CHAPTER 71

Multidisciplinary Versus Interdisciplinary Approaches to Dental and Periodontal Problems

Dennis P. Tarnow, Mitchell J. Bloom

CHAPTER OUTLINE

Educational Trends Toward Multidisciplinary Specialist Education in Implant Treatment

The Future

Traditionally, periodontal treatment has been delivered using an *interdisciplinary* model of therapy, with general dentists and specialists each providing their respective aspects of care to the same patients according to a comprehensive plan of therapy (Figs. 71.1 to 71.22). Conversely, a *multidisciplinary* approach is centered on a single provider delivering care across a range of dentistry disciplines. This practitioner can be a general dentist or a specialist, as traditional modes of practice have evolved and in some aspects look quite different from the classic model. The interdisciplinary system has worked well because the patient benefits from the best mix of talent from a "team" of dentists. Regardless of whether an interdisciplinary or multidisciplinary approach is utilized, it is critical for primary providers to have a thorough understanding of the signs, symptoms, local and systemic risk factors, and pathophysiology of disease processes as they relate to periodontal and dental implant therapy. Additionally, they must possess a strong working knowledge of the range of treatment options available along with their respective indications, contraindications, benefits, and liabilities to effectively formulate a proper treatment plan. At this point the dentist can then decide whether he or she has the requisite knowledge, expertise, and experience to meet the patient's needs to proceed in a multidisciplinary fashion or should refer the patient to a specialist for care at a more advanced level.

FIG. 71.1 Complex interdisciplinary implant care scenario. Extraoral preoperative condition. Aesthetic compromise is evident in this challenging treatment

scenario where there is significant gingival display.

FIG. 71.2 Intraoral preoperative condition. A concave soft-tissue profile that contributes to a dark shadow and aesthetic compromise is evident bilaterally *(arrows).*

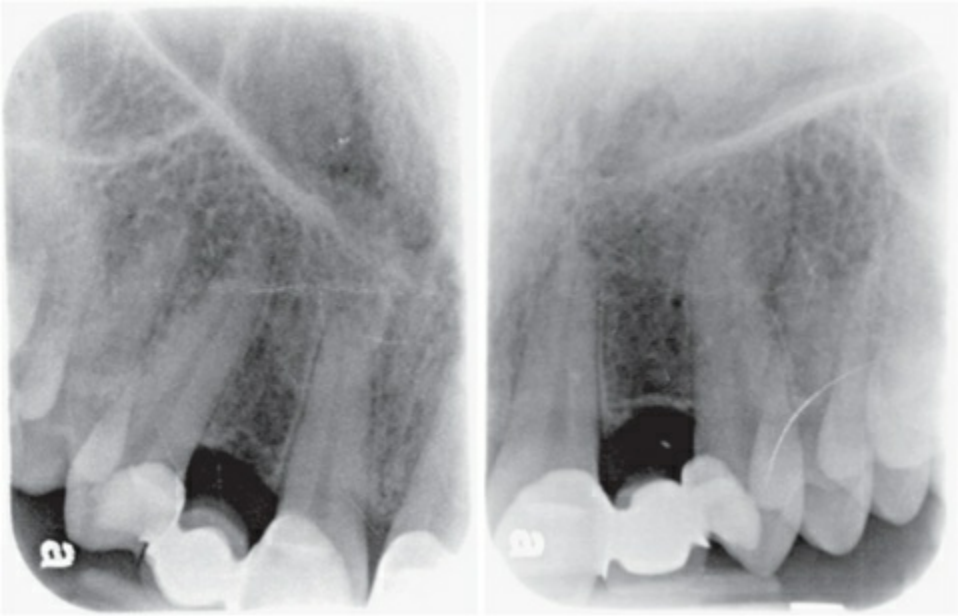

FIG. 71.3 Preoperative radiographs. The roots of adjacent teeth do not converge to interfere with proper orientation of the positions of the planned dental implants. However, there is limited space between the adjacent tooth roots.

FIG. 71.4 Intraoral preoperative clinical view. Soft-tissue contours as seen with the existing restorations removed.

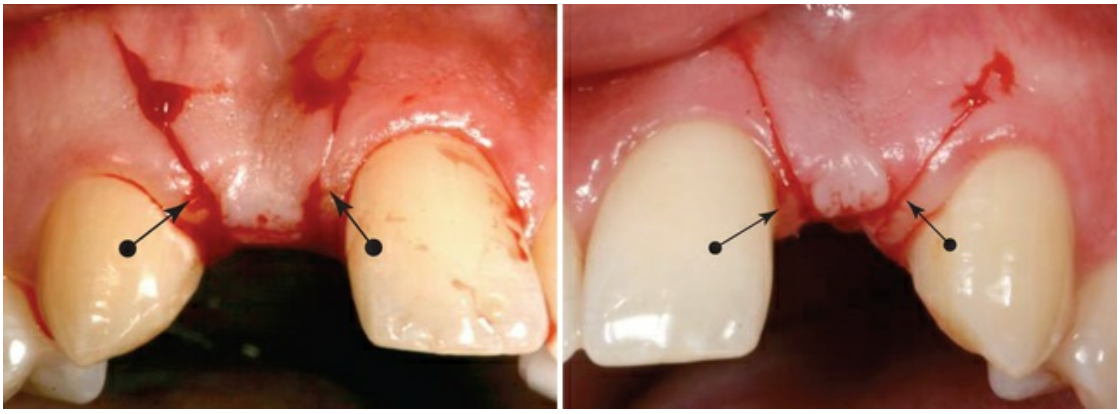

FIG. 71.5 Implant surgery. Initial incisions using a papilla-sparing technique to minimize disturbing the healthy supracrestal attachment on the surfaces of the adjacent teeth.

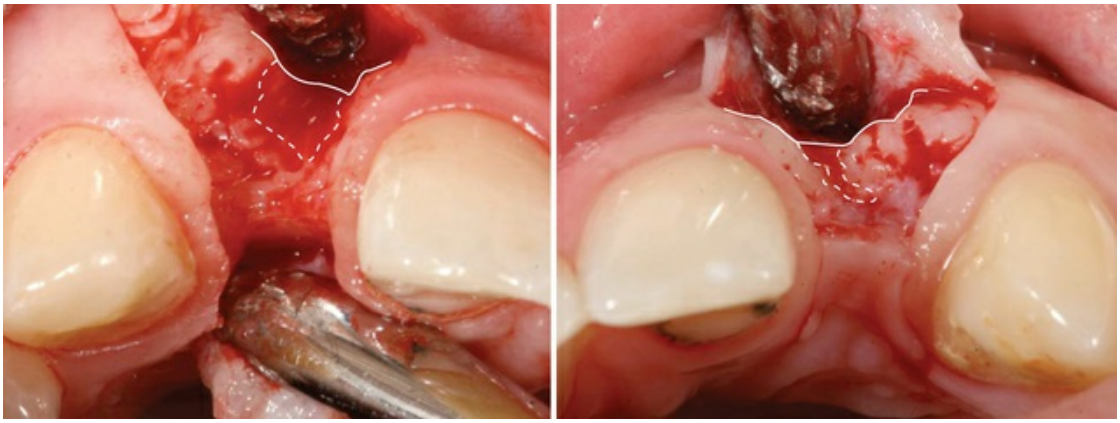

FIG. 71.6 Intraoperative clinical view. Edentulous right and left treatment areas both show concave bony defects labially.

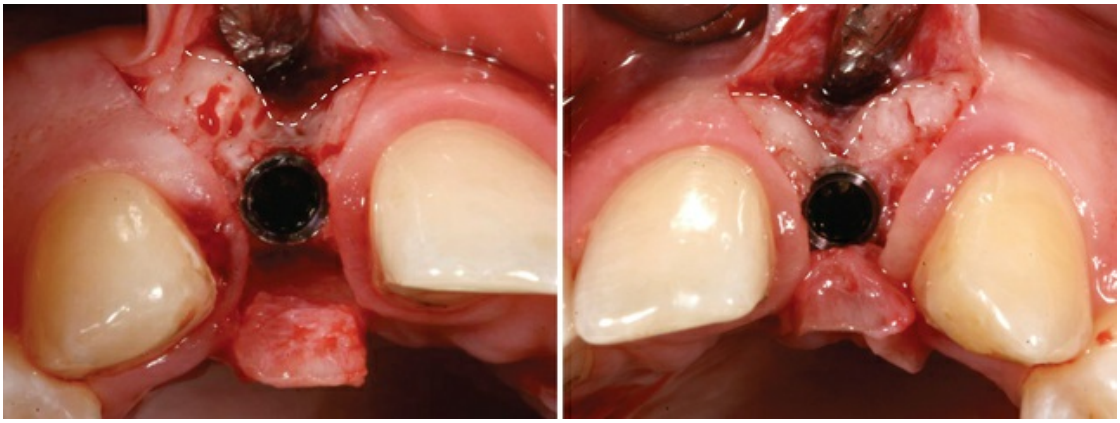

FIG. 71.7 Intraoperative clinical view. Implants placed in a prosthetically guided orientation that is palatal to the buccal depression.

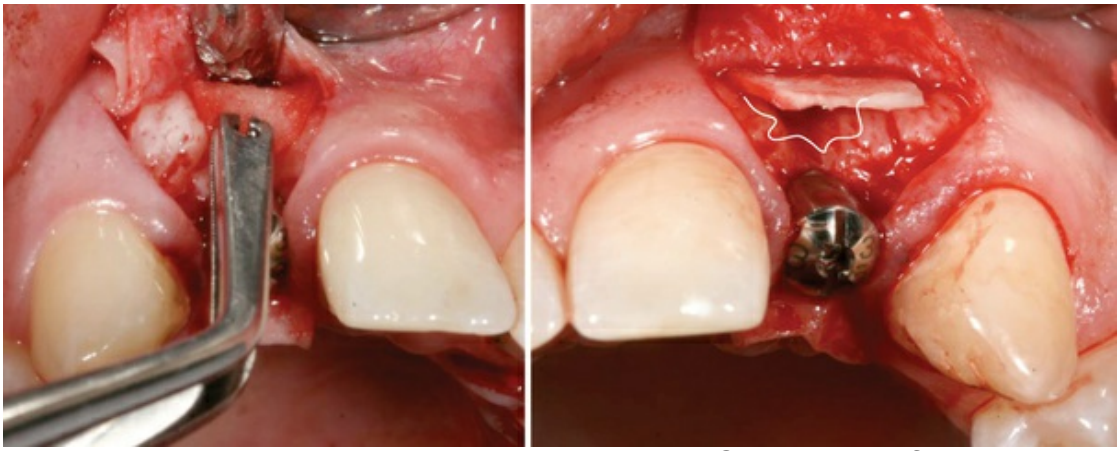

FIG. 71.8 Intraoperative clinical view. Correction of bony defects using guided bone regeneration technique. Resorbable barrier membranes are shown in position after being trimmed to a suitable shape and fitted in place.

FIG. 71.9 Intraoperative clinical view. A particulate bone graft material is placed and shaped to fill the bony depression under the previously fitted membrane.

FIG. 71.10 Implant healing abutments, which act to facilitate coronal and labial positioning of the soft-tissue flap, were previously placed. This will work in conjunction with the augmentation procedure to correct the preoperative soft-tissue concavity.

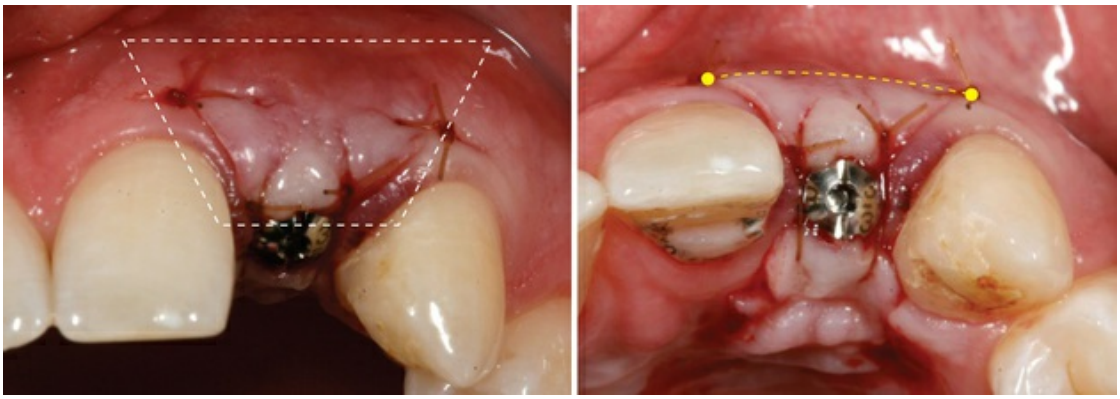

FIG. 71.11 Convex ridge shape after augmentation is shown after completion of the surgical procedure.

FIG. 71.12 The gingival third of the provisional restoration has been reduced so it does not impinge on the surgical site. The vertical position of the soft-tissue height on completion of the surgery is favorable as compared with that of the adjacent natural teeth.

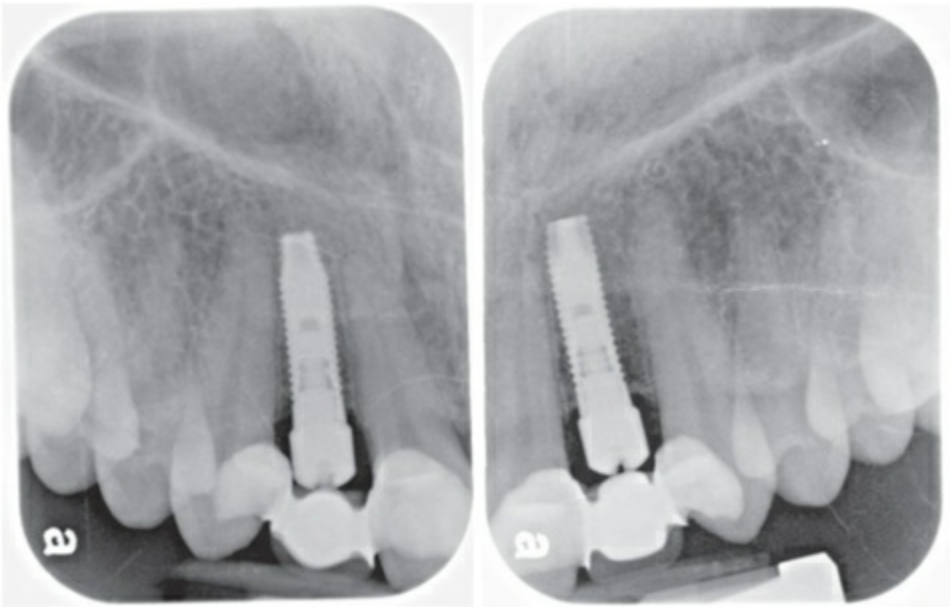

FIG. 71.13 Postoperative radiograph. The dental implants are in good position. Given the amount of available space between the adjacent tooth roots, a narrow-diameter implant was selected as part of the treatment plan to yield a biologically and prosthetically favorable result.

FIG. 71.14 Postoperative clinical view at 1 week after surgery. The soft tissue is healing well. Note the favorable soft-tissue response where the papillae were not disturbed using a conservative incision design.

FIG. 71.15 Postoperative clinical view 3 months after surgery. The soft tissues have healed favorably with maintenance of the free gingival margin position situated to yield a prosthetic clinical crown of appropriate length.

FIG. 71.16 Screw-retained single provisional crowns inserted and connected to the dental implants to begin nonsurgical sculpting of the peri-implant soft tissue.

FIG. 71.17 The peri-implant soft tissue is sculpted three-dimensionally to represent the cross section of the natural tooth being replaced to create a more natural appearance in the final restoration than possible with prefabricated round healing abutments.

FIG. 71.18 Peri-implant soft tissue after nonsurgical sculpting. Notice the early stages of papillae reforming in the spaces between the natural teeth and dental implants.

FIG. 71.19 Custom abutments in place on the dental implants. Gold plating of the custom abutments was done to impart a hue to the peri-implant sulcus and soft tissue to optimize the aesthetic outcome.

FIG. 71.20 Final crowns are seen here on the date of insertion. The crown contours dictate the gingival contours.

FIG. 71.21 Radiograph following final crown insertion. Note the customized emergence profile of the prosthetic components on the dental implants.

FIG. 71.22 Final aesthetic outcome from both an intraoral and extraoral perspective.

Many of the early innovators in the field of implant dentistry were general practitioners. Subsequently, their early accomplishments were built on using rigid and narrowly defined surgical and prosthetic protocols whose effectiveness and predictability were supported by well-documented long-term research studies put forth by Dr. P.I. Brånemark. His namesake implant design, when used precisely as directed with respect to case type and patient selection, strict surgical protocols, specialized

armamentarium, and a narrow range of treatment options, made it possible for clinicians to achieve highly predictable treatment outcomes. The initial offering of training in the Brånemark method was limited only to specialist prosthodontists and oral surgeons, the former group focusing on the restorative aspect of care and the latter group on the surgical phase of therapy. However, as implant dentistry continued to evolve, periodontists became increasingly more active in the field, ultimately sharing the same role and stature as their oral surgeon colleagues in this arena. The same was true for many general practitioners with respect to their prosthodontist colleagues in terms of delivering implant restorative care.

The range of indications for the use of dental implants expanded beyond the limited mandibular full arch case type Brånemark initially taught to include partial edentulism, single teeth, and even orthodontic and maxillofacial applications. Regenerative techniques have been developed as well to address hard- and soft-tissue deficiencies that, for many patients, had previously deemed them unsuitable candidates for dental implant therapy. Autogenous intraoral block grafting, guided bone regeneration, maxillary sinus grafting, transposition of the inferior alveolar nerve, ridge splitting, distraction osteogenesis, and biologics are among the many strategies that have emerged to overcome limitations for less-than-optimal sites.

Early implant designs and materials were subject to limitations and even prone to problems. Those with machined surfaces suffered from a significantly higher failure rate in sites with poor-quality bone, whereas those with rough surfaces, coupled with other design flaws, were prone to late failure resulting from inflammatory peri-implant disease or prosthetic complications. With all of these variables in play and emerging so rapidly during the formative years, implant dentistry was relegated largely to the specialty care arena. Through innovative implant designs, advances in material science, opportunities for simplified surgical techniques, digital planning and manufacturing technologies, systematic treatment protocols, and better data to appreciate success and risk factors, predictable outcomes have become readily achievable. The widespread emergence and acceptance of implant dentistry and the

fact that it is both a surgical and prosthetic modality puts it at the center of many of the trends transforming traditional practice models.

Periodontology, like other specialties, has evolved to embrace a more global view of patient care. It is suggested that in addition to learning all of the standard periodontal procedures of the past, the contemporary periodontist should also be able to *restore* simple implant cases such as those located outside of the aesthetic zone (Figs. 71.23 to 71.32). Periodontists will continue to be trained to manage hard and soft tissues and perform all of the latest periodontal plastic surgical procedures to preserve and reconstruct pleasing gingival architecture in the aesthetic zone to the highest level of sophistication and complexity. However, as the definition of what is deemed a successful outcome continues to evolve and the bar for the definition is raised, the surgeon must remain acutely aware of the restorative aspects of care and abreast of related advances. In other words, it has become essential that periodontists not limit their knowledge and care to the treatment of periodontal disease alone.

FIG. 71.23 Multidisciplinary simple implant care scenario: favorable soft-tissue parameters combined with a low smile line. Preoperative view of the maxillary right first premolar. With the exception of a small degree of gingival recession, all other aspects of the surrounding periodontium are intact.

FIG. 71.24 A fracture extending in a mesiodistal orientation is evident on the occlusal surface of the maxillary first premolar.

FIG. 71.25 Healed ridge 3 months after tooth extraction. Note the wide zone of keratinized tissue present and favorable maintenance of the height of the adjacent interdental papillae.

FIG. 71.26 The healed ridge demonstrates favorable buccolingual dimension and soft-tissue quality. Based on preoperative clinical and radiographic evaluation, placement of a dental implant in an uncomplicated fashion can be expected.

FIG. 71.27 Surgical access for placement of the dental implant using a horizontal incision that extends intrasulcularly to the nearest buccal and palatal line angles of the adjacent teeth.

FIG. 71.28 The endosseous implant is properly positioned to facilitate an optimal prosthetic outcome in the final restoration.

FIG. 71.29 After a period of healing during which the implant was submerged, stage II surgery to expose it was accomplished. In this scenario, a fixed provisional restoration was secured to the implant to serve as a matrix and begin sculpting the resultant soft-tissue profile in lieu of using a conventional nonanatomic round healing abutment. Note the position of the flap margin on the prosthetic crown. It is located occlusal to the expected cementoenamel junction (CEJ) location to compensate for expected soft-tissue healing and remodeling and yield a favorable aesthetic outcome.

FIG. 71.30 The healed peri-implant sulcus demonstrates the three-dimensionally generated result achieved using a provisional crown for soft-tissue sculpting. Note the recreation of the interdental papilla, the result of a favorable relationship between the interproximal bone height of the adjacent teeth and reestablishment of contact areas between the natural teeth and the provisional restoration.

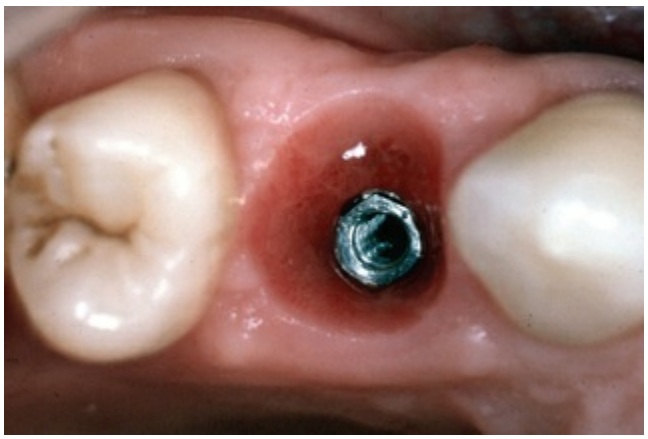

FIG. 71.31 Occlusal view of the anatomic peri-implant sulcus formed by the contours of the provisional restoration subgingivally.

FIG. 71.32 Final implant-supported restoration in place.

Surgical specialists (i.e., periodontists) who are trained according to a multidisciplinary approach will provide even greater benefit to their patients from this evolved philosophy. Consider the case for immediate dental implant placement along with simultaneous fabrication and insertion of a provisional restoration at the time of tooth extraction. This treatment is a series of steps that integrates both surgical and restorative areas of dentistry. As such, suitable depth of knowledge in all phases is needed to allow for proper diagnosis, case selection, and clinical delivery of care for predictable outcomes and to yield the wide range of benefits this treatment offers to both the patient and the doctor. Even when the role of implant surgeons is limited to the surgical phase of therapy, achieving the best and most predictable outcomes requires that they possess a thorough understanding of the realities and intricacies related to the fabrication and delivery of the planned prosthesis. This "restorative" knowledge and experience will help them to place implants in as close to ideal orientation in all three spatial dimensions and to avoid such common errors as excessive implant angulation by understanding the restorative challenges that may otherwise result. Additionally, the well-versed periodontist will be better able to communicate effectively with restorative colleagues and may even serve as a resource to guide and educate those who might have less familiarity with the subject matter when an interdisciplinary approach is utilized.

Educational Trends Toward Multidisciplinary Specialist Education in Implant Treatment

For the multidisciplinary model of practice to be able to deliver care at the level presently available through the interdisciplinary model, the provider (general practitioner or specialist) needs to be comprehensively trained with a broader scope and depth of expertise than typical contemporary norms often deliver. This is reflected in the many changes and opportunities in continuing and postgraduate training, particularly those centered on the surgical aspects of dental implant therapy.

Continuing education offerings span a broad range. Some are limited to didactic teaching with laboratory simulation, whereas others take the form of clinical fellowship-style programs that encompass a patient care component lasting a year or longer. As such, some general practitioners and traditionally trained prosthodontists who have sought out advanced postgraduate training might add some aspects of surgical care (commensurate with the scope and level of their respective training) to the range of services they personally provide. Conversely, members of the surgical specialties (e.g., periodontists and oral surgeons) would have received a level of training that would enable them to recommend, guide, and, if necessary, provide a range of restorative treatments. Indeed, rigidly defined accreditation standards for some postgraduate specialties have already been revised and reflect this trend toward encouraging multidisciplinary training. Traditional nonsurgical restorative training programs now include basic implant surgical training in their curricula. Advanced education specialty programs in prosthodontics, among other topics, now include an increased allocation of time in their didactic and clinical curricula in the area of diagnosis, as well as training to the level of competency with respect to simple single-tooth implants in healed ridges of favorable dimension and in sites outside the aesthetic zone.

The Future

It has already become the accepted norm that not all surgery will be done by a periodontist or oral surgeon, nor is it likely that all restorative work will be done by a general dentist or prosthodontist. Instead, simple cases that require surgery and restoration will probably be performed entirely by either a well-trained general dentist or a specialist. In fact, many periodontists have already begun working with their restorative colleagues by making the final impression or index of the implant at the time of surgery and forwarding it to them. In such a scenario, the restorative dentist may now only need to insert the final restoration when it comes back from the laboratory, thus expediting treatment and enhancing the experience for both the patient and the doctor. Although it is conceivable that simple implant cases will more likely be treated in a multidisciplinary fashion, an interdisciplinary approach will still exist and be utilized for patients who require advanced treatments, particularly when there is a deficiency of soft and/or hard tissues.

Periodontists of the future will have a multidisciplinary approach to patient care. They will continue to provide all of the specialty services that "classically" trained periodontists have done for decades, but they will also be well suited to better support their restorative colleagues.

SECTION VII

Supportive Care and Results of Periodontal Treatment

OUTLINE

Chapter 72 Supportive Periodontal Treatment
Chapter 73 Results of Periodontal Treatment

CHAPTER 72

Supportive Periodontal Treatment

Robert L. Merin

CHAPTER OUTLINE

Rationale for Supportive Periodontal Treatment
Maintenance Program
Classification of Posttreatment Patients and Risk Assessment
Referral of Patients to the Periodontist
Tests for Disease Activity
Conclusion

Preservation of the periodontal health of the treated patient requires a supportive program that is just as important as the therapy used to treat the periodontal disease. After phase I therapy has be4en completed, patients are placed on a schedule of periodic

recall visits for maintenance care to prevent the recurrence of the disease (Figs. 72.1 and 72.2).

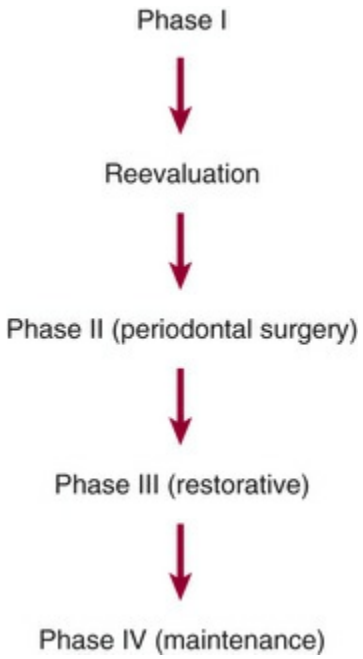

FIG. 72.1 Incorrect sequence of periodontal treatment phases. Maintenance phase should be started immediately after the reevaluation of phase I therapy.

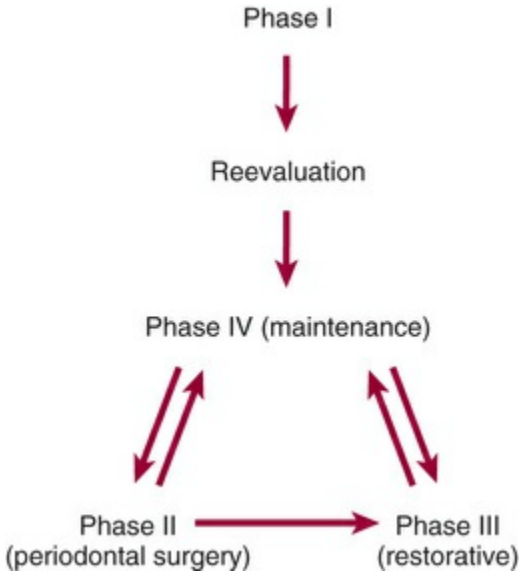

FIG. 72.2 Correct sequence of periodontal treatment phases.

Learning Box 72.1

The long-term preservation of the dentition is closely associated with the frequency and quality of recall maintenance.

Transfer of the patient from active treatment status to a maintenance program is a definitive step in total patient care that requires time and effort on the part of the dentist and staff. Patients must understand the purpose of the maintenance program, and the dentist must emphasize that preservation of the teeth depends on maintenance therapy.[5] Patients who are not maintained in a supervised recall program subsequent to active treatment show obvious signs of recurrent periodontitis (e.g., increased pocket depth, bone loss, or tooth loss).[6,7,11,12,16,17,37] The more often patients present for recommended supportive periodontal treatment (SPT), the less likely they are to lose teeth.[17,28,34,37,40,54,61] One study indicated that treated patients who do not return for regular recall have a 5.6 times greater risk for tooth loss than compliant patients.[12] Another study showed that patients with inadequate SPT after successful regenerative therapy have a 50-fold increase in risk of probing attachment loss compared with those who have regular recall visits.[15]

Learning Box 72.2

Patients who do not return for SPT lose five to six times more teeth than compliant patients,

Motivational techniques and reinforcement of the importance of the maintenance phase of treatment should be considered before performing definitive periodontal surgery.[7] Studies show that few patients display complete compliance with recommended maintenance schedules[1,33,34,38,39,59,61] (Fig. 72.3). *It is meaningless simply to inform patients that they are to return for periodic recall visits without clearly explaining the significance of these visits and describing what is expected of patients between visits.*

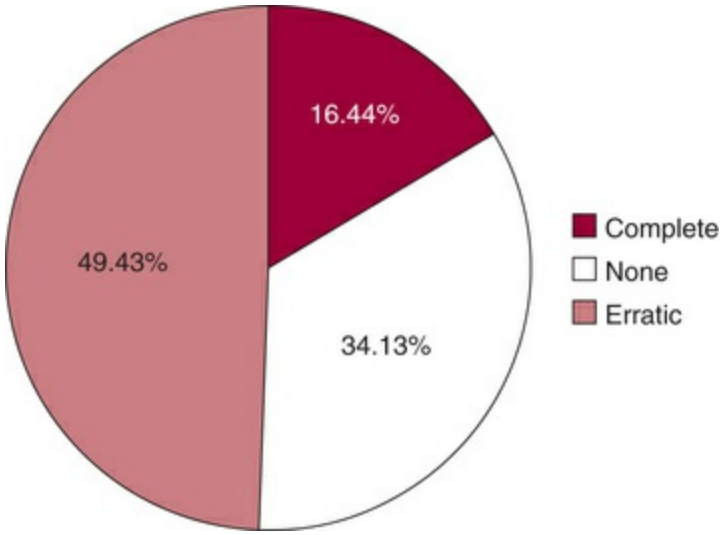

FIG. 72.3 Compliance with maintenance therapy in 961 patients studied for 1 to 8 years. (Modified from Wilson TG Jr, Glover ME, Schoen J, et al: Compliance with maintenance therapy in a private periodontal practice. *J Periodontol* 55:468, 1984.)

The maintenance phase of periodontal treatment starts immediately after the completion of phase I therapy (see Figs. 72.1 and 72.2). While the patient is in the maintenance phase, the necessary surgical and restorative procedures are performed. This ensures that all areas of the mouth retain the degree of health attained after phase I therapy.

Rationale for Supportive Periodontal Treatment

Studies indicate that even with appropriate periodontal therapy, some progression of disease is possible.[23,25,41,44,46,53,62] One likely explanation for the recurrence of periodontal disease is incomplete subgingival plaque/biofilm and calculus removal.[56,62] If subgingival biofilm is left behind during scaling, it regrows within the pocket. The regrowth of subgingival biofilm is a slow process compared with that of supragingival biofilm. During this period (perhaps months), the subgingival biofilm may not induce inflammatory reactions that can be discerned at the gingival margin. The clinical diagnosis may be further confused by the introduction of adequate supragingival biofilm control because the inflammatory reactions caused by the biofilm in the soft-tissue wall of the pocket are not

likely to manifest clinically as gingival erythema and edema.[18] Thus inadequate subgingival biofilm control can lead to continued loss of attachment, even without the presence of clinical gingival inflammation. Scaling and root planing are generally not effective at sites with probing depths of 6 mm or greater.[5]

Bacteria are present in the gingival tissues in chronic and aggressive periodontitis cases.[9,14,19,43] Eradication of intragingival microorganisms may be necessary for a stable periodontal result.[19] Scaling, root planing, and even flap surgery may not eliminate intragingival bacteria in some areas.[9] These bacteria may recolonize the pocket and cause recurrent disease.

Bacteria associated with periodontitis can be transmitted between spouses and other family members.[2,55] Patients who appear to be successfully treated can become infected or reinfected with potential pathogens. This is especially likely in patients with remaining pockets.

Another possible explanation for the recurrence of periodontal disease is the microscopic nature of the dentogingival unit healing after periodontal treatment. Histologic studies have indicated that after periodontal procedures, tissues usually heal by the formation a long junctional epithelium instead of new connective tissue attachment to root surfaces.[10,49,50] It has been speculated that this type of dentogingival unit may be weaker and that inflammation may rapidly separate the long junctional epithelium from the tooth. Thus treated periodontal patients may be predisposed to recurrent pocket formation if maintenance care is not optimal.

Subgingival scaling alters the microflora of periodontal pockets.[35,42,47] In one study, a single session of scaling and root planing in patients with chronic periodontitis resulted in significant changes in subgingival microflora.[35] Reported alterations included a decrease in the proportion of motile rods for 1 week, a marked elevation in the proportion of coccoid cells for 21 days, and a marked reduction in the proportion of spirochetes for 7 weeks.

Although pocket debridement suppresses components of the subgingival microflora associated with periodontitis, periodontal pathogens may return to baseline levels within days or months.[3,46] The return of pathogens to pretreatment levels generally occurs in approximately 9 to 11 weeks but can vary dramatically among

patients.[3]

Learning Box 72.3

Scaling and root planing are generally not effective at sites with probing depths of 6 mm or greater.

Both the mechanical debridement performed by the therapist and the motivational environment provided by the appointment seem to be necessary for good maintenance results. Patients tend to reduce their oral hygiene efforts between appointments.[4,61] Knowing that their hygiene will be evaluated motivates them to perform better oral hygiene in anticipation of the appointment.

In one study, the proportion of spirochetes obtained in baseline samples of subgingival flora was highly correlated with clinical periodontal deterioration over 1 year.[31] However, subsequent reports in the same longitudinal study concluded that the arbitrary assignment of treated periodontitis patients to 3-month maintenance intervals appears to be as effective in preventing recurrences of periodontitis as assignment of recall intervals based on microscopic monitoring of the subgingival flora.[30,31] Microscopic monitoring was found not to be a reliable predictor of future periodontal destruction in patients on 3-month recall programs, presumably because of the alteration of subgingival flora produced by subgingival instrumentation.

In conclusion, there is a sound scientific basis for recall maintenance because subgingival scaling alters the pocket microflora for variable but relatively long periods.

Maintenance Program

Periodic recall visits form the foundation of a meaningful long-term prevention program. The interval between visits is initially set at 3 months but may vary according to the patient's needs.[5,20,26,27]

Periodontal care at each recall visit comprises three parts (Box 72.1). The first part involves examination and evaluation of the patient's current oral health. The second part includes the necessary

maintenance treatment and oral hygiene reinforcement. The third part involves scheduling the patient for the next recall appointment, additional periodontal treatment, or restorative dental procedures. The time required for a recall visit for patients with multiple teeth in both arches is approximately 1 hour.[45]

Box 72.1

Maintenance Recall Procedures

Part I: Examination

(Approximate time: 14 minutes)
Patient greeting
Medical history changes
Oral pathologic examination
Oral hygiene status
Gingival changes
Pocket depth changes
Mobility changes
Occlusal changes
Dental caries
Restorative, prosthetic, and implant status

Part II: Treatment

(Approximate time: 36 minutes)
Oral hygiene reinforcement
Scaling
Polishing
Chemical irrigation or site-specific antimicrobial placement

Part III: Report, Cleanup, and Scheduling

(Approximate time: 10 minutes)
Write report in chart.
Discuss report with patient.

Clean and disinfect operatory.
Schedule next recall visit.
Schedule further periodontal treatment.
Schedule or refer for restorative or prosthetic treatment.

Learning Box 72.4

There are three parts to an SPT appointment: (1) examination; (2) treatment; and (3) report, cleanup, and scheduling.

Examination and Evaluation

The recall examination is similar to the initial evaluation of the patient (see Chapter 32). However, because the patient is not new to the office, the dentist or hygienist primarily looks for changes that have occurred since the last evaluation. Analysis of the current oral hygiene status of the patient is essential. Updating of changes in the medical history and evaluation of restorations, caries, prostheses, occlusion, tooth mobility, gingival status, and periodontal and periimplant probing depths are important parts of the recall appointment. The oral mucosa should be carefully inspected for pathologic conditions (Figs. 72.4 to 72.9).

FIG. 72.4 (A) Hyperplastic gingivitis related to crown margins and plaque accumulation in a 27-year-old woman. (B) Four months after treatment, there is significant improvement. However, some inflammation around crown margins still exists, which cannot be resolved without replacing the crowns.

FIG. 72.5 (A) Patient was 38 years old when these original radiographs were taken and was treated with a combination of surgical and nonsurgical therapy. This

individual is a classic class C maintenance patient. (B) Pretreatment photograph. Note the inflammation and heavy calculus deposits. (C) Photograph taken 10 years after treatment. (D) Radiographs taken 5 years after treatment. (E) Radiographs taken 10 years after treatment. The radiographic appearance is as good as can be expected in such a severe case. Teeth #15 and #17 were extracted 8 years after treatment.

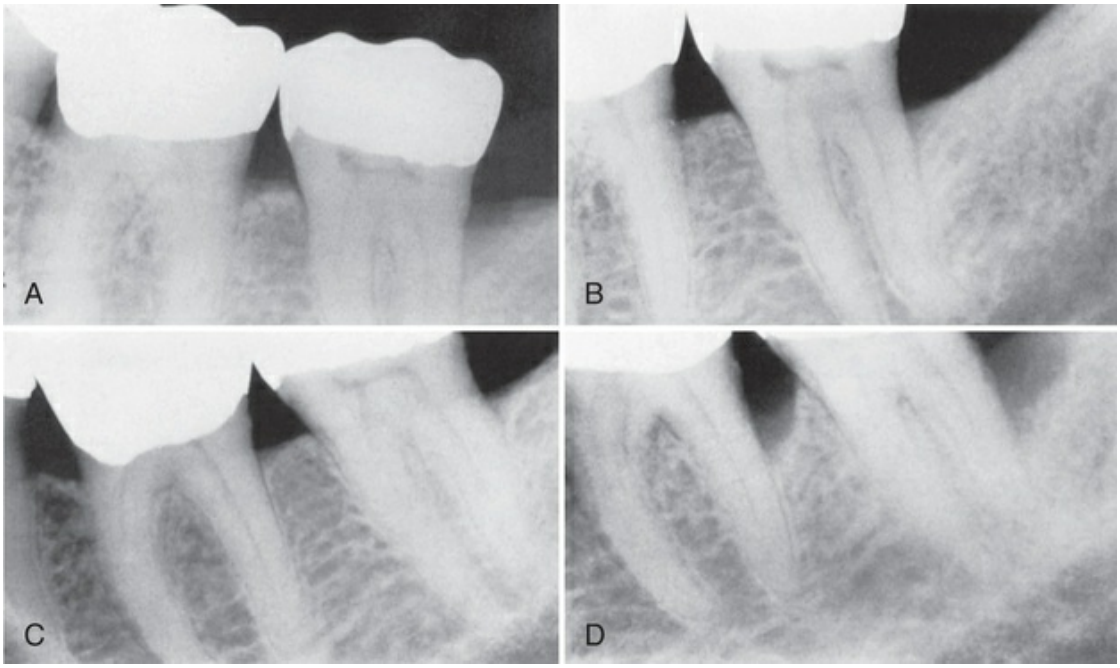

FIG. 72.6 This series of radiographs clearly shows the importance of maintenance therapy. (A) Original radiograph of a 58-year-old male. Note the deep distal bone loss on tooth #18 and the moderate distal lesion of tooth #19. Surgical treatment included osseous grafting. (B) Radiograph 14 months after surgical therapy. The patient had recall maintenance performed every 3 to 4 months. (C) Appearance 3 years after surgery, with regular recalls every 3 to 4 months. (D) Appearance after 2 years without recalls (7 years after surgery). Note the progression of the disease on the distal surfaces of teeth #18 and #19.

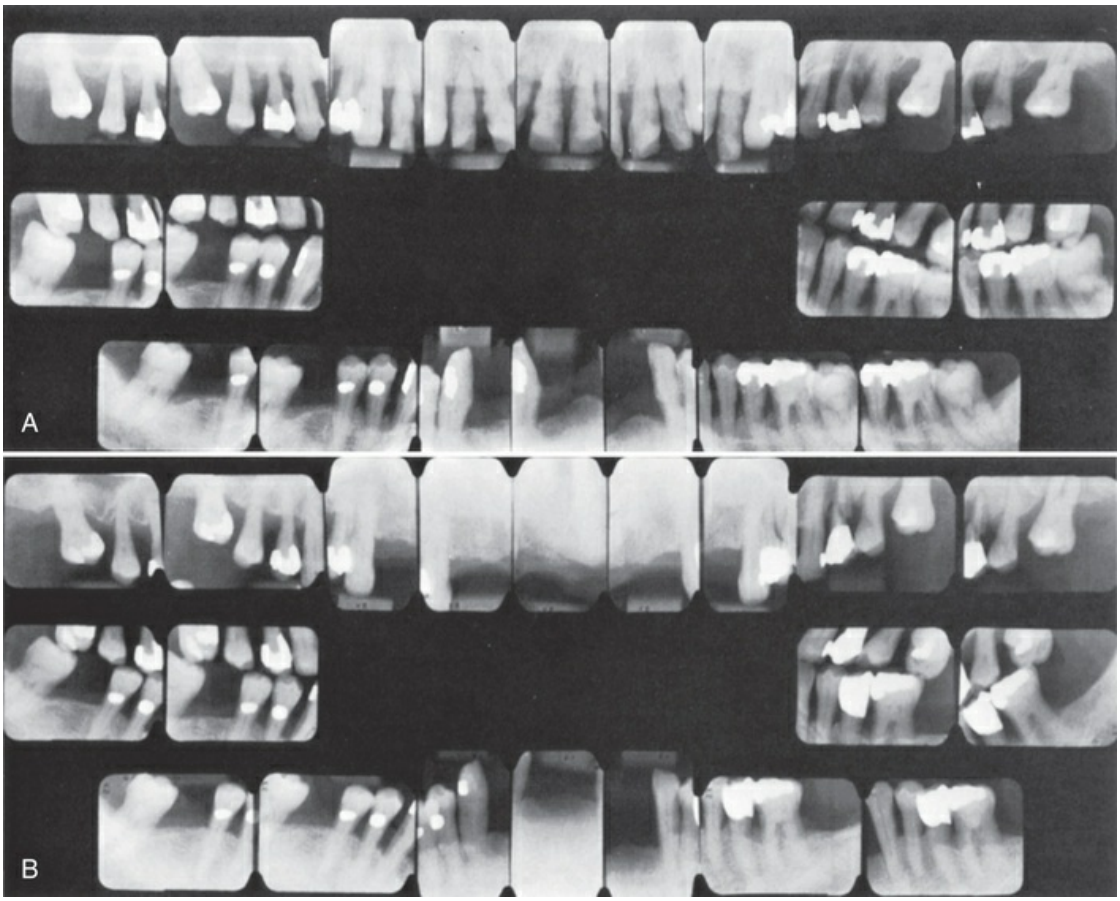

FIG. 72.7 Advanced cases sometimes do better than expected when the patient complies with maintenance therapy. (A) Initial radiographs showing an advanced case. The maxillary arch had extractions and nonsurgical treatment. A plastic partial denture was placed and was expected to grow into a full denture within a few years. The mandibular arch was treated with periodontal surgery, and a permanent, metal and plastic, removable partial denture was placed. (B) Radiographs taken 8 years later. The patient performed good oral hygiene and had 3-month recalls. Teeth #12 and #15 required extraction.

