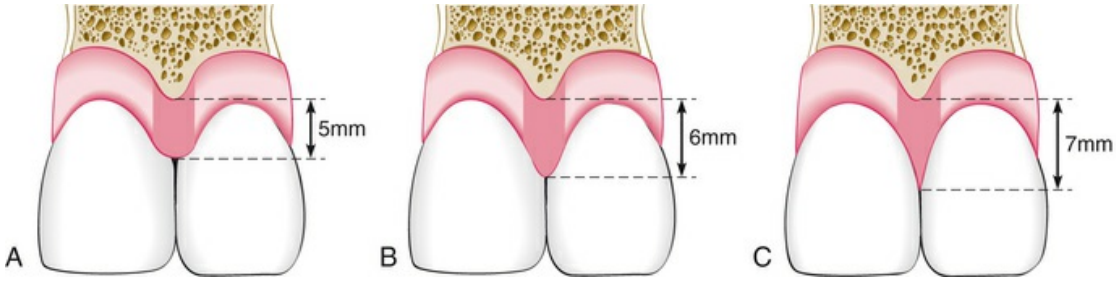

FIG. 70.7 The probability of complete fill of gingival embrasure by papilla. (A) With 5 mm from crest of bone to the apical contact point, there is a 98% chance of complete fill of the space. (B) At 6 mm from crest to contact, the chance of filled embrasure drops to 56%. (C) At 7 mm from crest to contact, the chance of complete fill drops to 27%.

Because there is individual variability to the required biologic width, this information relative to the papilla is applied by locating the lowest point of the interproximal contact in relation to the top of the epithelial attachment. The ideal contact should be 2 to 3 mm coronal to the attachment, which coincides with the depth of the average interproximal sulcus. In assessing the soft tissues to determine margin location, it is imperative that they be healthy and mature. Performing the analysis on inflamed or immature tissues will result in supragingival margins when the tissues heal. If the papillary sulcus measures greater than 3 mm, there is some risk of recession with restorative procedures. Critical adjustments to margin and soft tissue positions should be ultimately diagnosed with the use of well-designed and adapted provisional restorations. This will allow for treatment to be accurately designed based on the individual's unique biologic width.

The clinician most frequently confronts a normal or shallow sulcus with a papilla that appears too short rather than a tall papilla with a deep sulcus. Management of this situation is best approached by viewing the papilla as a balloon of a certain volume that sits on the attachment. This balloon of tissue has a form and height dictated by the gingival embrasure of the teeth. With an

embrasure that is too wide, the balloon flattens out, assumes a blunted shape, and has a shallow sulcus (Fig. 70.8).

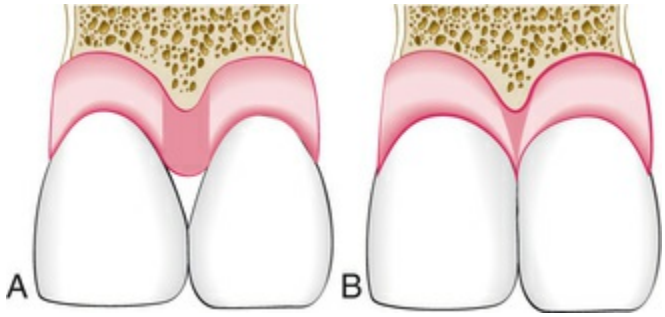

FIG. 70.8 Relationship between gingival embrasure volume and papillary form. (A) Gingival embrasure of the teeth is excessively large as the result of a tapered tooth form. Because of the large embrasure form, the volume of tissue sitting on top of the attachment is not molded to the shape of a normal papilla but rather has a blunted form and a shallower sulcus. (B) Ideal tooth form in which the same volume of tissue sits on top of the attachment as in part A. Because of the more closed embrasure form from the teeth in part B, however, the papilla completely fills the embrasure and has a deeper sulcus, averaging 2.5 to 3 mm. Note that the ideal contact position is 3 mm coronal to the attachment.

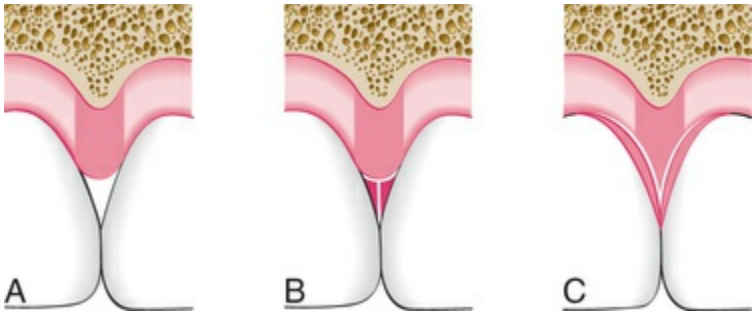
If the embrasure is the ideal width, the papilla assumes a pointed form, has a sulcus of 2.5 to 3 mm, and is healthy. If the embrasure is too narrow, the papilla may grow out to the facial and lingual, form a col, and become inflamed. This information is applied when evaluating an individual papilla with an open embrasure. The papilla in question is compared with the adjacent papillae. If the papillae are all on the same level, and if the other areas do not have open embrasures, the problem is one of gingival embrasure form. If the papilla in the area of concern is apical to the adjacent papillae, however, the clinician should evaluate the interproximal bone levels. If the bone under that papilla is apical to the adjacent bone levels, the problem is caused by bone loss. If the bone is at the same level, the open embrasure is caused by the embrasure form of the teeth and not a periodontal problem with the papilla. The papillae

in the anterior maxilla average 4 mm long and are the same heights at the mesial and distal sides of the tooth. Ultimately, deficient papillae and open gingival embrasures are most predictably corrected with restorations to close the space.

Correcting Open Gingival Embrasures Restoratively

There are two causes of open gingival embrasures: (1) the papilla is inadequate in height because of bone loss or (2) the interproximal contact is located too high coronally. If a high contact has been diagnosed as the cause of the problem, there are two potential reasons. If the root angulation of the teeth diverges, the interproximal contact is moved coronally, resulting in the open embrasure. However, if the roots are parallel, the papilla form is normal, and an open embrasure exists, then the problem is probably related to tooth shape, specifically an excessively tapered form. Restorative dentistry can correct this problem by moving the contact point to the tip of the papilla. To accomplish this, the margins of the restoration must be carried subgingivally 1 to 1.5 mm, and the emergence profile of the restoration is designed to move the contact point toward the papilla while blending the contour into the tooth below the tissue (eFig.70.26). This can be accomplished easily with direct bonded restorations because the soft tissue can clearly be seen (eFigs. 70.27 to 70.29). For indirect restorations, the desired restoration contours and embrasure form should be established in the provisional restorations, and the gingival tissues are allowed to adapt for 4 to 6 weeks before the tissue contour information is relayed to the laboratory for use in the final restorations.



EFIG. 70.26 Methods of altering gingival embrasure form. (A) Typical open gingival embrasure caused by excessively tapered tooth form. (B) Common method employed by restorative dentists to correct the embrasure, in which material is added supragingivally. This closes the embrasure by moving the contact to the tip of the papilla but results in overhangs that cannot be cleaned using dental floss. Removing these overhangs restoratively reopens the embrasure. (C) Correct method of closing the gingival embrasure, in which the margins of the restoration are carried 1 to 1.5 mm below the tip of the papilla. Note that this does not encroach on the attachment because the average interproximal sulcus probes 2.5 to 3 mm. This allows easy cleaning because of the convex profile. It also reshapes the papilla to a more pleasing profile aesthetically.

EFIG. 70.27 This patient has parallel roots, has recently completed orthodontic therapy, and is unhappy with the open gingival embrasure between

her central incisors. An evaluation of papillary height reveals that all are at an equal level. This can only mean that the open embrasure is the result of an overly tapered tooth form (see eFigs. 70.28 and 70.29).

EFIG. 70.28 One method of correctly altering tooth form of the patient in eFig. 70.27. A metal matrix band has been shaped to the desired tooth form and placed 1 to 1.5 mm below the tip of the papilla. Restorative material then was added to the tooth against the matrix band, forming the new mesial surface of the left central incisor.

EFIG. 70.29 One-year recall photograph after restoring the mesial surfaces of the right and left central incisors, moving the proximal contact to the tip of the papilla and extending the restorations 1 to 1.5 mm below the papilla, blending them into the tooth and making an easily cleaned area (see eFigs. 70.27 and 70.28).

Managing Gingival Embrasure Form for Patients With Gingival Recession

Management of the gingival embrasure form for patients who have experienced gingival recession varies, depending on whether the treatment is in the anterior or posterior regions of the mouth.[30] In aesthetic areas, it is necessary to carry the interproximal contacts apically toward the papilla to eliminate the presence of large, open embrasures. With multiple-unit restorations, it is also possible with tissue-colored ceramics to bake porcelain papillae directly on the restoration. In the posterior areas where the interroot widths are significantly greater, it is often impossible to carry the proximal contacts to contact the tissue without creating large overhangs on the restorations. In these situations, the contact should be moved far enough apically to minimize any large food traps while still leaving an embrasure of a convenient size to be accessed with an interdental brush for hygiene. It should be noted that developing excessively long interproximal contacts, whether on anterior or posterior teeth, always creates rectangular, somewhat unaesthetic, tooth forms.

Pontic Design

Classically, there are four options to consider in evaluating pontic design: hygienic, ridge lap, modified ridge lap, and ovate designs (Fig. 70.9). Regardless of design, the pontic should provide an occlusal surface that stabilizes the opposing teeth, allows for normal mastication, and does not overload the abutment teeth. The area of the pontic interfacing with the gingiva can be porcelain, metal, zirconia, lithium disilicate, or some other material with no variation in the biologic response of the tissue provided it has a smooth

surface finish.[25,53,63]

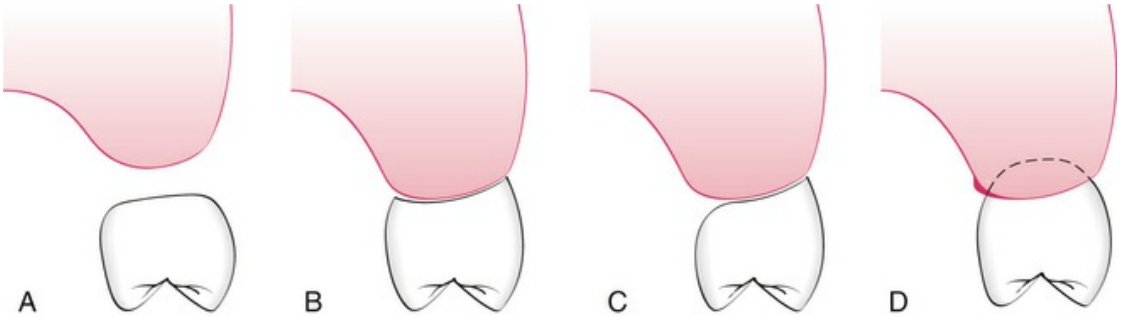


FIG. 70.9 Four options to designing the shape of a pontic. (A) Hygienic pontic. Tissue surface of the pontic is 3 mm from the underlying ridge. (B) Ridge-lap pontic. Tissue surface of the pontic straddles the ridge in saddle-like fashion. The entire tissue surface of the ridge-lap pontic is convex and very difficult to clean. (C) Modified ridge-lap pontic. Tissue surface on the facial is concave, following the ridge. However, the lingual saddle has been removed to allow access for oral hygiene. (D) Ovate pontic. The pontic form fits into a receptor site within the ridge. This allows the tissue surface of the pontic to be convex and also optimizes aesthetics.