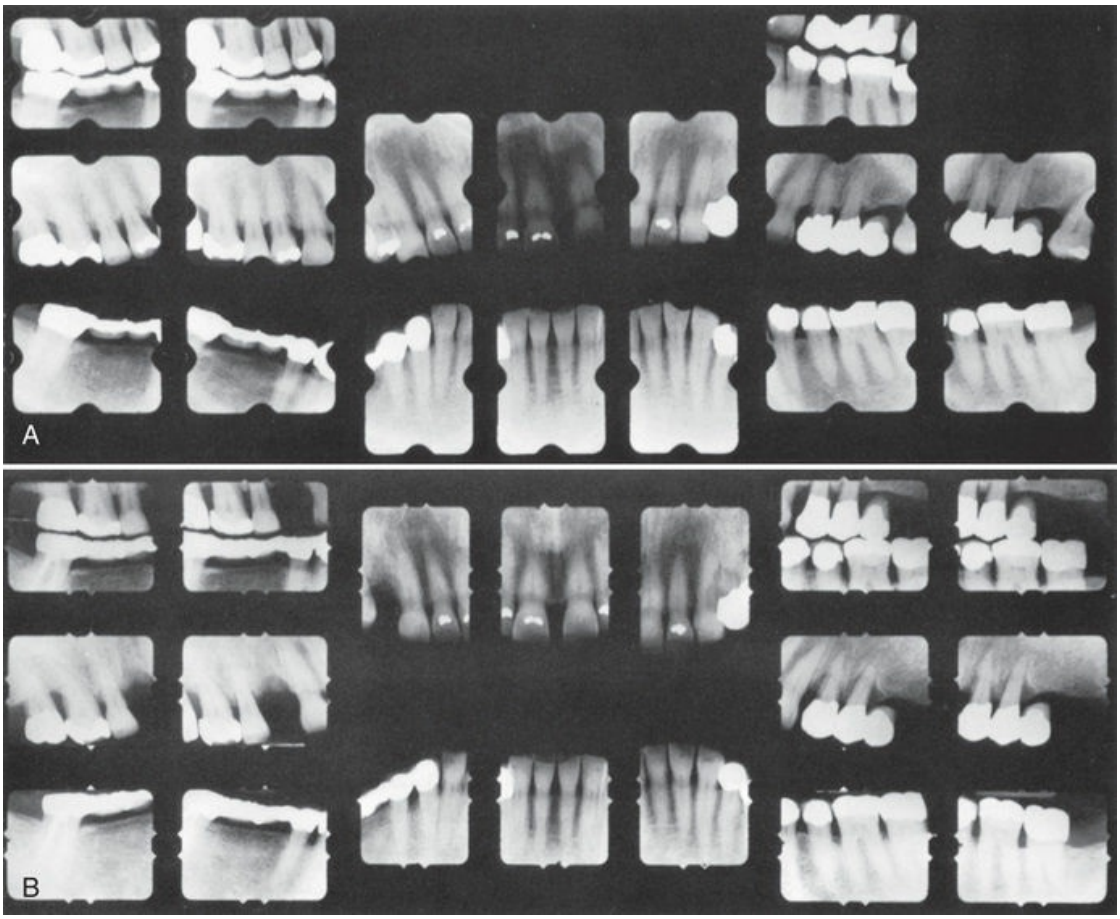

FIG. 72.8 (A) Initial radiographs. The patient was advised to have localized areas of periodontal surgery and periodontal recall every 3 months. However, the patient did not comply and only had dental cleanings once or twice yearly. (B) Radiographs 4 years later. Note the loss of teeth #5 and #15 and the increased bone loss of several premolars and molars.

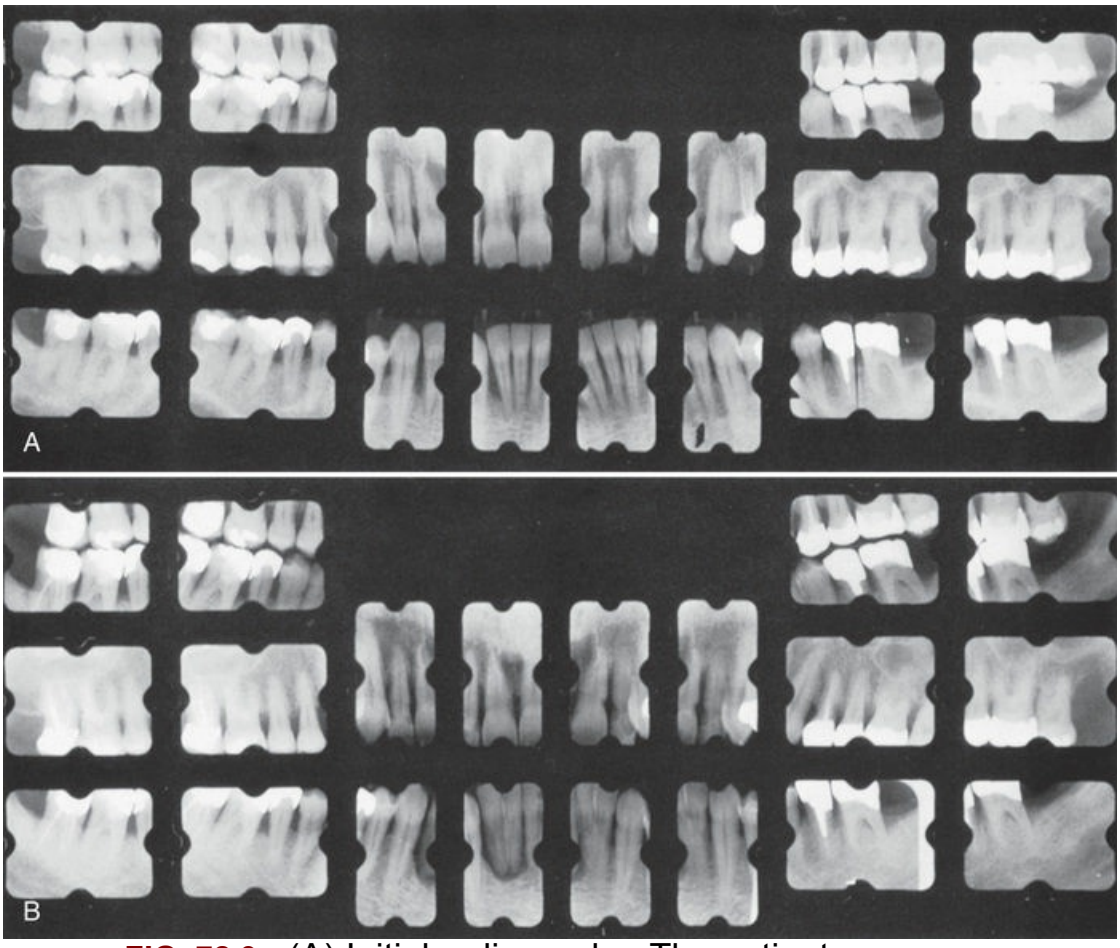

FIG. 72.9 (A) Initial radiographs. The patient was advised to have localized areas of periodontal surgery and periodontal recall every 3 months. However, the patient did not comply and had no treatment other than emergency care and occasional dental cleanings. (B) Radiographs 7 years later. Note the advanced bone loss and caries on many teeth.

Radiographic examination must be individualized,[22] depending on the initial severity of the case and the findings during the recall visit (Table 72.1). These are compared with findings on previous radiographs to check the bone height and look for repair of osseous defects, signs of trauma from occlusion, periapical pathologic changes, and caries.

TABLE 72.1

Radiographic Examination of Recall Patients for Supportive Periodontal Treatment

Patient Condition/Situation	Type of Examination

Clinical caries or high-risk factors for caries	Posterior bitewing examination at 6- to 18-month intervals
No clinical caries and no high-risk factors for caries	Posterior bitewing examination at 24- to 36-month intervals
Periodontal disease not under good control	Periapical or vertical bitewing radiographs of problem areas every 12 to 24 months
History of periodontal treatment with disease under good control	Bitewing examination every 24 to 36 months
Root form dental implants	Periapical or vertical bitewing radiographs after prosthetic placement and at 12 and 24 months, then every 24 to 36 months unless clinical problems arise
Transfer of periodontal or implant maintenance patients	Full-mouth series if a current set not available; if full-mouth series has been taken within 24 months, radiographs of implants and periodontal problem areas should be taken

Radiographs should be taken when they are likely to affect diagnosis and patient treatment. The recommendations in this table are subject to clinical judgment and may not apply to every patient.

Adapted from Guide to Patient Selection and Limiting Radiation Exposure. American Dental Association website, http://ada.org/2760/aspx, 2013.

Checking of Plaque/Biofilm Control

To assess the effectiveness of their plaque control, patients should perform their hygiene regimen immediately before the recall appointment. Plaque/biofilm control must be reviewed and corrected until the patient demonstrates the necessary proficiency, even if additional instruction sessions are required. A motivational interviewing technique of teaching may help to produce positive results.[57] Patients instructed in plaque/biofilm control have less biofilm and gingivitis than uninstructed patients,[6,51,52] and because the amount of supragingival plaque/biofilm is less, there is a decrease in the number of subgingival anaerobic organisms.[10,48]

Treatment

Following consultation, examination, consultation, and oral hygiene instruction, the required scaling and root planing are performed (see Chapter 50). Care must be taken not to instrument healthy sites with shallow sulci (1 to 3 mm deep) and an absence of gingival inflammation because studies have indicated that repeated subgingival scaling and root planing of sites not periodontally involved result in significant loss of attachment and gingival

recession, which will affect aesthetics.[29] Irrigation with antimicrobial agents or placement of site-specific antimicrobial devices may be performed in maintenance patients with remaining pockets.[3,24,32]

Recurrence of Periodontal Disease

Occasionally, lesions may recur, which is often due to inadequate plaque/biofilm control on the part of the patient or failure to comply with recommended SPT schedules. It should be understood, however, that it is the responsibility of the dentist to educate and motivate patients to improve their oral hygiene techniques. Surgery should not be undertaken unless the patient participates in disease prevention and demonstrates proficiency in plaque/biofilm control.[7,53,60]

Other causes for recurrence include the following:

1. Inadequate or insufficient treatment that has failed to remove all of the potential factors favoring biofilm accumulation (see Fig. 72.4). Incomplete calculus removal in areas of difficult access is a common source of problems.
2. Inadequate restorations placed after the periodontal treatment was completed.
3. Failure of the patient to return for periodic maintenance care (see Fig. 72.6). This may be a result of the patient's conscious or unconscious decision not to continue treatment or the failure of the dentist and staff to emphasize the need for periodic supportive therapy.
4. Presence of some systemic diseases that may affect host resistance to previously acceptable levels of biofilm.

A failing case can be recognized by the following:

1. Recurring inflammation revealed by gingival changes and bleeding of the sulcus on probing.
2. Increasing depth of sulci, leading to the recurrence of pocket formation.
3. Gradual increases in bone loss, as determined by

radiographs.

4. Gradual increases in tooth mobility, as ascertained by clinical examination.

The decision to retreat a periodontal patient should not be made at the preventive maintenance appointment but should be postponed for 1 to 2 weeks.[11] Often, the mouth appears improved at that time because of the resolution of edema and the resulting improved tone of the gingiva. Table 72.2 summarizes the symptoms of the recurrence of periodontal disease and their probable causes.

TABLE 72.2
Symptoms and Causes of Recurrence of Disease

Symptom	Possible Causes
Increased mobility	Increased inflammation
	Poor oral hygiene
	Subgingival calculus
	Inadequate restorations
	Deteriorating or poorly designed prostheses
	Systemic disease modifying host response to plaque
Recession	Toothbrush abrasion
	Inadequate keratinized gingiva
	Frenum pull
	Orthodontic therapy
Increased mobility with no change in pocket depth and no radiographic change	Occlusal trauma caused by lateral occlusal interference, bruxism, high restoration
	Poorly designed or worn-out prosthesis
	Poor crown-to-root ratio
Increased pocket depth with no radiographic change	Poor oral hygiene
	Infrequent recall visits
	Subgingival calculus
	Poorly fitting partial denture
	Mesial inclination into edentulous space
	Failure of new attachment surgery
	Cracked teeth
	Grooves in teeth
	New periodontal disease
	Gingival overgrowth caused by medication
Increased pocket depth with increased radiographic bone loss	Poor oral hygiene
	Subgingival calculus
	Infrequent recall visits
	Inadequate or deteriorating restorations
	Poorly designed prostheses
	Inadequate surgery
	Systemic disease modifying host response to plaque

	Cracked teeth
	Grooves in teeth
	New periodontal disease

Classification of Posttreatment Patients and Risk Assessment

The first year after periodontal therapy is important in terms of indoctrinating the patient in a recall pattern and reinforcing oral hygiene techniques. In addition, it may take several months to evaluate accurately the results of some periodontal surgical procedures. Consequently, some areas may have to be retreated because the results may not be optimal. Furthermore, the first-year patient often has etiologic factors that may have been overlooked and may be amenable to treatment at this early stage. For these reasons, the recall interval for first-year patients should not be longer than 3 months.

Patients who are on a periodontal recall schedule are a varied group. Table 72.3 lists several categories of maintenance patients and a suggested recall interval for each group. Patients can improve or may relapse to a different classification, with a reduction in or exacerbation of periodontal disease. When one dental arch is more involved than the other, the patient's periodontal disease is classified by the arch with the worse condition.

TABLE 72.3

Recall Intervals for Various Classes of Recall Patients

Merin Classification	Characteristics	Recall Interval
First year	First-year patient: routine therapy and uneventful healing.	3 months
	First-year patient: difficult case with complicated prosthesis, furcation involvement, poor crown-to-root ratios, or questionable patient cooperation	1–2 months
Class A	Excellent results well maintained for 1 year or longer	6 months to 1 year
	Patient displays good oral hygiene, minimal calculus, no occlusal problems, no complicated prostheses, no remaining pockets, and no teeth with less than 50%	

	of alveolar bone remaining	
Class B	Generally good results maintained reasonably well for 1 year or more, but patient displays some of the following factors:	3–4 months (decide on a recall interval based on the number and severity of negative factors)
	1. Inconsistent or poor oral hygiene	
	2. Heavy calculus formation	
	3. Systemic disease that predisposes to periodontal breakdown	
	4. Some remaining pockets	
	5. Occlusal problems	
	6. Complicated prostheses	
	7. Ongoing orthodontic therapy	
	8. Recurrent dental caries	
	9. Some teeth with less than 50% of alveolar bone support	
	10. Smoking	
	11. Positive family history or genetic test	
	12. More than 20% of pockets bleed on probing	
Class C	Generally poor results after periodontal therapy or several negative factors from the following list:	1–3 months (decide on a recall interval based on the number and severity of negative factors; consider retreating some areas or extracting severely involved teeth)
	1. Inconsistent or poor oral hygiene	
	2. Heavy calculus formation	
	3. Systemic disease that predisposes to periodontal breakdown	
	4. Many remaining pockets	
	5. Occlusal problems	
	6. Complicated prostheses	
	7. Recurrent dental caries	
	8. Periodontal surgery indicated but not performed for medical, psychological, or financial reasons	
	9. Many teeth with less than 50% of alveolar bone support	
	10. Condition too far advanced to be improved by periodontal surgery	
	11. Smoking	
	12. Positive family history or genetic test	
	13. More than 20% of pockets bleed on probing	

Table 72.3 is a traditional method of assigning the risk of a recurrence of periodontal destruction. A practitioner uses the listed risk factors and his or her own diagnostic and prognostic gestalt to assign a risk category and maintenance schedule. New risk factor assessment tools for the prevention of periodontal destruction have been developed.[21,26,27,36] The Periodontal Risk Assessment (PRA) (Fig. 72.10) and the Periodontal Risk Calculator (PRC) have the most studies documenting their ability to predict the progression of

periodontitis and tooth loss.[26] The PRC is marketed by the PreViser Corporation and offers a web-based system for periodontal risk analysis and prognosis.[21] The PRA is offered free of charge by the Clinical Research Foundation and the University of Bern at http://www.perio-tools.com/PRA/en/index.asp. Patient data are entered into the online form, and the program automatically calculates whether the patient is at low risk, moderate risk, or high risk; an appropriate recall interval is then suggested. Fig. 72.9A is a sample assessment from the PRA website. Because the different assessment tools use different risk factors and algorithms, they will not be in complete agreement. In one study, 57 patients were assessed with the PRC and PRA.[36] The PRC classified 14 as low risk, 17 as medium risk, and 26 as high risk, whereas the PRA classified 8 as low risk, 28 as medium risk, and 21 as high risk.[36]

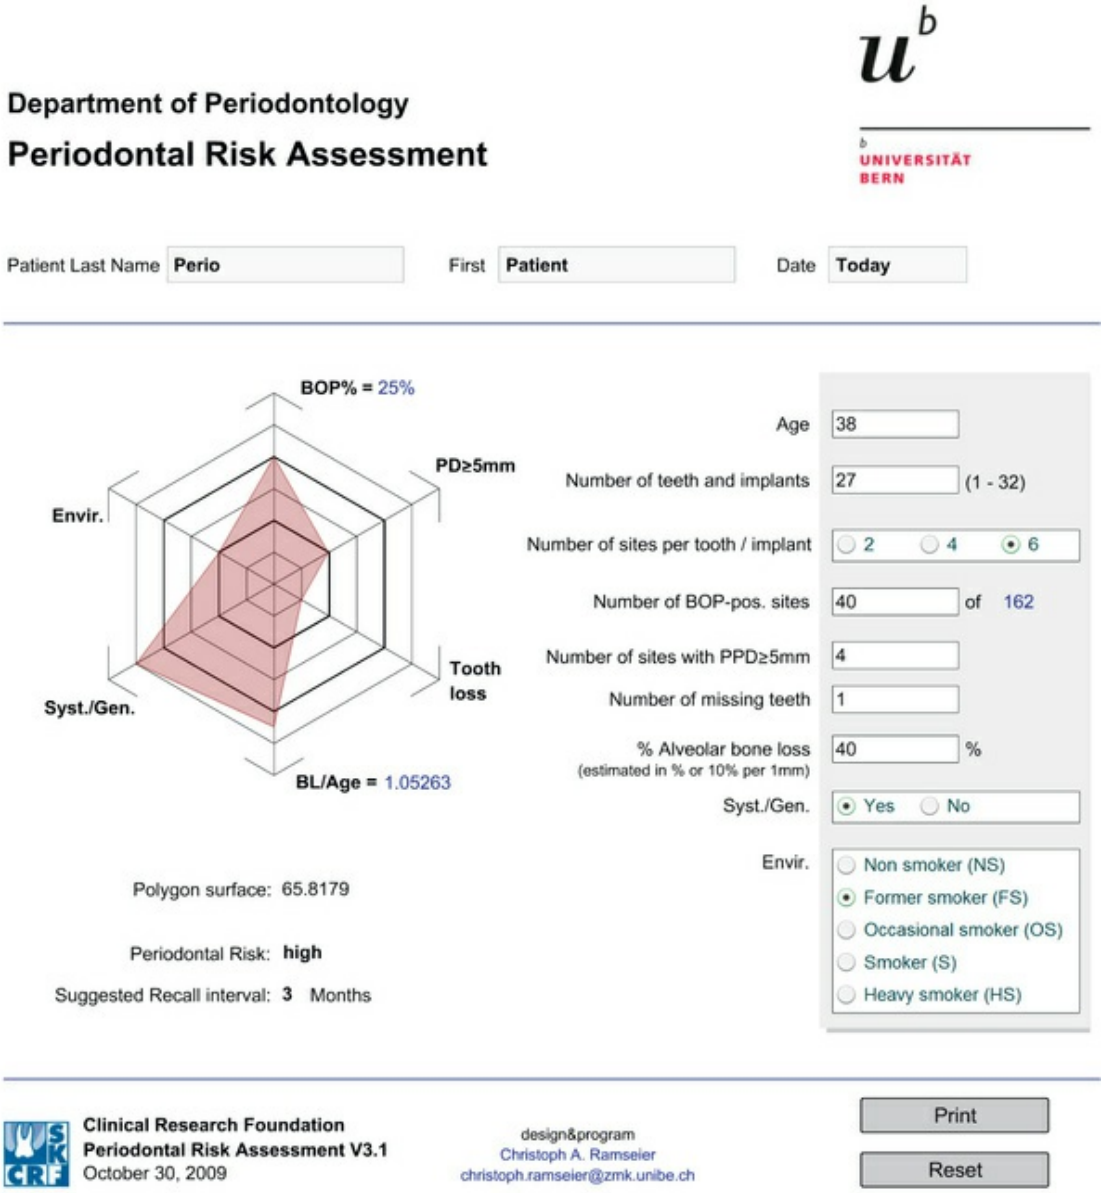

FIG. 72.10 Sample Periodontal Risk Assessment(PRA) report completed and downloaded from http://www.perio-tools.com/PRA/en/index.asp.

Currently, there is no universally accepted objective method of predicting periodontitis progression, and there has been little research to determine if the risk calculators are more accurate than good clinical judgment.[21] In summary, maintenance care is a critical phase of therapy. The long-term preservation of the dentition is closely associated with the frequency and quality of recall maintenance.

Learning Box 72.5

The therapist should use risk assessment to determine SPT frequency.

Referral of Patients to the Periodontist

A general dentist can properly manage many periodontal patients, as a greater number of people retain their teeth throughout their lifetime. Another important fact to consider is that as the proportion of older people in the population increases, more teeth will be at risk for periodontal disease. Numerous studies indicate possible links between periodontal disease and systemic diseases, such as heart disease, stroke, diabetes, and adverse pregnancy outcomes. Therefore the prevalence of patients requiring SPT is likely to increase in the future.

This expected increase in the number of periodontal patients will necessitate a greater understanding of periodontal problems and an increased level of expertise for the solution of such problems on the part of the general practitioner. General dentists must know when co-management with a periodontist is indicated. Specialists are needed to treat difficult periodontal cases, patients with systemic health problems, dental implant patients, and those with a complex prosthetic construction that requires predictable results.

The criteria for cases to be treated in the general dental office and cases to be referred to a specialist vary for different practitioners and patients. The American Academy of Periodontology has issued guidelines to help the general practitioner decide when co-management with a periodontist is indicated.[4] The diagnosis will indicate the type of periodontal treatment required. If periodontal destruction necessitates surgery on the distal surfaces of second molars, extensive osseous surgery, or complex regenerative procedures, the patient is usually best treated by a specialist. Patients who require localized nonsurgical therapy or minor flap surgery can usually be managed by the general practitioner. General dentists have a primary responsibility to do what is best in the interest of the patient. According to Christensen, quality

dentistry for a complex case requires a team effort partnering with a periodontal specialist to provide optimal care for the patient.[13]

The decision to have the general practitioner treat a patient's periodontal disease should be guided by consideration of the risk that the patient will lose a tooth or teeth due to periodontal involvement or the periodontal disease negatively affecting the patient's systemic health.

The most important factors in the decision to refer a patient to a periodontist are the severity and location of the periodontal disease. Teeth with pockets of 5 mm or more, as measured from the cementoenamel junction, may have a questionable prognosis, as do teeth with furcation invasions even when more than 50% of bone support remains. Therefore patients with strategically important teeth that have moderate to severe attachment loss or furcation invasions are usually best treated by specialists.

An important question remains: Should the maintenance phase of therapy be performed by the general practitioner or the specialist? This should be determined by the extent and severity of periodontal disease present. Class A recall patients should be maintained by the general dentist, whereas class C patients should be maintained by the specialist (see Table 72.3). Class B patients can alternate recall visits between the general practitioner and the specialist (Fig. 72.11). The suggested rule to decide who should maintain the recall therapy is determined by the initial category of the patient's disease and the result of the therapy. Patients with moderate to severe initial bone loss, advanced grades 2 or 3 furcation invasions, or pockets that could not be completely eradicated are those who should be seen by the periodontist. The specialist and the general dentist must work together, respect the other's knowledge and skills, and decide on a maintenance schedule that is in the best interest of the patient.

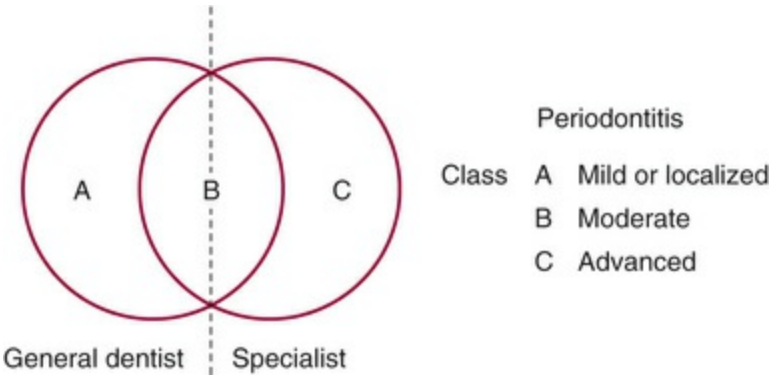

FIG. 72.11 Scheme for determining which practitioner should perform periodontal maintenance in patients with different degrees of periodontitis.

Learning Box 72.6

Quality dentistry for a complex case requires a team effort partnering with a periodontal specialist to provide optimal care for the patient.[13]

Tests for Disease Activity

Periodontal patients, even though they have received effective periodontal therapy, are at risk of disease recurrence for the remainder of their lives.[23,24] In addition, pockets in and around the furcation areas are difficult to eliminate even with surgical therapy. These areas with pockets may continue to lose attachment.[3] Comparison of sequential probing measurements, which may be facilitated by a dental practice management software, gives the most accurate indication of the rate of loss of attachment. A number of other clinical and laboratory variables have been correlated with disease activity.

No accurate method exists to predict disease activity, and clinicians rely on the information obtained from evaluating multiple risk factors.[21,25,30,58] Patients whose disease is clearly refractory are candidates for bacterial culturing and antibiotic therapy in conjunction with additional mechanical therapy.

New methods will undoubtedly be developed in the future to help predict disease activity.[3] The clinician must be able to interpret

whether a test may be useful in determining disease activity and future loss of attachment.[8] Tests should be adopted only when they are based on research that includes a critical analysis of the sensitivity, specificity, disease incidence, and predictive value of the proposed test.[21]

Conclusion

The long-term preservation of the dentition is closely associated with the frequency and quality of recall maintenance. The therapist should use risk assessment and educate the patient on the need for periodontal maintenance. Supportive periodontal therapy is a lifetime effort to prevent the disease from recurring. Patients who do not return for supportive periodontal therapy lose more teeth than compliant patients.

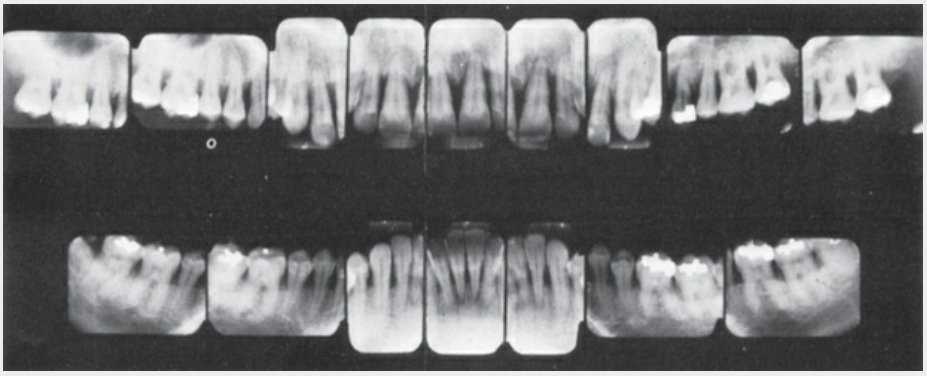
Case Scenario 72.1

Patient:
38-year-old female

Chief Complaint:
"My gums have been bleeding, and my teeth are shifting."

Background Information
The patient's dental care has been irregular.

Current Findings:
The patient has advanced generalized chronic periodontitis.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. Teeth #30 and #31 have similar pocket depths. Tooth #30 was found to have grade 1 bifurcation bone loss. How does the grade 1 bifurcation affect the prognosis of #30 versus #31, which does not have any bifurcation bone loss? A. Prognosis for tooth #31 is worse B. Prognosis for tooth #30 is worse C. Prognosis is the same for grade 1 and grade 0 D. Prognosis is the same for all grades of furcation involvement	**Answer: C** **Explanation:** See Reference 44.

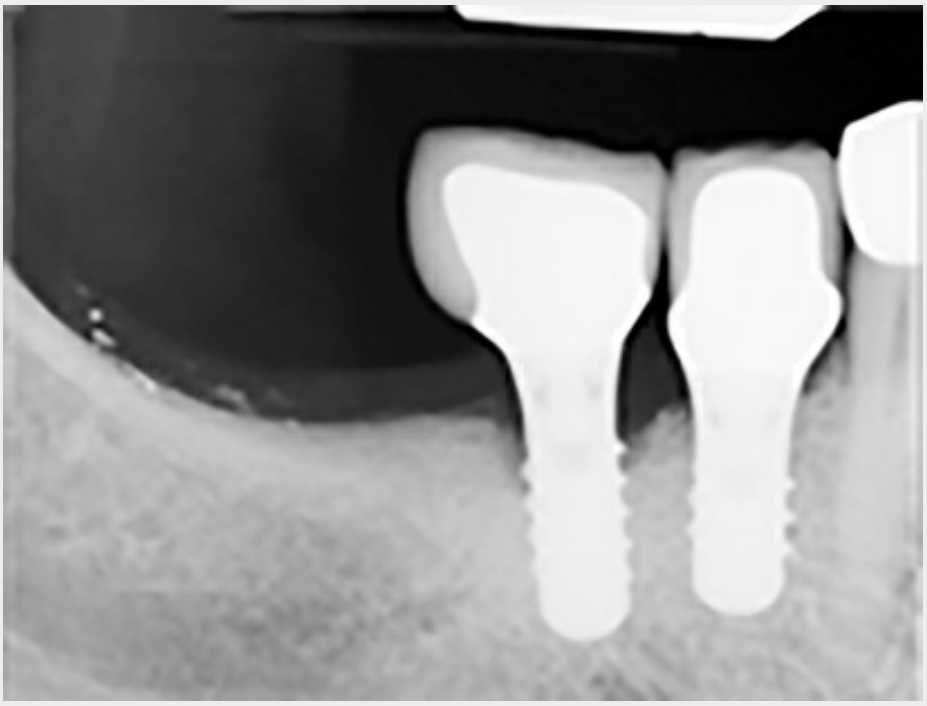
Case Scenario 72.2

Patient:
Female age 62

Chief Complaint:
Exam and x-ray to check implant at no. 29 one year after crown placement.

Patient History:
Implant at tooth site no. 30 was restored 38 months ago, and the implant at tooth site no. 29 was restored 14 months ago. Patient is a heavy bruxer, has lost teeth due to fractures, and is not wearing her bite guard.

Clinical Findings:
No. 30 has no pockets greater than 3 mm, and there is no bleeding on probing. When the occlusion was checked with blue articulating paper, the entire occlusal surface was blue.



Case-Based Questions	Solution and Explanation
1. What is the best diagnosis? A. Peri-implant bone loss B. Peri-implantitis C. Occlusal overload D. A and C	**Answer: D**
2. What is the best treatment for the implant in no. 30 position? A. Peri-implant surgery B. Occlusal adjustment and evaluate again in four months C. Antibiotics D. SPT only	**Answer: B**

CHAPTER 73

Results of Periodontal Treatment

Robert L. Merin

CHAPTER OUTLINE

Prevention and Treatment of Gingivitis
Prevention and Treatment of Loss of Attachment
Tooth Mortality
Conclusion

The prevalence of periodontal disease, the resulting high rate of tooth mortality, and the potential for multiple systemic health complications aggravated by chronic periodontitis raise an important question: Is periodontal treatment effective in preventing and controlling the chronic infection and progressive destruction of periodontal disease? Current concepts of evaluating health care require a scientific basis for treatment, referred to as *evidence-based*

therapy. Evidence is now overwhelming that periodontal therapy is effective in preventing periodontal disease, slowing the destruction of the periodontium, and reducing tooth loss.

Prevention and Treatment of Gingivitis

Learning Box 73.1

Gingivitis is reversible.

For many years, the belief that good oral hygiene is necessary for the successful prevention and treatment of gingivitis has been widespread among periodontists. In addition, worldwide epidemiologic studies have confirmed a close relationship between the incidence of gingivitis and the lack of oral hygiene.[8,9]

Löe and coworkers[20,38] provided conclusive evidence on the association between oral hygiene and gingivitis. After 9 to 21 days without performing oral hygiene measures, healthy dental students with previously excellent oral hygiene and healthy gingiva developed heavy accumulations of biofilm and generalized mild gingivitis. When oral hygiene techniques were reinstituted, the biofilm in most areas disappeared in 1 or 2 days, and gingival inflammation in these areas disappeared approximately 1 week after the biofilm was removed. Thus gingivitis is reversible and can be resolved by daily, effective biofilm removal.

A number of long-term studies have shown that gingival health can be maintained by a combination of effective oral hygiene maintenance and scaling procedures.[1,2,11,13–15,22,24,36,37] A 3-year study was conducted on 1248 General Telephone workers in California to determine whether progression of gingival inflammation is reduced in an oral environment in which high levels of hygiene are maintained.[36,37] Experimental and control groups were computer matched based on periodontal and oral hygiene status, past caries experience, age, and gender. During the study period, several procedures were instituted to ensure that the oral hygiene status of

the experimental group was maintained at a high level. Subjects were given a series of frequent oral prophylaxis treatments combined with oral hygiene instruction. Subjects in the control group received no attention from the study team except for annual examinations. They were advised to continue their usual daily practices and accustomed visits for professional care. After 3 years, the increase in biofilm and debris in the control group was four times as great as that in the experimental group. Similarly, gingivitis scores were much higher in control subjects than in the matching experimental group. Therefore chronic marginal gingivitis can be controlled with good oral hygiene and dental prophylaxis.

Learning Box 73.2

A number of long-term studies have shown that gingival health can be maintained by a combination of effective oral hygiene maintenance and scaling procedures.[1,2,11,13–15,22,24,36,37]

Prevention and Treatment of Loss of Attachment

Although periodontal therapy has been used for more than 100 years, it is only since the mid-1970s that a number of studies have been conducted to determine the effect of treatment on reducing the progressive loss of periodontal support for the natural dentition.

Prevention of Loss of Attachment

Löe and coworkers[19,20] conducted a longitudinal investigation to study the natural development and progression of periodontal disease. The first study group, established in Oslo, Norway, in 1969, consisted of 565 healthy male nondental students and academicians between 17 and 40 years of age. Oslo was selected mainly because this city had an ongoing preschool, school, and postschool dental program offering systematic preventive, restorative, endodontic, orthodontic, and surgical therapy on an annual recall basis for all

children and adolescents, complete with a documented attendance record, for the previous 40 years. Members of the study population had experienced maximum exposure to conventional dental care throughout their lives. A second study group, established in Sri Lanka in 1970, consisted of 480 male tea laborers between 15 and 40 years of age. They were healthy and in excellent physical condition by local standards, and their nutritional condition was clinically fair. The workers had never been exposed to any programs relative to the prevention or treatment of dental diseases. Oral care was unknown, and dental caries was virtually nonexistent.

The results of this study are interesting. As the members of the Norwegian group approached 40 years of age, the mean individual loss of attachment was slightly above 1.5 mm and the mean annual rate of attachment loss was 0.08 mm for interproximal surfaces and 0.1 mm for buccal surfaces. As the Sri Lankans approached 40 years of age, the mean individual loss of attachment was 4.5 mm, and the mean annual rate of progression of the lesion was 0.3 mm for interproximal surfaces and 0.2 mm for buccal surfaces. Fig. 73.1 shows a graphic interpretation of the difference between the two groups. This study suggests that without oral care, periodontal lesions progress continually and at a relatively even pace.

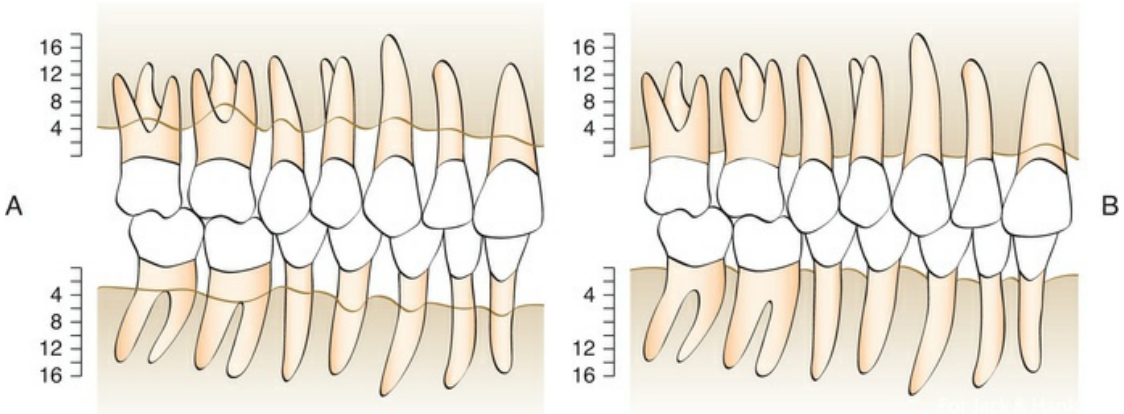

FIG. 73.1 (A) Mean periodontal support of teeth of Sri Lankan tea laborers at approximately 40 years of age. (B) Mean periodontal support of teeth of Norwegian academicians at approximately 40 years of age. (From Löe H, Anerud A, Boysen H, et al: The natural history of periodontal disease in man: the rate of periodontal destruction before 40 years of age. *J Periodontol* 49:607, 1978.)

Further analysis of the Sri Lankan laborers showed that they were not all losing attachment at the same rate (Figs. 73.2 and 73.3).[20] Virtually all gingival areas showed inflammation, but attachment loss varied tremendously. Based on interproximal loss of attachment and tooth mortality, three subpopulations were identified as individuals with "rapid progression" (RP) of periodontal disease (8%), individuals with "moderate progression" (MP) (81%), and individuals who exhibited "no progression" (NP) of periodontal disease beyond gingivitis (11%). At age 35, the mean loss of attachment in the RP group was 9 mm; in the MP group, 4 mm; and in the NP group, less than 1 mm. At the age of 45, the mean loss of attachment in the RP group was 13 mm and in the MP group it was 7 mm. Therefore under natural conditions and in the absence of therapy, 89% of the Sri Lankan laborers had severe periodontitis that progressed at a much greater rate than that observed in the Norwegian group.

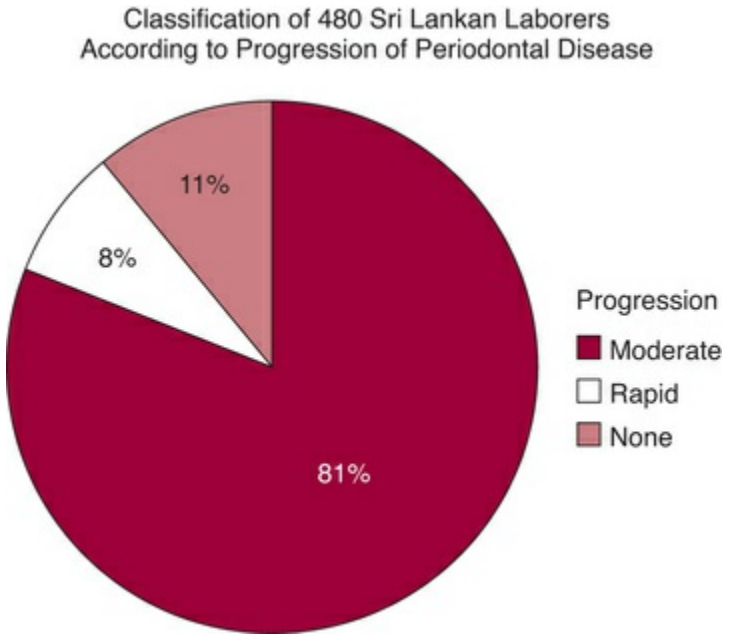

FIG. 73.2 Progression of periodontal disease in an untreated population. (Data from Löe H, Anerud A, Boysen H, et al: Natural history of periodontal disease in man: rapid, moderate and no loss of attachment in Sri Lankan laborers 14 to 46 years of age. *J Clin Periodontol* 13:431, 1986.)

Mean Loss of Attachment at Various Ages (mm)

Age	Progression Group	
	Rapid	Moderate
35	9	4
45	13	7

FIG. 73.3 Loss of attachment in untreated Sri Lankan laborers. (Data from Löe H, Anerud A, Boysen H, et al: Natural history of periodontal disease in man: rapid, moderate and no loss of attachment in Sri Lankan laborers 14 to 46 years of age. *J Clin Periodontol* 13:431, 1986.)

In the previously discussed study of General Telephone workers in California, loss of attachment was measured clinically and alveolar bone loss was measured radiographically.[36,37] After 3 years, the control group showed loss of attachment at a rate more than three times that of the matching experimental group during the same period (Fig. 73.4). In addition, subjects who received frequent oral prophylaxis and were instructed in good oral hygiene practices showed less bone loss radiographically after 3 years than did control subjects. It is clear that loss of attachment can be reduced by good oral hygiene and frequent dental prophylaxis.

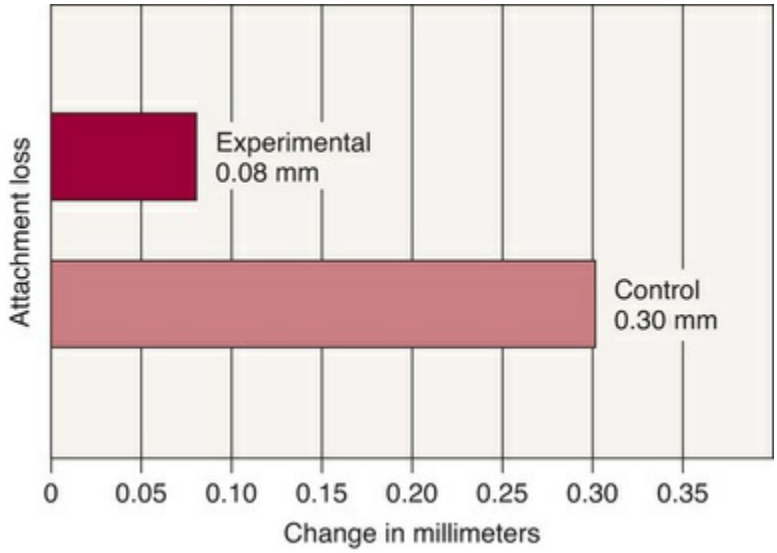

FIG. 73.4 Change in mean attachment level from baseline to third-year examination for experimental and control groups. (From Suomi JD, Greene JC, Vermillion JR, et al: The effect of controlled oral hygiene procedures on the progression of periodontal

disease in adults: results after third and final year. *J Periodontol* 42:152, 1971.)

Treatment of Loss of Attachment

A longitudinal study of patients with moderate-to-advanced periodontal disease conducted at the University of Michigan indicated that the progression of periodontal disease can be terminated for 3 years postoperatively regardless of the modality of treatment.[29-32] With long-term observations, the average loss of attachment was only 0.3 mm over 7 years.[30] These results indicated a more favorable prognosis for treatment of advanced periodontal lesions than previously assumed.

Learning Box 73.3

Patient compliance for regular, thorough biofilm removal by the patient with periodic maintenance therapy can predictably stop ongoing attachment loss.

Another study was conducted in 75 patients with advanced periodontal disease to determine the effect of biofilm control and surgical pocket elimination on the establishment and maintenance of periodontal health.[16] This study indicated that no further alveolar bone loss occurred during the 5-year observation period. The meticulous biofilm control practiced by the patients in this study was considered a major factor in the excellent results produced. After 14 years, results for 61 of the initial 75 individuals were reported.[14] Repeated examinations demonstrated that treatment of advanced forms of periodontal disease resulted in clinically healthy periodontal conditions and that this state of health was maintained in most patients and sites during the 14-year period. A more detailed analysis of the data, however, revealed that a small number of sites in a few patients lost a substantial amount of attachment. Approximately 43 surfaces in 15 different patients were exposed to recurrent periodontal disease of significant magnitude. The frequency of sites that lost more than 2 mm of attachment during the 14 years of maintenance was 0.8% to 0.1% per year.

Neither of these studies used a control group because failing to treat advanced periodontal patients cannot be justified for ethical reasons. However, in a study in a private practice, an effort was made to find and evaluate patients with diagnosed moderate-to-advanced periodontitis who had not followed through with recommended periodontal therapy.[3] Thirty patients ranging in age from 25 to 71 years were evaluated after periods ranging from 18 to 115 months. All of these untreated patients had progressive increases in pocket depth and radiographic evidence of progressive bone resorption.

In a study of the progression of periodontal disease in the absence of therapy, two different populations were monitored.[18] One group of 64 Swedish adults with mild-to-moderate periodontal disease and one group of 36 American adults with advanced destructive disease were monitored but not treated for 6 years and 1 year, respectively. During the course of 6 years, 11.6% of all sites in the Swedish population (1.9% per year) showed attachment loss of greater than 2 mm, and the corresponding figure for the American population was 3.2% per year. Thus the frequency of sites with disease progression was 20 to 30 times higher in untreated groups of patients than in the treated and well-maintained groups described in the preceding discussion.[18] Thus treatment is effective in reducing loss of attachment.

Tooth Mortality

The ultimate test for the effectiveness of periodontal treatment is whether the loss of teeth can be prevented. Sufficient studies from both private practice and research institutions are now available to document that therapy reduces or prevents loss of teeth.

The combined effect of subgingival scaling every 3 to 6 months and controlled oral hygiene was evaluated over a 5-year period in 1428 factory workers in Oslo.[22] Tooth loss was significantly reduced in all patients. This study showed that frequent subgingival scaling reduces tooth loss even when oral hygiene is “not good” (Table 73.1).

TABLE 73.1

Average Loss of Teeth During a 5-Year Period Compared With Normal Loss of Teeth in 1428 Men and Women Ages 20 Through 59

	GRADE OF ORAL HYGIENE		
	Good	Fairly Good	Not Good
"Normal" loss of teeth[a]	1.1	1.4	1.8
Actual loss of teeth during 5-year period	0.4	0.6	0.9

[a]Estimate based on data recorded at initiation of study period.

From Lovdal A, Arno A, Schei O, et al: Combined effect of subgingival scaling and controlled oral hygiene on the incidence of gingivitis. *Acta Odontol Scand* 19:537, 1961.

The previously mentioned longitudinal study conducted at the University of Michigan included 104 patients with a total of 2604 teeth.[29-32] After 1 to 7 years of treatment, 53 teeth were lost for various reasons (Table 73.2). Approximately 32 teeth were lost during the first and second years after the initiation of treatment. The remaining 21 teeth were lost in a random pattern over the next 6 years. Therefore the loss of teeth caused by advanced periodontal disease after treatment was minimal (1.15%).

TABLE 73.2

Tooth Mortality After Treatment of Advanced Periodontitis in 104 Patients With 2604 Teeth Treated Over a 10-Year Period

Teeth Lost[a]	Reason
2	Pulpal disease
3	Accidents
4	Prosthetic considerations
14	Various reasons; for example, one patient wanted a maxillary denture for cosmetic reasons
30	Periodontal
53	All reasons

[a]Two percent of the teeth were lost during the study period. Note that US health surveys conducted in the 1960s indicated that an average of 4.3 teeth were lost after age 35 in the general population.[9]

Data from Ramfjord SP, Knowles JW, Nissle RR, et al: Longitudinal study of periodontal therapy. *J Periodontol* 44:66, 1973.

Another study was undertaken to test the effect of periodontal therapy in cases of advanced disease.[16-17] The subjects were 75

patients who had lost 50% or more of their periodontal support (Fig. 73.5). Treatment consisted of oral hygiene measures, scaling procedures, extraction of untreatable teeth, periodontal surgery, and prosthetic therapy if indicated. After completion of periodontal treatment, none of the patients showed further loss of periodontal support for the next 5 years. None of the teeth were extracted in the 5-year posttreatment period. Patients in this study were selected because of their capacity to meet the high requirements of biofilm control after repeated instruction in oral hygiene techniques. This fact does not detract from the validity of the study but tends to indicate the etiologic importance of bacterial biofilm. The results indicate that periodontal surgery coupled with a detailed biofilm control program not only temporarily cures the disease but also reduces further progression of periodontal breakdown, even in patients with severely reduced periodontal support.

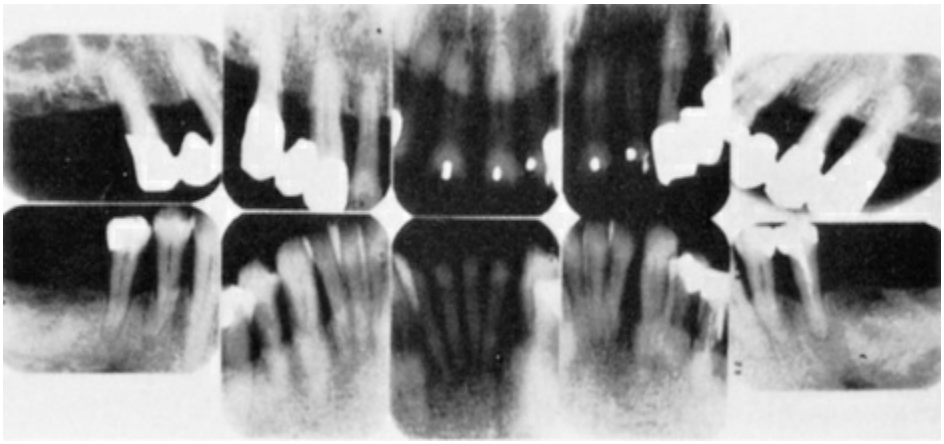

FIG. 73.5 Radiographs taken 5 years after typical periodontal treatment. Note the advanced bone loss, despite the teeth retained in a healthy condition for the duration of the study. (From Lindhe J, Nyman S: The effect of plaque control and surgical pocket elimination on the establishment and maintenance of periodontal health: a longitudinal study of periodontal therapy in cases of advanced disease. *J Clin Periodontol* 2:67, 1975.)

After 14 years, 61 of the original patients were still in the study.[17] Recurrence of destructive periodontal disease in isolated sites of the dentition resulted in loss of a certain number of teeth during the observation period (Fig. 73.6). In the 6 to 10 years after active therapy, one tooth in each of three different patients was lost, and

during the final observation period (11 to 14 years), three teeth in one patient, two teeth in each of three patients, and one tooth in each of four patients had to be extracted because of recurrent periodontal disease. In addition, three teeth in each of three different patients and one tooth in each of five patients were extracted because of the development of extensive caries, periapical lesions, or other endodontic complications. Throughout the course of the study, the total loss was 30 teeth (for all reasons) from the total of 1330 teeth. Therefore the tooth mortality rate was 2.3%.

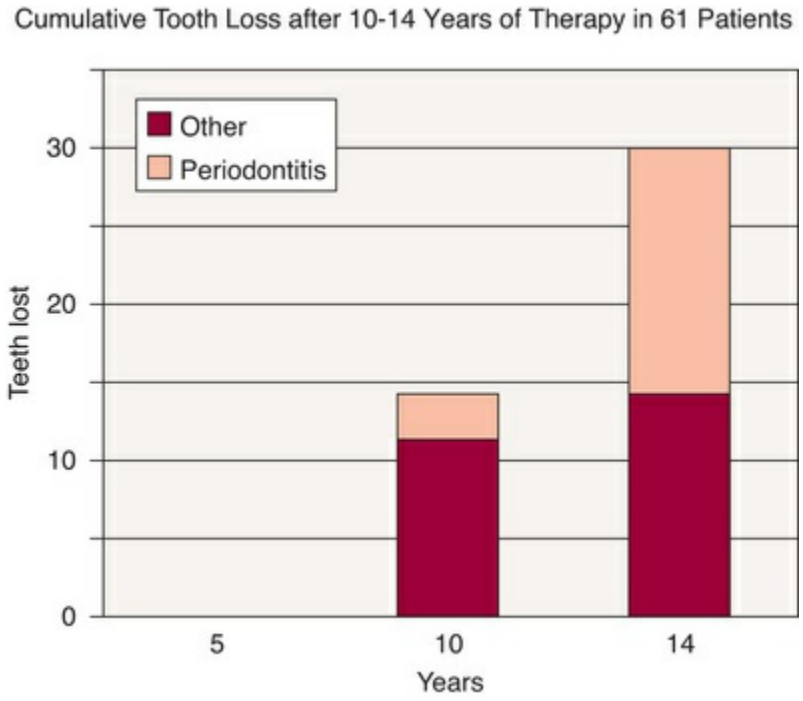

FIG. 73.6 Tooth loss in treated patients with very advanced periodontal disease. (Data from Lindhe J, Nyman S: Long-term maintenance of patients treated for advanced periodontal disease. *J Clin Periodontol* 11:504, 1984.)

University-based studies on the treatment of moderate to severe periodontitis continue to show minimal tooth loss in patients who comply with periodontal maintenance therapy. [5,26]

Several studies in private practice have attempted to measure the frequency of tooth loss after periodontal therapy. In one study, 180 patients who had been treated for chronic destructive periodontal disease were evaluated.[33] The average age of the patients before treatment was 43.7 years. A total of 141 teeth were lost. From the

beginning of treatment to the time of the survey, the majority of patients did not lose any teeth (Fig. 73.7). Three of 180 patients (1.7%) lost 35 teeth; approximately 25% of the teeth were lost. Twelve additional patients lost 46 teeth, or 32.6% of the teeth were lost. Many patients in the study had advanced alveolar bone loss, including extensive furcation involvements. However, only a relatively small number (141) of the teeth were lost in the study group of 180 patients between the beginning of periodontal treatment and the time of the study.

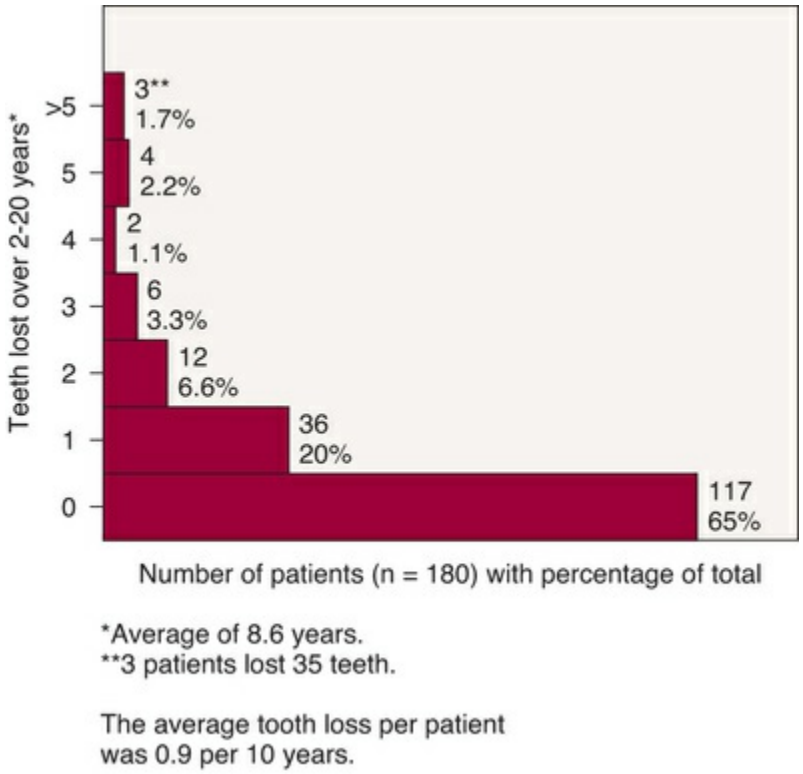

FIG. 73.7 Tooth mortality. Average tooth loss per patient was 0.9 per 10 years. (Modified from Ross IF, Thompson RH, Galdi M: The results of treatment: a long term study of one hundred and eighty patients. *Parodontologie* 25:125, 1971.)

The teeth were lost for several reasons, including periodontal disease, caries, and other nonperiodontal causes. The length of time after treatment varied from 2 to 20 years, with an average of 8.6 years. Of considerable significance is the large number of teeth (81 teeth, or 57.5%) lost by a few patients (15 patients, or 8.4%). Even when this group is considered with the remaining 165 patients, the

periodontal care helped to retain most teeth because the average loss was slightly less than one tooth (0.9) over the 10 years after treatment.

In a follow-up study, the long-term results of periodontal therapy were evaluated after 15 to 34 years (average of 22.2 years).[7] The average tooth loss at this time was 1.6 teeth per 10 years. Patients were classified into three groups according to tooth loss. Approximately 62% had an average tooth loss of 0.45 per 10 years and were considered "well maintained"; 28% lost an average of 2.6 teeth per 10 years and were considered "downhill"; and 10% lost an average of 6.4 teeth per 10 years and were considered "extreme downhill" (Fig. 73.8).

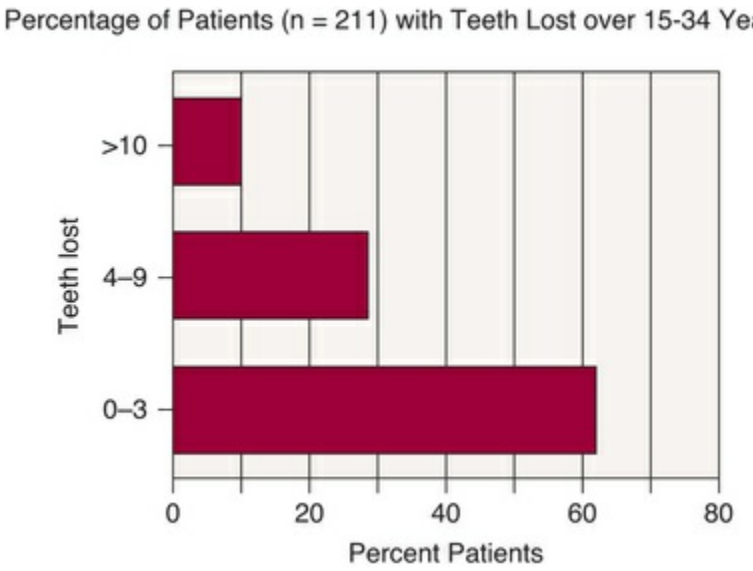

FIG. 73.8 Tooth mortality 15 to 34 years after initiation of therapy (average of 22.2 years). Average tooth loss per patient was 1.6 teeth per 10 years. Compare with the same study population in Fig. 73.7. As the treated population ages, the rate of bone loss appears to increase. (Modified from Goldman MJ, Ross IF, Goteiner D: Effect of periodontal therapy on patients maintained for 15 years or longer: a retrospective study. *J Periodontol* 57:347, 1986.)

Another study included all patients in a practice who had been treated 5 or more years previously and had received regular preventive periodontal care since that time.[28] The 442 patients had an average of 10.1 years since treatment. Two-thirds of the patients

were older than 40 years of age at the time of treatment. These patients had been seen every 4.6 months, on average, for their preventive periodontal care, which consisted of oral hygiene instruction and prophylaxis (Figs. 73.9 and 73.10).

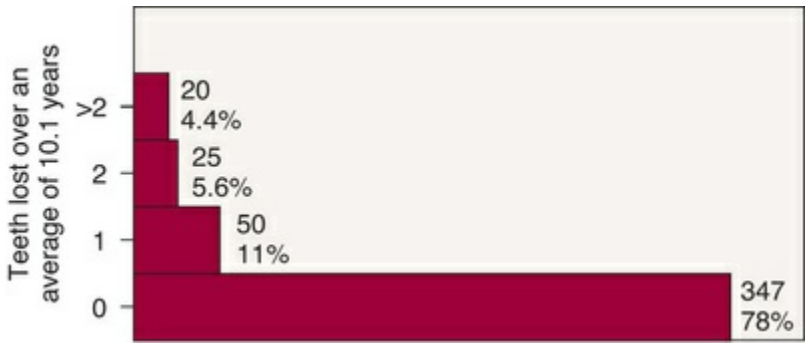

FIG. 73.9 Tooth mortality in 442 periodontal patients treated over 10 years. (Courtesy Dr. R.C. Oliver, Rio Verde, AZ.)

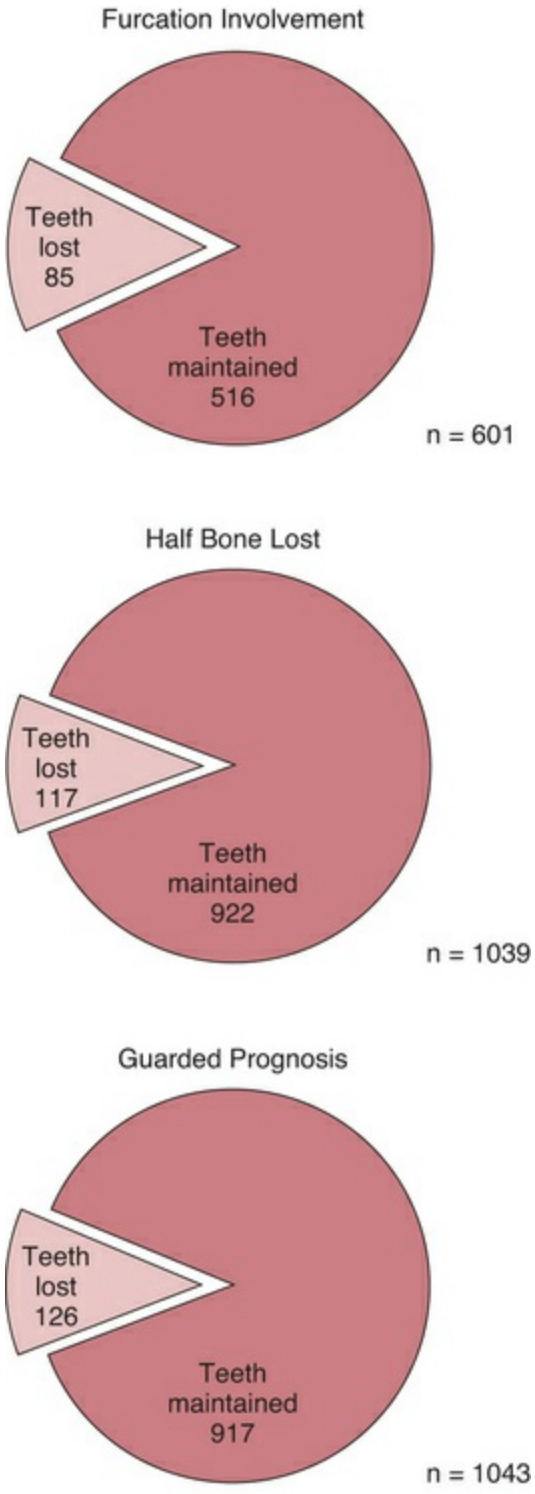

FIG. 73.10 Loss of teeth with advanced periodontal disease over 10 years. (Courtesy Dr. R.C. Oliver, Rio Verde, AZ.)

The total tooth loss resulting from periodontal disease was 178 of more than 11,000 teeth available for treatment. More important, 78% of the patients did not lose a single tooth after periodontal therapy, and 11% lost only one tooth. Considering that more than

600 teeth had furcation involvements at the time of the original treatment and that far more than 1000 teeth had less than half the alveolar bone support remaining, there was minimal tooth loss. During the same average 10-year period after periodontal therapy, only 45 teeth were lost through caries or pulpal involvement. Even more surprising are the statistics over an average 10-year period for teeth with a poor prognosis. Only 85 (14%) of a total of 601 teeth with furcation involvement were lost, and 117 (11%) of 1039 teeth with half or less of the bone remaining were lost. Of the 1043 teeth listed as having a "guarded prognosis" by the clinician performing the initial examination, only 126 (12%) were lost over this 10-year period. The average tooth mortality rate was 0.72 tooth lost per patient per 10 years.

In a third study in a private practice, 600 patients were followed for 15 to 53 years after periodontal therapy (Figs. 73.11 and 73.12).[10] The majority (76.5%) had advanced periodontal disease at the start of treatment. There were 15,666 teeth present, for an average of 26 teeth per patient. During the follow-up period (an average of 22 years), a total of 1312 teeth were lost from all causes. Of this number, 1110 were lost for periodontal reasons. The average tooth mortality rate per patient was 2.2 teeth, and when this is converted to a 10-year rate, an average of one tooth was lost per 10 years in each patient. During this period of observation, 666 teeth with a questionable prognosis were lost out of a total of 2141. This means that 31% of the teeth with a questionable prognosis were lost over 22 years of treatment. A total of 1464 teeth with furcation involvement were treated, and 31.6% were lost during the period of study. Approximately 83% of the patients lost fewer than three teeth over the 22-year average treatment period and were classified as "well maintained." The remaining 17% of the patients were divided into two groups: "downhill" (4 to 9 teeth lost) or "extreme downhill" (10 to 23 teeth lost). Thus 17% of the patients studied accounted for 69% of the teeth lost from periodontal causes. This study also indicated that relatively few teeth are lost after periodontal therapy. In addition, few teeth with a guarded prognosis, including those with furcation involvement, are lost, and a small percentage of patients lose most of the teeth.

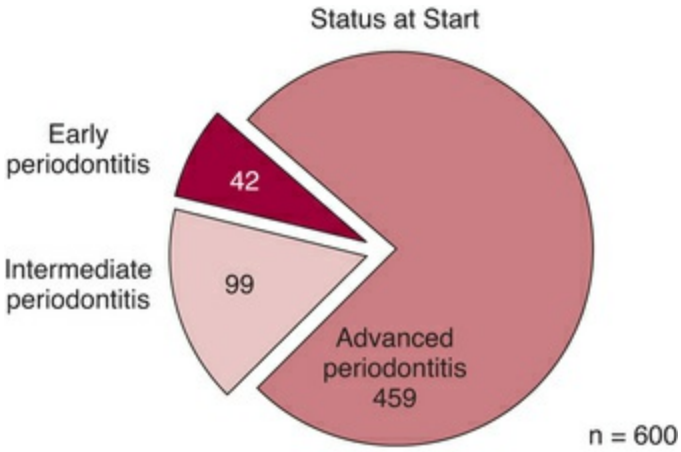

FIG. 73.11 Status at the start of a study of 600 patients. (Data from Hirschfeld L, Wasserman B: A long-term survey of tooth loss in 600 treated periodontal patients. *J Periodontol* 49:225, 1978.)

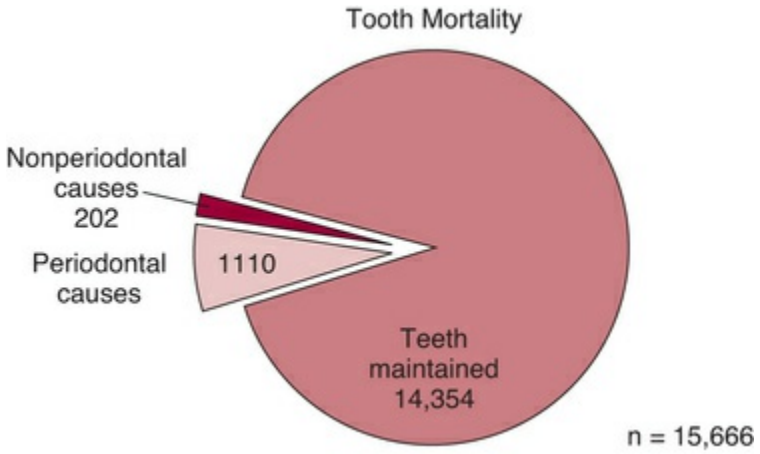

FIG. 73.12 Loss of teeth in 600 patients over 15 to 53 years from nonperiodontal and periodontal causes. (Data from Hirschfeld L, Wasserman B: A long-term survey of tooth loss in 600 treated periodontal patients. *J Periodontol* 49:225, 1978.)

Clinical studies have also indicated a relatively low rate of tooth loss in patients who are involved in a supportive periodontal maintenance program. One study showed that 0.9% of teeth were lost over 7.8 years, whereas another showed 1.5% were lost over a 9.8-year period after the initiation of active periodontal treatment.[4,6] Another study showed that questionable teeth in patients with aggressive periodontitis can be maintained for longer than 15 years if the patient is compliant. [41]

A study at the University of Bern looked at the outcome of

multirooted teeth treated for longer than 11.5 years.[42] The study found that grade 1 furcation status was not a risk factor for tooth loss compared with no furcation bone loss in patients treated for periodontal disease. Risk factors for the loss of multirooted teeth included furcation involvements grades 2 and 3, smoking, and lack of compliance with regular maintenance therapy (Fig. 73.13).

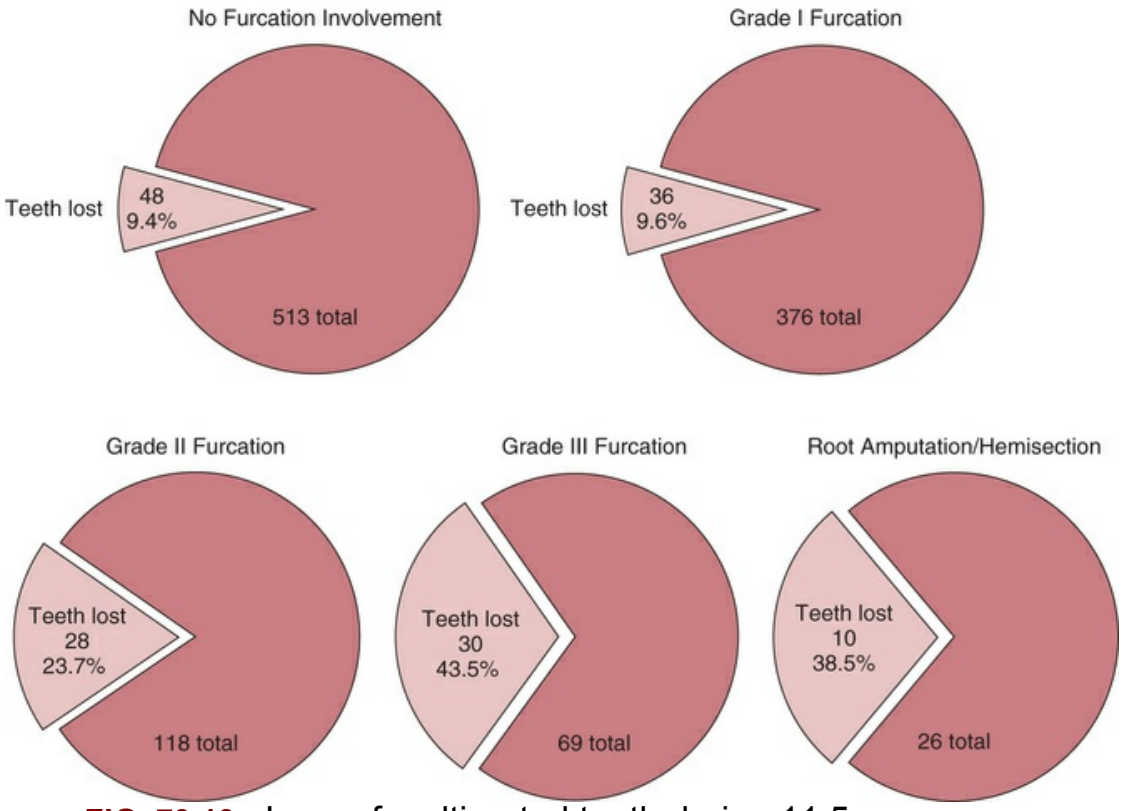

FIG. 73.13 Loss of multirooted teeth during 11.5 years of supportive periodontal therapy. (Data from Salvi GE, Mischler DC, Schmidlin K, et al: Risk factors associated with longevity of multi-rooted teeth: long-term outcomes after active supportive periodontal therapy. *J Clin Periodontol* 41:701–707, 2014.)

Learning Box 73.4

Numerous studies indicate the possibility of maintaining teeth in patients with aggressive periodontitis if the patient can perform excellent biofilm removal along with regular supportive periodontal care.

Three studies give insight into tooth mortality in untreated patients. The studies of Löe and coworkers[20,21] in Sri Lankan laborers showed that after age 35, an average of 5 and 16 teeth were lost per 10 years in the "moderate progression" and "rapid progression" groups, respectively (Fig. 73.14). In a previously discussed study in private practice,[3] an effort was made to find and evaluate patients with diagnosed moderate-to-advanced periodontitis who did not follow through with recommended periodontal therapy. Patients with untreated periodontal disease were losing teeth at a rate greater than 0.61 per year (6.1 teeth per 10 years). A total of 83 teeth were lost in 30 patients, but the investigators excluded one patient who had lost 25 teeth. Including this patient would have increased the tooth loss in untreated patients to an even higher rate. In another study, reporting on patients with moderate-to-advanced periodontitis examined at the Department of Periodontology at the University of Kiel in Germany, Kocher and associates[12] found a marked increase in tooth loss in the untreated patients compared with the treated patients when they were examined after 7 years.

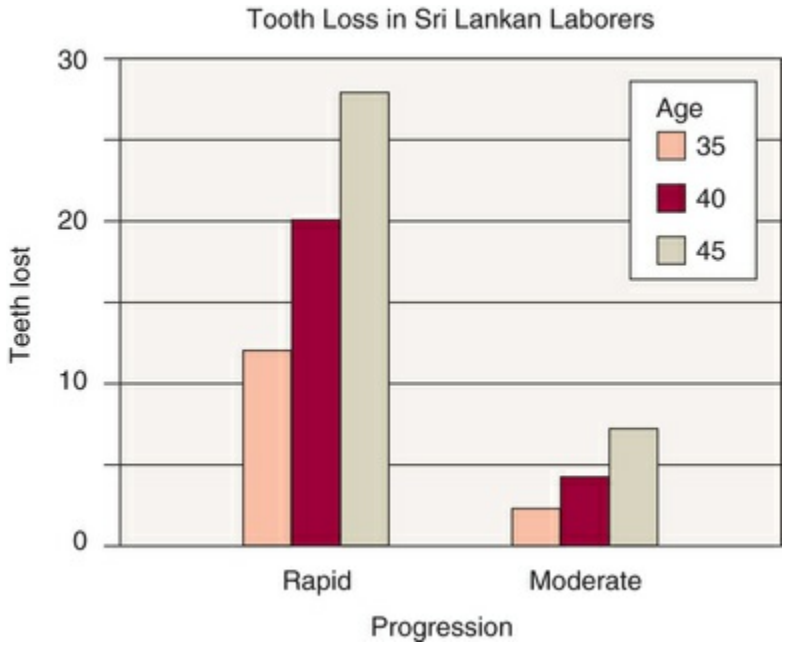

FIG. 73.14 Tooth loss in a population with untreated periodontal disease. (Data from Löe H, Anerud A, Boysen H, et al: Natural history of periodontal disease in man: rapid, moderate and no loss of attachment in Sri Lankan laborers 14 to 46 years of age. *J Clin Periodontol* 13:431,

1986.)

When Tables 73.3 and 73.4 are compared, it is obvious that tooth mortality is much greater in untreated groups.

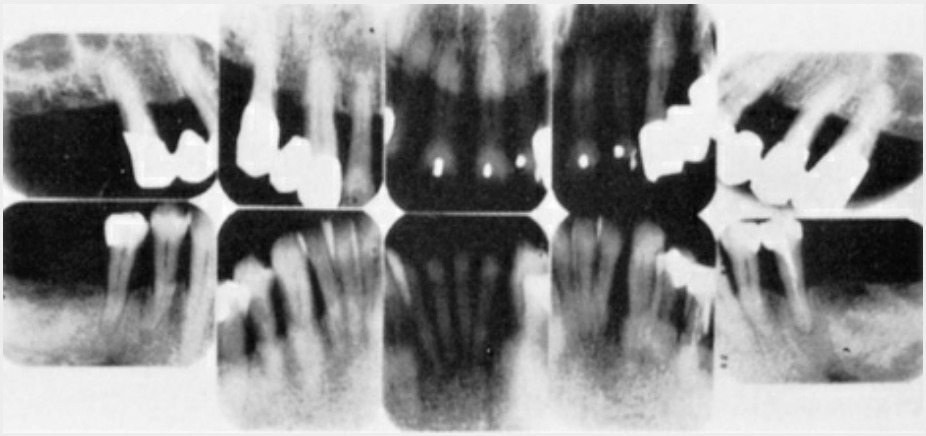
Conclusion

The prevalence of periodontal disease and the resulting high rate of tooth mortality have increased the need for effective treatment. Strong evidence now indicates that periodontal disease can contribute to numerous health problems, including pregnancy complications, heart disease, stroke, and diabetes.[25,27,34,35] For patients with periodontitis, treatment effectively prevents periodontal disease and stops the progression of the disease. In addition, overwhelming evidence suggests that periodontal therapy greatly reduces tooth mortality. Every dental practitioner should be familiar with the philosophy, recognition, and techniques for periodontal therapy. Failure to diagnose and treat periodontal disease or not to make periodontal treatment available to patients causes unnecessary dental problems and tooth loss and places the patient at risk for other systemic health problems.

Case Scenario 73.1



Patient:

60-year-old female

Chief Complaint:

"I just moved to your area, and I'd like your help with my periodontal therapy."

Background Information

Patient is seeking supportive periodontal therapy because she moved to your area. She was treated in the Lindhe study for advanced periodontal disease with surgical treatment and has been maintained for 5 years.

Current Findings:

Oral hygiene is good. Three pockets are 4 mm but have not changed in 5 years. There is no bleeding on probing. Mobility has not changed in 5 years, and the patient can chew comfortably.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the best periodontal diagnosis for this case? A. Advanced periodontitis B. Aggressive periodontitis C. Refractory periodontitis D. Reduced but healthy periodontium	**Answer: D**

Soft Tissue Interface
Clinical Comparison of Teeth and Implants
Conclusion

The history of modern implant dentistry began with the introduction of titanium implants.[41] In the 1950s, Per-Ingvar Brånemark, a Swedish professor of anatomy, had a serendipitous finding while studying blood circulation in bone that became a historical breakthrough in medicine. He discovered an intimate

bone-to-implant apposition with titanium that offered sufficient strength to cope with load transfer. He called the phenomenon *osseointegration* and developed an implant system with a specific protocol to predictably achieve it. The implants were used to anchor prosthetic replacement teeth in the edentulous jaw,[27] and the first patient was successfully treated in 1965.[30,72] Subsequent clinical studies proved that commercially pure (CP) titanium implants, placed with a strict protocol, including an unloaded healing period, could predictably achieve osseointegration and retain a full-arch prosthesis in function with long-term success (15 years).[8]

« Flash Back

The history of modern implant dentistry began with the introduction of titanium implants. In the 1950s, Per-Ingvar Brånemark, a Swedish professor of anatomy, had a serendipitous finding while studying blood circulation in bone that became a historical breakthrough in medicine. He coined the phenomenon *osseointegration* and developed an implant system with a specific protocol to achieve it predictably.

Today, implant designs, surgical placement techniques, healing times, and restorative protocols continue to evolve with the goal of improving outcomes. It is important for clinicians to know peri-implant anatomy, to understand the biology, and to appreciate the functional capacity of osseointegrated implants. This chapter reviews implant geometry and surface characteristics, as well as the anatomic and biologic relationships of peri-implant tissues.

Implant Geometry (Macrodesign)

Numerous implant systems with various geometric (macrodesign) designs have been developed and used before the current implant systems in use today. Previous implant designs included blade vents (narrow, flat shape; tapped into bony trough prepared with rotary burs),[69] press-fit cylindrical (bullet shape; pressed or tapped into prepared hole),[102] subperiosteal (custom-made framework;

adapted to the surface of jawbone),[37] and transmandibular (long rods or posts; placed through the anterior mandible).[107] Some of these implant systems were initially stable and appeared to be successful over short-term periods (e.g., 5 years) but failed to remain stable, became symptomatic or loose, and failed over longer periods.[100,124] Lacking predictability, these implant systems are no longer used.

Since the time of the Brånemark studies, millions of patients have been treated worldwide using variations of these techniques with implants of different geometries and surface characteristics. Similar research including that of André Schroeder in Switzerland in the mid-1970s contributed to the success of endosseous dental implants. The serendipitous finding of Brånemark was that when a hole is prepared into bone without overheating or otherwise traumatizing the tissues, an inserted biocompatible implantable device would predictably achieve an intimate bone apposition, as long as micromovements at the interface were prevented during the early healing period. The history of the research endeavors in Sweden provides a better understanding of the relevant biologic parameters involved.[72]

The macroscopic configuration of implants has varied widely; the most common types are listed in Box 74.1. Currently, most endosseous implants have a cylindrical or tapered, screw-shaped/threaded design. The disastrous results with other implant configurations were largely responsible for the evolution toward the current popular designs.[13] See online for a detailed description of the various implant designs including blades, pins, disks, root form, transmandibular, and subperiosteal implants.

Box 74.1

Implant Geometry (Macrodesign)

1. Endosseous implants
    - Blade like
    - Pins
    - Root form, cylindrical (hollow and full)

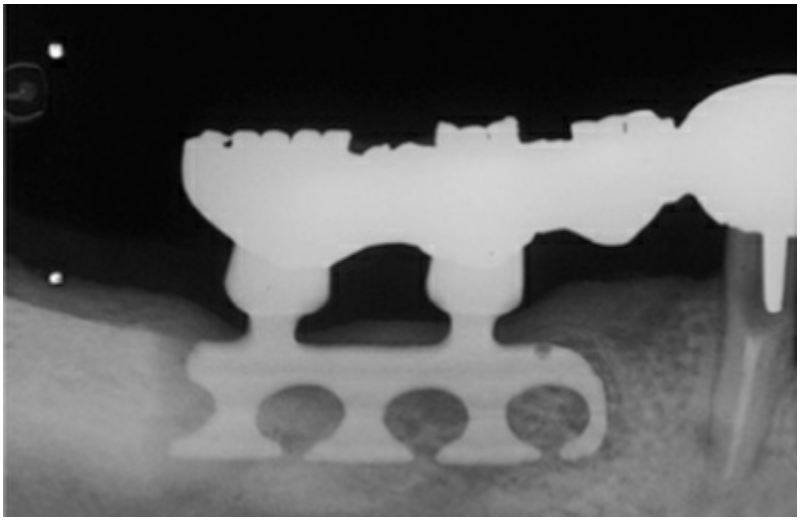
- Disk like
- Screw shaped
- Tapered and screw shaped

2. Subperiosteal (custom frame) implants
3. Transmandibular implants

Blade Implants

Blade implants were designed and developed by Linkow[69] and used clinically in the 1960s and 1970s. Blade implants were inserted into the jawbone after mucoperiosteal flap elevation and preparation of a channel with a high-speed rotary bur. They were tapped into the narrow trench. One or several posts pierced through the mucoperiosteum after suturing of the flaps. After a few weeks of healing, a fixed prosthesis was fabricated by a classic method and cemented on top of it.

Because the high-speed drilling leads to extensive bone necrosis at the histologic level, fibrous scar tissue forms. This allows downgrowth of the epithelium, which leads to marsupialization of the blade implants (eFig. 74.1).[59] If a bacterial infection occurs, it can lead to an intractable peri-implantitis with ample bone loss. More important, removal of such implants after complications implies sacrificing surrounding jawbone. Because of its retentive geometry, the blade implant cannot simply be extracted or removed by a trephine, as with a cylindrical or screw-shaped implant.



EFIG. 74.1 Blade implant shows a large radiolucency,

indicating that the fibrous encapsulation has led to deep pocketing and subsequent bone loss. Neighboring teeth bear the load of the implant restoration.

The interface between blade vent implant and bone was called *fibroosseous integration,* which was defined as tissue-to-implant contact: interposition of healthy dense collagen fibers at the interface between the implant and bone.[14] At that time, the fibrous tissue was thought to be the replacement of the periodontal ligament[119]; however, it was fibrous scar tissue following the bone necrosis initiated by high-speed drilling. This allows epithelial downgrowth around the post caused by the bacterial infection, which leads to encapsulation of blade implant with the fibrous scar tissue.

Most of the studies reported less than 50% success rate for 5-year duration with the complication of pocket formation exceeding 6 mm, followed by the significant alveolar bone loss around the implant.[36,110] It was also more complicated and invasive surgery to remove the failed implant, which was sacrificing significant surrounding jawbone. As a result of the poor long-term success, as well as the high complication rate, the use of blade vent implants has been significantly reduced. Removal of failed blade implants often requires significant cutting and bone removal despite being mobile.

Pins

Although seldom used at present, in the classic technique, three diverging pins were inserted either transgingivally or after reflection of mucoperiosteal flaps in holes drilled by spiral drills. At the point of convergence, the pins were interconnected with cement to ensure the proper stability because of their divergence. On top of this arrangement, a single tooth could be installed. In edentulous jaws, several of these pin triads could be used to interconnect with a fixed prosthesis.

As with blade implants, the bone necrosis during drilling leads to fibrous encapsulation, marsupialization, and loss of the implants because of infections. A positive aspect, however, is that when such

implants must be removed, removing the connection at the place of convergence is sufficient to allow easy extraction of each individual pin. Thus bone loss from removal is minimal.

Disk Implants

Disk implants are rarely used at present. The concept developed by Scortecci is based on the lateral introduction into the jawbone of a pin with a disk on top.[104] Once introduced into the bone, the implant has strong retention against vertical extraction forces. Implants have been used with one, two, and even three disks. Unfortunately, as mentioned previously for blade implants, the cutting of the bone by means of high-speed drills leads to a fibrous scar tissue surrounding the implant, as revealed frequently by peri-implant radiolucencies. Data on the clinical success of disk implants are mostly anecdotal.

Root Form (Cylindrical) Implants

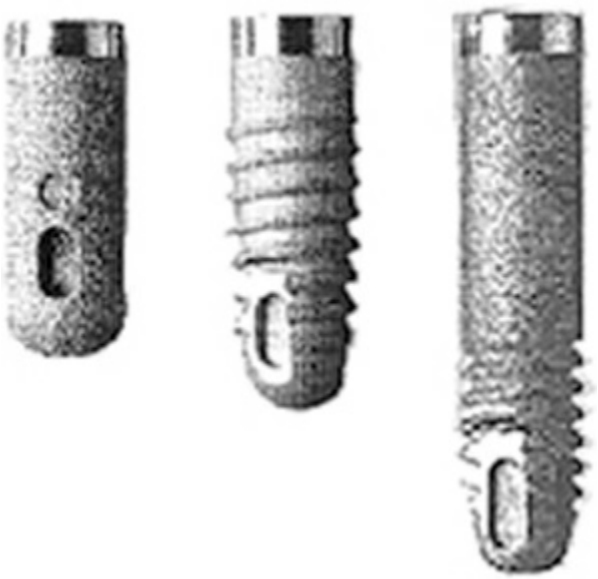
The first implant in this category, designed and developed by Schroeder and colleagues between 1974 and 1985, was called an *ITI* (International Team for Implantology) *hollow-cylinder, plasma-sprayed, one-stage implant*[102] (eFig. 74.2). It was thought that the hollow geometry should provide large bone-to-implant contact and holes would be favorable for the additional fixation of the implant. However, the survival rates were less favorable compared with the other system.[7] Thus this system was withdrawn from clinical use.

EFIG. 74.2 International Team for Implantology (ITI) hollow cylinder implant. Note the hollow geometry, which should provide large bone-to-implant contact, and holes that theoretically should be favorable for the additional fixation of the implant.

When discussing cylindrical implants, it is important to distinguish between hollow and full cylindrical implants. Straumann and coworkers introduced hollow cylinders in the mid-1970s with the ITI system.[111] The idea was that implant stability would benefit from the large bone-to-implant surface provided by means of the hollow geometry. It was also thought that the holes (vents) would favor the ingrowth of bone to offer additional fixation. The same concept was used in the Core-Vent system developed by Niznick.[81] Although it was not clarified whether the cause was geometry or the associated surface characteristics (titanium plasma–sprayed surface, titanium alloy), survival statistics were disappointing for hollow cylinder implants.[115]

Solid cylindrical implants were used by Kirsch and became available under the name IMZ, referring to the *internal mobile shock absorber*.[65] The IMZ system, developed by Kirsch, prevailed in the market (eFig. 74.3). The characteristic function of this system was the *internal mobile element* (IME) shock absorber, which was able to connect with the adjacent natural tooth. The system presented successful results in the short term, but long-term success rates were unacceptable (38% in 10 years), leading to the limited use of

this implant design.[50] For this reason, this implant is rarely seen in the market.



EFIG. 74.3 The IMZ implants. The roughened surface of the fixture had an advantage of higher integration of bone. Conversely, the surface characteristic added to the high frequency of peri-implantitis in long-term use.

Even when an intimate bone apposition is achieved, extraction forces on such cylindrical implants lead to strong shear forces at the bone-to-implant interface. Only the microscopic surface irregularities offer some mechanical retention by interdigitation of bone growing onto the implant surface. With a screw-based geometry, forces acting parallel to the long axis of the implants are dispersed in many directions.[106]

Transmandibular Implants

Transmandibular implants were developed to retain dentures in the edentulous lower jaw. They were indicated for use in the extremely resorbed edentulous mandible with a minimal alveolar ridge height less than 10 mm. The implant was inserted through a submandibular skin incision and required general anesthesia. Two models were available in the 1960s. The first, called the *staple-bone implant,* was developed by Small. It consisted of a splint adapted to

the lower border of the mandible, to which it is fixed by stabilizing pins.[108] Two transmandibular screws were driven transgingivally into the mouth. The reported implant survival rate was 93% after 5 years and continued to exceed 90% after 15 years.[107,109] The other model, introduced by Bosker, has two metal splints, one below the lower border of the mandible and one positioned intraorally to connect the four posts piercing through the soft tissues.[24] The Bosker implant seemed less reliable than the staple-bone implant, achieving only 70% survival after 5 years in the mandibular symphyseal area.[115] Both transmandibular implants presented with the gingival hyperplasia or infection, with the incidence of 10% to 15% of all cases.[107] Despite the good long-term survival data reported (especially for the staple implant), because of the high incidence of complications and the necessity of using general anesthesia for implant placement, the transmandibular implant design is rarely used today.