The key differences between the four pontic designs relate to the aesthetics and access for hygiene procedures. The primary method for cleaning the undersurface of pontics is to draw dental floss mesiodistally along the undersurface. The shape of this undersurface determines the ease with which plaque and food debris can be removed in the process. The hygienic and ovate pontics have convex undersurfaces, which makes them easiest to clean. The ridge lap and modified ridge-lap designs have concave surfaces, which are more difficult to access with the dental floss. Although the hygienic pontic design provides the easiest access for hygiene procedures, it is much less aesthetic and objectionable by some patients.

The ovate pontic is the ideal pontic form, particularly in areas of aesthetic concern.[61] It is created by forming a receptor site in the edentulous ridge with a diamond bur, electrosurgery, pressure, or wound healing. The site is shaped to create either a flat or a concave

contour so that when the pontic is created to adapt to the site, it will have a flat or convex outline. The depth of the receptor site depends on the aesthetic requirements of the pontic. In highly aesthetic areas such as the maxillary anterior region, it is necessary to create a receptor area that is 1 to 1.5 mm below the tissue on the facial aspect. This creates the appearance of a free gingival margin and produces optimal aesthetics (Fig. 70.10). This site can then be tapered to the height of the palatal tissue to facilitate hygiene access from the palatal side. In the posterior areas, a deep receptor site can complicate hygiene access. In these situations, the ideal site has the facial portion of the pontic at the same level as the ridge, and then the site is created as a straight line to the lingual side of the pontic. This removes the convexity of the ridge and produces a flat, easily cleanable tissue surface on the pontic (Fig. 70.11).

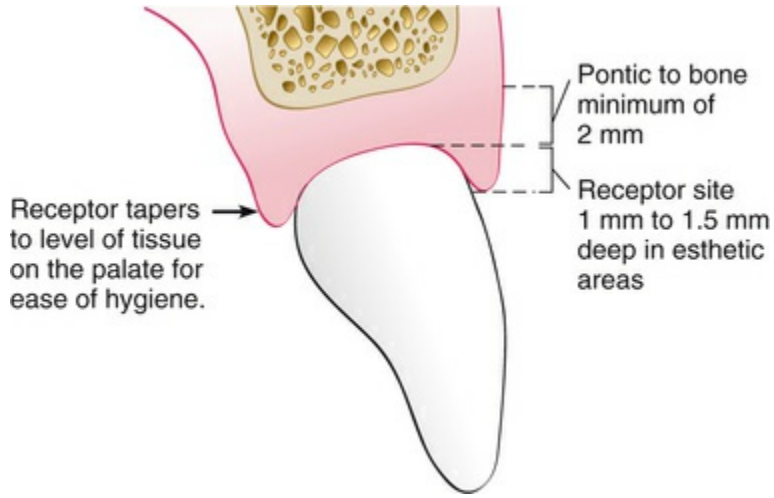

FIG. 70.10 Ideal shape and form of an ovate pontic in the aesthetic area. The receptor site has been created 1 to 1.5 mm apical to the free gingival margin on the facial aspect. This creates the illusion of the pontic erupting from the tissue. On the palatal side, the pontic is tapered so that the receptor site is not extended below tissue; this allows easier access for oral hygiene. Note that when the receptor site is created, the bone must be a minimum of 2 mm from the most apical portion of the pontic.

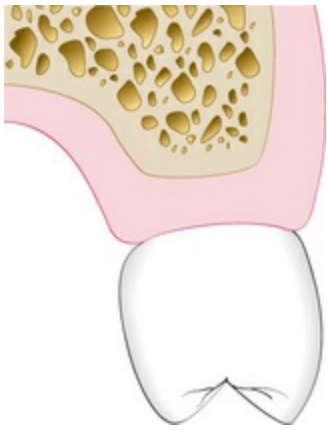

FIG. 70.11 Option for creating an ovate pontic receptor site in less aesthetic areas of the mouth. Rather than creating the receptor site so that the pontic extends into the ridge, it is possible to create a flattened receptor site in which the pontic sits flush with the ridge. This facilitates oral hygiene.

Ridge Modification Procedures for Ideal Pontic Contours

When the ridge is being surgically modified, it is important to know the thickness of soft tissue above the bone. This measurement is obtained by probing to the bone through the anesthetized tissue. If the tissue is removed to less than 2 mm in thickness, significant rebound in ridge height may occur. If it is necessary to reduce the tissue height to less than 2 mm above the bone to create the desired pontic form, some bone will need to be removed to achieve the desired result.