Subperiosteal Implants

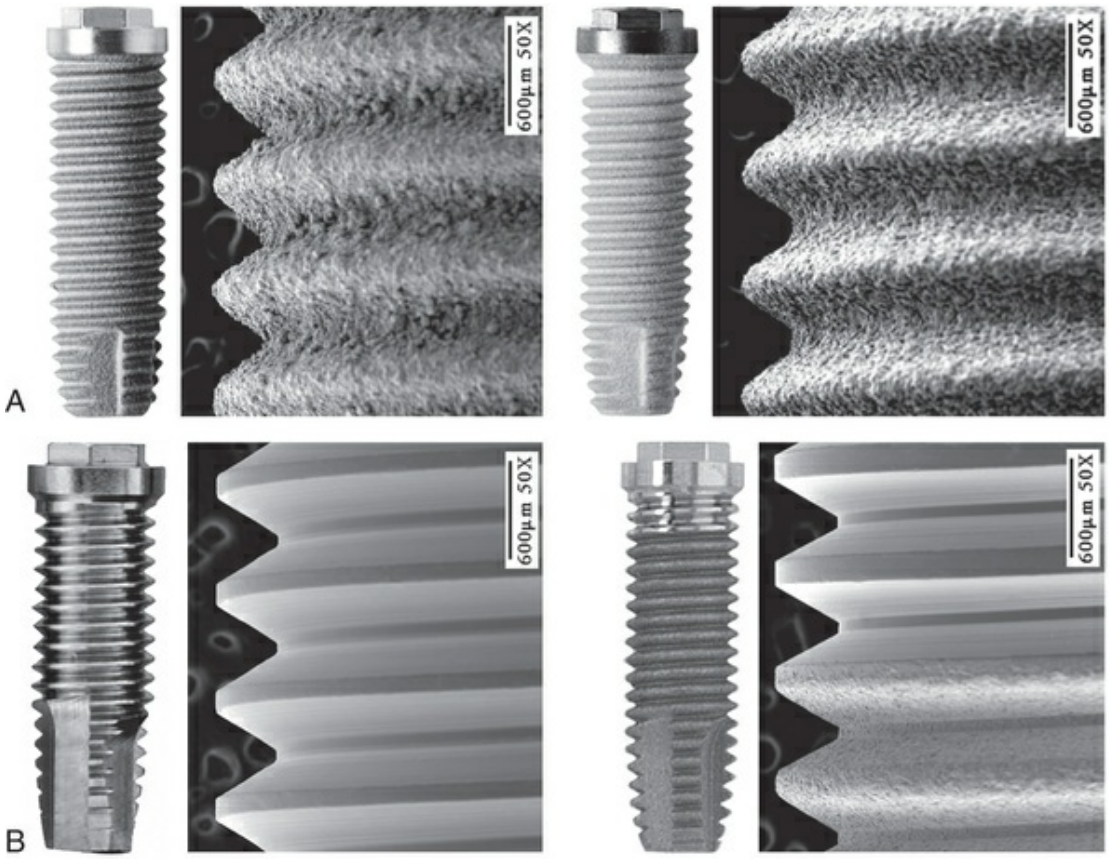
Subperiosteal implants are customized according to a plaster model derived from an impression of the exposed jawbone, before the surgery planned for implant insertion. The implant was designed with several posts, typically four or more for an edentulous jaw, which passed through the gingival tissues.[11]

Subperiosteal implants are designed to retain an overdenture, although fixed prostheses have also been cemented onto the posts. As a result of epithelial migration, the framework of subperiosteal implants usually becomes surrounded by fibrous connective tissue (scar), including the space between the implant and the bone surface. The marsupialization, as described earlier, often leads to infectious complications, which frequently necessitates removal of the implant. Furthermore, while being loaded by jaw function, jawbone resorption occurs rapidly, resulting in a lack of adaptation of the frame to the bone surface. As a result of this type of outcome, subperiosteal implants are now rarely used.

The subperiosteal implant was used in the treatment of atrophic mandibles. The implant is custom designed to fit the mandibular jawbone using a plaster model obtained from an impression of the

exposed mandible. It consisted of a cast metal framework with a subperiosteal component in contact with the bone and a transgingival component (posts), which were used to retain the dental prosthesis. The number of transgingival posts on the implants depends on the number of missing teeth, averaging four to six for the totally edentulous jaw. Several clinical studies reported poor survival rates of less than 50% for 5 to 10 years, with the frequent complication of gingival inflammation, involving tissue reaction around the post caused by the lack of soft tissue attachment to the metal post. These complications led to the development of sinus tract resorption of the cortical bone and exposure of framework.[82,125] As a result of this higher rate of failure, as well as the significant complications and surgical invasion, subperiosteal implants are rarely used.

The most common implant design being used today is the screw-shaped or threaded cylindrical implant (eFig. 74.4A). A threaded implant design is preferred because it engages bone well and is able to achieve good primary stabilization. Even systems that started with cylindrical press-fit (nonthreaded) designs progressively evolved to a threaded geometry. The (longitudinal) shape of implants may be parallel or tapered (eFig. 74.4B). Although a majority of all implants have been parallel walled, the use of a tapered implant design has been advocated because it requires less space in the apical region (i.e., better for placement between roots or in narrow anatomic areas with labial concavities). Tapered implants have also been advocated for use in extraction sockets (eFig. 74.5).



EFIG. 74.4 (A) Illustration of a parallel, threaded implant. (B) Illustration of a tapered, threaded implant.

EFIG. 74.5 A tapered, threaded implant design is helpful to minimize apical bone fenestration in areas such as the anterior maxilla, as the result of the presence of labial concavities. Tapered implant

designs are also advantageous for immediate implant placement into extraction sockets.

Implant Surface Characteristics (Microdesign)

Implant surface characteristics (microtopography) have been shown to positively influence the healing process.[31,63,77,88] Accordingly, modification of implant surface characteristics has been a major area of research interest and development. Modifications in surface energy, chemical composition, and surface topography are known to influence cellular activity and tissue responses, leading to enhanced osteogenesis.[26,32,75,118] At the molecular level, modified implant surfaces increase adsorption of serum proteins, mineral ions, and cytokines, which subsequently promote cellular migration and attachment.[64,88,104] Implant surface characteristics can also aid in the retention of a fibrin clot, thus providing a migratory pathway for the differentiating osteogenic cells to reach the implant surface.[38,39,90] Today, implants are treated with a variety of technologies to modify surface characteristics (microscale or nanoscale) to enhance bone formation.

Additive Processes

The additive process modifies the microstructure/macrostructure and chemical nature of the implant surface by adding materials or chemicals to the existing surface. Several methods are used to add materials or chemicals to the implant surface, such as inorganic mineral coatings, plasma spraying, biocoating with growth factors, fluoride, and particulates or cements containing calcium phosphates, sulfates, or carbonates. The addition of materials, such as hydroxyapatite (eFig. 74.6), to the implant surface has been shown to enhance or accelerate the initial bone cells, adaptation or proliferation.[42,43,54,122] In general, additive surface modifications tend to increase the surface texture greater than subtractive surface modifications, resulting in topographically "rougher" implant surfaces (eFig. 74.7). Surface roughness can also be increased by

oxidizing or adding an oxide layer (eFig. 74.8).

EFIG. 74.8 Roughened surfaces are achieved by plasma spraying, by acid etching, or as shown here by oxidizing (TiUnite surface). (Courtesy Nobel Biocare Services AG, Zurich, Switzerland.)

Subtractive Processes

The subtractive process modifies the microstructure and chemical nature of the implant surface by removing or altering the existing surface. The roughness of implant surface can be modified by machining, acid etching, blasting, or a combination of these processes to enhance the amount or speed of osseointegration.[36,43,94] The changes are most notable at the microscopic level (eFigs. 74.9 and 74.10). Implant surfaces that are modified at the microscopic level with techniques such as acid etching are thought to promote favorable cellular responses and increased bone formation in close proximity to the surface[16,57] (eFig. 74.11).

EFIG. 74.11 Histologic appearance of bone apposition. (A) At 2 weeks, bone is deposited on the bony wall of the tissue chamber and on the implant surface. Both layers are connected by a scaffold of tiny trabeculae. Woven bone is characterized by the intense staining of the mineralized matrix and the numerous osteocytes located in large lacunae (undecalcified ground section, surface-stained with toluidine blue and basic fuchsin).

(B) At 4 weeks, the volume density of this scaffold has increased both by the formation of new trabeculae and by deposition of more mature, parallel-fibered bone onto the primary scaffold. Woven bone is mainly recognized by the numerous large osteocytic lacunae (bright). The gap between bone and implant surface is an artifact. (C) At 8 weeks, growth and reinforcement result in a further increase in bone density and an almost perfect coating of the implant surface with bone. Remodeling has started, replacing the primary bone by secondary osteons (*arrows*).

Implant Surface Chemical Composition

There have been unsuccessful trials with oral implants made of carbon or hydroxyapatite. The lack of resistance, because of material properties, to occlusal forces led to frequent fractures. The so-called noble metals or alloys, however, do not resist corrosion and have thus been abandoned. Today, the majority of oral implants are made of CP titanium or titanium alloys. The following discussion relates to titanium implants.

Titanium is a reactive metal that oxidizes within nanoseconds when exposed to air. Because of this passive oxide layer, the titanium then becomes resistant to corrosion in its CP form. Some alloys, such as titanium-aluminum 6%, vanadium 4% (Ti6Al4V), are known to provoke bone resorption as the result of leakage of some toxic components. The oxide layer of CP titanium reaches 10 nm of thickness. It grows over the years when facing a bioliquid. It consists mainly of titanium dioxide (TiO_2).

All titanium oxides have dielectric constants, which are higher than most other metal oxides. This factor may explain titanium's tendency to adsorb biomolecules, as seen during surgery when the blood creeps up the surface during implant insertion. The biomolecules normally appear as folded-up structures to hide their insoluble parts, while putting water-soluble radicals on their surface. Thus they will adhere to the TiO_2 surface after displacing the original water molecules sitting on its surface. Although initially attracted by weak van der Waals forces, the high dielectric constant of titanium oxides and the polarizability of the molecules

after adsorption will lead to high bond strengths, which are considered irreversible when they surpass 30 kcal/mol.[61] In fact, because of its propensity for being covered by an uninterrupted oxide layer, which has ceramic-like properties similar to other metal oxides (e.g., aluminum oxides), titanium makes the coating of implants superfluous. This should be stressed because many authors hope for even better osseointegration potential with calcium phosphate (CaP)–coated surfaces and strongly advocate their use. To date, clinical results with CaP-coated implants have not been encouraging from a long-term perspective.[22]

Thus the overall view of potential advantages for different implant surface characteristics is complex, and only clinical observations can determine their validity. For good-quality bone, after 15 years of follow-up, clinical success rates of 99% have been reported for implants with a turned surface.[67] Enhanced implant surface characteristics are likely to be most beneficial for the more challenging situations, such as poor quality bone and early and immediate loading.

Implant Surface Free Energy and Microscopic Roughness

When an implant is brought into contact with bodily tissues and fluids, in this case mostly bone, it faces a "bioliquid," an aqueous environment. Within milliseconds, water, ions, and small biomolecules are absorbed. One could imagine that this absorbed layer renders all surfaces equal. However, the large molecules and the cells that will subsequently adhere to this surface are influenced by the surface characteristics of this pellicle layer. The composition and structure of the initial layer are largely determined by the underlying surface.[97] Thus the three-dimensional shape of the molecules will be modified during their adherence to this pellicle layer and will unveil different radicals, depending on this metamorphosis.

The surface free energy, often called *wettability,* is an important parameter for these interactions. It can be assessed through the shape of a standardized drop of liquid put on the clean implant surface. The angle of this drop toward the underlying surface

reveals that the cohesive forces between liquid molecules are stronger than the adhesive forces between the liquid and the surface. Thus a ball-shaped drop would reveal a low surface free energy.

Surface topography at the cellular and molecular level means microscopic roughness. A surface roughness can be measured with a profilometer, a stylus that follows the surface and measures the peak-to-valley dimensions (expressed as Ra values) or the spacing between irregularities (expressed as Scx values). Wennerberg and Albrektsson[120] provide guidelines for topographic evaluation of implant surfaces.[120] No implant surface is smooth, although several reports have incorrectly referred to the "turned" (machined) implant surface as "smooth" (see eFig. 74.9). Roughened implant surfaces speed up the bone apposition; as demonstrated in vitro, more prostaglandin E_2 (PGE_2) and transforming growth factor beta 1 (TGF-β_1) are produced on rough than on smooth surfaces.[64] Rough surfaces may show some disadvantages, such as increased ion leakage and increased adherence of macrophages and subsequent bone resorption.[76]

It was also reported that in vitro adsorption of fibronectin was higher on smooth than on rough CP titanium surfaces.[45] Fibronectin is a glycoprotein quickly adhering on hard surfaces and known to determine subsequent cell adhesion.[84] Microtopography also influences the number and morphology of cell adhesion pseudopods and cell orientation.[53] Grooves in an implant surface will guide the cell migration along their direction. Bone growth can enter altered microtopographic features such as pits and porosities with internal dimensions that are only a few microns.

Lack of load can also be detrimental and can lead to cortical bone resorption. This is well documented in orthopedics and is termed *stress shielding*.[55] This phenomenon has not been properly evaluated for oral implants in which marginal bone resorption is thought to be associated with chronic inflammation of the overlying soft tissues.

The use of finite element analysis (FEA) has become popular but lacks value by itself; invalid assumptions, such as the isotropic nature of the bone, must be used in the modeling. The deviation of FEA data from in vivo data has been well documented.[74] FEA data

should be considered “descriptive” models that require confirmation by biologic data. However, as with photoelastic studies, FEA analyses do provide some insight on stress concentrations and their relation to implant geometry and the prosthetic superstructures.

Hard Tissue Interface

The primary goal of implant installation is to achieve and maintain a stable bone-to-implant connection (i.e., osseointegration).[29,30] Histologically, osseointegration is defined as the direct structural and functional connection between ordered, living bone and the surface of a load-bearing implant without intervening soft tissues (Fig. 74.1).[27,28] Clinically, osseointegration is the asymptomatic rigid fixation of an alloplastic material (implant) in bone with the ability to withstand occlusal forces.[12,126] The hard tissue interface is a fundamental requirement for and an essential component of implant success.

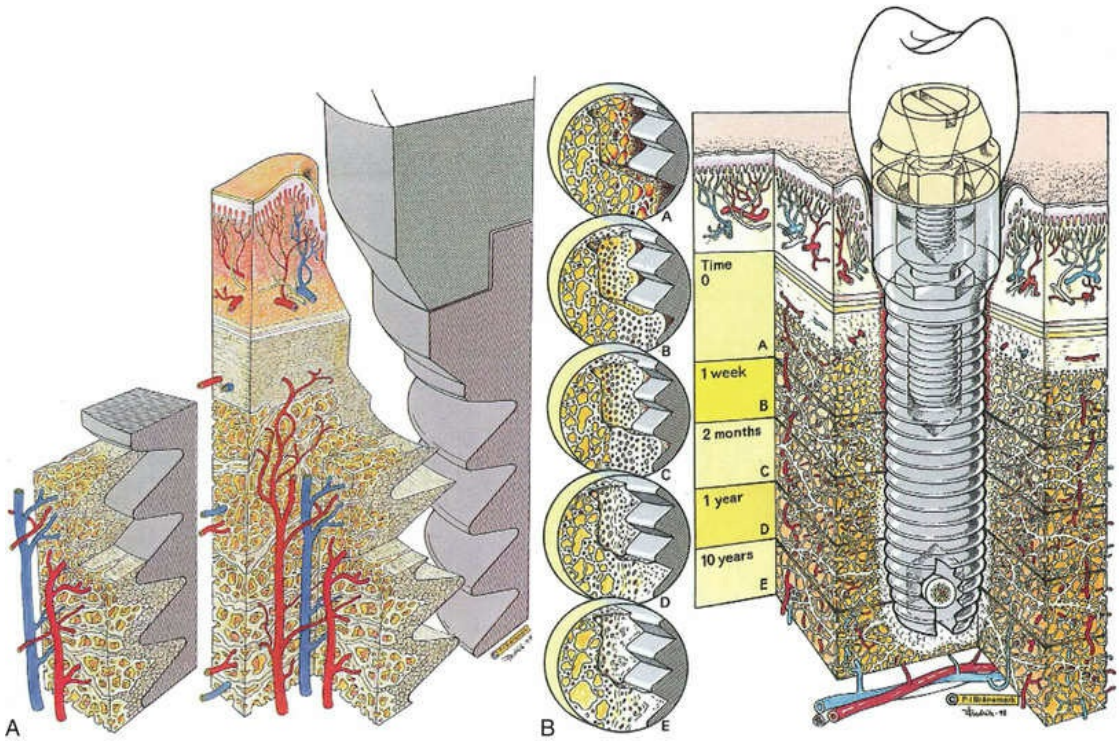

FIG. 74.1 (A) Three-dimensional diagram of the tissue and titanium interrelationship showing an overall view of the intact interfacial zone around the

osseointegrated implant. (B) Physiologic evolution of the biology of the interface over time.

Key Fact

Histologically, osseointegration is defined as the direct structural and functional connection between ordered, living bone and the surface of a load-bearing implant without intervening soft tissues. Clinically, osseointegration is the rigid fixation of an alloplastic material (implant) in bone with the ability to withstand occlusal forces.

Initial Bone Healing

The osseointegration process observed after implant insertion can be compared with bone fracture healing. Implant site osteotomy preparation (bone wounding) initiates a sequence of events, including an inflammatory reaction, bone resorption, release of growth factors, and attraction by chemotaxis of osteoprogenitor cells to the site. Differentiation of osteoprogenitor cells into osteoblasts leads to bone formation at the implant surface. Extracellular matrix proteins, such as osteocalcin, modulate apatite crystal growth.[123] Specific conditions, optimal for bone formation, must be maintained at the healing site to achieve osseointegration.

Immobility of the implant relative to the bone must be maintained for bone formation at the surface. A mild inflammatory response enhances the bone healing, but moderate inflammation or movement above a certain threshold is detrimental.[6] When micromovements at the interface exceed 150 μm, the movement will impair differentiation of osteoblasts and fibrous scar tissue will form between the bone and implant surface.[91] Therefore it is important to avoid excessive forces, such as occlusal loading, during the early healing period.

Bone tissue damage and debris created by the osteotomy site preparation must be cleared up by osteoclasts for normal bone healing. These multinuclear cells, originating from the blood, can resorb bone at a pace of 50 to 100 μm per day. There is a coupling

between bone apposition and bone resorption (Fig. 74.2). Preosteoblasts, derived from primary mesenchymal cells, depend on a favorable oxidation-reduction (redox) potential of the environment. Thus a proper vascular supply and oxygen tension are needed. If oxygen tension is poor, the primary stem cells may differentiate into fibroblasts, form scar tissue, and lead to implant failure (nonintegration).

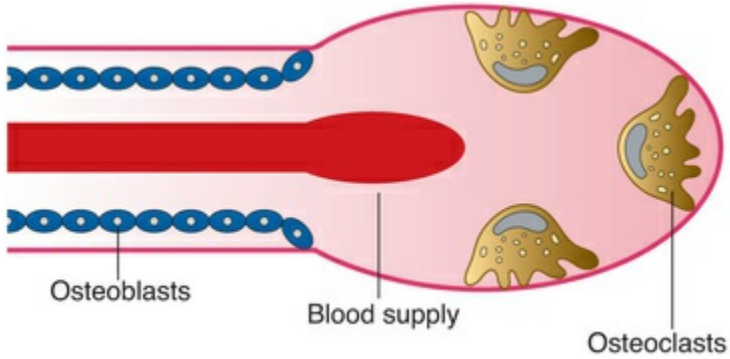

FIG. 74.2 The basic multicellular unit is the basic remodeling process for bone renewal. Osteoclasts are imported by the vascular supply, and the resorption lacunae are soon filled by the lining osteoblasts.

If bone is overheated or crushed during preparation, it will become necrotic and may lead to nonmineralized (soft tissue) scar formation or be sequestered. The critical temperature for bone cells that should not be exceeded is 47°C (116.6°F) at an exposure time of 1 minute.[6] Thus preparation of implant osteotomy sites requires profuse irrigation (cooling) along with gentle, intermittent, moderate-speed drilling using sharp drills. Another complicating factor, well recognized from open wound fractures, is that microbial contamination jeopardizes the normal bone healing. Accordingly, strict aseptic techniques should be maintained.

Key Fact

Immobility of the implant must be maintained during the early postinsertion healing for bone formation at the surface. Moderate inflammation or movement above a certain threshold is

detrimental and may lead to implant failure. If micromovements exceed 150 μm, the movement will impair the differentiation of osteoblasts, and fibrous scar tissue will form between the bone and implant surface.

New bone formation follows a specific sequence of events. Woven bone is quickly formed in the gap between the implant and the bone; it grows fast, up to 100 μm per day, and in all directions. Characterized by a random orientation of its collagen fibrils, high cellularity, and limited degree of mineralization, the biomechanical capacity of woven bone is poor (Fig. 74.3A). Thus any occlusal load should be well controlled or avoided in the early phase of healing. After several months, woven bone is progressively replaced by lamellar bone with organized, parallel layers of collagen fibrils and dense mineralization. Contrary to the fast-growing woven bone, lamellar bone formation occurs at a slow pace (only a few microns per day). Ultimately, after 18 months of healing, a steady state is reached where lamellar bone is continuously resorbed and replaced (Fig. 74.3B).[27] At the light microscopic level, an intimate bone-to-implant contact has been extensively reported (Fig. 74.4).[98] Once the bone-to-implant interface has reached a steady state, it can maintain itself over decades, as ascertained by human histology from implants retrieved because of hardware fractures.[10]

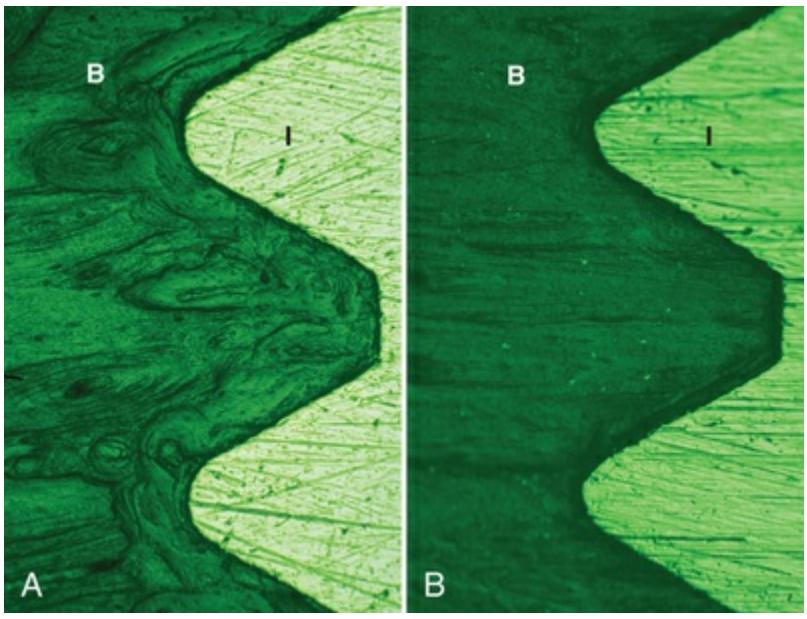

FIG. 74.3 (A) After initial healing, woven bone, as characterized by its irregular pattern, is laid down. (B) After weeks or months, progressively a lamellar bone is laid down, with regular concentric lamellae. *B,* Bone; *I,* implant. (Courtesy Professor T. Albrektsson, Gothenburg, Sweden.)

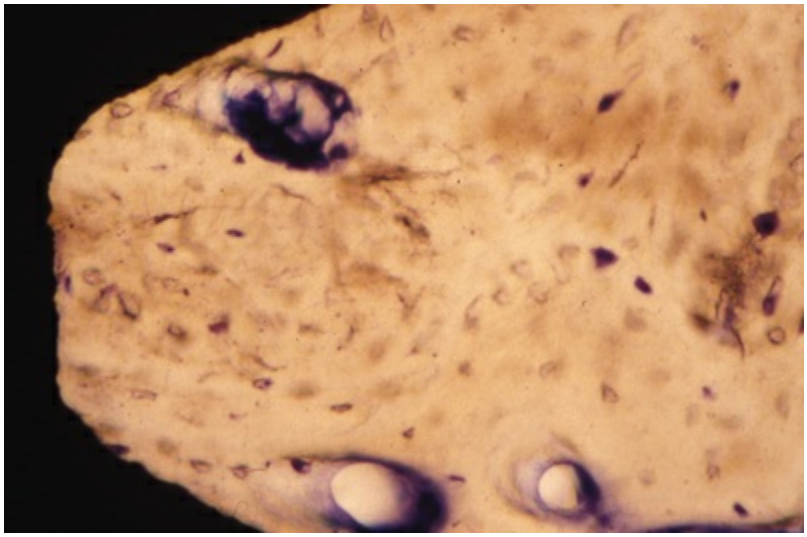

FIG. 74.4 Once a steady state has been achieved at the bone-to-implant interface, an intimate contact can be observed, with some marrow spaces seen in between at the light microscopic level.

« Flash Back

The biomechanical capacity of woven bone is poor. New bone formation adjacent to an implant follows a specific sequence of events with woven bone forming quickly in the gap; it grows fast (100 μm per day) and in all directions. It is characterized by a random orientation of its collagen fibrils, high cellularity, and a limited degree of mineralization.

Bone Remodeling and Function

Clinically, both primary stability and secondary stability of an implant are critical to success. Primary stability, achieved at the time of surgical placement, depends on the implant geometry

(macrodesign), as well as the quality and quantity of bone available for implant anchorage at a specific site. Studies using resonance frequency analysis (RFA) have reported decreased implant stability in the early weeks of postinsertion healing.[18,44,56,93] Secondary stability, achieved over time with healing, depends on the implant surface (microdesign), as well as the quality and quantity of adjacent bone, which will determine the percentage of contacts between the implant and bone.[18,48,96,113] For example, areas such as the anterior mandible have dense cortical bone and provide rigid primary stabilization and good support throughout the healing process. Conversely, areas such as the posterior maxilla have thin cortical bone, and large marrow spaces provide less primary stability. For this reason, the posterior maxilla has been associated with lower success rates compared with other sites with greater bone density and support.[17,60] Interestingly, a new implant with unique knife-edge wide threads (macrodesign) has been shown, in completely healed sites, to maintain stability without the typical drop in the implant stability quotient (ISQ) through the early bone remodeling phase.[73]

Once osseointegration is achieved, implants can resist and function under the forces of occlusion for many years. Longitudinal biomechanical assessments seem to indicate that during the first weeks after placement of one-stage implants, decreased rigidity is observed.[46] This may be indicative of bone resorption during the initial phase of healing. Subsequently, rigidity increases and continues to increase for years.[112] Thus when a prosthesis is installed immediately (in 1 day) or early (in 1 to 2 weeks), care must be taken to control against overload. It is important to recognize that sites with limited primary stability or less bone-to-implant contact (e.g., posterior maxilla) will likely go through a period of even less bone support in the early stages of bone healing due to the initial phase of bone resorption.

Soft Tissue Interface

Not surprisingly, for two decades, research and clinical interest focused on the bone-to-implant interface of osseointegrated implants, and the overlying soft tissues were largely ignored.

Except for a few descriptive sentences, the classic handbook by Brånemark and colleagues[27] presented no data or information about the soft tissue interface. This may be due in part to the fact that most patients were fully edentulous and the Brånemark system implants had turned (machined) surfaces, which are less likely to be associated with soft tissue inflammatory problems.[5] Today, there is greater interest in and appreciation for peri-implant soft tissues and the soft tissue-to-implant interface as a function of aesthetics and maintenance of a seal or barrier against microbial invasion.

Peri-implant soft tissues are similar in appearance and structure to periodontal soft tissues (see Chapter 3).[5] Clearly, both implants and teeth emerge through the soft tissues on the alveolar ridge. The soft tissues consist of connective tissue covered by epithelium. There is a gingival/mucosal sulcus, a long junctional epithelial attachment, and a zone of connective tissue above the supporting bone (Fig. 74.5). Despite the apparent similarities in soft tissues around teeth and implants, the presence of a periodontal ligament around teeth and not around implants is an important, distinct difference. Whereas natural teeth have a periodontal ligament with connective tissue fibers inserting into the cementum and suspending them in the alveolar bone, osseointegrated implants do not. There are no inserting collagen fibers anywhere along the interface of osseointegrated implants. Bone is in direct contact with the implant surface without intervening soft tissues.

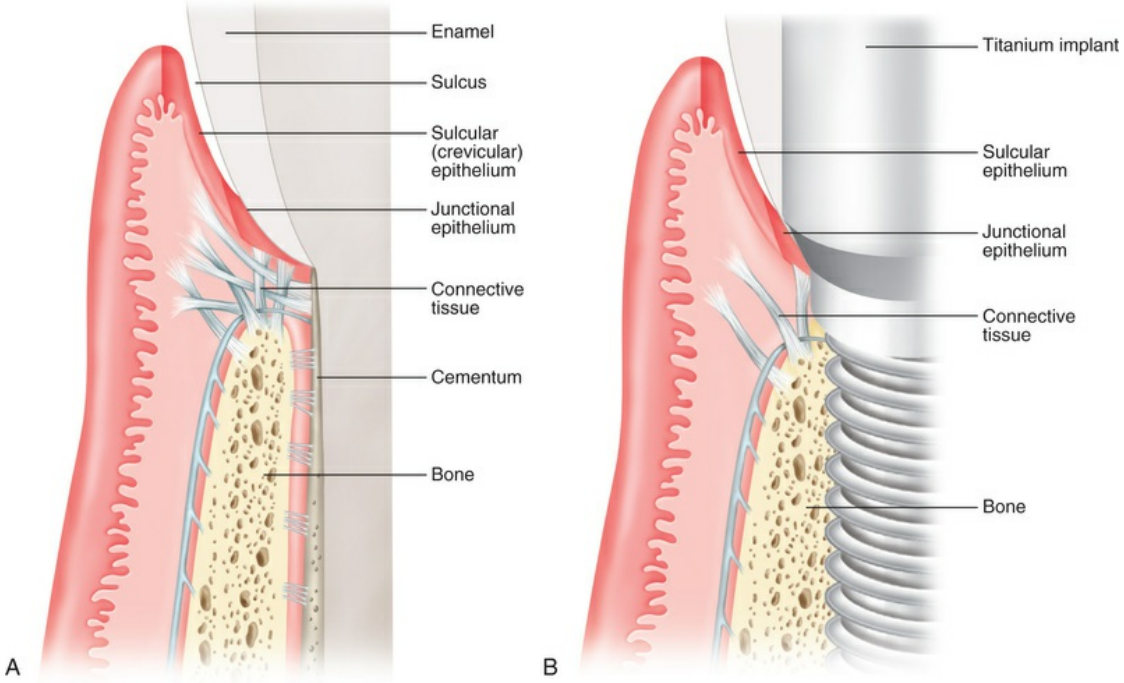

FIG. 74.5 Schematic illustration of hard and soft tissue around a tooth and an implant. (A) Hard and soft tissue anatomy around a natural tooth demonstrates bone support with a periodontal ligament, a connective tissue zone above the crest of bone with connective tissue fibers (Sharpey's) inserting into dentin, a long junctional epithelial attachment, a gingival sulcus lined with sulcular epithelium, and oral gingival epithelium (outer surface of gingiva). (B) Hard and soft tissue anatomy around an implant demonstrates some similarities and some distinct differences. There is supporting bone in direct approximation to the implant surface without any intervening soft tissues (i.e., no periodontal ligament). A connective tissue zone is present above the level of bone with fibers running parallel to the implant surface and no inserting fibers. There is a long junctional epithelial attachment, a gingival/mucosal sulcus lined with sulcular epithelium, and oral gingival/mucosal epithelium (outer surface of soft tissue). (From Rose LF, Mealey BL: *Periodontics: medicine, surgery, and implants,* St. Louis, 2004, Mosby.)

« Flash Back

Sharpey's fibers are bundles of collagenous fibers that pass into the

outer circumferential lamellae of alveolar bone and the cementum of teeth.

Clinically, the thickness of the peri-implant soft tissues varies from 2 to several millimeters (Fig. 74.6). An animal study determined the total height of the peri-implant "biologic width" to be approximately 3 to 4 mm, where about 2 mm is the epithelial attachment and about 1 to 2 mm is the supracrestal connective tissue zone.[19] Consistent with this finding, a human histologic study determined the height of the peri-implant "biologic width," consisting of an epithelial attachment and supracrestal connective tissue, to be about 4 to 4.5 mm[47] (Fig. 74.7).

FIG. 74.6 Clinical appearance of normal, healthy peri-implant tissue with implant restoration removed. Soft tissue thickness varies from site to site, depending on quantity and quality of tissue, as well as the anatomy of the surrounding area (e.g., adjacent to natural teeth with healthy periodontal attachment versus adjacent to a space). Note that the intrasulcular tissue appears more erythematous as the result of the thin, nonkeratinized layer of epithelium overlying the connective tissue.

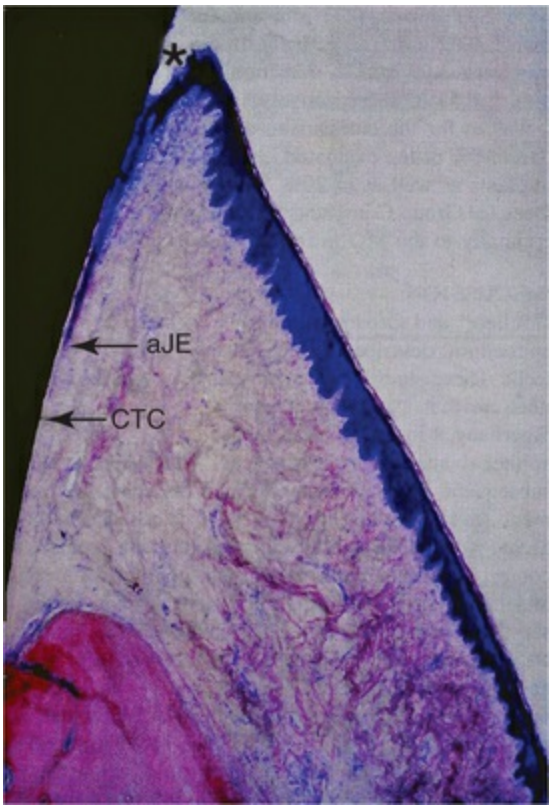

FIG. 74.7 Buccolingual section (basic fuchsin stain; original magnification, ×12.5; one-part SLA implant, 3 months unloaded) showing the gingiva and the most coronal part of alveolar bone. Rete peg formation is only apparent in the area of the keratinized oral gingival epithelium. The oral sulcular epithelium exhibits no keratinization. In the area of the most coronal point of the junctional epithelium (cJE), the soft tissues are slightly torn away (artifact) because of nondecalcified histologic processing. The most apical point of the junctional epithelium is indicated *(aJE).* No rete peg formation is evident adjacent to the basal cell layer of the junctional epithelium (JE), all showing healthy and physiologic soft tissue structures. In addition, the area of connective tissue contact *(CTC)* adjacent to the machined titanium surface is marked. A slight round cell infiltrate in the connective tissue indicates a mild inflammation. Note bone remodeling/new bone formation in the crestal bone region indicated by saturated, dark red stained areas.

Epithelium

As in the natural dentition, the oral epithelium around implants is continuous with a sulcular epithelium that lines the inner surface of the gingival sulcus; the apical part of the gingival sulcus is lined with long junctional epithelium.[71] Ultrastructural examination of the long junctional epithelial attachment adjacent to dental implants has demonstrated that epithelial cells attach with a basal lamina and hemidesmosomes[2,4,49,62,115] (Fig. 74.8). Histologic studies indicate that these epithelial structures and the surrounding lamina propria cannot be distinguished from those structures around teeth.[33] In health, the dimension of the sulcular epithelium is about 0.5 mm,[95] and the dimension of the epithelial attachment is about 2 mm,[19] which is higher than that of the periodontal epithelial attachment.

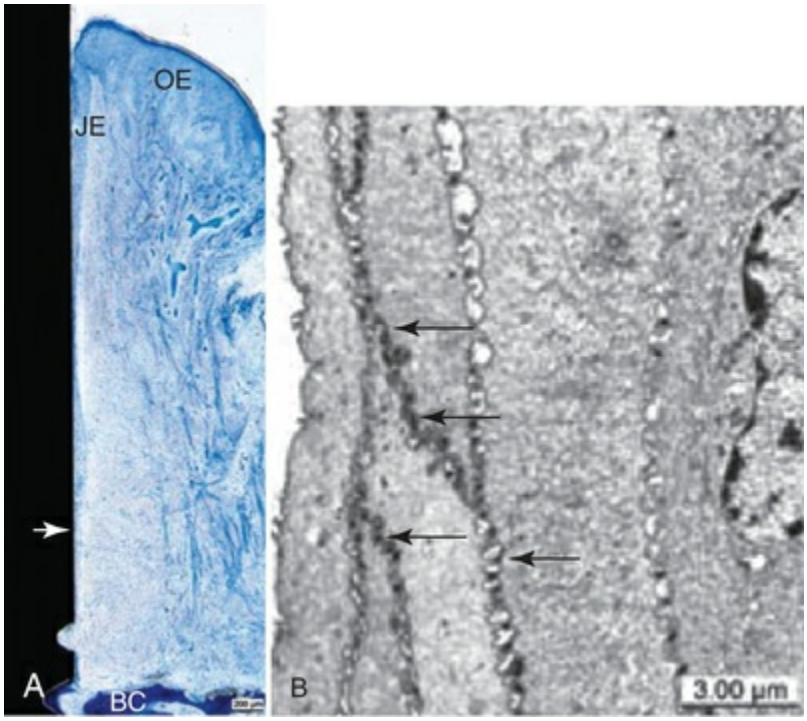

FIG. 74.8 (A) Overview of ground section showing peri-implant tissues covered with keratinizing oral epithelium *(OE).* Junctional epithelium *(JE)* is interposed between connective tissue and alveolar bone crest *(BC).* Apical end of junctional epithelium *(arrow).* Toluidine blue stain. (Bar = 200 µm.) (B) Transmission electron microscopic view of sulcular epithelium showing tightly sealed intercellular spaces by numerous spot desmosomes *(arrows),* contributing to low permeability of this portion of peri-implant

mucosa. Bar = 3 μm.[14]

The apical edge of the epithelial attachment is about 1.5 to 2 mm above the bone margin.[89] In healthy peri-implant tissues, progressive epithelial downgrowth does not occur, indicating that factors other than inserted collagen fiber bundles (i.e., Sharpey's fibers in natural dentition) prevent it.

Connective Tissue

Peri-implant connective tissue morphology closely resembles that of the natural dentition except that it lacks a periodontal ligament, cementum, and inserting fibers (Fig. 74.9). No significant differences were found at the biochemical level between the peri-implant and the periodontal soft tissues,[34] whereas the dimension of the peri-implant connective tissue is 1 to 2 mm, which is higher than that of the average periodontal connective tissue.[19,89]

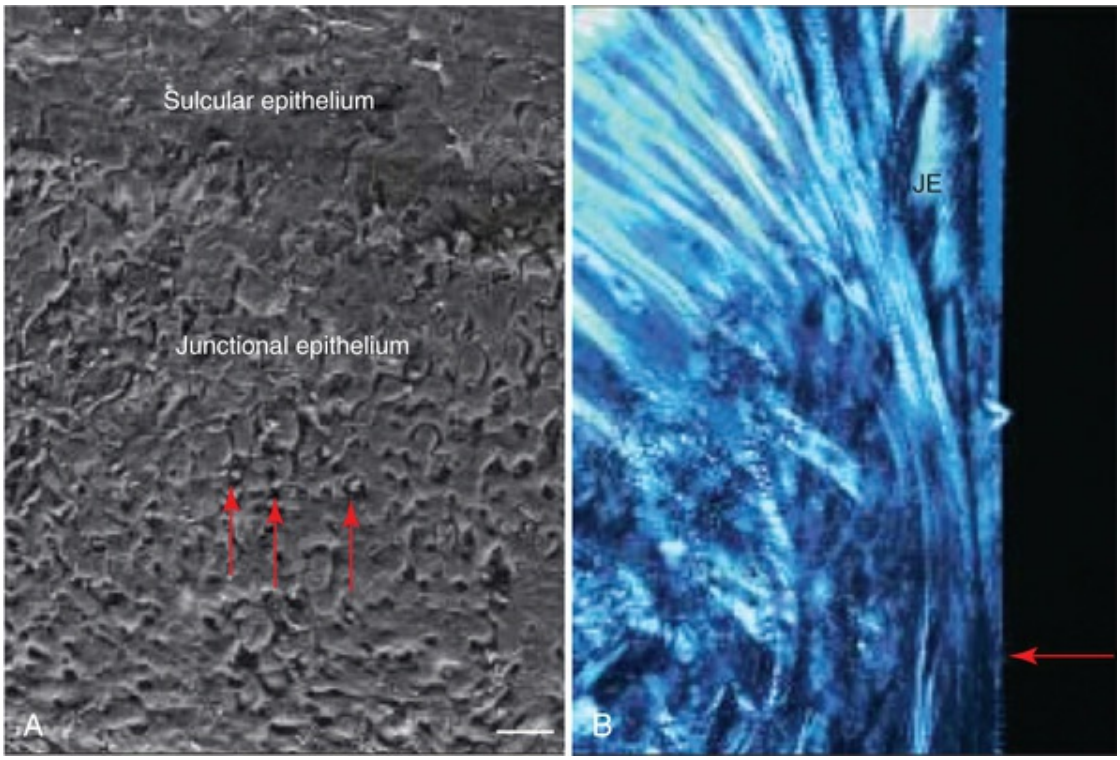

FIG. 74.9 (A) Scanning electron microscope (SEM) image of the junctional epithelium. Note the neutrophils located between the cells *(red arrows).* Bar = 40 μm. (B) Higher magnification of Fig. 74.8 with polarized

light showing the apical extent *(red arrow)* of the junctional epithelium *(JE)*. Note the dense collagen fibers running apicocoronal (i.e., parallel to the implant surface).

The zone of supracrestal connective tissue has an important function in the maintenance of a stable soft tissue–implant interface and as a seal or barrier to the "outside" oral environment. The orientation of connective tissue fibers adjacent to an implant differs from that of periodontal connective tissue fibers. In the absence of cementum and inserting connective tissue fibers (i.e., as in a natural tooth), most peri-implant connective tissue fibers run in a direction more or less parallel to the implant surface. Even when the fiber bundles are oriented perpendicularly, which occurs more often in the gingiva than in the mucosa surrounding implants, the bundles are never embedded in the implant surface.

The fiber bundles can also have a cufflike circular orientation.[20,93] The role of these fibers remains unknown, but it appears that their presence helps to create a soft tissue "seal" around the implant. The adaptation of the connective tissue to an implant surface may also be affected by the mobility of the soft tissue around the implant. The connective tissue in direct contact with the implant surface is characterized by an absence of blood vessels and an abundance of fibroblasts interposed between collagen fibers.[68] Several animal and human studies have shown that the alignments of connective fibers were circular and horizontal around the implants[1,15,35,48,51,52,99] (Fig. 74.10).

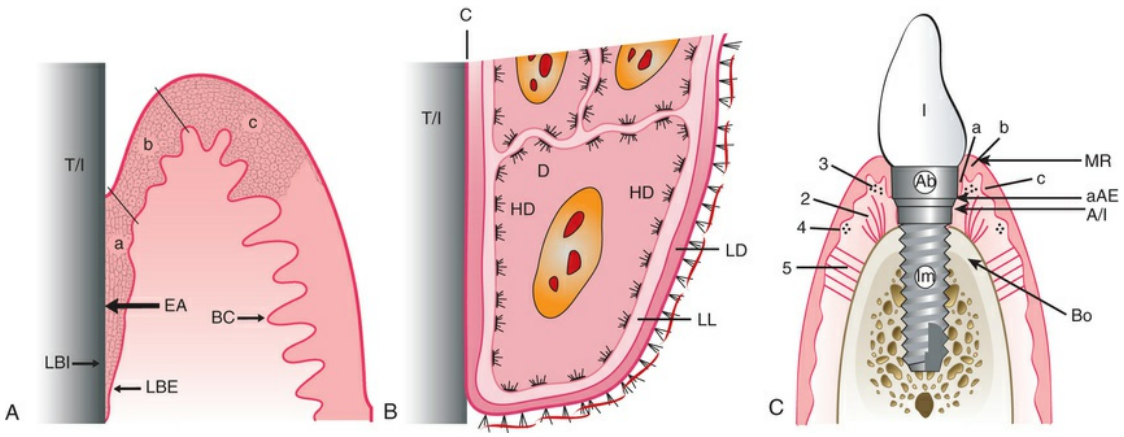

FIG. 74.10 (A) Histologic scheme of epithelial

attachment *(EA)* (identical for tooth and implant). *T/I,* Titanium implant; *BC,* basal complex; *LBI,* lamina basalis interna; *LBE,* lamina basalis externa (only location where cell divisions occur); *a,* long junctional epithelial attachment zone; *b,* sulcular epithelial zone; *c,* oral epithelial zone. (B) At the electron microscopic level, basal complex at the epithelial attachment (three most apical cells) and connection with stroma. *HD,* Hemidesmosomes; *D,* desmosome; *LL,* lamina lucida; *LD,* lamina densa; *C,* cuticle. (C) Implant, abutment *(Ab)*, and crown within alveolar bone and soft tissues. *Im,* Endosseous part of implant; *MR,* margin of gingiva/alveolar mucosa; *Bo,* marginal bone level; *1,* implant crown; *2,* vertical alveolar-gingival connective tissue fibers; *3,* circular gingival connective tissue fibers; *4,* circular gingival connective tissue fibers; *5,* periosteal-gingival connective tissue fibers; *a*, junctional epithelium; *b,* sulcular epithelium; *c,* oral epithelium; *A/I,* abutment/implant junction; *aAE,* apical (point) of attached epithelium.