It is important when considering an ovate pontic to realize that certain soft-tissue ridge parameters must exist to optimize the ovate pontic form. First, the ridge height needs to match the ideal height of the interproximal papillae where interproximal embrasures are planned, either between pontics or next to abutment teeth. Second, the gingival margin height must also be at the ideal level, or the pontic will appear too long. Third, the ridge tissue must be facial to the ideal cervical facial form of the pontic so that the pontic can emerge from the tissue. If any of these three areas is inadequate, some form of ridge augmentation is needed to produce a ridge that can have an adequate receptor site created (eFig. 70.30). Any ridge

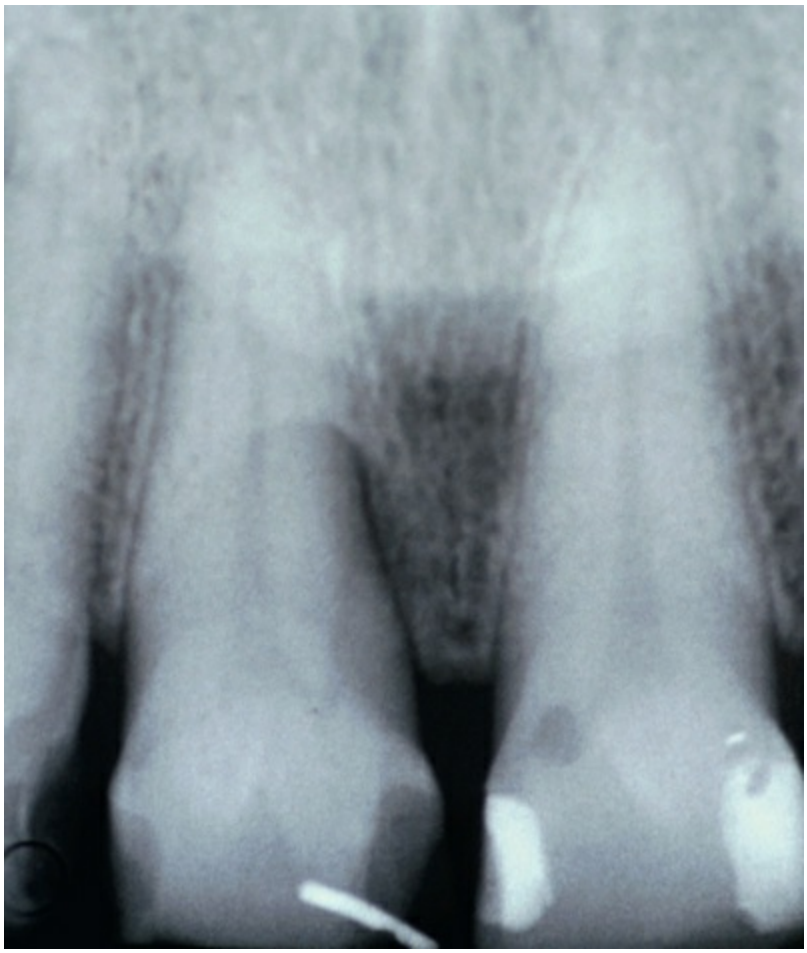
augmentation procedures should be completed before, or in conjunction with, fabricating an ovate pontic. When constructing the final restorations, the contours of the developed ovate pontic receptor site can be conveyed to the laboratory by capturing a soft-tissue impression 4 to 6 weeks after the site has been created.

EFIG. 70.30 Ridge considerations when an ovate pontic is desired. For an ovate pontic to be properly created, the soft-tissue ridge must be labial to the desired cervical portion of the pontic. When the pontic is facial to the ridge, it is not possible to create what appears to be a "free gingival margin" correctly. The shaded area represents the necessary amount of tissue that would be augmented to produce an ideal ovate pontic in this particular site.

The ovate pontic can serve another important periodontal function by maintaining the interdental papilla next to abutment teeth after extraction.[61] When a tooth is removed, the gingival embrasure form is lost. The normal response of the papilla to this loss of embrasure form is to recede 1.5 to 2 mm, which corresponds to the additional soft tissue that exists above bone on the interproximal versus the facial aspect. However, this recession can be prevented. By inserting the correct pontic form 2.5 mm into the extraction site the day the tooth is removed, the gingival embrasure form and papilla can be maintained. At 4 weeks, the 2.5-mm extension can be reduced to a 1- to 1.5-mm extension to facilitate hygiene. This procedure can maintain the papilla next to the

abutment teeth as long as the bone on the abutment tooth is at a normal level (eFigs. 70.31 to 70.38).

EFIG. 70.31 Patient who will have the right central incisor extracted because of periodontal disease. The patient is choosing to have a fixed partial denture rather than an implant as the method of replacement. An ovate pontic will be used to maintain the papillary form after the removal of this central incisor (see eFigs. 70.32 to 70.38).



EFIG. 70.32 Note the radiographic appearance of a palatal well caused by a deep palatal groove on this right central incisor of the patient in eFig. 70.31. Two attempted periodontal surgeries have failed to correct this, and it still probes 10 mm with suppuration.

EFIG. 70.33 Because the patient in eFig. 70.31 desired to alter the aesthetics of her remaining anterior teeth, all the anterior teeth were prepared before removal of the right central incisor.

EFIG. 70.34 The key to maintenance of the interproximal papilla is that the ovate pontic must extend 2.5 mm into the extraction site on the day of extraction. This will maintain gingival embrasure form and therefore maintain interproximal papillary height.

EFIG. 70.35 Note that when the provisional restoration

is seated on the day of the extraction, 2.5 mm of the pontic extend upward into the extraction socket. Also note the open gingival embrasures present to allow space for the papillae to rebound coronally.

EFIG. 70.36 Nine months after placement of the provisional restoration. (At 4 weeks after placement, the pontic was shortened to extend 1.5 mm into the extraction site to facilitate oral hygiene.) Note maintenance of papillary form and free gingival margin height, predictable in this patient because she has excellent interproximal and facial bone.

EFIG. 70.37 Ovate pontic site after removal of the provisional restoration and before final impressions. Note that the papillary form has been maintained because of the ovate pontic maintaining gingival embrasure volume.