More recent studies have shown histologic evidence of connective tissue attachment perpendicular to the microgrooved implant surface on both animal and human studies.[78-80] These laser-microtextured grooves (Fig. 74.11) have been shown to be able to stop the epithelial downgrowth and establish connective tissue insertion right at the most coronal part of the laser microgrooved area. (Fig. 74.12). A prospective controlled clinical study showed that laser-grooved surface resulted in shallower probing depth and less peri-implant crestal bone loss than that seen around implants with machined collars.[25,85]

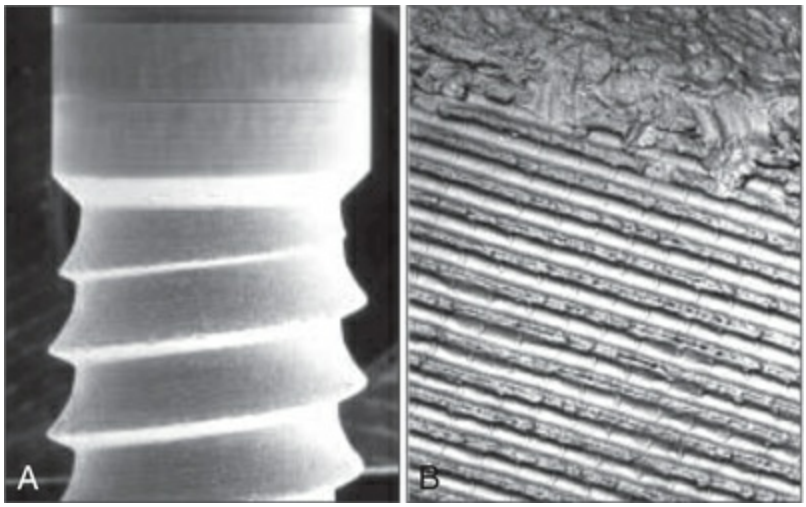

FIG. 74.11 (A) Laser-microtextured surface. (B) Machined collar, original magnification, ×500. (Botos S, Yousef H, Zweig B, et al: The effects of laser microtexturing of the dental implant collar on crestal bone levels and peri-implant health. *Int J Oral Maxillofac Implants* 26:492–498, 2011. With the permission of Dr. Spyros Botos.)

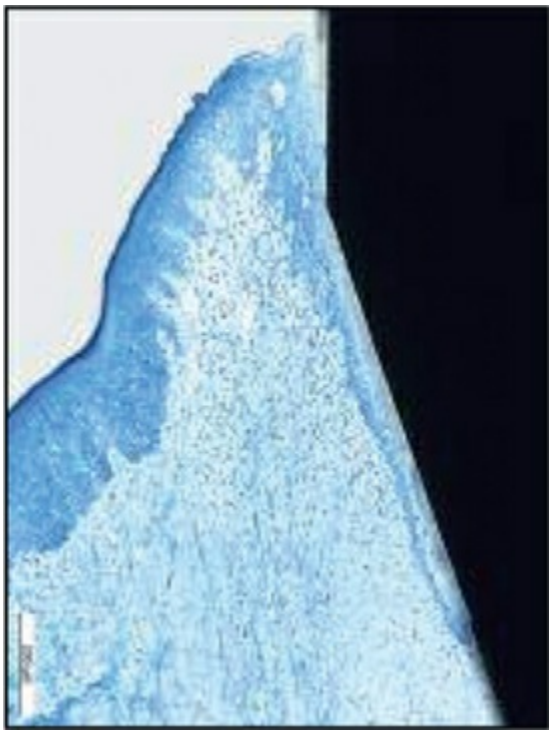

FIG. 74.12 Laser-ablated surface: epithelial downgrowth was stopped right at the coronal-most microgrooved area *(arrow).* Apical to the junctional epithelium, healthy connective tissue fibers attached perpendicularly to the laser-ablated channels. (Courtesy Dr. Myron Nevins.)

This connective tissue interface has been examined by probing attachment level measurements in patients. Probing attachment levels were consistently found coronal to the alveolar crest in patients with peri-implant tissue health, indicating the presence of a zone of direct connective tissue contact to the implant surface. This means that the probing depth measurement performed with a periodontal probe may be about 1.5 mm higher above the bone level in healthy tissues. At inflamed sites, the probe may penetrate to the bone, with the probing depth measurement reflecting the total soft tissue thickness above bone. In cases with inflammatory peri-implant tissue disease, increasing probing depth and reduced attachment levels have been reported.[3,40,86,117]

Keratinized Tissue

Questions emerged decades ago, as it did for the natural dentition, about the need for keratinized tissue to surround implants. Prospective and cross-sectional studies, evaluating screw-shaped implants with a machined surface, suggest that the presence or absence of keratinized gingiva is not a prerequisite for long-term stability.[101] However, it has been suggested that implants surrounded by mucosa only (i.e., nonkeratinized) are more susceptible to peri-implant problems. An animal study observed that ligature-induced peri-implantitis occurs more frequently when alveolar mucosa surrounds the implant as compared with when keratinized mucosa surrounds the implant.[116]

Keratinized mucosa tends to be more firmly anchored by collagen fibers to the underlying periosteum than nonkeratinized mucosa, which has more elastic fibers and tends to be movable relative to the underlying bone. In clinical studies evaluating intraoral implants, with or without peri-implant keratinized mucosa, no clinically significant difference in implant success was reported.[66,121] However, when there is a lack of keratinized tissue, patients tend to complain about pain and discomfort while performing oral hygiene procedures or other functions in the area. The symptoms are alleviated by increasing the amount of keratinized (firmly bound) tissue around the implant(s) via soft tissue grafting (see online Fig. 65.5, A–L).[9,66,121] Finally, although it

may not be comparable to intraoral implants, mobility of soft tissues surrounding extraoral implants is associated with a higher incidence of implant failure.[9]

Vascular Supply and Inflammation

The vascular supply of the peri-implant gingival or alveolar mucosa may be limited, as compared with periodontal gingiva, due to the lack of a periodontal ligament (Fig. 74.13).[21] This is especially true in the tissue immediately adjacent to the implant surface. However, capillary loops in the connective tissue under the junctional and sulcular epithelium around implants appear to be anatomically similar to those found in the normal periodontium (Fig. 74.14).[114]

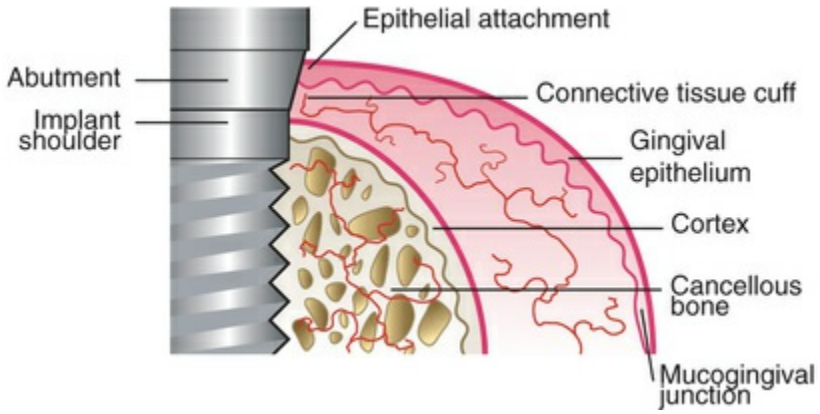

FIG. 74.13 Schematic illustration of the blood supply in the connective tissue cuff surrounding the implant/abutment, which is scarcer than in the gingival complex around teeth because none originates from a periodontal ligament.

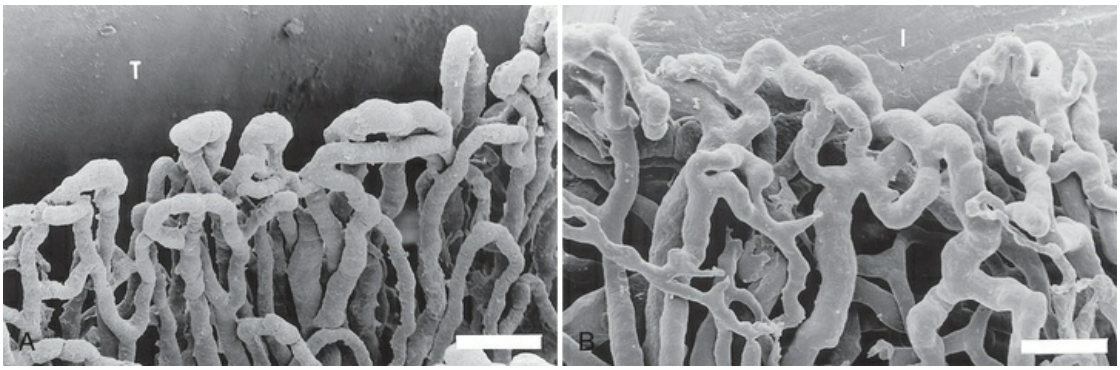

FIG. 74.14 (A) Microvascular topography surrounding a tooth. (B) Microvascular topography surrounding an implant. Bar = 5 μm.[105] (Courtesy Drs. N. Selliseth and K. Selvig, Bergen, Norway.)

Emerging knowledge indicates that the peri-implant gingival or alveolar mucosa has the same morphology as the corresponding tissues around teeth. These soft tissues also react the same way to plaque accumulation. Studies investigating the histology (light microscopic and ultrastructural) of healthy and inflamed tissues surrounding implants in humans have indicated that the inflammatory response to plaque is similar to that observed in periodontal tissues.[95] Polymorphonuclear cells and mononuclear cells transmigrate normally through the peri-implant sulcular epithelium (Fig. 74.15).[95]

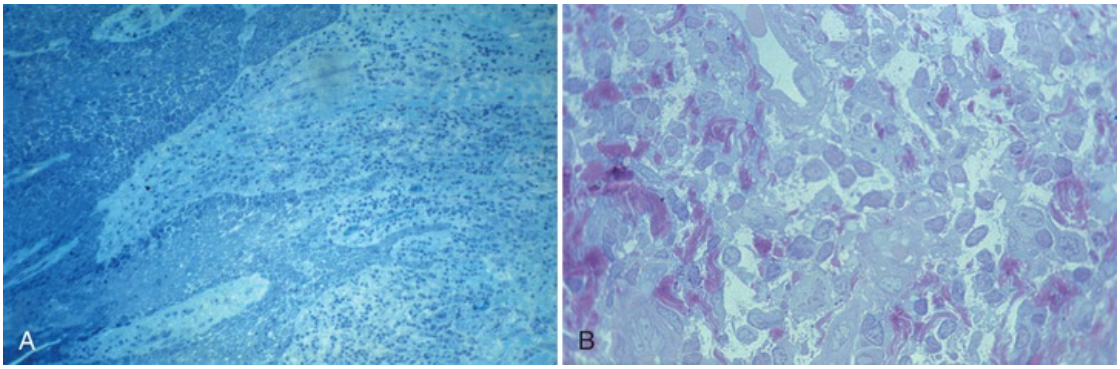

FIG. 74.15 (A) Histologic slide from healthy gingiva surrounding a well-functioning implant in a human patient. No morphologic characteristics differentiate tissue around implant from that around teeth. (B) When gingivitis occurs, a profuse migration of inflammatory cells through the pocket epithelium can be observed. (Courtesy Professor Mariano Sanz, Madrid, Spain.)

Clinical Comparison of Teeth and Implants

Although the soft tissue-to-implant (abutment) interface offers striking similarities with tissue surrounding the natural dentition,

some differences should be considered. At the bone level, the lack of a periodontal ligament is the most striking difference. The following discussion elaborates on the clinical perspectives of these similarities and differences.

At the bone level, the absence of the periodontal ligament surrounding an implant has important clinical consequences. This means that no resilient connection exists between implants and supporting bone. Implants cannot intrude or migrate to compensate for the presence of a premature occlusal contact (as teeth can). Implants and the rigidly attached implant restorations do not move. Thus any occlusal disharmony will have repercussions at either the restoration-to-implant connection, the bone-to-implant interface, or both.

Proprioception in the natural dentition comes from the periodontal ligament. The absence of a periodontal ligament around implants reduces tactile sensitivity[58] and reflex function.[23] This can become even more challenging when osseointegrated, implant-supported, fixed prostheses are present in both jaws.

The lack of a periodontal ligament and the inability of implants to move contraindicates their use in growing individuals. Natural teeth continue to erupt and migrate during growth, whereas implants do not. Implants placed in individuals prior to the completion of growth can lead to occlusal disharmonies with implants.[83] Likewise, it may be problematic to place one or more implants in a location adjacent to teeth that are very mobile from the loss of periodontal support because, as the teeth move in response to or away from the occlusal forces, the implant(s) will bear the entire load.

Overload, because of improper superstructure design, parafunctional habits, or excessive occlusal load, may cause microstrains and microfractures in the bone, which will lead to bone loss and a fibrous inflammatory tissue at the implant interface.[114]

Conclusion

A thorough understanding of bone biology is essential for clinicians to fully appreciate the phenomenon and limitations of

osseointegration. Many factors can interfere with the predictable establishment and maintenance of a long-term rigid connection between the implant surface and the surrounding bone that is able to sustain occlusal loads. The bone-to-implant interface and its rigidity are a predominant biomechanical aspect of coping with the time and intensity of loading. The quality of the soft tissue-to-implant interface also plays an important role in the long-term maintenance of stable marginal bone levels around implants. Clinicians must familiarize themselves with the underlying molecular and cellular events to evaluate the future evolution of implant design and implant protocols, including surgical placement, restoration, and maintenance.

Case Scenario 74.1

Patient:
47-year-old male

Chief Complaint:
"I'm here for a routine check of my teeth and implants."

Background Information
The patient reports that he recently moved to the area (job transfer) from another state. He has no complaints but wants to establish a new dentist for follow-up care. He denies any health conditions, does not take any medications except vitamins, and does not use tobacco. He does not have allergies to any medications. He reports that he has implants that replace his maxillary central incisors. The implant crowns have been in place for about 6 to 7 years.

Current Findings:
Exam reveals good periodontal and peri-implant health. Hygiene (biofilm control) is good. Tissues are pink without signs of swelling or erythema. Dentition is intact and appears to be stable. There is no obvious pathology and no need to repair/replace restorations. Routine periodontal/peri-implant maintenance is recommended. Radiographic evaluation of implants #8 and #9 show good bone support with crestal levels maintained just slightly below the

implant-abutment junction.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What mediates the attachment of cells to the implant surface? A. Lamina lucida B. Lamina densa C. Hemi-desmosomes D. Desmosomes	**Answer: B** **Explanation:** There is not a true connective tissue attachment on dental implant. The lamina densa form scar-like tissue around the dental implant surface.
2. The peri-implant sulcular complex includes all of the following EXCEPT: A. Bone B. Junctional epithelium C. Connective tissue attachment D. Sulcular epithelium	**Answer: A** **Explanation:** Sulcular complex around the dental implant is considered a soft tissue complex, which does not include hard tissue.
3. How can the connective tissue fibers around a dental implant be described? A. Circular B. Vertical alveolar-gingival C. Periosteal-gingival D. All of the above	**Answer: D** **Explanation:** Several animal and human studies have shown that the alignments of connective fibers around implants are circular and horizontal.
4. The apical extent of the junctional epithelium is _____ the implant/abutment interface. A. above B. equal to C. below	**Answer: A** **Explanation:** The peri-implant soft tissues consist of connective tissue covered by epithelium. Apical to the long junctional epithelial attachment is a zone of connective tissue above the supporting bone.
5. What typically surrounds the top of the dental implant? A. Bone and epithelium B. Connective tissue alone C. Bone and connective tissue D. Epithelium alone	**Answer: C** **Explanation:** In healthy patients, the most coronal aspect of the implant is surrounded by bone and connective tissue.

CHAPTER 75

Clinical Evaluation of the Implant Patient

Perry R. Klokkevold, David L. Cochran

CHAPTER OUTLINE

Case Types and Indications
Risk Factors and Contraindications
Posttreatment Evaluation
Conclusion

Over the past several decades, following the landmark research and development of osseointegrated dental implants by Brånemark and colleagues,[15-17] treatment options and treatment planning in dentistry have evolved tremendously. Initially, prosthetic reconstructions with osseointegrated implants were limited to use in the edentulous patient, with many reports documenting excellent long-term success.[1,2,25]

Shortly thereafter, the original implant treatment protocols were adapted for use in partially edentulous patients. There were some transitional challenges associated with the early use of dental

implants being adapted to the partially edentulous patient, but ultimately successes were achieved for this population as well. Modifications in implant design, procedural techniques, and treatment planning greatly improved implant therapy for the partially edentulous patient. Currently, the long-term success of dental implants used to replace single and multiple missing teeth in the partially edentulous patient is very good[29,40,42,48,52] (see Chapter 87). The implementation of bone augmentation procedures further increased the option for patients with inadequate bone volume to be successfully restored with implant-retained prostheses.[27,34,53] Virtually any patient with an edentulous space could be a candidate for endosseous implants, and studies suggest that success rates of 90% to 95% can be expected in healthy patients with good bone and normal healing capacity.[24]

The ultimate goal of dental implant therapy is to satisfy the patient's desire to replace one or more missing teeth in an aesthetic, secure, functional, and long-lasting manner. To achieve this goal, clinicians must accurately diagnose the dentoalveolar condition, as well as the overall mental and physical well-being of the patient. It is necessary to determine whether implant therapy is possible, practical, and, perhaps most important, whether it is indicated for the particular patient who is seeking implants. Local evaluation of potential jaw sites for implant placement (e.g., measuring available alveolar bone height, width, and spatial relationship) and prosthetic restorability are essential considerations in determining whether an implant(s) is possible. However, making as assessment of the patient and determining whether that patient is a good candidate for implants is an equally important part of the evaluation process. The patient evaluation includes identifying factors that might increase the risk of failure or the possibility of complications, as well as determining whether the patient's expectations are reasonable.

This chapter presents an overview of the clinical aspects of dental implant therapy, including an assessment of possible risk factors and contraindications. It also provides guidelines for the pretreatment evaluation of potential implant patients and the posttreatment evaluation of patients with implants.

Case Types and Indications

Edentulous Patients

The patients who seem to benefit most from dental implants are those with fully edentulous arches. These patients can be effectively restored, both aesthetically and functionally, with an implant-assisted removable prosthesis, an implant-supported removable prosthesis, or an implant-supported fixed prosthesis.

The original design for the edentulous arch was a fixed-bone–anchored bridge that used five to six implants in the anterior area of the mandible or the maxilla to support a fixed, hybrid prosthesis. The design is a denture-like complete arch of teeth attached to a substructure (metal framework), which in turn is attached to the implants with cylindrical titanium abutments (Fig. 75.1). The prosthesis is fabricated without flange extensions and does not rely on any soft tissue support. It is entirely implant supported. Usually, the prosthesis includes bilateral distal cantilevers, which extend to replace posterior teeth (back to premolars or first molars).

FIG. 75.1 Clinical photograph of patient with a complete maxillary denture opposing a full-arch implant-supported fixed prosthesis in the mandibular arch.

Another implant-supported design used to restore an edentulous arch is the ceramic-metal fixed bridge (Fig. 75.2). Some patients prefer this design because the ceramic restoration emerges directly from the gingival tissues in a manner that makes its appearance similar to that of natural teeth.

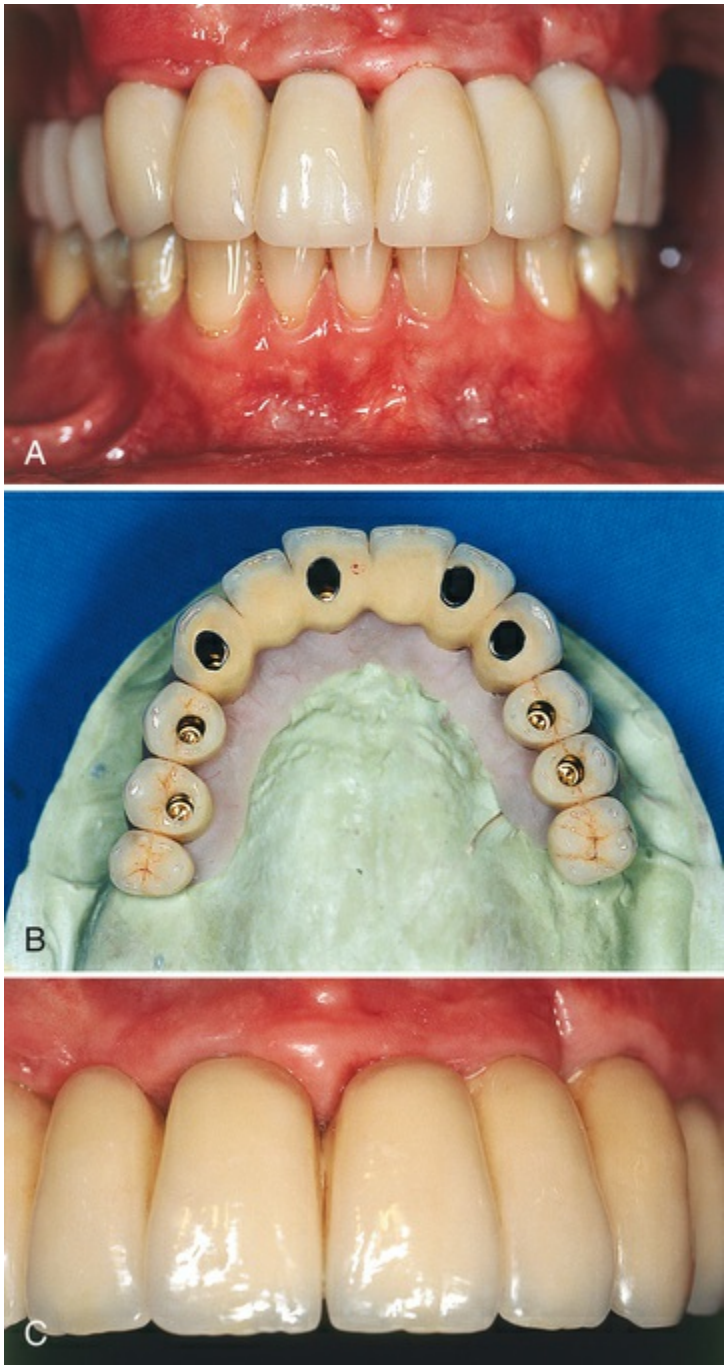

FIG. 75.2 (A) Clinical photograph of acrylic provisional fixed full-arch prosthesis in the maxilla. (B) Clinical photograph of the final ceramometal restoration,

anterior view. (C) Occlusal view of final restoration on master cast. (Courtesy Dr. Russell Nishimura, Westlake Village, California.)

One limitation of both hybrid and ceramometal implant-supported fixed prostheses is that they provide very little lip support and thus may not be indicated for patients who have lost significant alveolar dimension. This is often more problematic for maxillary reconstructions because lip support is more critical in the upper arch. Furthermore, for some patients, the lack of a complete seal (i.e., spaces under the framework) allows air to escape during speech, thus creating phonetic problems.

Depending on the volume of existing bone, the jaw relationship, the amount of lip support, and phonetics, some patients may not be able to be rehabilitated with an implant-supported fixed prosthesis. For these patients, a removable, complete-denture type of prosthesis is a better choice because it provides a flange extension that can be adjusted and contoured to support the lip, and there are no spaces for unwanted air escape during speech. This type of prosthesis can be retained and stabilized by two or more implants placed in the anterior region of the maxilla or mandible. Methods used to secure the denture to the implants vary from separate attachments on each individual implant to clips or other attachments that connect to a bar, which splints the implants together (Fig. 75.3). It is also possible to design a removable prosthesis to intimately and securely attach to a precision-fit substructure (e.g., milled bar), making it an implant-supported removable prosthesis.

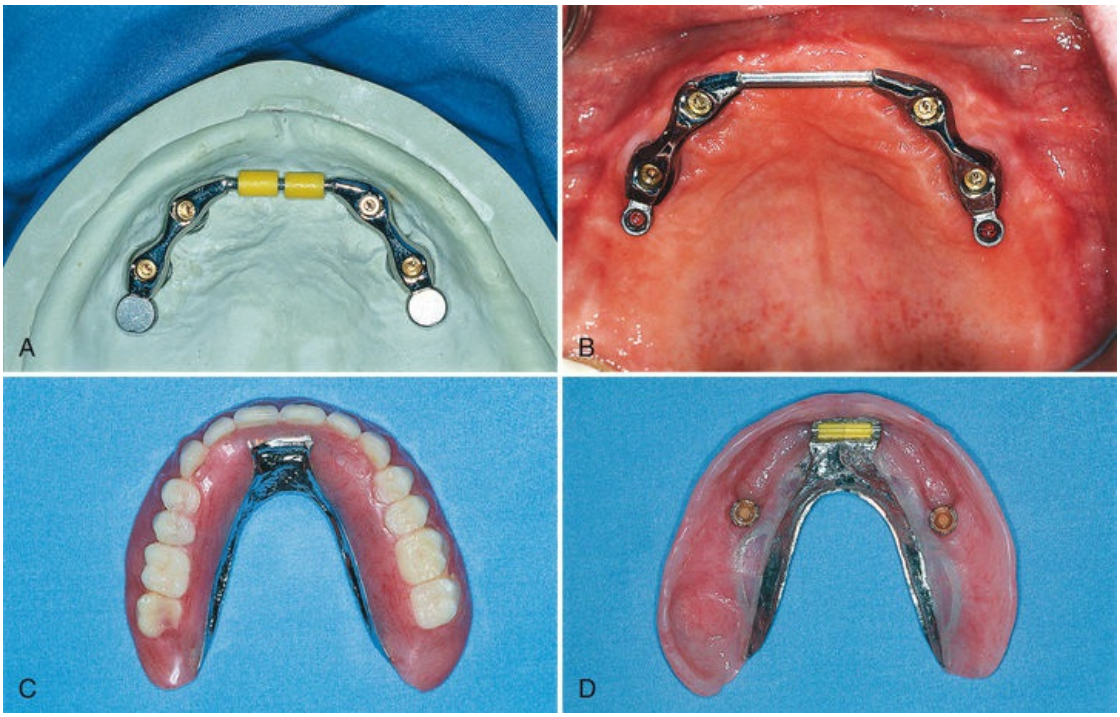

FIG. 75.3 (A) Maxillary overdenture bar attached to four implants with anterior clips and posterior extracoronal resilient attachments (ERAs). (B) Clinical view of maxillary overdenture bar. (C) Palateless maxillary complete overdenture. (D) Tissue surface of the same maxillary implant-assisted overdenture showing clips and ERAs. (Courtesy Dr. John Beumer, University of California, Los Angeles, Maxillofacial Prosthodontics.)

Although the stability of the implant-retained overdenture does not compare with the rigidly attached, implant-supported fixed prosthesis, the increased retention and stability over conventional complete dentures is an important advantage for denture wearers.[55] Additionally, implant-assisted and implant-supported prostheses are thought to lessen the amount of alveolar bone loss associated with long-term use of removable prostheses that bear directly on the alveolar ridges.

Partially Edentulous Patients

Multiple Teeth

Partially edentulous patients with multiple missing teeth represent another viable treatment population for osseointegrated implants, but the remaining natural dentition (occlusal schemes, periodontal

health status, spatial relationships, and aesthetics) introduces additional challenges for successful rehabilitation.[41] The juxtaposition of implants with natural teeth in the partially edentulous patient presents the clinician with challenges not encountered with implants in the edentulous patient. As a result of distinct differences in the biology and function of implants compared with natural teeth, clinicians must educate themselves and use a prescribed approach to the evaluation and treatment planning of implants for partially edentulous patients (see Chapter 77). In general, endosseous dental implants can support a freestanding fixed partial denture. Adjacent natural teeth are not necessary for support, but their close proximity requires special attention and planning.[11] The major advantage of an implant-supported restoration in the partially edentulous patient is that it replaces missing teeth without invasion or alteration of adjacent teeth. Preparation of natural teeth becomes unnecessary, and larger edentulous spans can be restored with implant-supported fixed bridges.[49] Moreover, patients who previously did not have a fixed option, such as those with Kennedy class I and II partially edentulous situations, can be restored with an implant-supported fixed restoration (Fig. 75.4).

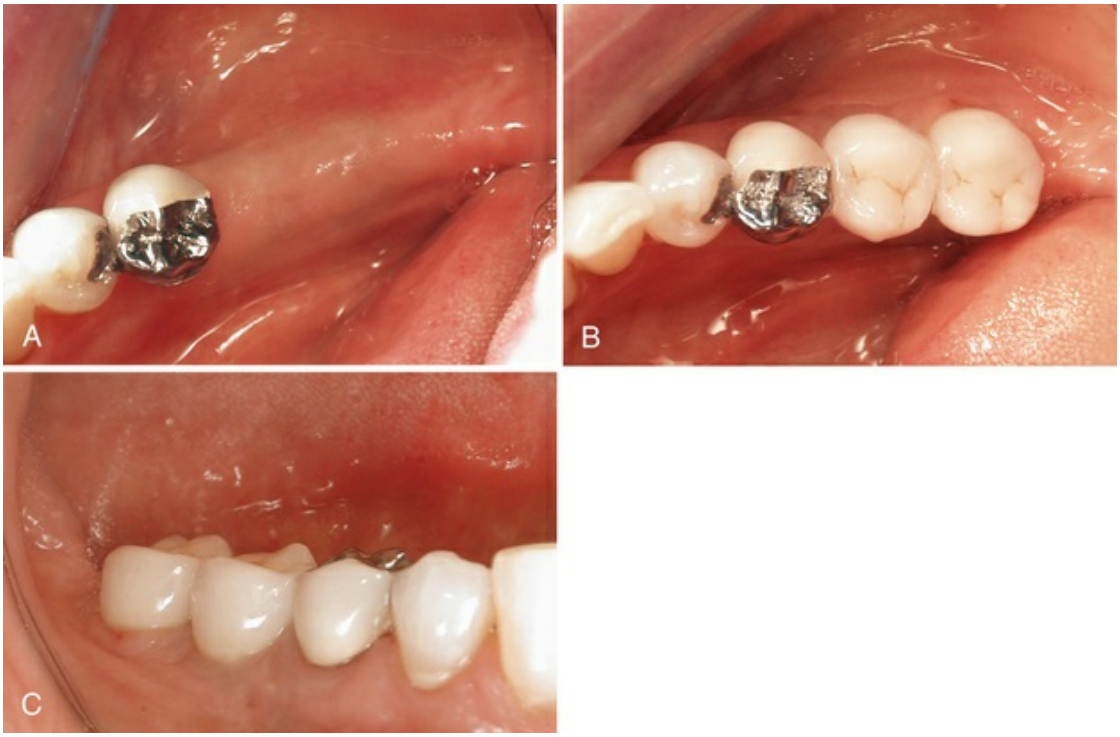

FIG. 75.4 (A) Clinical view of a partially edentulous posterior mandible (Kennedy class II distal extension). (B) Occlusal view of the same patient as in part A restored with an implant-supported fixed restoration replacing teeth #18 and #19. Note that the dimensions of the crowns are smaller than typical mandibular molars (i.e., closer to bicuspid size). (C) Buccal view of the same restorations.

Early attempts to use endosseous implants to replace missing teeth in the partially edentulous patient were a challenge partly because the implants and armamentarium were designed for the edentulous patient and did not have much flexibility for adaptation and use in the partially edentulous patient. Today, clinicians have many choices in terms of implant length, diameter, and abutment connection to choose for the optimal replacement of any missing tooth, large or small (Fig. 75.5).

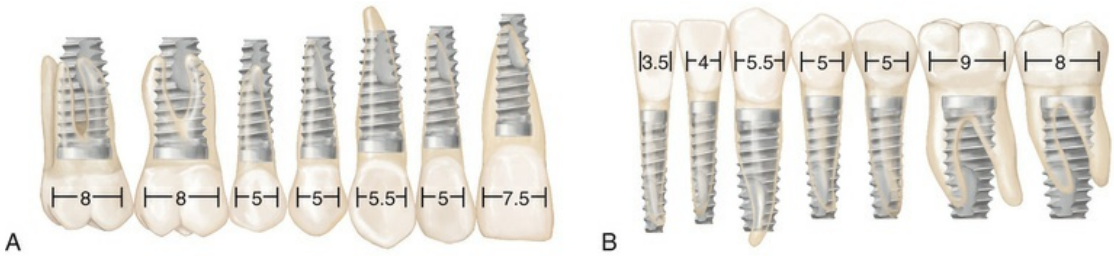

FIG. 75.5 Diagram representing the use of wide-, narrow-, and standard-diameter implants for molars, mandibular incisors, and other teeth (different-sized implants superimposed over various teeth). (A) Maxillary teeth. (B) Mandibular teeth.

The primary challenge with partially edentulous cases is an underestimation of the importance of treatment planning for implant-retained restorations with an adequate number of implants to withstand occlusal loads. For example, one problem that required correction was the misconception that two implants could be used to support a long-span, multiunit fixed bridge in the posterior area. Multiunit fixed restorations in the posterior jaw are more likely to experience complications or failures (mechanical or biologic) when they are inadequately supported in terms of the

number of implants, quality of bone, or strength of the implant material (see Chapter 77). Better treatment planning with the use of an adequate number and size of implants, particularly in areas of poor-quality bone, has solved many of these problems.

« Flash Back

The Kennedy Classification refers to a system developed by Dr. Edward Kennedy for the classification of an edentulous jaw and partial dentures. It is based on the distribution of edentulous spaces. Kennedy class I is a bilateral free-end posterior edentulous area. Kennedy class II is a unilateral free-end posterior edentulous area. Kennedy class III is a single bounded edentulous area that does not cross the midline (unilateral). Kennedy class IV is a single anterior bounded edentulous area that crosses the midline (bilateral).

Single Tooth

Patients with a missing single tooth (anterior or posterior) represent another type of patient who benefits greatly from the success and predictability of endosseous dental implants (Video 75.1). Replacement of a single missing tooth with an implant-supported crown is a much more conservative approach than preparing two adjacent teeth for the fabrication of a tooth-supported fixed partial denture. It is no longer necessary to "cut" healthy or minimally restored adjacent teeth to replace a missing tooth with a nonremovable prosthetic replacement (Fig. 75.6). Reported success rates for single-tooth implants are excellent.[23]

FIG. 75.6 Single-tooth replacement. (A) Implant in place. (B) Metalloceramic crown.

Replacement of an individual missing posterior tooth with an implant-supported restoration has been successful as well. The greatest challenges to overcome with the single-tooth implant restorations were screw loosening and implant or component fracture. Because of the increased potential to generate forces in the posterior area, the implants, components, and screws often failed. Both of these problems have been addressed with the use of wider-diameter implants and internal fixation of components (Fig. 75.7). Wide-diameter implants often have a wider platform (restorative interface) that resists tipping forces and thus reduces screw loosening. The wide-diameter implant also provides greater

strength and resistance to fracture as a result of increased wall thickness (i.e., the thickness of the implant between the inner screw thread and the outer screw thread). Implants with an internal connection are inherently more resistant to screw loosening and thus have an added advantage for single-tooth applications.

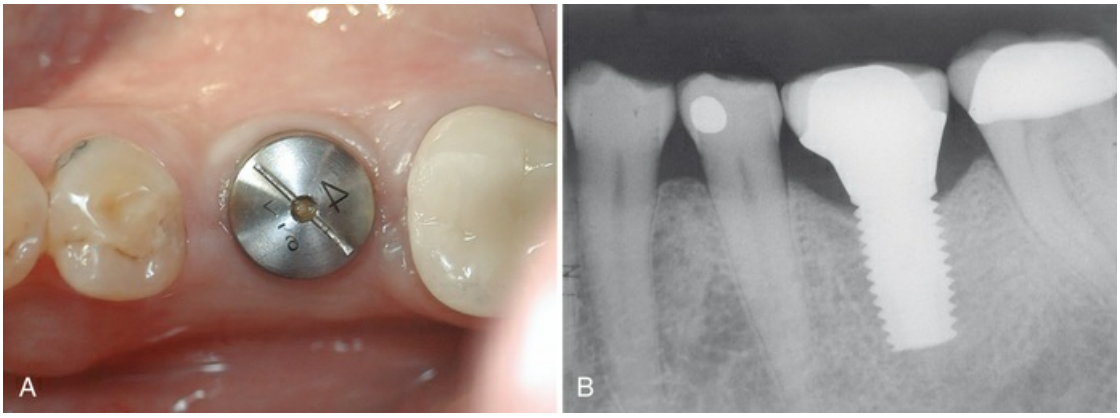

FIG. 75.7 (A) Occlusal view of healing abutment, which is attached to a wide-diameter implant used to replace a single missing molar. (B) Radiograph of the same patient depicted in part A, showing the wide-diameter implant supporting the final restoration (molar replaced with a single-tooth implant-supported crown).

Aesthetic Considerations

Anterior single-tooth implants present some of the same challenges as the single posterior tooth supported by an implant, but they also are an aesthetic concern for patients. Some cases are more aesthetically challenging than others because of the nature of each individual's smile and display of teeth. The prominence and occlusal relationship of existing teeth, the thickness and health of periodontal tissues, and the patient's own psychological perception of aesthetics all play a role in the aesthetic challenge of the case. Cases with good bone volume, bone height, and tissue thickness can be predictable in terms of achieving satisfactory aesthetic results (see Fig. 75.6). However, achieving aesthetic results for patients with less-than-ideal tissue qualities poses difficult challenges for the restorative and surgical team.[12] Replacing a single tooth with an implant-supported crown in a patient with a high

smile line, compromised or thin periodontium, inadequate hard or soft tissues, and high expectations is probably one of the most difficult challenges in implant dentistry and should not be attempted by novice clinicians.

Pretreatment Evaluation

A comprehensive evaluation is indicated for any patient who is being considered for dental implant therapy. The evaluation should assess all aspects of the patient's current health status, including a review the patient's past medical history, medications, and medical treatments. Patients should be questioned about parafunctional habits, such as clenching or grinding teeth, as well as any substance use or abuse, including tobacco, alcohol, and drugs. The assessment should also include an evaluation of the patient's motivations, level of understanding, compliance, and overall behavior. For most patients, this involves simply observing their demeanor and listening to their comments for an impression of their overall sensibility and coherence with other patient norms.

An intraoral and radiographic examination must be done to determine whether it is possible to place implant(s) in the desired location(s). Properly mounted diagnostic study models and intraoral clinical photographs are useful parts of the clinical examination and treatment-planning process to aid in the assessment of spatial and occlusal relationships. Once the data collection is completed, the clinician will be able to determine whether implant therapy is possible, practical, and indicated for the patient.

Conducting an organized, systematic history and examination is essential to obtaining an accurate diagnosis and creating a treatment plan that is appropriate for the patient. Each treatment plan should be comprehensive and provide several treatment options for the patient, including periodontal and restorative therapies. Then, in consultation, the clinician can agree on the final treatment plan with the patient. Information gathered throughout the process will help the clinician's decision making and determination of whether a patient is a good candidate for dental implants. A thoughtful and well-executed evaluation can also

reveal deficiencies and indicate what additional surgical procedures may be necessary to accomplish the desired goals of therapy (e.g., localized ridge augmentation, sinus bone augmentation). Each part of the pretreatment evaluation is briefly discussed here.

Key Fact

Every treatment plan should be comprehensive. It should provide multiple treatment options, including periodontal and restorative therapies. Then, once presented with good information, the patient can ask questions and make an informed decision about the final treatment plan. Information gathered throughout the process will help the clinician's decision making and determination of whether a patient is a good candidate for dental implants.

Chief Complaint

What is the problem or concern in the patient's own words? What is the patient's goal of treatment? How realistic are the patient's expectations? The patient's chief concern, desires for treatment, and vision of the successful outcome must be taken into consideration. The patient will measure implant success according to his or her personal criteria. The overall comfort and function of the implant restoration are often the most important factors, but satisfaction with the appearance of the final restoration will also influence the patient's perception of success. Furthermore, patient satisfaction may be influenced simply by the impact that the treatment has on the patient's perceived quality of life. Patients will evaluate for themselves whether the treatment helped them to eat better, look better, or feel better about themselves.

The clinician could consider an implant and the retained prosthesis a success using standard criteria of symptom-free implant function, implant stability, and lack of peri-implant infection or bone loss. At the same time, however, the patient who does not like the aesthetic result or does not think the condition has improved could consider the treatment a failure. Therefore it is critical to inquire, as specifically as possible, about the patient's expectations before initiating implant therapy and to appreciate the

patient's desires and values. With this goal in mind, it is often helpful and advisable to invite patients to bring their spouses or family members to the consultation and treatment-planning visits to add an independent "trusted" observer to the discussion of treatment options. Ultimately, it is the clinician's responsibility to determine if the patient has realistic expectations for the outcome of therapy and to educate the patient about realistic outcomes for each treatment option.

Clinical Correlation

It is essential to listen to a patient's chief concerns. The patient will ultimately decide whether the implant is successful based on his or her personal criteria. The overall comfort and function of the implant restoration are often the most important factors, but satisfaction with the appearance will also influence the patient's perception of success. Patient satisfaction will be influenced by the impact of treatment on their perceived quality of life. Patients will evaluate for themselves whether the implant treatment helped them to eat better, look better, or feel better.

Medical History

A thorough medical history is required for any patient in need of dental treatment, regardless of whether implants are part of the plan. This history should be documented in writing by the patient's completion of a standard health history form and verbally through an interview with the treating clinician. The patient's health history should be reviewed for any condition that might put the patient at risk for adverse reactions or complications.

Patients must be in reasonably good health to undergo surgical therapy for the placement of dental implants. Any disorder that may impair the normal wound-healing process, especially as it relates to bone metabolism, should be carefully considered as a possible risk factor or contraindication to implant therapy (discussed later).

A thorough physical examination is warranted if any questions arise about the patient's health status.[15] Appropriate laboratory tests

(e.g., coagulation tests for a patient receiving anticoagulant therapy) should be requested to evaluate further any conditions that may affect the patient's ability to undergo the planned surgical and restorative procedures safely and effectively. If any questions remain about the patient's health status, a medical clearance for surgery should be obtained from the patient's treating physician.

Dental History

A review of a patient's past dental experiences can be a valuable part of the overall evaluation. Does the patient report a history of recurrent or frequent abscesses, which may indicate a susceptibility to infections or diabetes? Does the patient have many restorations? How compliant has the patient been with previous dental recommendations? What are the patient's current oral hygiene practices?

The individual's previous experiences with surgery and prosthetics should be discussed. If a patient reports numerous problems and difficulties with past dental care, including a history of dissatisfaction with past treatment, the patient may have similar difficulties with implant therapy. It is essential to identify past problems and to elucidate any contributing factors. The clinician must also assess the patient's dental knowledge and understanding of the proposed treatment, as well as the patient's attitude and motivation toward implants.

Intraoral Examination

The oral examination is performed to assess the current health and condition of existing teeth, as well as to evaluate the condition of the oral hard and soft tissues. It is imperative that no pathologic conditions are present in any of the hard or soft tissues in the maxillofacial region. All oral lesions, especially infections, should be diagnosed and appropriately treated before implant therapy. Additional criteria to consider include the patient's habits, level of oral hygiene, overall dental and periodontal health, occlusion, jaw relationship, temporomandibular joint condition, and ability to open wide.

After a thorough intraoral examination, the clinician can evaluate

potential implant sites. All sites should be clinically evaluated to measure the available space in the bone for the placement of implants and in the dental space for prosthetic tooth replacement (Box 75.1). The mesial-distal and buccal-lingual dimensions of edentulous spaces can be approximated with a periodontal probe or other measuring instrument. The orientation or tilt of adjacent teeth and their roots should be noted as well. There may be enough space in the coronal area for the restoration but not enough space in the apical region for the implant if roots are directed into the area of interest (Fig. 75.8). Conversely, there may be adequate space between roots, but the coronal aspects of the teeth may be too close for emergence and restoration of the implant. If either of these conditions is discovered, orthodontic tooth movement may be indicated. Ultimately, edentulous areas need to be precisely measured using diagnostic study models and imaging techniques to determine whether space is available and whether adequate bone volume exists to replace missing teeth with implants and implant restorations. Fig. 75.9 diagrams the minimal space requirements for standard-, wide-, and narrow-diameter implants placed between natural teeth, and the minimal interocclusal space needed to restore implants.

Box 75.1

How Much Space Is Required for Placement of One or More Implants?[a]

Alveolar Bone

Assuming an implant is 4 mm in diameter and 10 mm long, the minimal width of the jawbone needs to be 6 to 7 mm, and the minimal height should be 10 mm (minimum of 12 mm in the posterior mandible, where an additional margin of safety is required over the mandibular nerve). This dimension is desired to maintain at least 1 to 1.5 mm of bone around all surfaces of the implant after preparation and placement.

Interdental Space

Edentulous spaces need to be measured to determine whether enough space exists for the placement and restoration with one or more implant crowns. The minimal space requirements for the placement of one, two, or more implants are illustrated diagrammatically in Fig. 75.9. The minimal mesial-distal space for an implant placed between two teeth is 7 mm. The minimal mesial-distal space required for the placement of two standard-diameter implants (4-mm diameter) between teeth is 14 mm. The required minimal dimensions for wide-diameter or narrow-diameter implants will increase or decrease incrementally according to the size of the implant. For example, the minimal space needed for the placement of an implant 6 mm in diameter is 9 mm (7 mm + 2 mm). Whenever the available space between teeth is greater than 7 mm and less than 14 mm, only one implant, such as placement of a wide-diameter implant, should be considered. Two narrow-diameter implants could be positioned in a space that is 12 mm. However, the smaller implant may be more vulnerable to implant fracture.