EFIG. 70.38 Two-year recall photograph of the final fixed prosthesis of the patient in eFig. 70.31. Note how the final ovate pontic also has maintained papillary form.

The "full ridge-lap pontic" is an outdated design that straddles the convexity of the ridge buccolingually and creates an undersurface that is entirely concave and cannot be cleaned. It is not recommended for use in any situations. However, a *modified ridge-lap pontic* can be an acceptable design if inadequate ridge exists to create an ovate pontic. With the modified ridge-lap design, the pontic follows the convexity of the ridge on the facial aspect but stops on the lingual crest of the ridge without extending down the lingual side of the ridge. Although the facial aspect of the undersurface has a concave shape, the more open lingual form allows adequate access for oral hygiene.

Occlusal Considerations in

Restorative Therapy

Key Fact

A mutually protective occlusion is created when all the teeth touch at the same time in a normal closing arc, but when the mandible moves, all contacts are on the anterior teeth.

Chapter 55 presents details on the biology of occlusion and related clinical evaluation procedures. The importance of occlusal trauma as a factor in periodontal disease and its role in orofacial pain have been deemphasized in numerous papers.[8,14,34,35,44,45,54,65,71] However, the role that occlusion plays in restorative dentistry has been reemphasized. The increased use of dental implants and nonmetallic restorations has resulted in increased concern over force management. Some of these materials are more sensitive to occlusal trauma, and resulting fracture, than are metal restorations. Consequently, for the clinician who wants a high degree of predictability, understanding occlusion is critical. The clinician must know how to create an occlusion, with the following guidelines as a goal:

1. There should be even, simultaneous contacts on all teeth in maximal intercuspal position (MIP). This distributes the force of closure over all the teeth instead of the few teeth that may touch first.
2. When the mandible moves from maximum intercuspal position (MIP), some form of canine or anterior guidance is desirable, with no posterior tooth contacts. This mutually protective occlusion reduces the ability and force of the muscles of mastication, while it more evenly distributes the forces. It has been shown that, as a result of the class III lever action, the anterior teeth receive approximately one-ninth the force of a second molar.[24,60]
3. The anterior guidance needs to be in harmony with the patient's envelope of function. The harmony of this relationship is demonstrated by a lack of fremitus and

mobility on the anterior teeth, by the ability of the patient to speak clearly and comfortably, and by the patient's general sense of comfort with the overbite, overjet, and guidance created during chewing and when holding the head upright.

4. The occlusion should be created at a occlusal vertical dimension (OVD) that is stable for the patient. It is generally accepted that the patient's existing vertical dimension is at equilibrium between the eruptive forces of the teeth and the repetitive contracted length of the elevator muscles. It has been demonstrated that vertical dimension can be altered with no sense of pain from muscles and joints.[8,10,21,29] However, if this alteration lengthens the pterygomasseteric sling beyond its ability to adapt, the patient will not maintain the vertical change and will close the occlusal vertical dimension back down by intruding the teeth.[11,33,39-41]
5. When managing a pathologic occlusion or when restoring a complete occlusion, the clinician needs to work with a repeatable condylar reference position. Centric relation, defined as the most superior condylar position, provides such a starting point.[20] Centric relation has been shown to be reproducible over multiple appointments, allowing the clinician to create the occlusion indirectly on an articulator and return it to the same reference position in the mouth.[13,38,43,73] It is the only position that has been shown to shut off lateral pterygoid muscle contraction.[19] Because it is a border position, any mandibular movement will result in the condyle moving inferiorly. Therefore centric relation is the most predictable position from which an interference-free occlusion can be created.

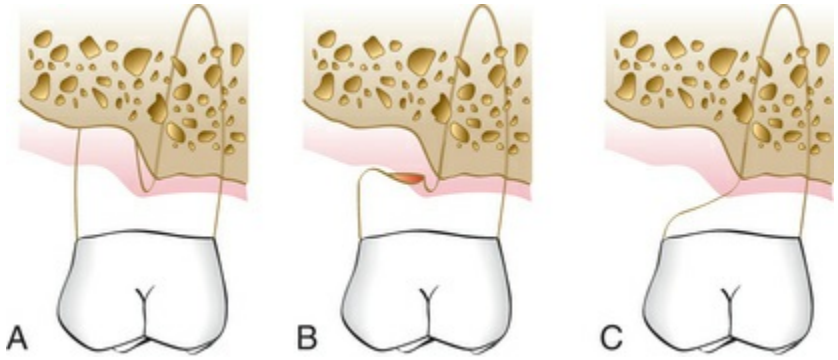
To manage the occlusion as previously described, the clinician must be able to make accurate casts, use a facebow, and create centric relation records so that the information can be transferred to a suitable articulator. Although the details of these procedures are beyond the scope of this chapter, they are a routine part of any restorative treatment plan and must be mastered for the clinician to achieve predictable, long-term restorative success. The reader is

referred to Chapter 55 for a more comprehensive overview of occlusal evaluation and therapy.