Interocclusal Space

The restoration consists of the abutment, the abutment screw, and the crown (it may also include a screw to secure the crown to the abutment if it is not cemented). This restorative "stack" is the total of all the components used to attach the crown to the implant. The dimensions of the restorative stack vary slightly depending on the type of abutment and the implant-restorative interface (i.e., internal or external connection). The minimum amount of interocclusal space required for the restorative "stack" on an external hex-type implant is 7 mm.

[a]All of the minimal space requirements discussed here are generic averages. The actual space limitations for any particular implant system must be determined according to the manufacturer's specifications.

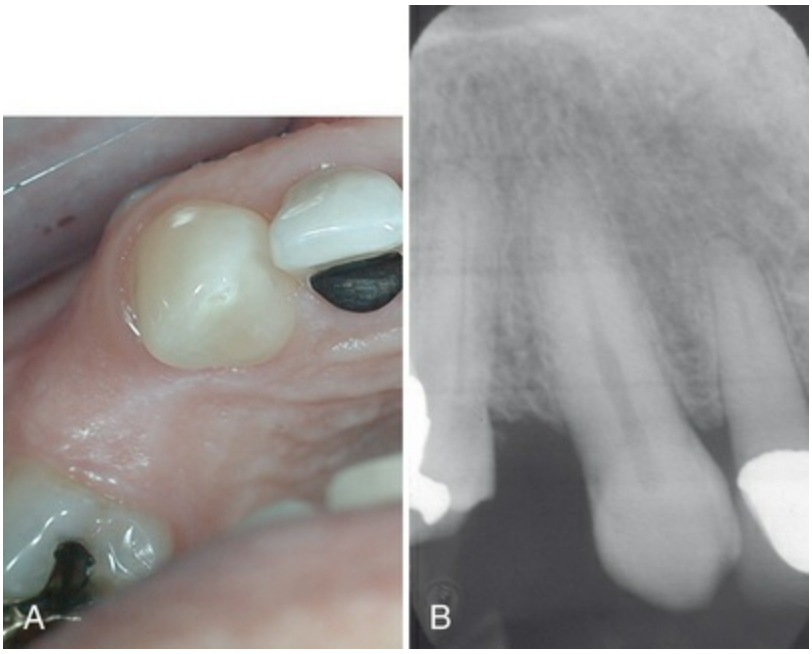

FIG. 75.8 (A) Clinical photograph of maxillary premolar space with apparently adequate space between the remaining teeth for an implant-supported crown. (B) Radiograph clearly shows a lack of space between the roots of the adjacent teeth as a result of convergence into the space (same patient as in part A).

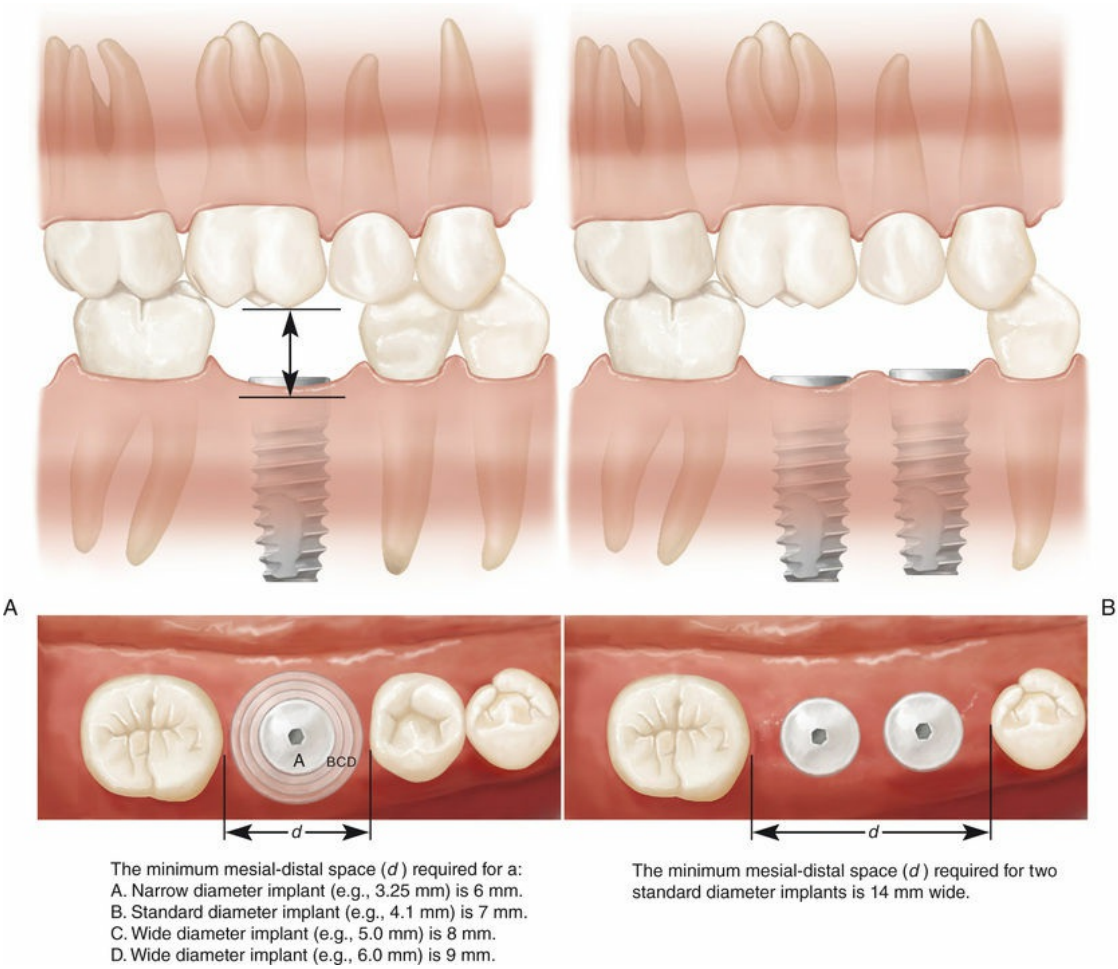

FIG. 75.9 (A) Minimum amount of mesial-distal space *(d)* required for placement of single-tooth implant between natural teeth: *A,* 6 mm for narrow-diameter implant (3.25 mm); *B,* 7 mm for standard-diameter implant (4.1 mm); *C* and *D,* 8 mm and 9 mm, respectively, for wide-diameter implants (5 mm and 6 mm). (B) Minimum amount of mesial-distal space *(d)* required for placement of two standard-diameter implants (4.1 mm) between natural teeth is 14 mm. This allows approximately 2 mm between teeth/implants and between implant/implant. Minimum amount of space required between implant/restoration interface and opposing occlusal surfaces for restoration of an implant. This dimension will vary depending on implant design and manufacturer component dimensions. The minimal dimension of 7 mm is based on an externally hexed implant and UCLA abutment.

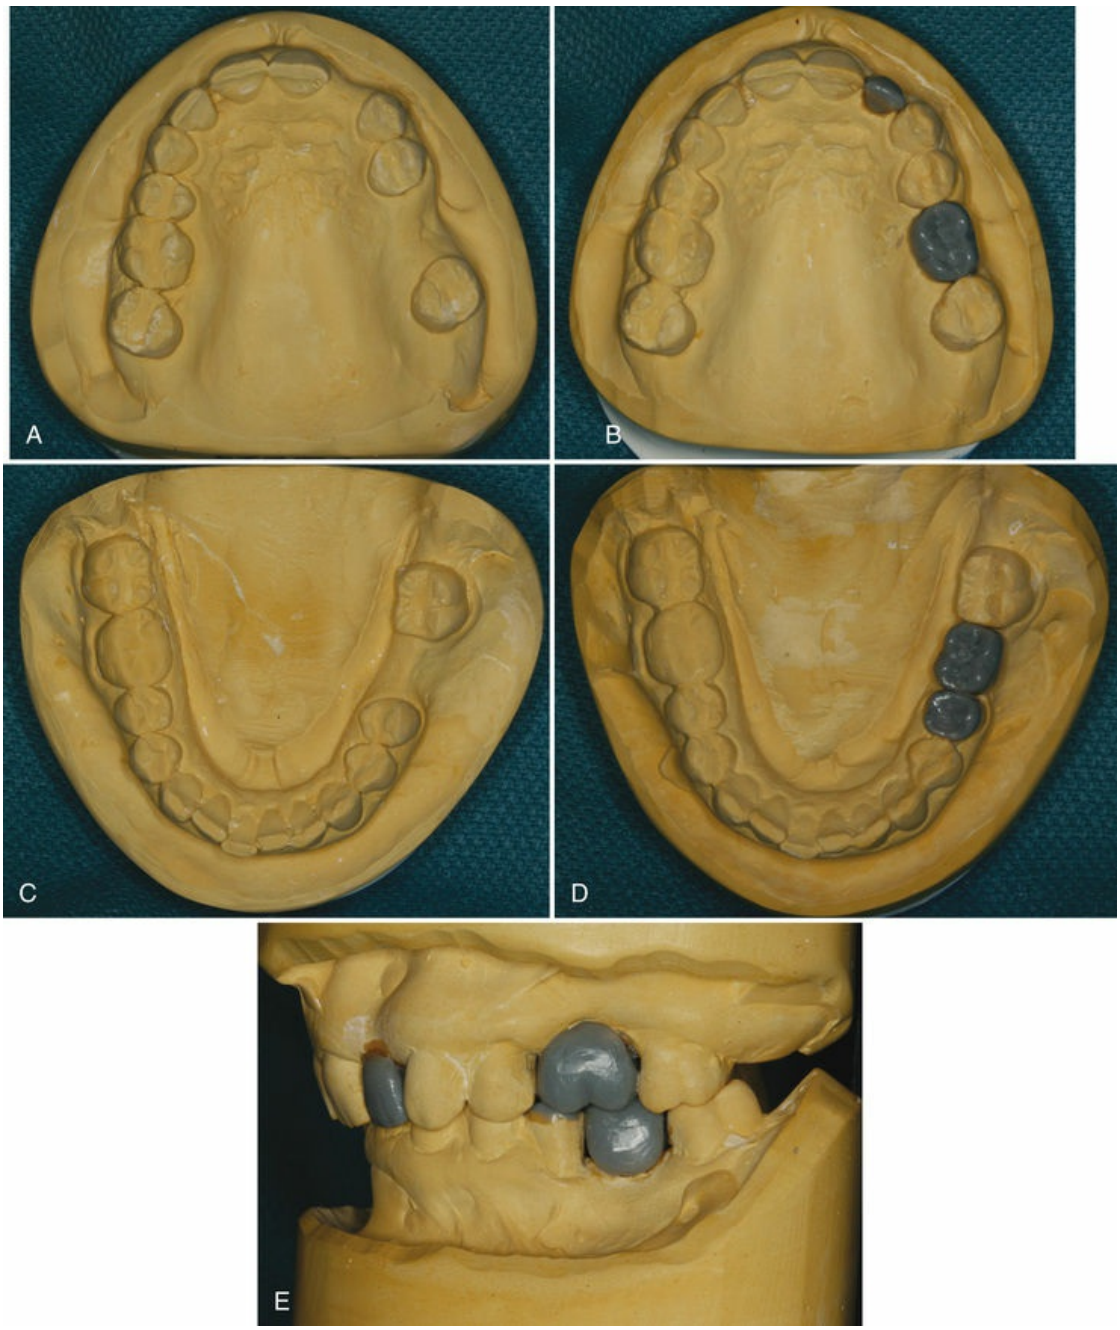
Diagnostic Study Models

Mounted study models are an excellent means of assessing potential sites for dental implants. Properly articulated models with diagnostic wax-up of the proposed restorations allow the clinician to evaluate the available space and to determine potential limitations of the planned treatment (eFig. 75.1). This is particularly useful when multiple teeth are to be replaced with implants or when a malocclusion is present.



EFIG. 75.1 Photographs of a diagnostic model with proposed lateral incisor and first molar tooth replacement waxed up to evaluate the amount of space and contours. (A) Diagnostic cast of maxillary arch with missing left lateral incisor and left first molar. (B) Diagnostic wax-up of lateral incisor and first molar in the maxillary arch. (C) Diagnostic cast of mandibular arch with missing left first molar. (D) Diagnostic wax-up of first molar. (E) Articulated maxillary and mandibular diagnostic models with wax-up of lateral incisor and first molars to evaluate dimensions and contours.

Hard Tissue Evaluation

The amount of available bone is the next criterion to evaluate. Wide variations in jaw anatomy are encountered, and it is therefore important to analyze the anatomy of the dentoalveolar region of interest both clinically and radiographically.

A visual examination can immediately identify deficient areas (Fig. 75.10), whereas other areas that appear to have good ridge width will require further evaluation (Fig. 75.11). Clinical examination of the jawbone consists of palpation to feel for anatomic defects and variations in the jaw anatomy, such as concavities and undercuts. If desired, it is possible with local anesthesia to probe through the soft tissue (intraoral bone mapping) to assess the thickness of the soft tissues and measure the bone dimensions at the proposed surgical site.

FIG. 75.10 Clinical photographs of edentulous areas with obvious deficient areas of alveolar dimension noted on visual examination: (A) anterior maxilla, (B) posterior maxilla, (C) anterior mandible, and (D) posterior mandible. These clinical images all represent buccal-lingual deficiencies in the alveolar dimensions.

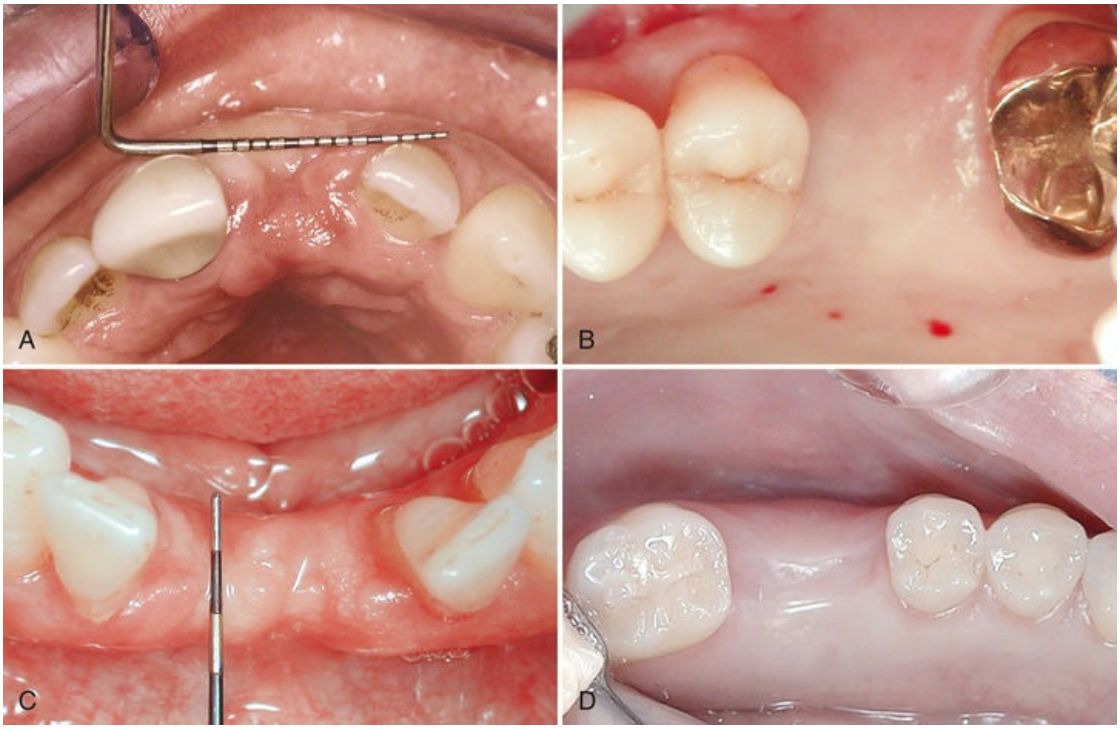

FIG. 75.11 Clinical photographs of edentulous areas with apparent good alveolar dimension noted on visual examination: (A) anterior maxilla, (B) posterior maxilla, (C) anterior mandible, and (D) posterior mandible. It is likely that these sites have adequate bone volume for implant placement. However, it is also possible to find alveolar deficiencies despite the appearance of wide ridges.

The spatial relationship of the bone must be evaluated in a three-dimensional view because the implant must be placed in the appropriate position relative to the prosthesis. It is possible that an adequate dimension of bone is available in the anticipated implant site (see Box 75.1), but that the bone and thus the implant placement might be located too lingual or too buccal for the desired prosthetic tooth replacement.[30] Bone augmentation procedures may be necessary to facilitate the placement of an implant in an acceptable prosthetic position despite the availability of an adequate quantity of bone (i.e., the bone is in the wrong location). Bone augmentation procedures are discussed in Chapters 79 and 80.

Radiographic Examination

Radiographic assessment of the quantity, quality, and location of available alveolar bone in potential implant sites ultimately determines whether a patient is a candidate for implants and if a particular implant site needs bone augmentation. Appropriate radiographic procedures, including periapical radiographs, panoramic projections, and cross-sectional imaging, can help identify vital structures such as the floor of the nasal cavity, maxillary sinus, mandibular canal, and mental foramen (see Chapter 76). In addition to the absolute dimensional measurement of the alveolar bone, it is important to determine whether the volume of bone radiographically (as well as clinically) is located in a position to allow for the proper position of the implant to facilitate restoration of the tooth/teeth in proper aesthetic and functional relationship with the adjacent and opposing dentition. The best way to evaluate the relationship of available bone to the dentition is to image the patient with a diagnostically accurate guide using radiopaque markers that are positioned at the

proposed prosthetic locations, ideally with appropriate restorative contours (see Fig. 76.5).

Key Fact

Implant planning should be "prosthetically driven." This can be achieved with a diagnostic wax-up of the proposed prosthesis and radiographic imaging with radiopaque markers, ideally tooth-shaped, that show the desired tooth position(s) relative to the available bone.

Soft Tissue Evaluation

Evaluation of the quality, quantity, and location of soft tissue present in the anticipated implant site helps to anticipate the type of tissue that will surround the implant(s) after treatment is completed (keratinized vs. nonkeratinized mucosa). For some cases, clinical evaluation may reveal a need for soft tissue augmentation (Box 75.2). Areas with minimal or no keratinized mucosa may be augmented with gingival or connective tissue grafts. Other soft tissue concerns, such as frenum attachments that pull on the gingival margin, should be thoroughly evaluated as well.

Box 75.2

How Much Keratinized Tissue Is Required for the Health and Maintenance of Implants?

Debate continues about whether it is necessary to have a zone of keratinized tissue surrounding implants. Despite strong opinions and beliefs about the need for keratinized mucosa around implants versus this mucosa being unnecessary, neither argument has been proved.

Some studies have concluded that, in the presence of good oral hygiene, a lack of keratinized tissue does not impair the health or function of implants.[54] Others strongly believe that keratinized mucosa has better functional and aesthetic results for implant

restorations. Keratinized mucosa is typically thicker and denser than alveolar mucosa (nonkeratinized). It forms a strong seal around the implant with a cuff of circular (parallel) fibers around the implant, abutment, or restoration that is resistant to retracting with mastication forces and oral hygiene procedures. Implants with coated surfaces (i.e., hydroxyapatite [H] or titanium plasma spray [TPS] coating) demonstrate greater peri-implant bone loss and failures in the absence of keratinized mucosa.[13,38]

Risk Factors and Contraindications

Clearly, there are numerous indications for the use of endosseous dental implants to replace missing teeth. Most patients who are missing one or more teeth can benefit from the application of an implant-retained prosthesis provided they meet the requirements for surgical and prosthetic rehabilitation. Edentulous patients who are unable to function with complete dentures and who have adequate bone for the placement of dental implants can be especially good dental implant candidates. More and more partially edentulous patients are also being treated with dental implant restorations. Many patients, whether they are missing one, several, or all of their teeth, can be predictably restored with implant-retained prostheses.

In this era of high implant success and predictability and thus possible complacency, it is imperative for clinicians to recognize risk factors and contraindications to implant therapy so that problems can be minimized and patients can be accurately informed about risks. As such, the clinician must be knowledgeable in this area and inform patients about risk factors and contraindications before initiating treatment. Contraindications for the use of dental implants, although relatively few and often not well defined, do exist. Some conditions are probably best described as “risk factors” rather than “contraindications” to treatment because implants can be successful in almost all patients; implants may be less *predictable* in some situations, and this distinction should be recognized. Ultimately, it is the clinician's responsibility with the patient to make decisions as to when implant therapy is not indicated.

Table 75.1 lists some conditions and factors that are thought to increase the risk for implant failure or otherwise deem the patient a poor candidate for implant therapy. Some of these conditions are briefly discussed here.

TABLE 75.1

Risk Factors and Contraindications for Implant Therapy

	Risk Factor	Contraindication
Medical and Systemic Health–Related Issues		
Diabetes (poorly controlled)	??—Possibly	Relative
Bone metabolic disease (e.g., osteoporosis)	??—Probably	Relative
Radiation therapy (head and neck)	Yes	Relative/absolute
Bisphosphonate therapy (intravenous)	??—Probably	Relative/absolute
Bisphosphonate therapy (oral)	??—Possibly	Relative
Immunosuppressive medication	??—Probably	Relative
Immunocompromising disease (e.g., HIV, AIDS)	??—Possibly	Relative
Psychological and Mental Conditions		
Psychiatric syndromes (e.g., schizophrenia, paranoia)	No	Absolute
Mental instability (e.g., neurotic, hysteric)	No	Absolute
Mentally impaired; uncooperative	No	Absolute
Irrational fears; phobias	No	Absolute
Unrealistic expectations	No	Absolute
Habits and Behavioral Considerations		
Smoking; tobacco use	Yes	Relative
Parafunctional habits	Yes	Relative
Substance abuse (e.g., alcohol, drugs)	??—Possibly	Absolute
Intraoral Examination Findings		
Atrophic maxilla	Yes	Relative
Current infection (e.g., endodontic)	Yes	Relative
Periodontal disease	??—Possibly	Relative

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Medical and Systemic Health–Related Issues

Although few absolute medical contraindications to implant therapy exist, some relative contraindications are important to consider. The clinician must consider medical and health-related conditions that affect bone metabolism or any aspect of the patient's capacity to heal normally.[10] This category includes conditions such as diabetes, osteoporosis, and immune compromise; medications; and medical treatments such as chemotherapy and irradiation.

Diabetes Mellitus

Diabetes is a metabolic disease that can have significant effects on the patient's ability to heal normally and resist infections. This is particularly true for patients whose diabetes is not well controlled. Patients with poorly controlled diabetes often have impaired wound healing and a predisposition to infections, whereas patients with well-controlled diabetes experience few, if any, problems (see Chapter 14).

There is concern about the success and predictability of implants in patients with diabetes. Several studies have reported moderate failure rates in patients with diabetes, with implant success ranging from 85.6% to 94.3%.[8,26,36,39] A prospective study demonstrated 2.2% early failures and 7.3% late failures in patients with diabetes.[51] After 5 years, the overall success rate for this group of diabetic patients was 90%.[47] None of these studies was able to correlate gender, age, smoking, diabetes type, or level of diabetic control with implant failure. In a meta-analytical review of implant failures in patients who were not diabetics, the early implant failure rate was 3.2% and the late implant failure rate 5.2%.[22] The finding that patients with diabetes experience slightly more late failures may be related to less tissue integrity caused by reduced tissue turnover and impaired tissue perfusion. These results suggest that diabetes may be a risk factor for implants, particularly for late failures. However, the risk does not appear to be particularly high.

Bone Metabolic Disease

Osteoporosis is a skeletal condition characterized by decreased mineral density. The two main classifications are primary (three types) and secondary (multiple types) osteoporosis. *Primary osteoporosis* has been attributed to menopausal changes (type I), age-related changes (type II), or idiopathic causes (type III). *Secondary osteoporosis* has been attributed to many different diseases and conditions, including diabetes, alcoholism, malnutrition, and smoking.[31]

All the various types of osteoporosis share the same fundamental problem of decreased bone mineral density and the concern that this condition may impair the patient's ability to achieve and maintain implant osseointegration. The premise that implants will not perform as well in a patient with osteoporosis is reasonable

given that osseointegration depends on bone formation adjacent to the implant surface and that success rates are highest in dense bone and lowest in poor-quality, loose trabecular bone. However, to date, there is no clear evidence to suggest that implants will not be successful in patients with osteoporosis, so the issue continues to be debated.[9,19] On the positive side, although the evidence is weak, case reports have demonstrated successful implant treatment in patients with osteoporosis.[30] Some investigators advocate the use of longer healing times for osseointegration to occur before loading the implants in patients with osteoporosis.[28] Conversely, in a retrospective analysis of 49 patients who received sinus bone augmentation, individuals (11 patients) with lower bone mass density had significantly lower implant success rates as compared with age- and sex-matched controls.[14] Other parameters evaluated in this study did not demonstrate any significant differences.

Interestingly, there is a trend in aging adults (men older than 50 years and postmenopausal women) for bone mass to decrease progressively through bone demineralization at a rate of 1% to 2% per year and in some individuals as much as 5% to 8% per year throughout their later life.[21,35] If one considers this decline in bone mass with aging along with a continually increasing life expectancy in the population, the number of individuals with osteopenia or osteoporosis will continue to increase, and the concern about this condition's influence on implant success will become increasingly more important for clinicians.

Bisphosphonate Therapy

Some prescribed medications, including steroids and bisphosphonates, may be cause for concern relative to the potential implant patient. A brief statement regarding the risk of bisphosphonate therapy is offered here. Readers are encouraged to review more detailed explanations in Chapters 14 and 39 and to consult online information as well as other resources to get updated information about this important subject as more is learned and recommendations are developed.

Although there is heightened awareness and great concern about risk of bisphosphonate-related osteonecrosis of the jaw (BRONJ), the causal relationship and pathogenesis of the problem has not

been defined. A review of available literature offers information that will guide clinicians in their decision making, but it is far from definitive. The prevalence and incidence remains uncertain. In general, the risk of BRONJ is between 1 in 10,000 and 1 in 100,000 but may increase to 1 in 300 after an oral surgical procedure. The great majority of BRONJ cases will likely remain in the population of patients who receive intravenous administration of bisphosphonates. Cofactors, such as smoking, steroid use, anemia, hypoxemia, diabetes, infection, and immune deficiency, have not been firmly established but may be important.[45] Rarely does BRONJ in the oral bisphosphonate patient appear to progress beyond stage 2, and many cases reverse with discontinuation of oral medication. Procedures reported to have contributed to the development of BRONJ include extractions, periodontal surgery, root canal treatment, and dental implant surgery.[46] Dental implant therapy, as well as other surgical procedures, should be avoided in individuals who have been treated with intravenous (IV) bisphosphonate therapy and carefully considered with caution in patients treated with oral bisphosphonate therapy, particularly those with a history of more than 3 years of use.[3]

Immune Compromise and Immune Suppression

Corticosteroid therapy, whether used for hormone replacement, cancer treatment, immune suppression, or another chronic condition, may suppress the immune response, impair wound healing, or compromise the normal adrenal response to stress. See Chapters 14 and 39 for more information on the treatment of patients taking corticosteroids. Individuals undergoing chemotherapy or taking medications that impair healing potential (e.g., steroids) are probably not good candidates for implant therapy because of the effects these agents have on normal healing. This is especially true for cancer chemotherapy. A lowered resistance to infection may also be problematic for these patients. Past history of chemotherapy or immunosuppressive therapy may not be problematic if the patient has recovered from the side effects of treatment.

Patients with an immunocompromising disease, such as human immunodeficiency virus (HIV) infection or acquired

immunodeficiency syndrome (AIDS), are not good candidates for implants when their immune system is seriously impaired. Patients with very low or undetectable viral loads and normal (T cell counts) immune function may be candidates for implant therapy (see Chapter 30).

Radiation Therapy

Patients with a history of radiation treatment to the head and neck region may not heal well after surgery. Soft tissue dehiscence may follow surgical manipulation, which may lead to osteoradionecrosis (ORN), a serious condition of nonhealing exposure and infection of bone. This is especially problematic for patients who have received radiation dosages greater than 60 Gy. Surgical procedures, or any procedure that may initiate a wound, are generally avoided in patients with a history of radiation therapy. If deemed necessary, surgical procedures can be done in conjunction with hyperbaric oxygen (HBO) therapy to reduce the risk of ORN.

Several studies have documented poor success rates for implants in patients with a history of radiation therapy.[32,33,44] In a literature review, Sennerby and Roos[50] found irradiation to be associated with high failure rates, as did Esposito and colleagues[24] in their review. Beumer and colleagues[12] reported success rates as low as 60.4% in the irradiated maxilla. Granstrom and colleagues[32] reported a significant improvement in survival rates for implants in patients treated with HBO. However, in a systematic review, Coulthard and colleagues[18] concluded that the evidence is lacking to support the clinical effectiveness of HBO in irradiated patients receiving implants. The application of implants in patients with a history of irradiation, with or without the use of HBO, is not resolved and continues to be debated. Clearly, irradiation is a risk factor for implant success and may be a contraindication.

Psychological and Mental Conditions

In general, any type of psychological abnormality can be considered a contraindication to dental implant treatment because of the patient's uncooperativeness, lack of understanding, or behavioral problems. Physiologically, there is no reason to suspect that

implants could not become osseointegrated in these patients. However, the patient's ability to tolerate the number and type of treatment appointments required for implant placement, restoration, and maintenance could be problematic. All psychological conditions have the potential to be absolute contraindications to implant treatment depending on the severity of the condition. The exception might be individuals who demonstrate good cooperative behavior with only mild psychological or mental impairment. The clinician should take great care before accepting a mentally or psychologically impaired individual for treatment with implants.

Habits and Behavioral Considerations

Patients have a variety of habits and behaviors that may increase the risk of failure for dental implants. Smoking, clenching or grinding of teeth, and drug or alcohol abuse are among the most well-known habits that should be identified because of the increased risk for implant failure or complications.

Smoking and Tobacco Use

Moderate to heavy smoking has been documented to result in higher rates of early implant failure and adversely affect the long-term prognosis of dental implant restorations.[6,20,43] This is particularly true for implants placed in poor-quality bone such as the posterior maxilla.[39] The mechanisms of action responsible for higher implant failures associated with smoking are not understood. Plausible explanations include the effect of smoking on white blood cells, vasoconstriction, wound healing, and osteoporosis.[4,37] Smoking is a known risk factor for osteoporosis and thus may adversely affect implant success through its effect on bone metabolism. Smoking cessation may improve the success rate of implants.[5] In a meta-analytical review, Bain and coworkers[7] found that implants with an altered surface microtopography (Biomet 3i, Osseotite; dual acid-etched surface) seemed to significantly lessen the adverse effects of smoking on implant success.

Parafunctional Habits

Parafunctional habits, such as clenching or grinding of teeth (consciously or unconsciously), have been associated with an increased rate of implant failure (e.g., failure to integrate, loss of integration, implant fracture). Repeated lateral forces (i.e., parafunctional habits) applied to implants can be detrimental to the osseointegration process, especially during the early healing period. Patients with known parafunctional habits should be advised of an increased risk of complications or failures as a result of their clenching or grinding. Many consider bruxism to be a contraindication to implant treatment, especially in the case of a short-span, fixed partial denture or a single-tooth implant. If implants are planned for a patient with parafunctional habits, protective measures should be employed, such as creating a narrow occlusal table with flat cusp angles, protected occlusion, and the regular use of occlusal guards.

Substance Abuse

Drug and alcohol abuse should be considered a contraindication for implant therapy for reasons similar to the psychological problems discussed earlier. Patients with drug or alcohol addictions can be irresponsible and noncompliant with treatment recommendations. Depending on the severity and duration of an individual's addiction, some patients may be malnourished or may even have impaired organ function and therefore may not be good surgical candidates because of poor healing capacity. All elective treatments, including implant therapy, should be refused until addictions are treated and controlled.

Posttreatment Evaluation

Periodic posttreatment examination of implants, the retained prosthesis, and the condition of the surrounding peri-implant tissue are important components of successful treatment. Aberrations and complications can often be treated if discovered early, but many problems will go unnoticed by the patient. Thus periodic examination is essential to discovering problems early and to

intervening and preventing problems from getting worse. Several parameters are available to evaluate the condition of the prosthesis, the stability of the implants, and the health of surrounding peri-implant tissues after implant integration and prosthetic restoration. Intraoral radiographs should be taken at the time of placement (baseline), at the time of abutment connection (to confirm seating and serve as another baseline), at the time of final restoration delivery (loading), and subsequently to monitor marginal or peri-implant bone changes. Periapical radiographs have excellent resolution and provide adequate details for evaluating bone support around implants if taken at a perpendicular direction.

The long-term success of dental implants is dependent on the health and stability of supporting peri-implant tissues. Good oral hygiene and regular professional care are essential to maintaining peri-implant health, and the importance of good oral hygiene should be stressed as early as possible. Patients should be taught to maintain good oral hygiene. Their performance should be monitored and reinforced at each visit.

See Chapter 86 for a detailed description of important clinical and radiographic monitoring methods as well as oral hygiene and implant maintenance protocols.

Conclusion

Today, clinicians are able to predictably replace missing teeth with endosseous dental implants. Whether missing a single tooth, several teeth, or all teeth, many patients can be candidates for dental implant therapy. It is important for clinicians to recognize factors that influence implant success. In addition to the quantity, quality, and location of available bone, the patient's health, risk factors, and contraindications must be assessed. Patients should be informed about risk factors and provided with treatment options both with and without dental implants. Periodic evaluation, good oral hygiene, and regular maintenance are important aspects of care for the long-term success and the prevention of complications with dental implants.

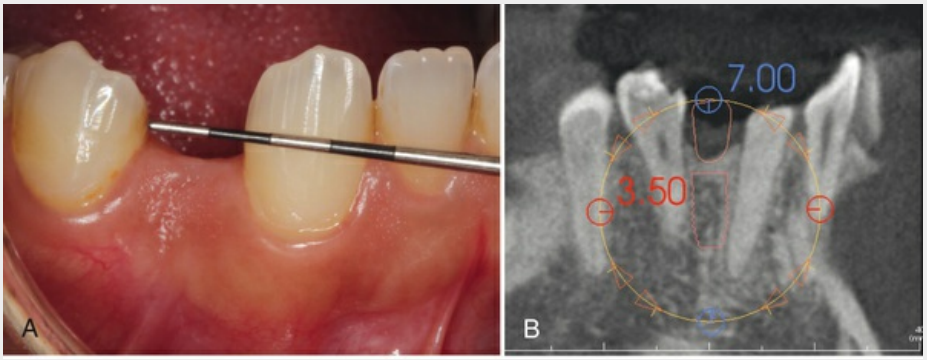
Case Scenario 75.1

Patient:
27-year-old female

Chief Complaint:
"I want to replace my missing tooth with an implant."

Background Information
The patient was congenitally missing the mandibular right lateral incisor. She has worn a removable partial denture for as long as she can remember but now wants to replace the tooth in a more permanent fashion.

Current Findings:
The mandibular right cuspid has drifted mesial to close the space for the missing lateral incisor. The open space is distal to the cuspid. The mesial-distal dimension of the edentulous space is 4.5 mm. A scan of the area reveals that the mesial-distal space between the roots of the cuspid and the premolar is about 4 to 4.5 mm.



Case-Based Questions	Solution and Explanation
1. What are the options for replacing this missing tooth? A. Single tooth implant B. Fixed partial denture #27 and #28 C. Removable partial denture D. All of the above	**Answer: D** **Explanation:** Some options are better than others, but all of these are possible. The implant option is challenging due to limited space.

2. How much space is needed to replace a tooth in this position? A. 4 mm B. 5 mm C. 6 mm D. 7 mm	**Answer: C** **Explanation:** The minimum required mesial-distal space for a narrow (3.2–3.5 mm) diameter implant is 6 mm. It is desirable to maintain a minimum of 1 to 1.5 mm of bone around all surfaces, especially between the implant and the adjacent tooth.
3. What is the ideal amount of interocclusal space required for the implant crown, abutment, and screw? A. 4 mm B. 5 mm C. 6 mm D. 7 mm	**Answer: D** **Explanation:** The minimum amount of interocclusal space is probably about 4 to 5 mm, but the restorative unit would be very short. The ideal amount of interocclusal space required for an implant crown is 7 mm.

CHAPTER 76

Diagnostic Imaging for the Implant Patient

Sotirios Tetradis, Sanjay M. Mallya, Perry R. Klokkevold

CHAPTER OUTLINE

Standard Projections
Cross-Sectional Imaging
Interactive "Simulation" Software Programs
Patient Evaluation
Clinical Selection of Diagnostic Imaging
Conclusion

Several radiographic imaging options are available for the diagnosis and treatment planning of patients receiving dental implants.[2,17,18] Options range from standard projections routinely available in the dental office to more complex radiographic techniques typically available only in radiology centers. Standard

projections include intraoral (periapical, occlusal) and extraoral (panoramic, lateral cephalometric) radiographs. More complex imaging techniques include cone-beam computed tomography (CBCT) and multislice computed tomography (MSCT). The CBCT and MSCT image data files can be reformatted and viewed on a personal computer using simulation software, making the diagnosis and treatment-planning process interactive and visually more meaningful. Often, combinations of various modalities are used because no single modality can provide all information pertinent to the radiographic evaluation of the implant patient. Familiarity with the benefits and limitations of various techniques and awareness of the specific clinical questions that need to be answered should guide the decision-making process and selection of radiographic examinations for individual patients.

Multiple factors influence the selection of radiographic technique(s) for a particular case, including cost, availability, radiation exposure, and case type. The decision is a balance between these factors and the desire to minimize risk of complications to the patient. Accurately identifying vital anatomic structures and being able to perform implant placement surgery without injury to these structures are critical to treatment success. Diagnostic imaging must always be interpreted in conjunction with a good clinical examination.

This chapter discusses common imaging techniques used for evaluation of the implant patient. Indications for each technique are outlined, along with the advantages and limitations of each technique.

Key Fact

Accurate identification of vital anatomic structures is critical to treatment success when performing dental implant surgery. Diagnostic imaging must always be interpreted along with a clinical examination.

Standard Projections

Standard diagnostic imaging modalities include periapical, panoramic, lateral cephalometric, and occlusal radiographs. Table 76.1 summarizes the advantages and disadvantages of each modality.

TABLE 76.1

Advantages and Disadvantages of the Various Radiographic Projections

Modality	Advantages	Disadvantages
Periapical and occlusal radiography	High resolution and detail, easy acquisition, low radiation exposure, relatively inexpensive	Unpredictable magnification, small imaged area, 2D representation of anatomy
Panoramic radiography	Easy to acquire, images the full dentoalveolar ridge, low radiation dose, relatively inexpensive	Unpredictable magnification, unequal magnification in vertical and horizontal dimensions, 2D representation of anatomy, not detailed
Lateral cephalometric radiography	Easy to acquire, predictable magnification, low radiation dose, relatively inexpensive	Limited use in area of midline, 2D representation of anatomy
Multislice computed tomography	3D representation, no magnification, sufficient detail, digital format, images whole arch	Requires special equipment, expensive, higher radiation dose
Cone-beam computed tomography	3D representation, no magnification, sufficient detail, digital format, images whole arch, low radiation dose	Requires special equipment, relatively expensive

2D, Two-dimensional; *3D*, three-dimensional.

Periapical Radiographs

Periapical radiographs are often the first imaging modality used to evaluate the implant patient.[19,20] These radiographs provide an overall assessment of the quantity and quality of the edentulous alveolar ridge and the adjacent teeth. They are easy to obtain in the dental office, are relatively inexpensive, and deliver low radiation dose to the patient[8] (Table 76.2). Dentists are familiar with the depicted anatomy and possible pathology. Because these direct-exposure projections do not use intensifying screens, intraoral radiographs offer the highest detail and spatial resolution of all radiographic modalities (Fig. 76.1). Thus intraoral radiographs are the projection of choice when subtle, localized pathology, such as a retained root tip, needs to be detected and evaluated.

TABLE 76.2

Radiation Dose (Effective Dose in μSv) Received From Common Projections During Evaluation of the Implant Patient Data

Modality	Effective Dose (μSv)
Full-mouth x-ray (FMX) series	177
Panoramic	20
Limited field-of-view CBCT	47
Medium field-of-view CBCT	98
Large field-of-view CBCT	117
MSCT, Maxillofacial	913

CBCT, Cone-beam computed tomography; *CT,* computed tomography; *MSCT,* multislice computed tomography.

In Fayad M, Johnson BR, editors: *3D imaging in endodontics: a new era in diagnosis and treatment.* Median effective doses for standard exposure protocols were derived from collation of data from several reports in the literature.

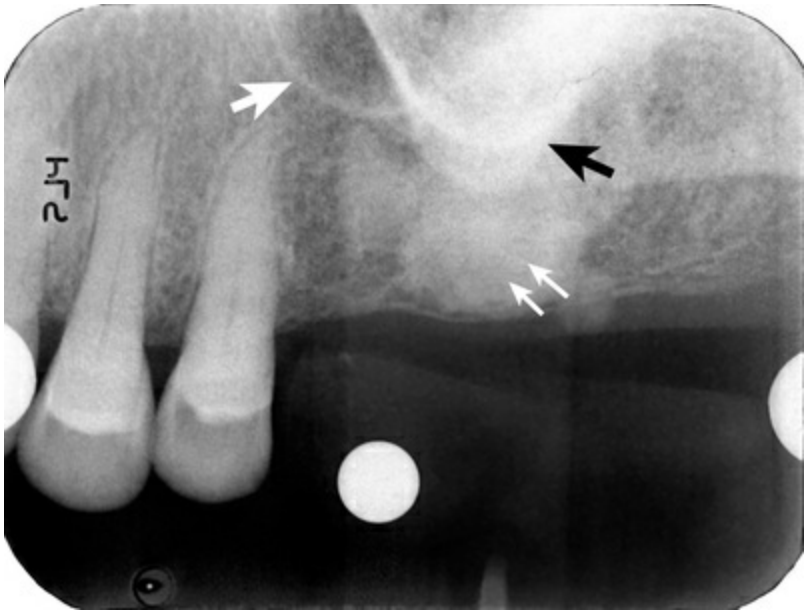

FIG. 76.1 The periapical radiograph offers a high-resolution, detailed image of the edentulous area. Healing of the extraction socket with dense bone (socket sclerosis) can be seen *(small white arrows).* Some anatomic structures, such as the maxillary sinus *(large white arrow)* and the zygomatic process of the maxilla *(black arrow),* can also be visualized.

The most significant disadvantage of periapical radiographs is

their susceptibility to unpredictable magnification of anatomic structures, which does not allow reliable measurements.[15] Foreshortening or elongation can be minimized by the use of paralleling technique. However, distortion is particularly accentuated in edentulous areas, where missing teeth and resorption of the alveolus necessitate receptor placement at significant angulation in relation to the long axis of the teeth and alveolar bone. Additionally, periapical radiographs are two-dimensional representations of three-dimensional objects and do not provide any information of the buccal-lingual dimension of the alveolar ridge. Structures that are distinctly separated in the buccal-lingual dimension appear to be overlapping. Also, the periapical image is limited by the size of film or sensor being used. Often, it is not possible to image the entire height of the remaining alveolar ridge, and when extensive mesial-distal areas need to be evaluated, multiple periapical radiographs are required.

Periapical radiographs are useful screening images that offer a detailed view of a small area of the alveolar arch. Limitations that must be considered include the possibility of distortion and the two-dimensional representation of anatomic structures.

Occlusal Radiographs

Occlusal radiographs are intraoral projections that offer easy, economic, low-radiation dose and high-resolution images covering a larger area than periapical projections.[20] Depending on receptor placement and the angulation of the x-ray tube, occlusal radiographs can provide an image of the mandibular width or can depict an extended area of the edentulous ridge. Occlusal radiographs have the same limitations of distortion and overlapping anatomy as periapical radiographs.

Occlusal radiographic projections offer an initial assessment of the implant patient, and they provide an overview of the mandibular width or can visualize larger areas of alveolar ridge compared with periapical radiographic projections.

Panoramic Radiographs

Panoramic radiographs are often used in the evaluation of the

implant patient because they offer several advantages over other modalities.[16] Panoramic radiographs deliver low radiation doses (see Table 76.2) to provide a broad picture of both arches and thus allow assessment of longer edentulous spans, angulation of existing teeth and occlusal plane, and important anatomy in implant treatment planning such as the maxillary sinus, nasal cavity, mental foramen, and mandibular canal (Fig. 76.2). Panoramic units are widely available and easy to operate, and dentists are familiar with the anatomy and pathology depicted by the images. Similar to intraoral projections, panoramic images are two-dimensional and thus do not offer diagnostic information for the buccal–lingual width of the alveolar arch.

FIG. 76.2 Panoramic radiograph. Both jaws are visualized on the same image. An overall assessment of superoinferior and mesial–distal dimensions of the alveolar ridge can be formulated. Tooth and root positions relative to planned implant sites can be evaluated. Important anatomic structures, such as the maxillary sinus and mandibular canal, can be identified.