Special Restorative Considerations

Root-Resected Teeth

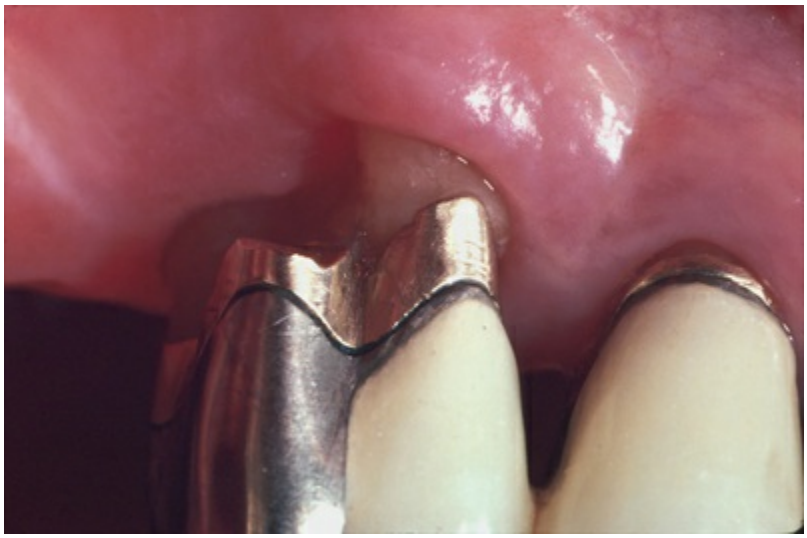
Although the availability of implant therapy has greatly reduced the frequency with which root-amputated teeth are saved, restoration of root-resected teeth is still a viable mode of treatment. Diagnosis and management of multirooted teeth with furcation involvement including the rationale for root resection are presented in detail in Chapter 62. Structural challenges are created in restoring these teeth because of the amount of tooth structure lost in the resection process (eFig. 70.39). Conservative tooth preparation will maintain as much of the remaining tooth as possible, but the resulting supragingival or minimally prepared subgingival finish lines will require additional metal display in the final restoration. A cast post and core may be indicated to create an adequate foundation for the final restoration. Because the remaining roots are often very thin mesiodistally, it is difficult to cement premade posts and have adequate bulk to place a foundation core on the mesial and distal surfaces of the post. This problem is avoided with the one-piece cast post and core restoration.



EFIG. 70.39 (A) Maxillary molar with a class III furcation and bone loss surrounding the distal buccal root. (B) Contour created when the distal buccal root is removed, but the coronal contour has not yet been reshaped. Note the overhang, which can trap food and

plaque and create gingival inflammation. (C) Correct contour after the restoration or reshaping of the tooth. Note this illustration is only of the facial portion of the tooth. The palatal portion of the crown and the palatal root do not appear. Note how the contour has been altered to allow easy access for an interdental brush to the gingival tissue and the tooth in the area in which the root was removed.

Another area of concern when restoring root-resected teeth is the development of appropriate contours for hygiene access. The primary concern is to avoid any excessively heavy convexities of contour that would prevent access (eFig. 70.40 and 70.41). Facially and lingually, the contours should be essentially a straight line from the margin coronally, while interproximally, the contour emerges from the margin as a straight line or is slightly convex as it slopes up to the contact point. The interproximal areas of root-amputated and hemisected teeth often present with surface concavities on the root trunk, and these areas cannot be adequately cleaned with floss because it will bridge across the concavity. The gingival embrasure form created in the restoration must be fluted into these areas so that the surfaces can be accessed with an interdental brush.



EFIG. 70.40 Photograph taken 6 weeks after the removal of the distal buccal root on this maxillary first molar. Note that the crown contour has not yet been altered. Also note the presence of a large overhang that easily traps debris.

EFIG. 70.41 Correct modification of the crown form seen in eFig. 70.40. The roof of the furcation of the remaining distal buccal root has been completely removed and the crown re-formed to allow easy access to the remaining roots and soft tissue.

Aesthetics is usually not a major concern unless the tooth in question is a maxillary molar with a mesiobuccal root amputation and the patient has a broad smile. The solution is to create an artificial mesiobuccal root with normal crown contour coronal to it and a furcation made of restorative material that is easily cleanable with an interdental brush.

Splinting

Splinting therapy may be applied with bonded external appliances, intracoronal appliances, or indirect cast restorations to connect multiple teeth, with the goal of improving tooth stability. Unstable teeth may be caused by a lack of periodontal support from bone loss, a lack of support from tooth loss, or the need to splint abutment teeth to support pontics. Indications for splinting are (1) mobility of teeth that is increasing or that impairs patient comfort, (2) migration of teeth, and (3) prosthetics in which multiple abutments are necessary.

Before considering splinting, the clinician must identify the

etiology of the instability.[2] Excessive occlusal forces from parafunction or deflective tooth contacts are frequent causes of excessive mobility. Whenever the occlusion is the cause, occlusal therapy is always performed first. The mobility is then evaluated over time to determine if it resolves before splinting is considered. In addition, any inflammation of the periodontal supporting apparatus must be controlled before making a decision on splinting because inflammation can produce mobility in the presence of normal occlusal forces and normal periodontal support. When the teeth are splinted, all the teeth in the splint share the occlusal load to some extent.[16] The rigidity of the splint and the number of teeth used determine how the forces are distributed.

The most common indication to splint mobile teeth is to improve patient comfort and to provide better control of the occlusion. If the anterior teeth are mobile, adequate crown length on the teeth being splinted is critical so that the interproximal connectors do not impinge on the interdental papilla. Also, adequate space must exist between the connector and the papilla for access with dental floss anteriorly and with an interproximal brush on posterior teeth.

Anterior Aesthetic Surgery

The importance of gingiva in relation to anterior aesthetics has been well documented.[9,28,58,64] Various methods for altering gingival levels have been described, including gingivectomy, apically positioned flaps with osseous recontouring, and the use of orthodontic therapy to position the gingival tissue level apically or coronally by intruding or extruding the teeth[5,12,32,68] (Video 70.1).

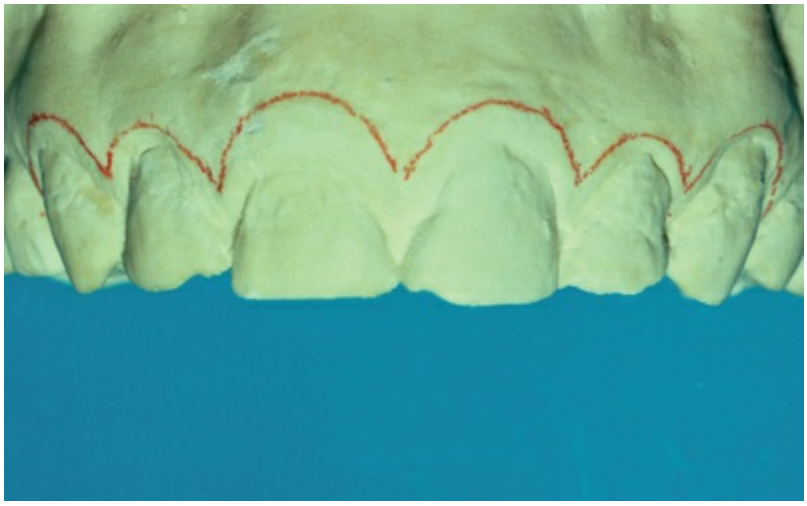
Whenever an alteration in gingival levels is contemplated, the expected outcome must be communicated to the patient to determine if the planned surgery is acceptable. Computer imaging can be used to provide the patient with a visual plan for the final aesthetic result.[17] However, the imaging process does not allow the dentist or patient to include the dynamics of lip movement in the evaluation of the proposed changes. Computer imaging provides enough information to depict the final outcome accurately when the planned surgery will alter the gingiva on one or two teeth while leaving the gingival levels of adjacent teeth in their existing

position.

However, when the surgery will involve many or all of the anterior teeth and will result in moving gingiva several millimeters, to the extent that a flap will be raised and bony levels altered, an additional guide is desirable before surgery. Constructing these guides directly on a stone cast is the easiest and least time-consuming method. Before constructing the guide, treatment planning is completed on the patient to determine the desired incisal edge position and the desired gingival level of the tissues. This will establish the amount of tooth display at rest and at full smile. The information is transferred to a stone cast of the patient's teeth, and the desired shape of the gingival margins for each tooth is drawn on the cast. The existing incisal edge position of each tooth is used as a reference in establishing the desired gingival level. A composite or acrylic resin veneer is then constructed on the cast, extending gingivally to the desired tissue position. The veneer guide can also be extended incisally to the desired incisal edge position so that this information can also be included in the veneer. The veneer is trimmed, polished, and tried in the patient's mouth.

When the patient approves the gingival levels established with the guide, the desired gingival correction can be completed using the veneer guide as a surgical template. In addition to locating the initial incisions at the correct level, the guide can also be employed after flap reflection to aid in the bony recontouring to ensure adequate biologic width and sulcus depth at the new gingival position. The surgeon replaces the flap at closure to the gingival level established with the guide. Employing an aesthetic template in this manner optimizes the predictability of the surgical therapy and establishes the ideal tissue framework to complete the aesthetic restorations (eFigs. 70.42 to 70.49).

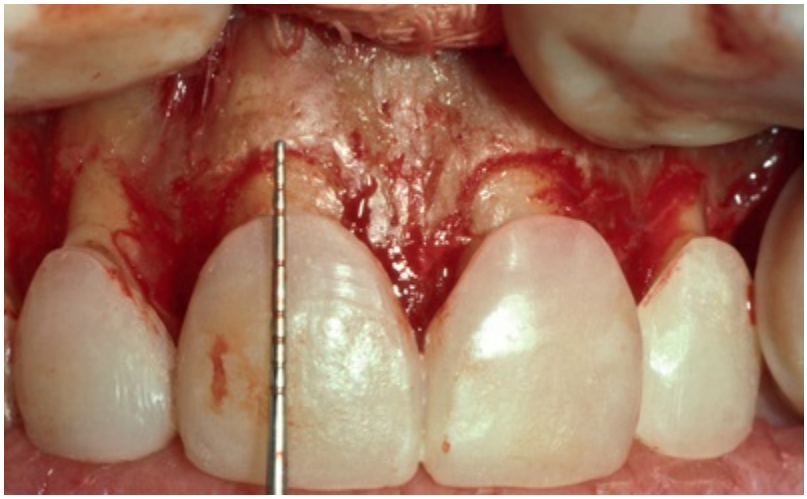
EFIG. 70.42 This patient is unhappy with the appearance of her maxillary teeth and the discrepancies of tissue height and tooth form (see eFigs. 70.43 to 70.49).



EFIG. 70.43 To create a surgical guide for the patient in eFig. 70.42, a stone cast is modified by drawing the desired soft-tissue profile with a red wax pencil.

EFIG. 70.44 A composite-resin surgical guide is fabricated on this stone cast, extending to the line drawn. This guide can be taken to the mouth for try-in and verification by the patient (see eFig. 70.42).