Panoramic images appear intuitively familiar. However, they combine characteristic physical and radiographic principles that make them distinct from other intraoral and extraoral radiographs. Although outside the scope of this chapter, familiarity with the principles underlying panoramic radiography is central for understanding, and thus compensating for, the limitations and constraints of the images. The reader is referred to other textbooks

for detailed discussion of this topic.[7,10] Briefly, the existence of ghost shadows, unpredictable horizontal and vertical magnification, distortion of structures outside the focal trough, projection geometry generated by the negative vertical angulation of the x-ray beam, and the propensity to patient-positioning errors do not allow consistently detailed and accurate measurements to be generated. As a result, panoramic radiographs do not provide the highly detailed images that are generated by intraoral radiographs.

Measurement distortion is more prevalent and varies across the radiographic image. On average, panoramic radiographs are 25% magnifications of actual size. Implant manufacturers often provide transparency sheets with implant size outlines of 25% magnification. However, it is important to appreciate that the 25% magnification is an estimate. The actual magnification may range from 10% to 30% in different areas within the same image and depends greatly on patient positioning during panoramic radiography. For this reason, precise measurements on panoramic projections are not possible. Nonetheless, panoramic radiographs offer an overall view of the maxilla and mandible that can be used to estimate bone measurements and evaluate the approximate relationships between teeth and other anatomic structures. More precise diagnostic imaging should be used to measure the proximity of critical anatomic structures, such as the maxillary sinus or the mandibular canal, to proposed implant positions.

Panoramic projections provide useful information for the initial assessment of the implant patient. However, because of magnification and distortion errors, panoramic radiographs should not be used for detailed measurements of proposed implant sites.

Cross-Sectional Imaging

Cross-sectional diagnostic imaging modalities include MSCT and CBCT. Conventional tomography also provides cross-sectional images with predictable magnification and has been used in the assessment of the implant patient. However, with the introduction and expansion of CBCT imaging, conventional tomography is becoming obsolete and is not described in this chapter.

Cone-Beam Computed Tomography

Cone-beam computed tomography (CBCT) is an imaging modality that offers significant advantages for the evaluation of implant patients.[5,14] CBCT was introduced to dentistry in the late 1990s,[1,12] and several CBCT units are commercially available for imaging of the craniofacial complex. The x-ray source and the detector are diametrically positioned and make a 180- to 360-degree rotation around the patient's head within the gantry. The x-ray beam is collimated and the resultant beam is cone or pyramid shaped. Typically, a single complete rotation, 180 to 500 basis projections of the region of interest, is generated. The computer uses these images to generate a digital, three-dimensional map of the face. Once this map is generated, multiplanar reconstructions—axial, coronal, sagittal, or oblique sections of various thicknesses—can be reconstructed from the data.

Key Fact

CBCT offers significant advantages for the evaluation of implant patients. The field of view (FOV) is an important feature that describes the extent of the imaged volume from large FOV (greater than 15 cm) to medium FOV (8 to 15 cm) and limited FOV (less than 8 cm). Limited FOV units image a small area, delivering less radiation and producing a higher-resolution image

An important feature of the various CBCT units is the field of view (FOV) describing the extent of the imaged volume. CBCT units are typically categorized as large FOV (greater than 15 cm), medium FOV (8 to 15 cm), and limited FOV systems (less than 8 cm). Fig. 76.3 depicts schematically the anatomic area covered by large, medium, and limited FOV scans. In general, large FOV units image a more extensive anatomic area, deliver a higher radiation exposure to the patient, and produce lower-resolution images (Fig. 76.4). Conversely, limited FOV units image a small area of the face, deliver less radiation, and produce a higher-resolution image (Fig. 76.5).

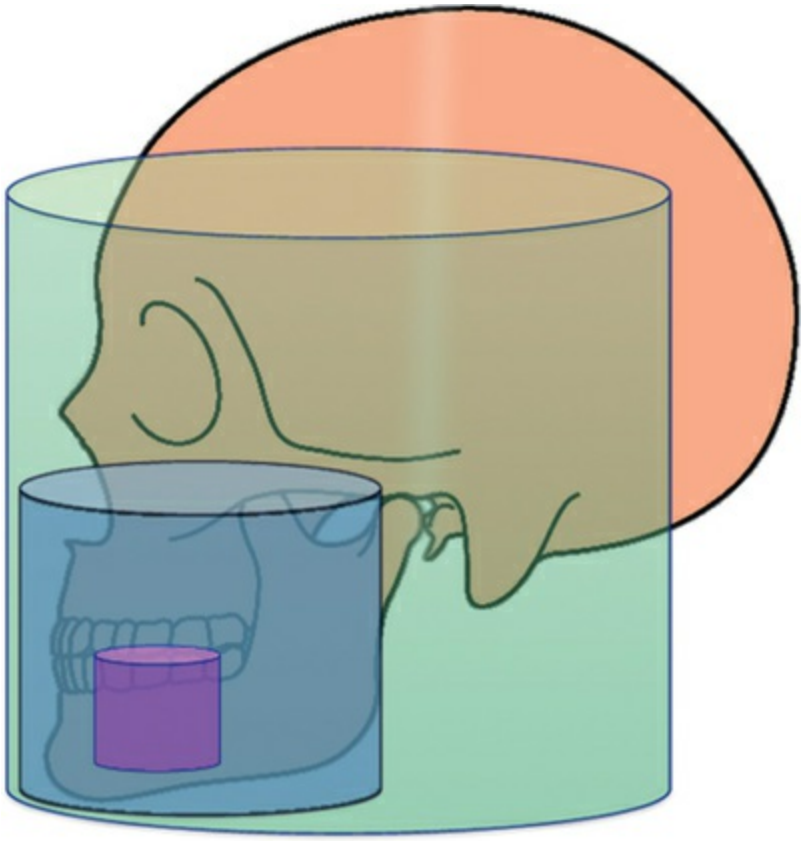

FIG. 76.3 Schematic diagram of the anatomic area imaged with large *(green),* medium *(blue),* and limited *(magenta)* field of view cone-beam computed tomography.

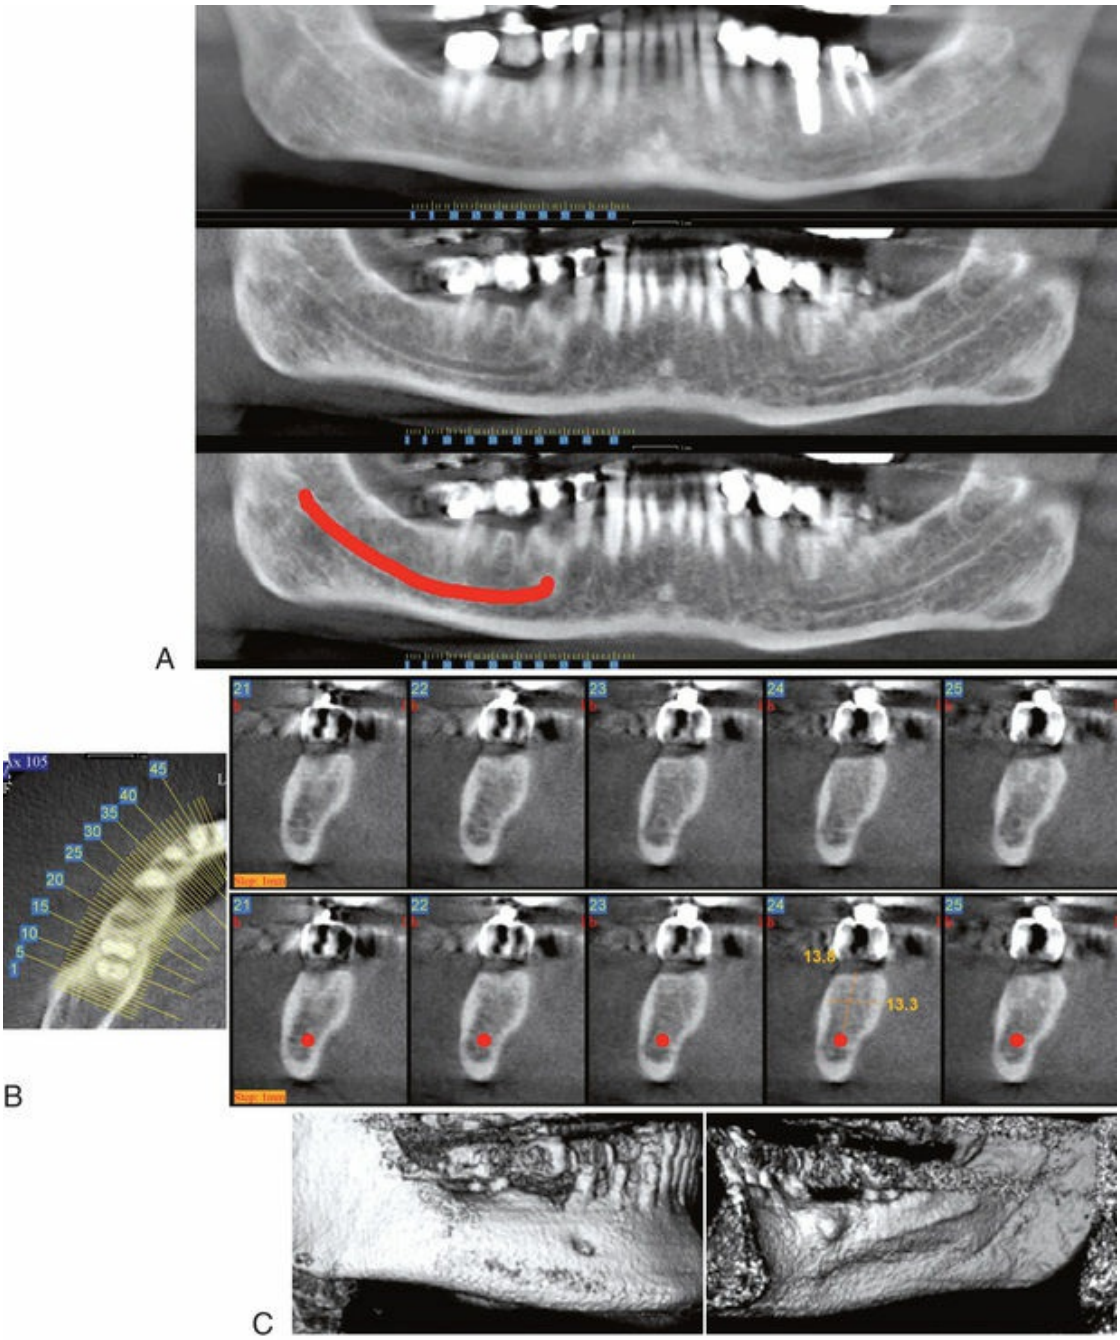

FIG. 76.4 Cone-beam computed tomography images for the evaluation of the edentulous space at the area of missing tooth #30 before implant placement using a large field-of-view unit (NewTom 3G, Verona, Italy, distributed by AFP Imaging, Elmsford, New York). Note the tooth-shaped marker used. (A) A series of "panoramic" reconstructions through the alveolar ridge reveals the relationship of the marker to the adjacent teeth. The top "panoramic" view is 12 mm thick so as to depict most of the extent of the alveolar ridge and adjacent teeth. The middle "panoramic" image is 1 mm thick through the area of the mandibular canal. Note

that adjacent teeth are out of the plane of the section and thus not depicted on the image. The bottom "panoramic" view is the same as the middle one, but the position of the mandibular canal has been depicted by the *red line*. (B) Scout axial view and series of cross sections through the area of the marker. The bottom row shows the same axial slices as the top row. However, the position of the *red line* drawn on the panoramic view is also depicted to help localization of the mandibular canal. The height and width of the alveolar ridge have been measured in a selected section. (C) Three-dimensional reconstructions provide an overall impression of the bone contours and shape of the alveolar ridge. Note the small exostosis on the lingual surface of the alveolar ridge.

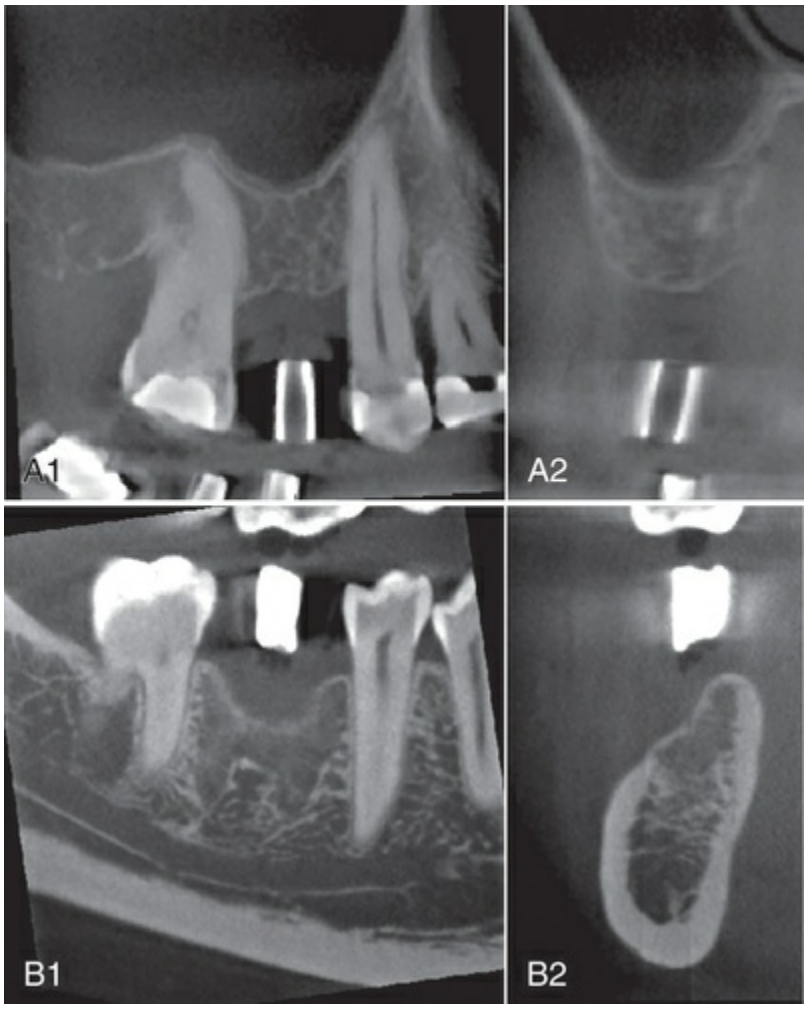

FIG. 76.5 Cone-beam computed tomography images

for the evaluation of the edentulous space at the area of missing tooth #4 (A) and missing tooth #30 (B) using a limited field-of-view scan (3D Accuitomo, J. Morita Corporation, Suita City, Osaka, Japan, distributed by J. Morita USA, Inc., Irvine, California). Sagittal and cross-sectional slices are shown. Although the anatomic area imaged is limited, the resolutions of the images are high. (A) Implant site #4 (maxillary right second premolar) in anterior–posterior (A1) and buccolingual (A2) cross-sectional views. (B) Implant site #30 (mandibular right first molar) in anterior–posterior (B1) and buccolingual (B2) cross-sectional views.

CBCT scans offer several advantages for evaluation of the implant patient, compared with two-dimensional (2D) imaging. True cross sections offer a precise and detailed evaluation of the height and width of the alveolar ridge. The images can be adjusted and printed without magnification, facilitating measurements directly on the prints or films with standard rulers (i.e., not magnified). Vertical and horizontal rulers adjacent to each section allow the clinician to check for magnification and make direct measurements. The digital format allows for image enhancement tools, rapid communication between the radiologist and the surgeon, and generation of multiple copies of the images. Various anatomic structures can be visualized and analyzed at all three coordinate axes, so that their superoinferior, anteroposterior, and buccolingual location can be identified with precision. CBCT images the entire arch, or even both arches, so several edentulous areas can be visualized with a single examination. The bone and soft-tissue contrast and resolution are appropriate for the diagnostic task.

In summary, CBCT scanning is a valuable imaging modality for three-dimensional and cross-sectional evaluation of the implant patient. It has similar advantages and disadvantages as CT scanning. The most significant difference is that CBCT imaging delivers much less radiation exposure to the patient.

Multislice Computed Tomography

Multislice CT (MSCT) was widely used in the evaluation of the

implant patient.[3,6] However, with the advent of CBCT, utilization of MSCT has been reduced significantly. However, MSCT is an excellent choice for evaluation of the implant patient if CBCT scanning is not available.[4]

Typical dental views reconstructed from a MSCT scan include a scout view (see Fig. 76.6A) as well as axial (Fig. 76.6B), panoramic (Fig. 76.6C), and cross-sectional (Fig. 76.6D) views of the jaws. Appropriate axial slices through the alveolar ridge of interest are selected as scout views. The curvature of the maxillary or mandibular ridge is then drawn on the axial slices, and panoramic images along the drawn line are created. Finally, cross-sectional slices, typically at every 1 to 2 mm and perpendicular to the drawn curvature, are created. In addition to these flat, two-dimensional views, complex, three-dimensional images with surface rendering can also be generated from the CT data (Fig. 76.6E). These images can provide useful information about the alveolar ridge defects that are easy to comprehend.

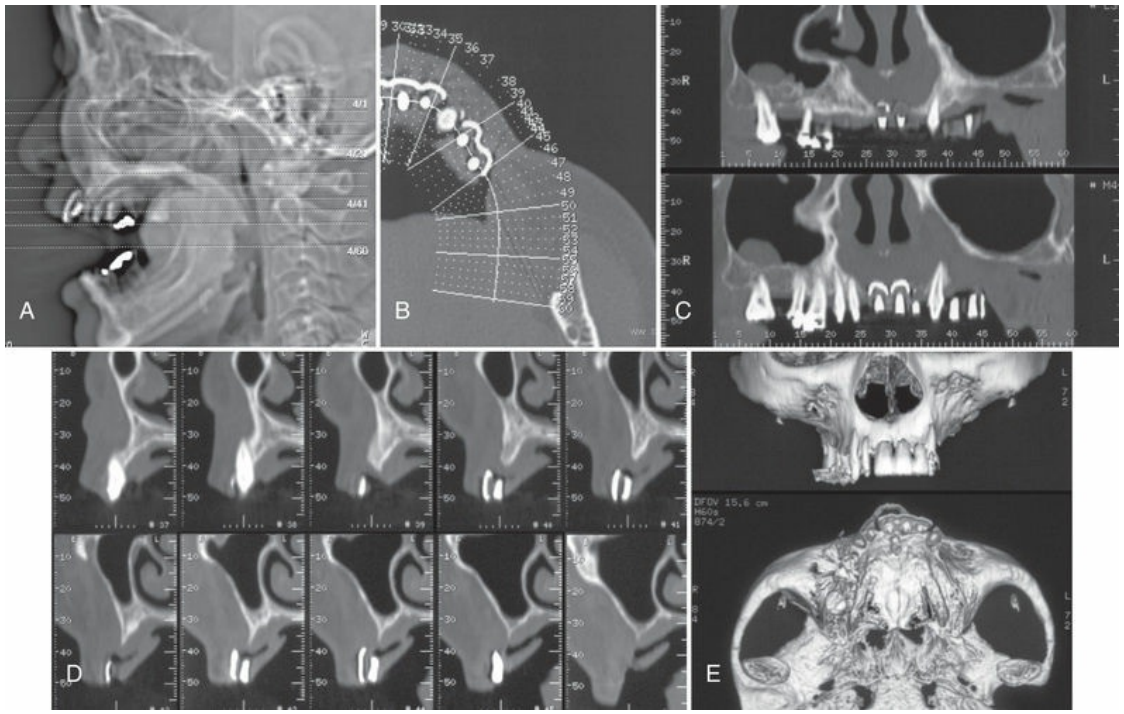

FIG. 76.6 Multislice computed tomography (MSCT) examination for evaluation of edentulous maxilla before implant placement. (A) Scout view of the patient's head; axial sections through the area of interest are indicated. (B) Axial slice through the

markers is used to display the orientation of the panoramic and cross-sectional images through the alveolar ridge. (C) Panoramic views through the alveolar ridge demonstrate the relation of the markers to adjacent teeth. (D) Cross-sectional slices through the area of the markers reveal the height and buccolingual dimension of the alveolar ridge, as well as the relation of the markers to the ridge. (E) Three-dimensional reconstructions provide an overall impression of the bone contours and shape of the alveolar ridge.

MSCT offers the same advantages and disadvantages as MSCT. However, the two modalities have basic differences that result from the different physical principles used during image acquisition. MSCT scans offers a greater *contrast resolution,* or the ability to distinguish two objects with small density differences. In contrast, CBCT scans have a limited capacity to separate muscle from fat or connective tissue compared with MSCT scans. Fortunately, the diagnostic tasks in implant treatment planning do not require high-contrast resolution. Because bone has a much higher radiodensity than surrounding soft tissues, both CBCT and MSCT clearly depict bone morphology and internal trabecular architecture. One of the most significant advantages of CBCT scanning versus MSCT scanning is the significantly lower radiation dose delivered to the patient[9,21,22] (Table 76.2).

MSCT scanning requires specialized equipment and setting. Radiologists and technicians need to be knowledgeable of the anatomy, anatomic variants, and pathology of the jaws, as well as considerations pertinent to implant treatment planning, so that optimal views will be provided. An MSCT scan delivers a much higher radiation dose to the patient than the other modalities used during implant treatment planning[13] (Table 76.2). Because a CT scan images the whole arch, radiation is delivered to the entire imaged area, regardless of how many or how few sites are actually needed. Metallic restorations can cause beam-hardening artifacts that impair the diagnostic quality of the images. This is particularly challenging in patients with heavily restored dentition. In general, the cost of MSCT is significantly higher than that of CBCT or the other standard intraoral and extraoral projections.

In summary, MSCT scanning offers many advantages during implant treatment planning, including accurate cross-sectional imaging and three-dimensional visualization of anatomic structures. High dose to the patient and artifacts caused by metallic restorations are concerns that should be considered.

Interactive "Simulation" Software Programs

Implant treatment planning can be greatly enhanced by the use of specialized software. In addition to measuring the quantity and quality of bone in potential implant sites, these programs use CT (MSCT or CBCT) scan data to simulate placement of implant and restorations. Using a database of commercially available implant images, the length, width, angulation, and position of implants can be "simulated" in the desired positions and evaluated relative to other structures in three dimensions. In cases of alveolar ridge deficiency or defects, or when sinus bone augmentation is indicated, the additional bone volume needed can be evaluated and quantified. The restoration of the implants can also be simulated and the distribution of mechanical forces onto the implant and adjacent bone predicted.

Software programs specialized in implant treatment planning, such as SIM/Plant (Materialise/Columbia Scientific, Glen Burnie, Maryland), can acquire information directly from CBCT or CT scan data. The clinician can use the reformatted images on a personal computer in an interactive manner to identify anatomic structures, simulate implant placement positions, and better appreciate relationships between planned implant positions and teeth or anatomic structures (Fig. 76.7). InVivo5 planning software (Anatomage, San Jose, California) acquires data directly from CBCT or CT scan DICOM (Digital Imaging and Communications in Medicine) files without the need for reformatting. The clinician can evaluate the case on a personal computer in an interactive manner to identify anatomic structures, simulate implant placement positions, and better appreciate relationships between planned implant positions and teeth or anatomic structures. Once implant

positions are confirmed, a computer-generated surgical guide is produced to facilitate the surgical placement of implants in the planned positions (Fig. 76.8).

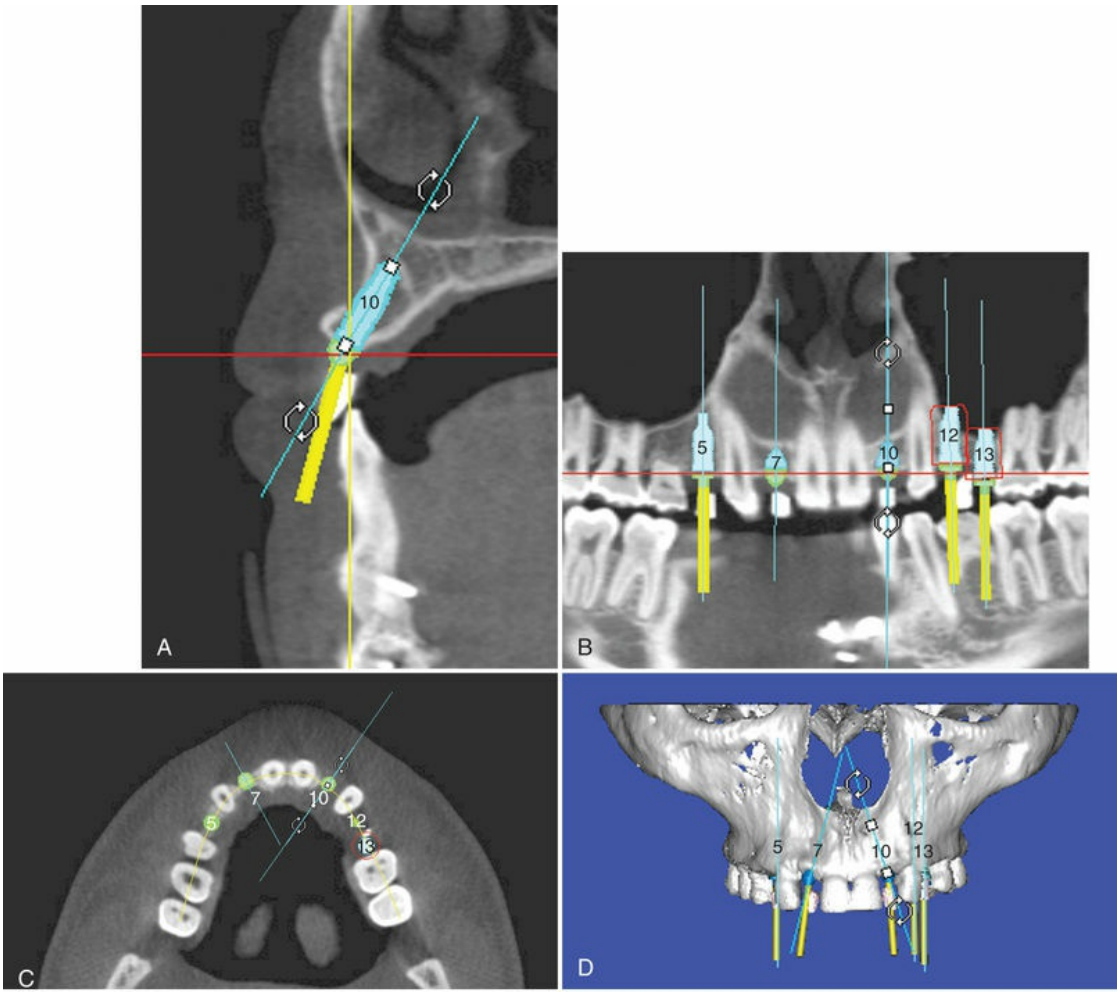

FIG. 76.7 SIM/Plant images. The SIM/Plant software program allows clinicians to measure bone height, width, density, and volume on a personal computer. Scan data are reformatted for interactive evaluation and manipulation. Implant positions can be simulated on the patient's scan data before surgery, allowing the surgeon to anticipate areas of deficiency. (A) Cross-sectional image through simulated implant in anterior maxilla, site #10. (B) Panoramic projection of multiple simulated implant positions, #5, 7, 10, 12, and 13. (C) Axial view of simulated implants. (D) Three-dimensional image of maxilla with simulated implants.

Patient Evaluation

Evaluation of the implant patient should be disciplined and objective. Specific questions that can affect implant placement and outcome should be considered and examined carefully and explicitly. The advantages and disadvantages of various radiographic projections should be considered and radiographic modalities chosen based on necessary information for the particular patient. The objectives for any radiographic evaluation, regardless of imaging technique used, should include an evaluation to (1) exclude pathology, (2) identify anatomic structures, and (3) measure the quantity, quality, and location of available bone.

Clinical Correlation

All diagnostic images, regardless of technique, should be evaluated to identify or exclude pathology and to identify normal anatomic structures.

Exclude Pathology

Healthy bone is a prerequisite for successful osseointegration and long-term implant success. The first step in the radiographic evaluation of the implant site is to establish the health of the alveolar bone and other tissues imaged within a particular projection. Local and systemic diseases that affect bone homeostasis can preclude, modify, or alter the placement of implants. Retained root fragments, residual periodontal disease, cysts, and tumors should be identified and resolved before implant placement. Systemic diseases, such as osteoporosis and hyperparathyroidism, alter bone metabolism and might affect implant osseointegration. Areas of poor bone quality should be identified and, if indicated, adjustments to the treatment plan incorporated. Maxillary sinusitis, polyps, or other sinus pathology should be diagnosed and treated when implants are considered in the posterior maxilla, especially if sinus bone augmentation procedures are planned (Fig. 76.9).

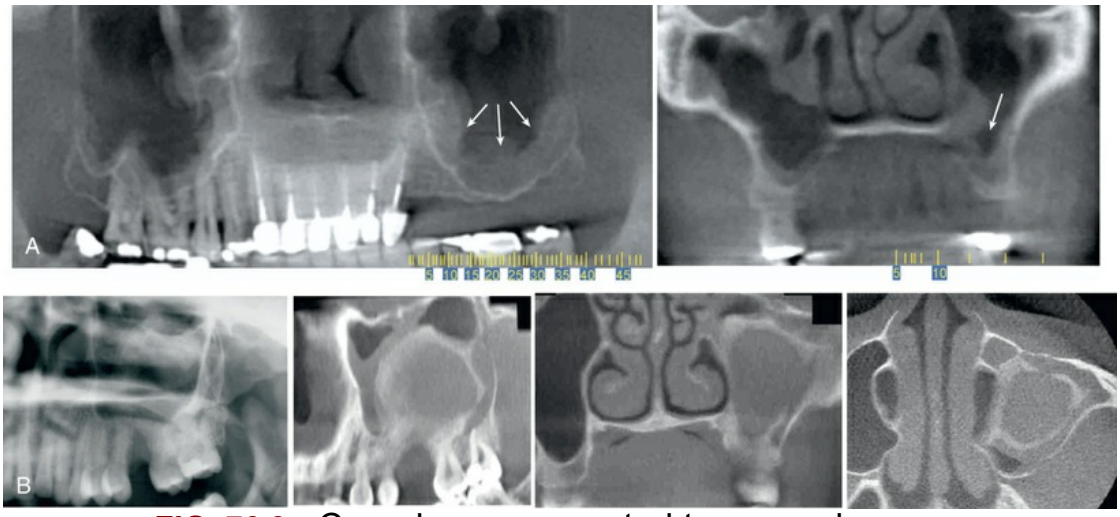

FIG. 76.9 Cone-beam computed tomography examination of the posterior left maxilla. Top row (A) shows reconstructed "panoramic" and coronal sections of the alveolar ridge. Note the thickened mucoperiosteal lining of the floor of the left maxillary sinus *(white arrow).* The patient has chronic maxillary sinusitis. Bottom row (B) shows conventional panoramic, reconstructed "panoramic," coronal, and axial sections of the alveolar ridge at the area of the missing first maxillary molar. A large radiolucent lesion at the edentulous alveolar ridge elevates the floor of the maxillary sinus and occupies most of the sinus. Biopsy revealed a keratocystic odontogenic tumor that was an incidental finding in this asymptomatic patient.

Identify Anatomic Structures

Several important anatomic structures are found close to desired areas of implant placement in the maxilla and mandible (Box 76.1). Familiarity with the radiographic appearance of these structures is important during treatment planning and implant placement. Their exact localization is central to prevent unwanted complications and unnecessary morbidity. Important anatomic structures in the maxilla include the floor and anterior wall of the maxillary sinus, incisive foramen, floor and lateral wall of the nasal cavity, and canine fossa. Important anatomic structures in the mandible that should be recognized include the mandibular canal, anterior loop of the mandibular canal, mental foramen, anterior extension of the canal, and submandibular fossa. The existence of anatomic variants,

such as incomplete healing of an extraction site, sinus loculation, division of mandibular canal (Fig. 76.10), or absence of a well-defined corticated canal, should also be recognized. See Chapter 58 for important periodontal and implant surgical anatomy.

(B) Same panoramic view with the accessory mandibular canal colored blue and the main canal colored red. (C) Cross-sectional views through the area of missing tooth #19. (D) Same cross-sectional images depicting the blue and red markings. Note that the position of the markings coincides with the position of the accessory and main mandibular canals (compare parts C and D).

Clinical Correlation

Several important anatomic structures need to be identified in the jaws prior to implant placement. Violation of structures such as nerves may cause serious complications. Familiarity with the radiographic appearance of vital structures is important, and the existence of anatomic variants should also be recognized.

Assess Bone Quantity, Quality, and Volume

The primary goal of diagnostic imaging for potential implant patients is to evaluate the available bone volume for implant placement in desired anatomic locations. The clinician should estimate and verify exact adequate height, width, and density to the recipient bone while avoiding damage to critical anatomic

structures. Failure to accurately assess the location of important anatomic structures can lead to unnecessary complications. For example, inadvertent penetration and damage to the inferior alveolar nerve can result in serious immediate-term (profuse bleeding), short-term, and long-term (nerve paresthesia/anesthesia) complications. The height and width of the alveolar bone should be accurately detailed. Depending on the technique, diagnostic imaging can estimate or measure the coronal–apical height, the buccal–lingual width, and the mesial–distal spacing available for implants that will be placed in proximity to teeth or relative to other planned implants.

This task can be simple in cases with good bone quality and sufficient bone volume in the desired implant location(s). However, in cases with moderate to severe bone resorption, alveolar defects, or recent extraction sites, obtaining a clear and accurate diagnostic image can be more challenging. The diagnostic imaging may reveal inadequate bone volume for the proposed implant(s) and indicate a need for bone augmentation or, depending on the severity of the deficiency, preclude the patient from the possibility of implant therapy (Fig. 76.11). When ridge augmentation is deemed necessary, radiographic evaluation prior to and after surgery informs treatment planning and ensures grafting integrity and quality (Fig. 76.12).

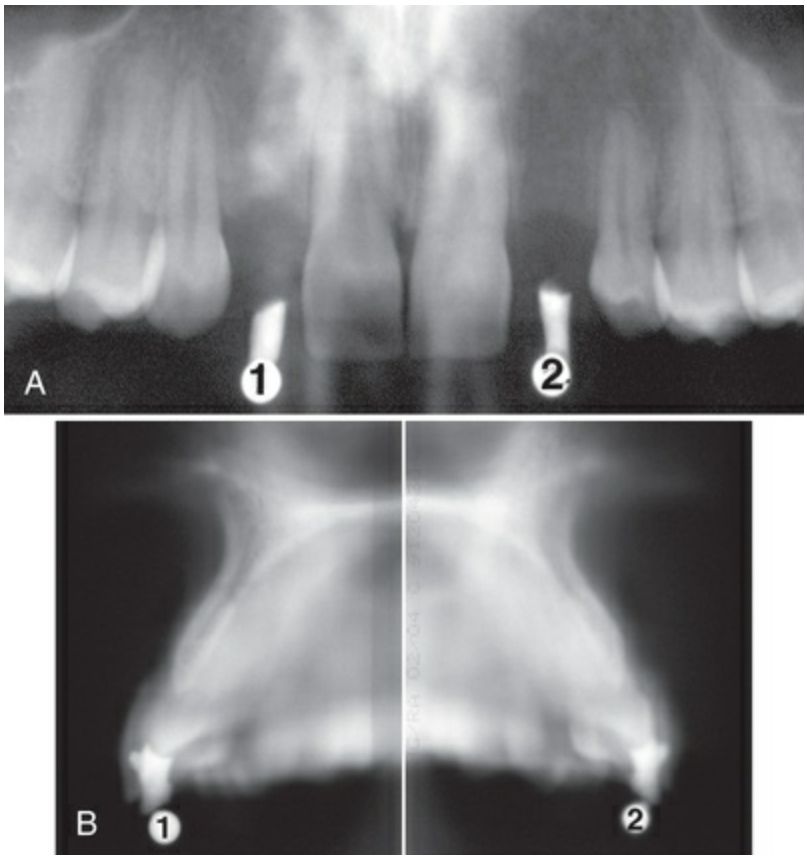

FIG. 76.11 Radiographic evaluation of a patient with congenitally missing maxillary lateral incisors before implant placement. (A) Panoramic radiograph reveals sufficient height and mesial-lateral width of the alveolar ridge. (B) Cross-sectional conventional tomography of the edentulous areas reveals a narrow (<4 mm) buccal-lingual width of the alveolar ridge that needs to be addressed by modifications in the treatment planning, such as bone augmentation.

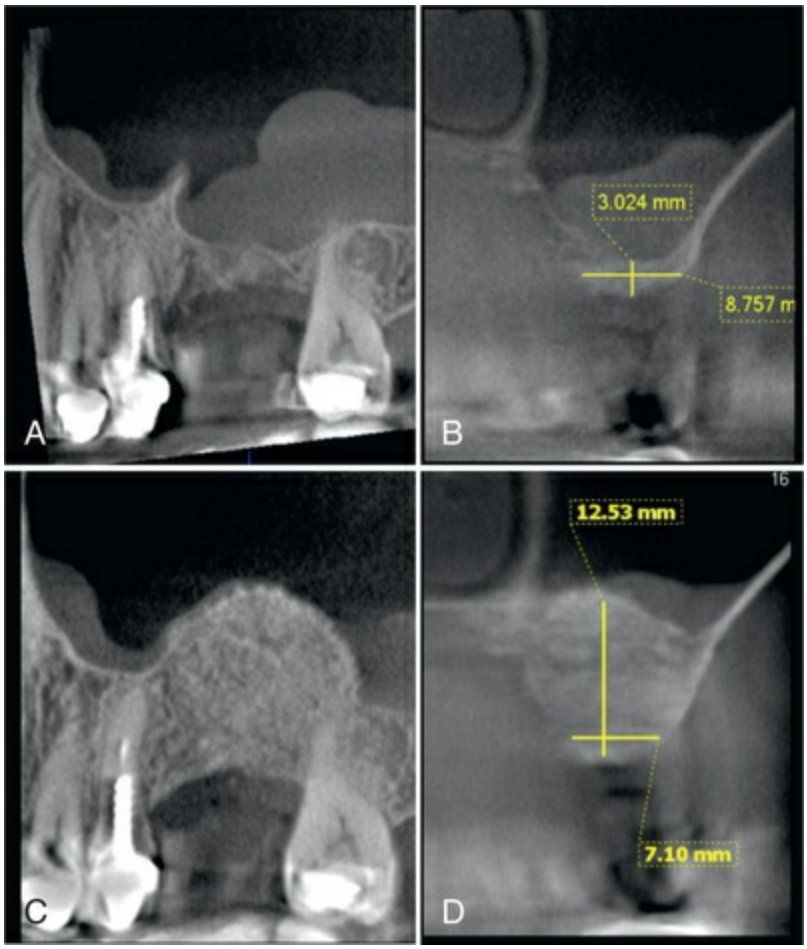

FIG. 76.12 Radiographic evaluation of a patient with missing left maxillary second premolar and first molar. Initial cone-beam computed tomography (CBCT) reveals an atrophic alveolar ridge (A) with inadequate height for implant placement (B). Also note the thickened mucoperiosteum at the floor of the maxillary sinus. CBCT after sinus grafting for ridge augmentation shows the uniformly opaque grafting area blending with alveolar trabeculation and a smooth sinus floor elevation (C), which provides adequate dimensions for implant placement (D).

In addition to the amount, the quality of the available bone should also be evaluated. A uniform, continuous cortical outline and a lacy, well-defined trabecular core reflect the normal bone homeostasis necessary for appropriate bone response around the implant. Thin or discontinuous cortex, sparse trabeculation, large marrow spaces, and altered trabecular architecture should be noted because they might predict poor implant stabilization and less desirable response of the bone. Poor bone quality may necessitate

modifications of the treatment planning, such as waiting longer for healing (osseointegration) to maximize bone-to-implant contact before loading.

Evaluate Relation of Alveolar Ridge With Existing Teeth and Desired Implant Position

Accurate placement (spatial position and angulation relative to adjacent teeth and occlusal plane) will greatly affect the restorative success and long-term prognosis of the implant (see Chapters 75 and 77). A significant variable during the preimplant evaluation is the relation of the desired implant position relative to the existing teeth, alveolar crest, and occlusal plane. Angled or custom abutments can accommodate slight variations in implant position and implant inclination. However, more significant deviations should be avoided.

Prolonged tooth loss is usually associated with atrophy of the alveolar ridge and, in the case of the maxilla, with pneumatization of the sinus floor toward the alveolar crest. Traumatic extractions can compromise the buccal or lingual cortex and alter the shape and buccolingual ridge dimension. Anatomic variants, such as lingual inclination of the alveolus or narrow ridges, should be considered during treatment planning of the implant patient (Fig. 76.13).

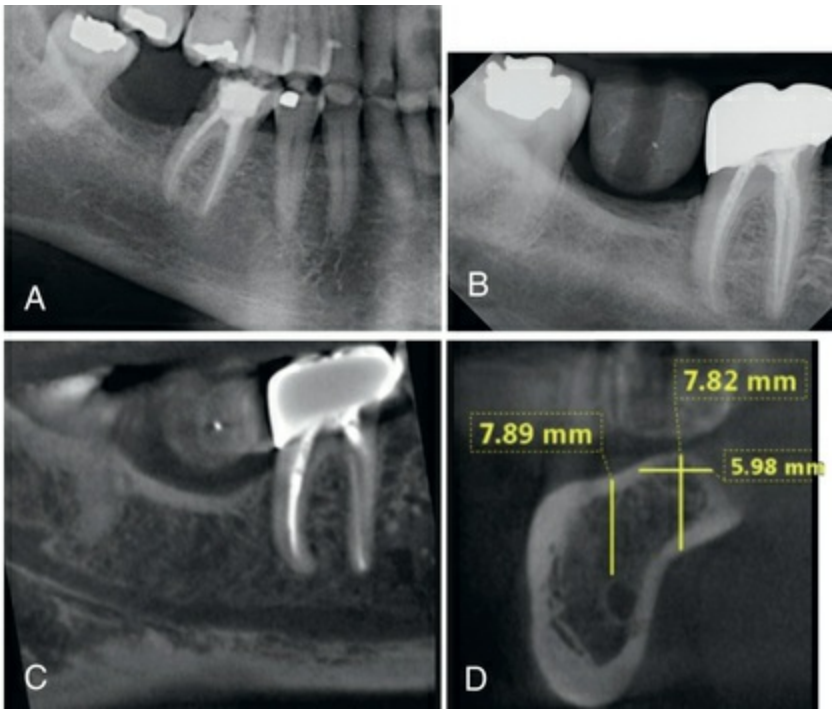

FIG. 76.13 Radiographic evaluation of a patient with an edentulous posterior left mandible before implant placement. Panoramic (A) and periapical (B) radiographs demonstrate sufficient height of the alveolar ridge with little or no resorption. Cone-beam computed tomography sections (C–D) reveal significant lingual inclination of the alveolar ridge with lingual concavity that is not depicted on conventional radiographs.

An important part of diagnostic imaging must include an evaluation of the available bone relative to the "prosthetically driven" implant position. This aspect of the patient evaluation is best accomplished with diagnostic models, wax-up of planned tooth replacement, and radiographic markers in the desired tooth positions during imaging. Steel balls, brass tubes, and gutta-percha have all been used to establish the proposed tooth positions relative to the existing alveolar bone. The use of these nonanatomic markers is helpful for evaluating bone height and width in specific anatomic locations. However, they do not accurately represent the tooth contours and do not allow the clinician to estimate variations in implant position and angulation relative to the position and emergence of the planned tooth replacement. Therefore it is more desirable and beneficial to use radiopaque tooth-shaped markers so that the existing alveolar bone can be evaluated relative to the entire

tooth position/contours (Fig. 76.14; see also Fig. 76.5). This is particularly important for anterior, aesthetic implant cases. Patients should always be imaged with radiographic guides (markers).