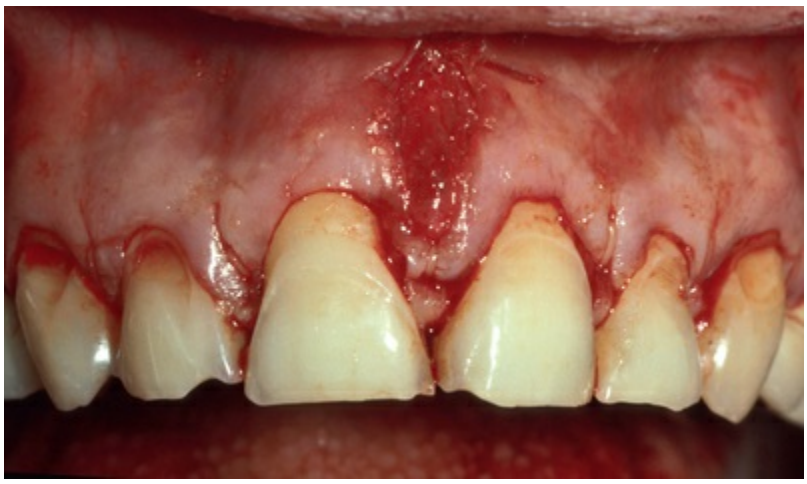
EFIG. 70.45 Photograph taken the day the surgical guide was tried-in. The patient in eFig. 70.42 approved the new length of the maxillary anterior teeth and the form created by altering the soft-tissue profile.



EFIG. 70.46 By placing the surgical guide during the surgery, it is possible to recognize where the bone needs to be placed. The surgical guide represents the desired final free gingival margin position and can be used as a reference for osseous recontouring. This patient had an average biologic width of 2 mm (see eFig. 70.42). Allowing an additional 1 mm for sulcus depth, the desired distance between the bone and the free gingival margin will be 3 mm. With this knowledge, the periodontist can use the guide and remove bone until it is 3 mm from the position of the guide on each tooth.

EFIG. 70.47 Surgical guide is also useful during suturing. Because the guide represents the desired free gingival margin position, it is possible to suture to the level of the guide, knowing that the surgery has

now recreated biologic width and a 1-mm sulcus. This shortens the amount of time necessary for healing and eliminates the need to wait for tissue rebound before restorative dentistry.



EFIG. 70.48 Soft-tissue profile as seen the day of surgery with the guide removed. Note that in this patient, the interproximal papillae were not changed because the interproximal papillary form and height were deemed acceptable (see eFigs. 70.42 to 70.47).

EFIG. 70.49 Photograph taken 4 years after placement of the final restoration of the patient in eFig. 70.42. Note the excellent soft-tissue health and the attainment of the desired free gingival margin and papillary form.

Case Scenario 70.1

Patient:
41-year-old female

Chief Complaint:
"My old crowns had a big open space between them by the gums."

Background Information
The patient has an ASA 1, a high smile, and a normal tissue biotype. Preexisting PFMs on central incisors had open gingival embrasure. Pocket depths are within normal limits, there is no bleeding on probing, and the patient practices good oral hygiene.

Current Findings:
Preexisting PFM crowns on maxillary central incisors had poor shade match and open gingival embrasures. Patient brushes and flosses as directed and has hygiene visits twice per year. RCT/post on the maxillary right central incisor is intact.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. To predictably close the open	**Answer: B**

gingival embrasure with the new crowns, the apical extent of the contact point should be _____ from the interdental bone crest. A. 4 mm B. 5 mm C. 6 mm D. 7 mm	**Explanation:** According to Tarnow 1992, contact points 5 mm from the interdental crest of bone will be completely filled in 98% of patients.
2. What is the apparent height of the papilla between the centrals most dependent on? A. Tissue biotype B. Prep design C. Crestal bone height D. Deep margin placement	**Answer: C** **Explanation:** The height of the interdental bone is the largest variable in determining the apparent height of the papilla. Tissue biotype plays a role, though less significant.
3. What risk does the subgingival margins as seen here create? A. Cement-induced periodontal inflammation B. Increased plaque retention C. Aesthetic concerns due to the darkened root of the right central incisor	**Answer: A** **Explanation:** Subgingival margins increase the risk for inflammation due to residual cement. This risk increases proportional to the subgingival depth of the margin. Healthy, robust gingiva mitigates this risk to some extent.

Case Scenario 70.2

Patient:
38-year-old male

Chief Complaint:
"My old veneers are black by the gums."

Background Information:
The patient has an ASA 1, a high smile, and a normal tissue biotype. Preexisting veneers on central incisors had black stains underneath the margins. Pocket depths are within normal limits, there is no bleeding on probing, and the patient practices good oral hygiene.

Current Findings:
Existing veneers had black color stains under the margins, which appeared to be well sealed. Stains are likely secondary to the use of ferric-sulfate hemostatic agents during the previous preparations, impressions, or delivery. No caries were detected, margins were equigingival, and the gingiva is healthy.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Restorative margins in the aesthetic zone should be placed as deep as possible to avoid aesthetic issues with stained margins. A. True B. False	**Answer: B** **Explanation:** False. Modern all-porcelain materials allow margins to be placed equigingival or at most 0.5 mm subgingival. Deeper margins will increase the risk for recession and make it difficult to properly isolate the area from moisture during bonding.
2. What does the first cord rest on when it is placed into the bottom of the socket? A. Connective tissue attachment B. Junctional epithelium C. Sulcular epithelium	**Answer: B** **Explanation:** The junctional epithelium lies at the base of the sulcus. It is 1 mm thick on average. It must be treated with care to avoid damage during cord placement, cementation, and probing.
3. Soft-tissue recession can be caused by trauma resulting from, for example, surgery, aggressive probing, aggressive cord placement, and aggressive root instrumentation. Periodontal tissues with which of the following characteristics are most at risk for recession? A. Stippling of the gingiva B. Blunted papilla C. Thin biotype D. Pocket depths of less than 2 mm	**Answer: C** **Explanation:** Thin biotype. Thin biotypes are more susceptible to recession due to manipulation or trauma. Extreme care must be exercised.