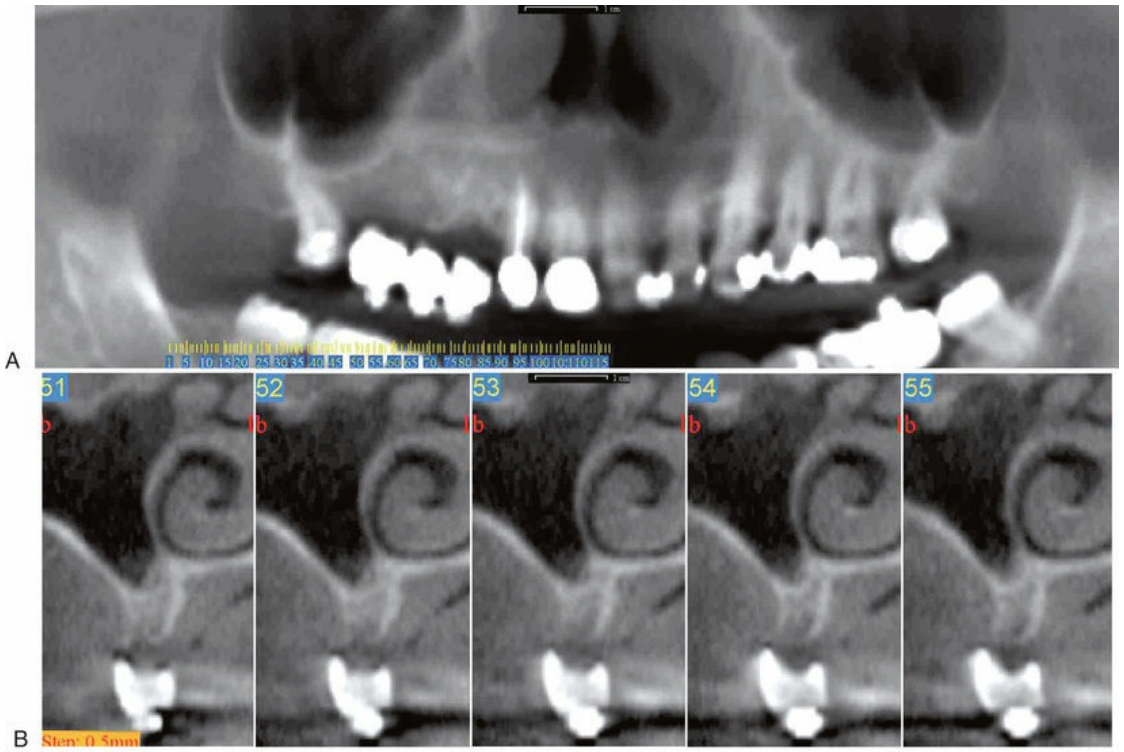

FIG. 76.14 (A) Panoramic view of partially edentulous maxilla with tooth-shaped markers in areas of missing teeth (potential implant sites). (B) Cross-sectional views from a cone-beam computed tomography examination before implant placement in the right maxilla. Appropriately sized and shaped tooth markers placed in the prosthetically desired locations of the planned restorations for the missing teeth help evaluate the existing alveolar ridge relative to the prospective tooth positions and contours.

Key Fact

An important part of diagnostic imaging must include an evaluation of the available bone relative to the "prosthetically driven" implant position. It is most beneficial to assess the prosthetic position in scans using radiopaque tooth-shaped

markers so the proper contours of the proposed restoration can be appreciated.

Clinical Selection of Diagnostic Imaging

Radiography is an important diagnostic tool for the evaluation of the implant patient. However, radiographic imaging alone is insufficient. It is important to correlate diagnostic information with a good clinical examination. Conversely, a clinical examination is insufficient to provide the information needed to plan implant treatment for a patient without some radiographic imaging.

Clinical Examination

Before taking any radiographs, a complete clinical examination of the implant patient is required. This should include the etiology and duration of tooth loss, any history of traumatic extraction, and a review of records and radiographs, if available. A clinical assessment of the edentulous area, covering mucosa, adjacent and opposing teeth, and occlusal plane, should be performed. Temporomandibular function, mandibular maximal opening, and protrusive and lateral movements should be evaluated.

Screening Radiographs

At this point, an overall assessment of the health of the jaws should be performed. The American Academy of Oral and Maxillofacial Radiology recommends panoramic radiography as the initial evaluation of the dental implant patient, supplemented with periapical radiographs as needed.[17] Periapical radiographs provide a high-resolution image of the alveolus and the surrounding structures, including adjacent teeth. For extended edentulous areas, panoramic, lateral cephalometric, and occlusal radiographs can be used to estimate bone height and width. Any pathology of the bone at the prospective implant site, as well as of the surrounding structures, should be identified and treated as indicated.

Key Fact

The American Academy of Oral and Maxillofacial Radiology recommends panoramic radiography as the initial evaluation of the dental implant patient, supplemented with periapical radiographs as needed. The organization also recommends that radiographic examination of any potential implant site should include cross-sectional imaging orthogonal to the site of interest.

Fabrication of Radiographic and Surgical Guides

Once the health of the soft and hard tissues is established, casts should be taken and a detailed analysis performed. The clinician should decide on the number of implants and their desired location. Next, a radiographic guide should be fabricated, usually with clear acrylic. The position of the desired implants is indicated by the use of radiopaque objects such as metallic balls, cylinders, or rods; gutta-percha; or composite resin. If CT imaging might be performed, the use of metallic markers should be avoided. The design of such a guide greatly enhances the diagnostic information provided by the radiographs because it correlates the radiographic anatomy with the exact position of the proposed implant location.

Cross-Sectional Imaging

The American Academy of Oral and Maxillofacial Radiology recommends that radiographic examination of any potential implant site should include cross-sectional imaging orthogonal to the site of interest.[17] The potential morbidity of a compromised anatomic structure and the poor performance and potential failure of a misplaced implant, combined with the wide availability of tomographic facilities, favor the use of cross-sectional imaging in most cases of implant treatment planning. It is crucial that the cross sections are perpendicular to the curvature of the mandible and parallel to the planned implant. Improper patient positioning can lead to an overestimation of the height and width of the available bone. If the surgeon believes that sections were performed at the

wrong angulation, new images should be requested. This might necessitate reexposure of the patient.

Intraoperative and Postoperative Radiographic Assessment

Various radiographic modalities can provide valuable information during implant placement. Because of the ease of acquisition and high resolution, periapical radiographs are most commonly used. Intraoperative radiographs can be taken during surgery to evaluate proximity to important anatomic structures. Sequential periapical radiographs guide the clinician to visualize changes in direction and depth of the drilling procedure and parallelism to adjacent teeth and other implants (Fig. 76.15). Digital radiographs are particularly advantageous during an intraoperative assessment of implant placement; images appear on the screen almost instantaneously and can be manipulated to extract the most pertinent diagnostic information (see Chapter 33).

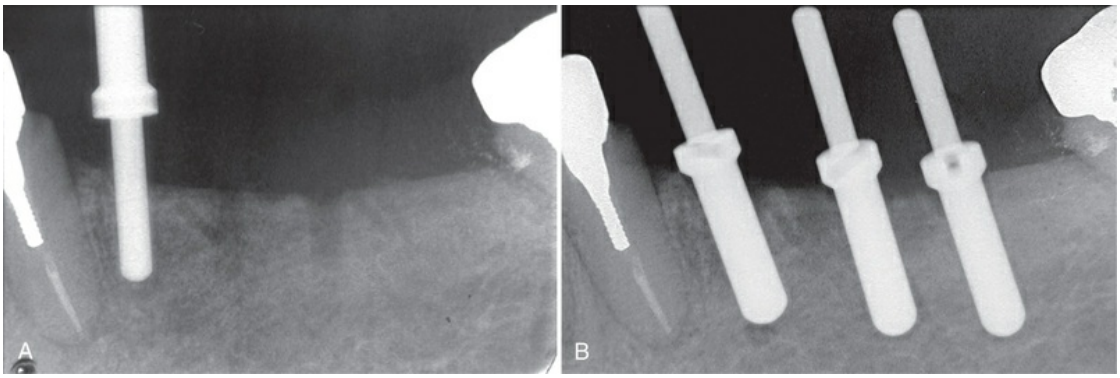

FIG. 76.15 Intraoperative periapical radiographs are valuable in assessing the proximity of adjacent teeth. (A) The 2-mm guide pin is used to determine the direction of the osteotomy site and its proximity to the adjacent root. (B) After angle correction, the osteotomy sites are completed to length with the final drill. Here the 3-mm guide pins confirm the correct angulation and spacing of the final osteotomy site preparation before implant placement.

Implant osseointegration, and the level of peri-implant alveolar

bone are major determinants of implant prognosis. Panoramic and periapical radiographs offer a fast, easy, and low-radiation depiction of the implant and surrounding tissues and aid in the assessment of implant success. To obtain an accurate assessment of peri-implant bone height, the x-ray beam should be directed perpendicular to the implant. In the case of threaded implants, the implant threads should be distinguishable and not overlapping (Fig. 76.16A).

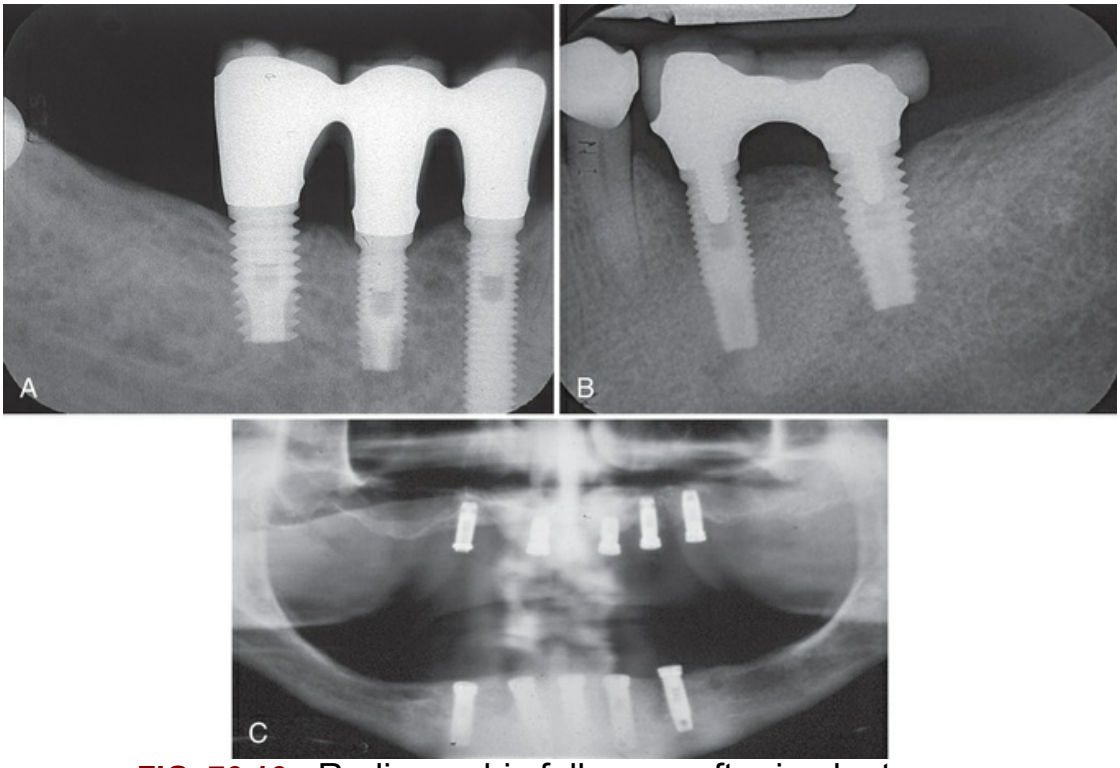

FIG. 76.16 Radiographic follow-up after implant placement in three different patients. (A) Periapical radiograph of three implants in the posterior right mandible. “Normal” bone remodeling around the anterior two implants and slight horizontal bone loss/remodeling around the molar/posterior implant is present. (B) Periapical radiograph of two implants in the left posterior mandible. Severe bone loss (50% of implant length) is seen around the anterior implant, whereas mild bone loss/bone remodeling is observed around the posterior implant. A moderate buccal cantilever in the restoration likely contributed to an adverse occlusal load and the resultant bone loss observed in this case. (C) Panoramic radiograph of

maxillary and mandibular implants in an edentulous patient prior to implant loading. The mandibular implants do not show signs of bone loss and appear to be osseointegrated. All maxillary implants show signs of moderate-to-severe peri-implant bone loss, and the success of osseointegration is questionable.

A 1.2-mm marginal bone loss during the first year after implant placement and 0.1 mm per year afterward are expected; however, further bone loss is considered abnormal.[2] Pathologic bone loss could be localized along the full extend of the implant (peri-implant bone loss) or around the crestal part of the implant ("saucerization"), and it could reflect poor osseointegration, peri-implantitis, or unfavorable stress distribution (Fig. 76.16B–C).

In select cases, when poor implant placement (Fig. 76.17) or compromise of vital anatomic structures (Fig. 76.18) is suspected, advanced imaging (CBCT, CT, or conventional tomography) provides a three-dimensional evaluation of the oral structures in relation to the implants. This information can be very important for proper assessment and treatment planning. The treating dentist should recognize relevant signs and symptoms and order appropriate imaging as soon after implant placement as possible. Implant removal, if necessary, would be less complicated before advanced osseointegration.

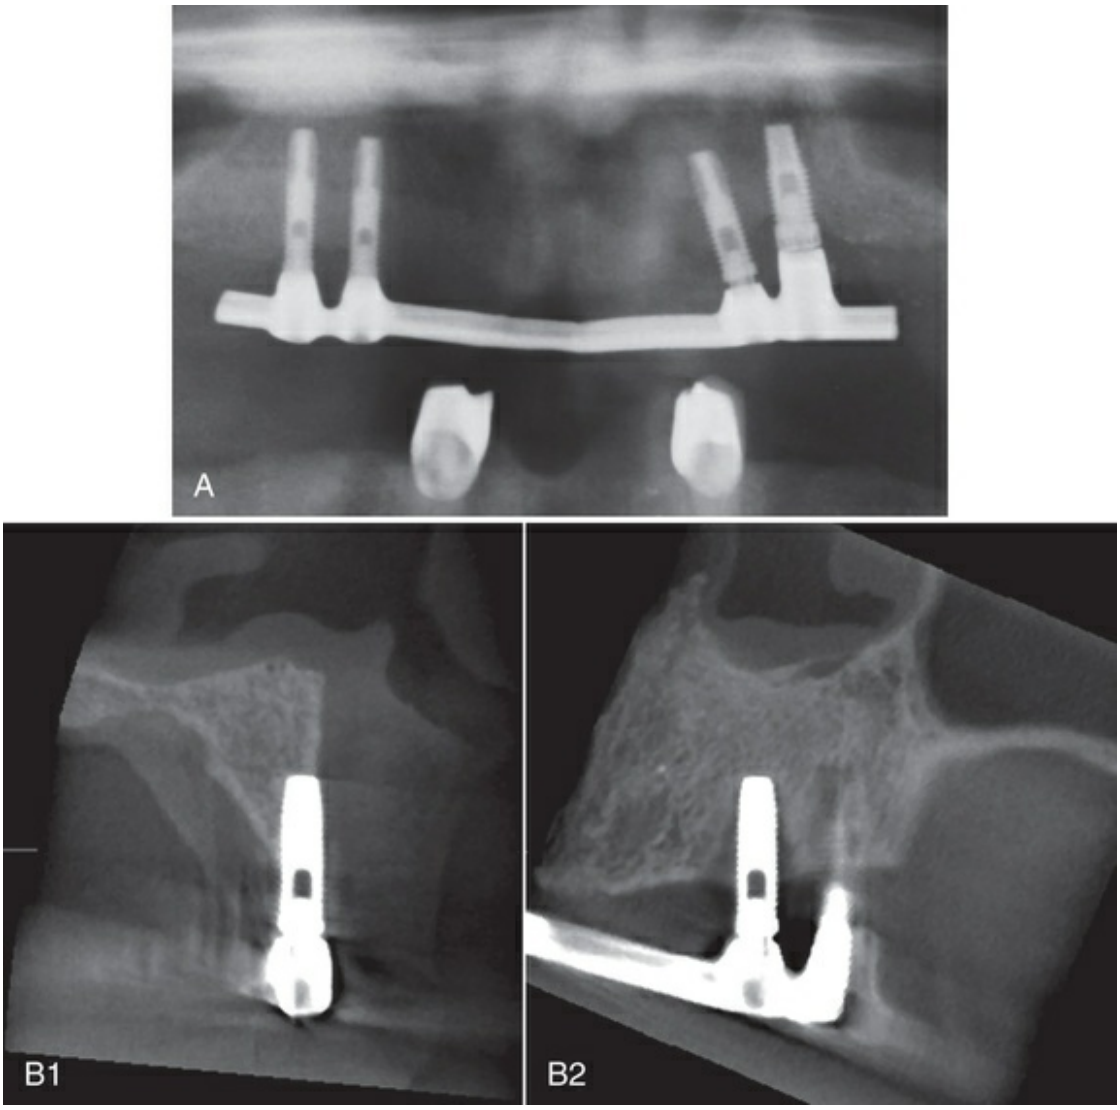

FIG. 76.17 Radiographic follow-up after implant placement. (A) Panoramic radiograph suggests mild-to-moderate bone loss around the neck of all implants. This is especially true for the implants in the left maxilla. These implants appear to be angled, and the distal implant is positioned more apical. The overdenture bar is not completely seated on the left implants. Note that superimposed overlapping anatomic structures in this panoramic radiograph impair the ability to clearly visualize and assess bone loss around implants. (B) Cross-sectional (B1) and sagittal cone-beam computed tomography (B2) images of the anterior implant in the left maxilla. Poor implant placement beyond the buccal cortex of the alveolar ridge (cross section) and peri-implant bone loss (sagittal) are revealed.

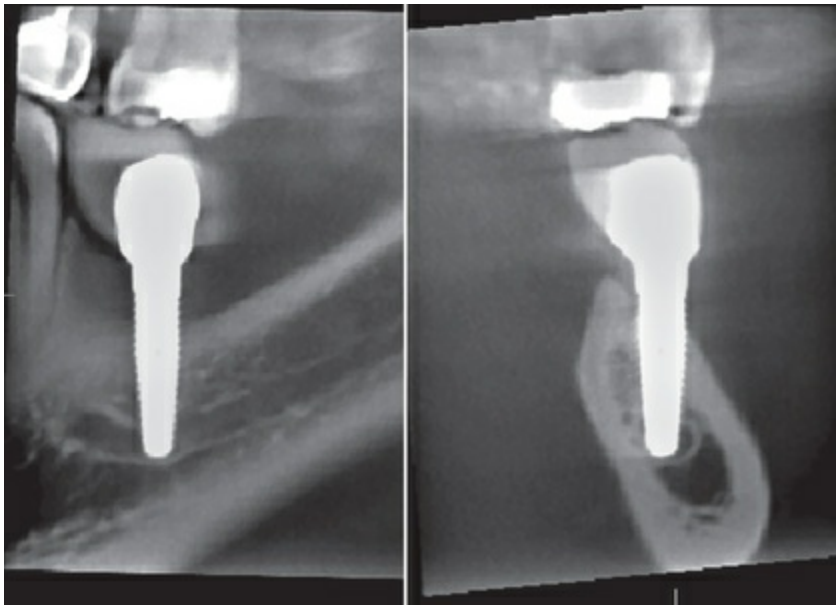

FIG. 76.18 Cone-beam computed tomography sagittal and cross-sectional images clearly demonstrate penetration of the implant into the mandibular canal.

Conclusion

Many radiographic projections are available for the evaluation of implant placement, each with advantages and disadvantages. The clinician must follow sequential steps in patient evaluation, and radiography is an essential diagnostic tool for implant design and successful treatment of the implant patient. Selection of appropriate radiographic modalities will provide the maximum diagnostic information, help avoid unwanted complications, and maximize treatment outcomes while delivering an "as low as reasonably achievable" radiation dose to the patient.[11]

Case Scenario 76.1

Patient:

38-year-old male

Chief Complaint:

"My upper right back tooth had recent sharp pain after I used my teeth to cut some copper wires at work."

Background Information

The patient is an electrician who presented to your office with an 11-mm narrow probing depth localized to the disto-buccal line angle of tooth #3. All clinical parameters suggest possible fracture. In an attempt to save this tooth, you have decided to use cone-beam computed tomography (CBCT) to perform an Endo survey in attempt to locate any fractures.

Clinical Findings:

A coronal section of a CBCT image for this tooth has identified a neurovascular bundle structure (circled in red) found on the lateral wall of the maxillary sinus.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. The neurovascular bundle structure (circled in red) is identified as the _____ artery. A. descending palatine artery	**Answer: D** **Explanation:** Intraosseous vessels are present throughout the jaws. It is important to identify the location, especially if planning a surgical procedure in the area. The posterior superior alveolar artery passes through the lateral wall of the sinus.

B. infraorbital artery C. maxillary artery D. posterior superior alveolar artery E. sphenopalatine artery	
2. The neurovascular bundle structure (circled in red) consists of a nerve from which cranial nerve? A. Olfactory nerve (CN I) B. Optic nerve (CN II) C. Oculomotor nerve (CN III) D. Trigeminal nerve (CN V) E. Facial nerve (CN VII)	**Answer: D** **Explanation:** The trigeminal nerve (CN V) supplies the tissues on the lateral side of face.
3. The above-identified nerve originates from the brain and exits the skull through which foramina? A. Foramen rotundum B. Foramen ovale C. Foramina of the cribriform plate D. Superior orbital fissure E. Stylomastoid foramen	**Answer: A** **Explanation:** See anatomy.

Case Scenario 76.2

Patient:
68-year-old female

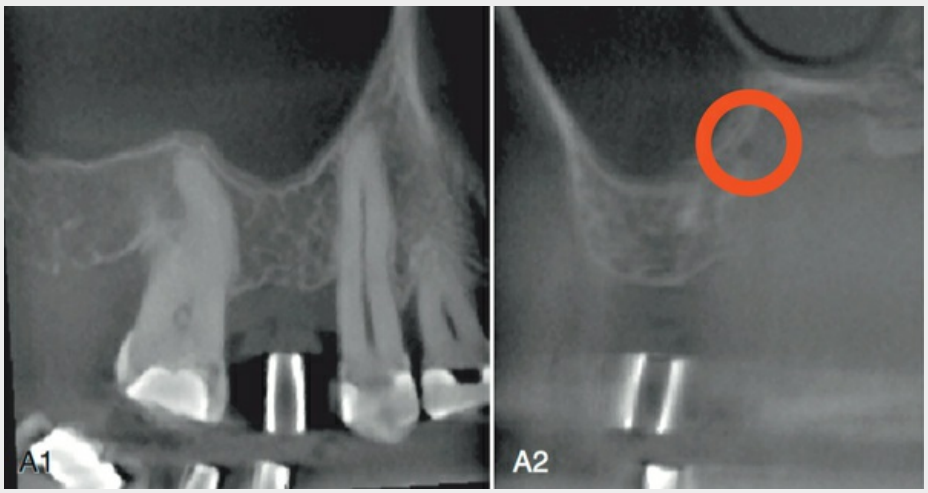
Chief Complaint:
"I had my upper right tooth extracted due to a huge cavity about 5 months ago. I would like to have it replaced as soon as possible because I can no longer smile confidently."

Background Information
Cone-beam computed tomography (CBCT) is an important tool for

assessing bone quality, quantity, and volume; excluding pathology; and identifying important anatomic structures. CBCT data in DICOM format for the #4 edentulous site was obtained from the patient's restorative dentist.

Current Findings:

Normal periapical demonstrates the extraction socket has healed completely. Sagittal and coronal sections of the potential implant site #4 are provided below.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Identify the structure circled in red. A. Abnormal anatomic structure B. Greater palatine artery C. Posterior superior alveolar artery D. Normal trabeculation bone pattern E. None of the above	**Answer: B** **Explanation:** See anatomy.

CHAPTER 77

Prosthetic Considerations for Implant Treatment

Todd R. Schoenbaum, Evelyn Chung, Ting-Ling Chang, Perry R. Klokkevold

CHAPTER OUTLINE

Implant Considerations
Abutment/Prosthesis Considerations for Single Units
Management of Partially Edentulous Implant Treatment in the Aesthetic Zone
Fully Edentulous: Prosthetic Considerations *(e-only)*
Conclusion

Ultimately, successful implant treatment requires a team of clinicians dedicated to excellence in surgical and the prosthetic aspects of the process. This chapter reviews the critical aspects of prosthetic implant treatment proven to maximize long-term functional, biologic, and aesthetic success.

Implant Considerations

Understanding the Anticipated Load on the System and Its Relation to Implant Diameter

Selecting the appropriate implants for the partially edentulous patient depends in part on the anticipated loads of that particular tooth location. The larger the anticipated loads, the more robust the implant must be to properly support the prosthesis. Notably, for any given implant design, larger-diameter implants result in stronger prostheses.[14] The implant connection design also plays a significant role and will be discussed later. However, the prosthetic advantages of a larger-diameter implant must be balanced with the surgical needs for sufficient (~1.5 mm) surrounding bone. In some locations, this constraint will present itself in the mesiodistal dimension, whereas in others the constraint will come from the buccolingual dimension of the alveolar ridge.

The anticipated load on the implant is affected by its position in the arch. The more posterior the implant is in the arch, the higher the anticipated load. Estimates have been made relating to the ratio of load from anterior to posterior,[45] but such generalizations oversimplify the complexity of the system. Although a tooth located more posteriorly will receive at least twice the load forces (and therefore require a larger implant diameter), there are several other factors that will influence the result. Anterior–posterior position in the arch is part of this consideration, but so are the number and integrity of the teeth distal to the implant position. A first molar implant with good second molars will receive significantly less force than that same molar with no other molar support.

Often overlooked, the size of the muscles of mastication can provide cursory evidence regarding just how much force a patient is able to produce on his or her dentition. Patients with very large muscles will generate greater forces on their teeth and implants. However, excessive forces do not always show up as attrition. These forces can be delivered in a largely vertical vector with little to no horizontal component. This information should be checked

and recorded at the initial patient examination. Patients with a history of cracked or broken teeth and crowns should be expected to place heavier loads on the implants used to replace them.

In the evaluation of the implant patient, special attention should be given to the arch opposing the location of expected implant treatment. If the opposing dentition is a removable appliance, then the implant will receive significantly lower forces.[48,53] Conversely, if the opposing dentition is implant-supported fixed restorations, the forces are likely to be quite high. This phenomenon is largely due to the lack of a periodontal ligament (PDL) around the implants. If the implant is opposing a removable appliance, it should be determined if there is any likelihood of converting to a fixed implant-supported prosthesis. If this is the case, then the implant in question should be planned with increased loads in mind.

Occlusal guards have long been employed to protect the dentition and prostheses against excessive forces and destructive wear habits. As implants lack the "cushioning effect" that the PDL provides to natural teeth, the occlusal guard can provide the patient with an added layer of protection against overloading of the implant system. The limiting factor with occlusal guards is patient compliance.

Clinicians looking for a more quantified approach to evaluating the loads placed on teeth and implants might consider digital occlusal analysis systems.

Clinical Correlation

The anticipated load on the implant is affected by its position in the arch. The more posterior the implant, the higher the anticipated load. Estimates have been made relating to the ratio of load from anterior to posterior, but such generalizations oversimplify the complexity of the system. Although a tooth located more posteriorly will receive at least twice the load forces, there are several other factors that will influence the result. Other important factors to consider are the number of implants, the stability of the surrounding dentition, and individual mastication forces.

Larger-diameter implants create stronger prosthetics and are less

likely to fracture.[14] The use of larger implants becomes more important under the following circumstances: enlarged masseter/temporalis muscles, a history of broken teeth and crowns, distal-most tooth in the arch, opposing other implants, and patients unwilling to wear an occlusal guard. However, the prosthetic advantages of larger platform implants must be balanced with the realities of the surgical site. In locations with space constraints, other prosthetic modalities may be employed to mitigate the anticipated risks. Innovations in implant connections, manufacturing tolerances, and alloys have created more and more robust systems that will improve the ability to withstand excessive forces.

Narrow-diameter implants have proven to be a reliable and useful approach to compromised spaces (<7 mm).[71] This constraint can be mesiodistal due to adjacent teeth or implants, or it can be buccolingual due to inadequate volume of the alveolar ridge. Use of such implants is best reserved for sites with low expected loads and constrained spaces, namely the incisors of both jaws.

Number of Implants

Partially edentulous patients with multiple adjacent missing teeth can present some unique challenges. If we use 4 mm as the diameter of a "regular" implant, and the guideline of 1.5 mm of circumferential peri-implant bone, we can quickly estimate the amount of space required for implants by multiplying 7 mm times the number of missing teeth.[135] Or more simply, one tooth requires 7 mm of mesiodistal space; two teeth require 14 mm, three teeth require 21 mm, and so on (Fig. 77.1). This is an oversimplification of the planning process, but makes initial estimations of treatment options easier.

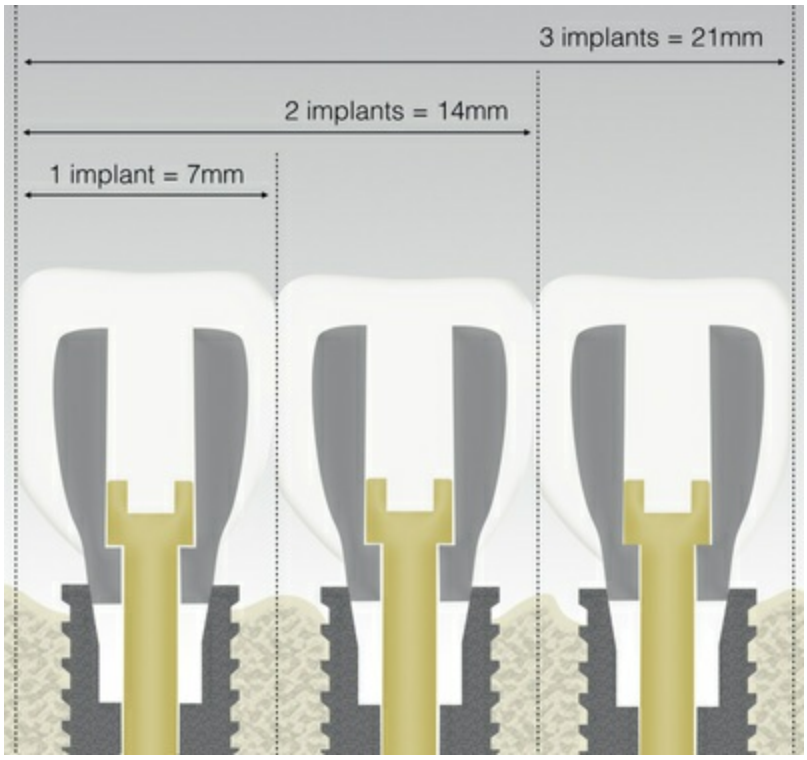

FIG. 77.1 Implants benefit from the presence of 1.5 mm of bone circumferentially. A "normal" diameter implant is ~4 mm. For treatment planning purposes, each implant should have 7 mm of space mesial–distally at the bone crest, two implants would need 14 mm, and so on.

Not every missing tooth needs an implant. Two implants with a three-unit fixed dental prosthesis (FDP) have proven to be quite reliable in many situations.[90] Material selection is key; weaker and unproven materials should be used with extreme caution. Gold alloy porcelain-fused-to-metal (PFMs) and zirconia-based FDPs have good (but not perfect) track records. Lithium disilicate materials (and recent derivatives) are not well tested for multiunit FDPs. The use of a pontic between two implants has aesthetic advantages in relation to the volume of the peri-implant tissues. This topic will be covered more in depth during the discussion on implants in the aesthetic zone.

Cantilevers off one or more implants can be a creative solution to complicated implant treatment planning situations. Such a design is certainly less durable than a noncantilevered approach, but it does have its place. Cantilever FDPs are best reserved to replace multiple missing incisors in patients with nonexcessive occlusal forces.[119] The

use of a cantilever pontic should be avoided in most posterior situations, unless multiple implants are splinted and the length of the cantilever is deemed acceptable.

Narrow-diameter implants can be implemented in areas with reduced dimensions, but only to a point. Narrower implants are inherently more fragile and more apt to suffer from catastrophic failure. Their minimal dimensions will make more aesthetic prosthetic materials (i.e., zirconia abutments) a riskier option. Although manufacturers will continue to produce smaller and smaller implants, their use in patients should be considered cautiously until proven to be successful.

When space constraints push the clinician to select smaller and riskier implants, alternative options should be seriously considered: orthodontics, tooth-borne FDPs (Fig. 77.2), bone augmentation, and additional extractions. Though the last option may sound overly aggressive, it can be the best choice in scenarios where adequate space cannot be created. This most commonly presents as a single missing mandibular incisor. The two missing incisors can then be replaced with a single implant. In this scenario the implant can be placed centrally between the two missing teeth or off to one side with a larger cantilever (Fig. 77.3). The centrally located implant will reduce the stress due to the decreased length of the cantilever, but the offset implant may allow for the creation of a more natural gingival architecture around the pontic.

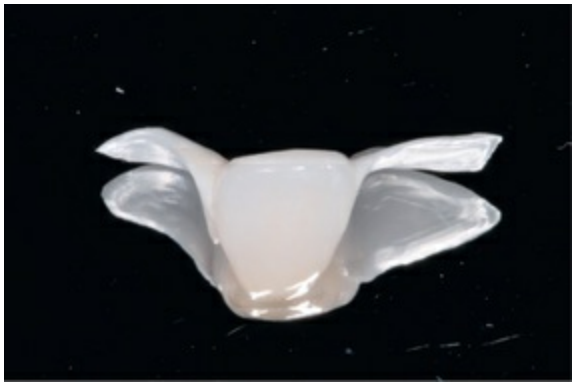

FIG. 77.2 It is important to understand that implants are not the only way to replace missing teeth. In this example a ceramic Maryland bridge is used to replace the upper left lateral incisor.

FIG. 77.3 Replacement of two consecutive missing teeth presents a unique challenge. Mesial–distal space requirements often preclude the use of two adjacent implants. The implant can be placed centrally (A–B) or in the position of one of the missing roots (C–E).

Implant-Abutment Connection

Of all the variations in implant designs, perhaps none is as important to prosthetic success as the connection design. The design of an implant abutment junction (IAJ) will influence everything from incidence of screw loosening, to maintenance of the hard and soft tissues, to leakage *inside* the implant. The implant(s) should be selected for a particular scenario based on a thorough consideration of the connection that best suits the case. There is no "one size fits all" solution. Certain connections are well suited for fully edentulous patients but are poor choices for a single unit, whereas another connection might be well proven in complicated aesthetic treatments but do poorly under heavy loads.

Currently available dental implants are classified into three types (Fig. 77.4) based on their abutment connection design: external connection, internal connection, and solid body (the abutment is contiguous with the implant body).

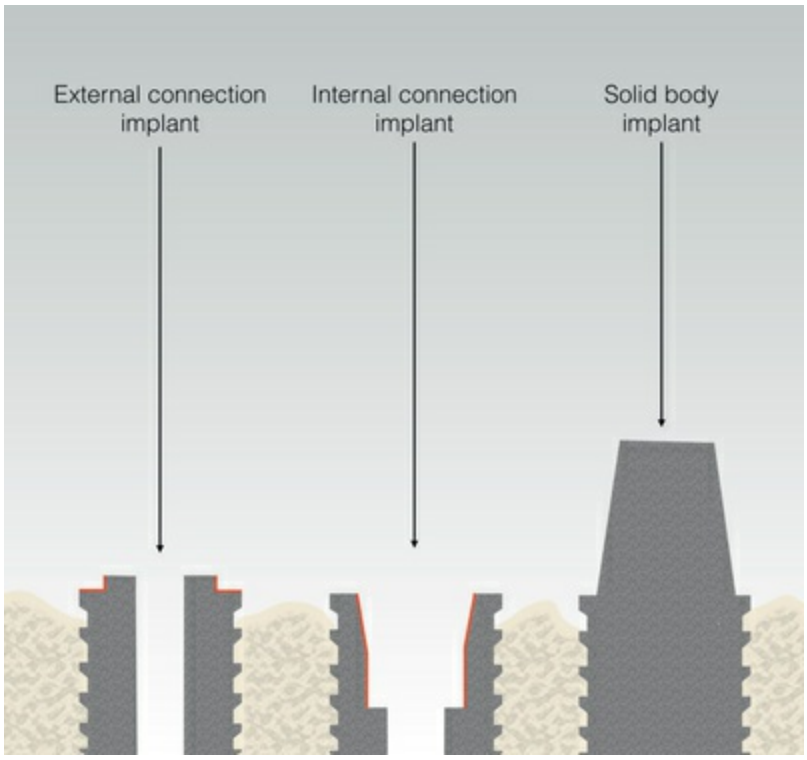

FIG. 77.4 Most currently available implants can be classified as one of three types: external connection, internal connection, or solid body. The external hex connection is primarily indicated for full-arch treatments. The solid body implant must be placed in the ideal position, as there is no way to correct the position with the abutment. The internal connection implant (of which there are many varieties) is indicated for most partially edentulous treatments. Note the abutment engagement areas, as highlighted in *red*.

The external connection implant is commonly referred to as an "external hex" implant due to the presence of a raised hexagon connection on most versions of this design. The external connection is one of the older connection designs still in common use today. It offers the advantages of an extremely extensive array of prosthetic products to address even the most complicated of clinical presentations. It is a robust implant and rarely suffers from fracture of the implant body itself. This is a well-tested and widely accepted implant design.[4,5] It is well suited to the restoration of fully edentulous patients desiring a fixed restoration. The wide platform of the implant creates a stable base, whereas the relatively short connection (0.7 mm tall) allows for easy correction of nonparallel implants.

The primary drawback of the external connection implant is screw loosening.[40,41,61,64] The short connection height does little to share the forces between the abutment and the implant body. Even if the hex portion is engaged, there is still very little vertical wall height to transfer the oblique forces of the prosthesis. Inevitably, these forces are transferred largely to the abutment screw, which stretches and deforms under load. Over time this will result in the need to tighten and replace the screws. This problem is significantly reduced with prostheses supported by multiple implants. It is primarily a problem with single tooth replacements on the external connection implant.

Key Fact

Perhaps the most important implant design factor relative to prosthetic success is the implant-abutment connection design. The design of an implant abutment junction (IAJ) will influence everything from incidence of screw loosening, to maintenance of the hard and soft tissues, to leakage inside the implant.

Compared with more modern implant designs, the external connection loses more crestal bone.[a] This is a multifactorial problem, but it is due in large part to the constant opening and closing of the IAJ under load.[55,95,106] This leads to bacterial infiltrate being pumped into and out of the internal aspects of the implant[5,59] and directly into the peri-implant tissues (Fig. 77.5). A move away from the external connection has mitigated (but not eliminated) both screw loosening and excessive crestal bone loss.

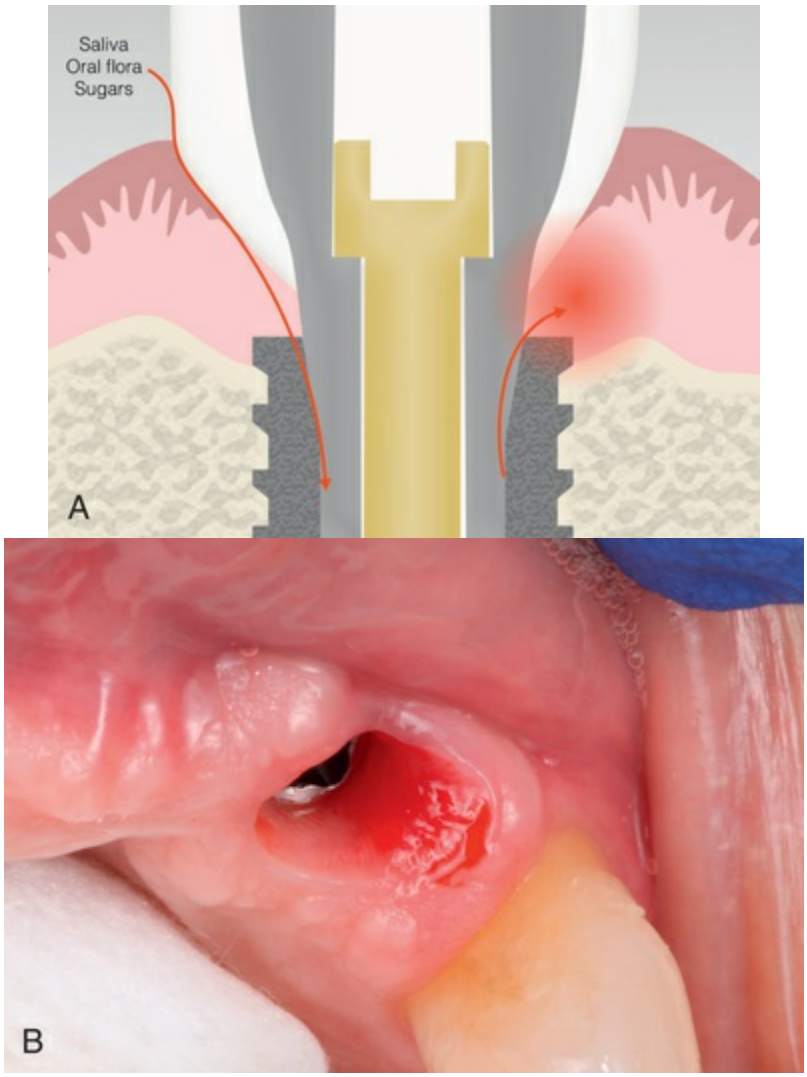

FIG. 77.5 All two-piece implants have hollow internal spaces. Under functional loads, the junction between the implant and the abutment will open slightly and allow saliva, oral flora, and nutrients into the internal aspects of the implant (A). In this oxygen-free environment, anaerobes will proliferate. They will be pumped into the peri-implant tissues and may be partially responsible for typical peri-implant bone loss or inflammation of the peri-implant tissues (B).

The internal connection (in all its variations) has become the implant of choice for most partially edentulous rehabilitations due to improved reliability compared with the external hex design.[49] For most systems, it is a misnomer to call it an "internal hex." The geometry of the connection itself comes in many variations including hexagons, octagons, 12-pointed stars, trilobes, circles with four flat sides, seven-splines, and others. The number of sides to the

connection allows the user various positions from which to orient a stock manufacturer abutment. Some manufacturers prescribe which lobe or point of the implant connection should be oriented buccally to address this. Although more sides on the connection allow for more flexibility in positioning a stock abutment, this does increase the difficulty of correctly aligning a custom abutment. There is no overwhelming, independent, peer-reviewed evidence that any one internal connection geometry is superior to all the others.

Many implant systems have begun to incorporate a tapered element into the implant abutment connection. The rationale for incorporating a taper into the connection is to further stabilize the IAJ,[88] thus minimizing leakage, abutment movement, and loosening of screws. This concept comes from the world of machining tools, like lathes and drill presses. For some unknown reason, the dental profession has taken to referring to any tapered connection implant as a "Morse taper," though few implant designs meet the very specific specifications of any Morse taper variation (~1.5-degree taper).

Regardless, upon fully torquing the abutment screw, implants with a very narrow taper do create a better seal and will have better long-term stability of the abutment and the screw. Both are advantages in terms of maintenance and persevering the peri-implant tissues at a maximum level. Some tapered connection implant systems even require a special tool to remove the abutments, as after screw removal the components can have such a strong friction fit.

When wide diameter external connection implants were introduced, they remained compatible with the abutments from the narrower implants. Some clinicians and scientists began experimenting with using these narrow abutments on wider implants; they referred to these connections as "platform switched."[74] This term has come to encompass any implant that has an abutment that is narrower than the implant neck (Fig. 77.6). The preponderance of evidence suggests that the platform-shifted design maintains bone at a higher level than that of a nonplatform switched design.[b] The reasons for this effect are less leakage at the IAJ (most are tapered connections),[9,38,73,92] less screw loosening,[101,110] less stress on the peri-implant bone,[29,52,85,86] and movement of the

nonosseointegrating surface of the abutment away from the bone. The latter concept creates a horizontal space on the implant for supracrestal connective tissue to establish a circumferential peri-implant seal, thereby allowing the bone to maintain its position at a higher level without having to remodel to a lower position.[111,112]

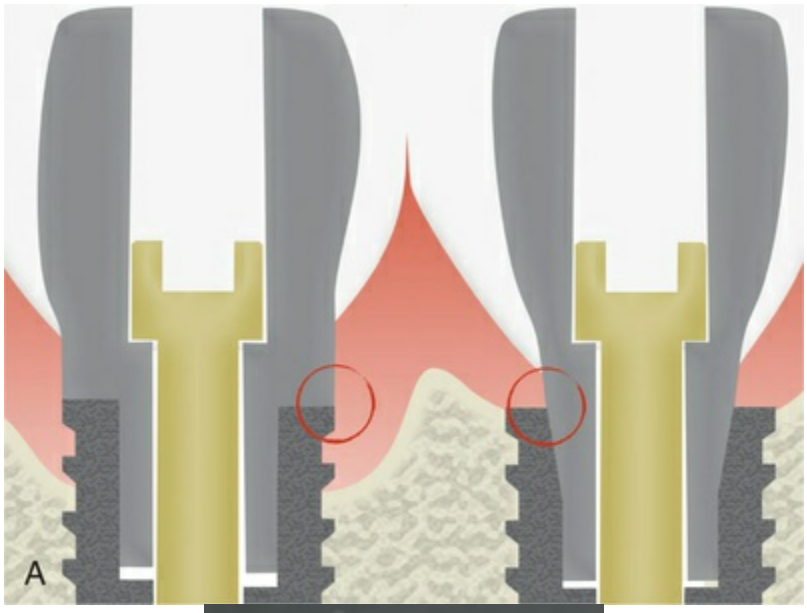

FIG. 77.6 The platform switched implant design (A, *right*) has an abutment that is narrower than the head of the implant (B). The majority of evidence suggests that this design better preserves bone than implants, which use abutments as wide or wider than the head of the implant (C).

The only potential downside to a platform-switched implant system is that the abutment is narrower and therefore more prone to breakage. Data on this concern are sparse, but it stands to reason that for any material (in particular zirconia), the thinner it is, the more easily it will suffer fracture. Many manufacturers have begun to address this problem by offering their zirconia abutments with a titanium insert that interfaces with the implant body (Fig. 77.7). This has the benefit of placing the more fragile zirconia outside the implant and prevents the possibility of the zirconia wearing the implant connection prematurely.

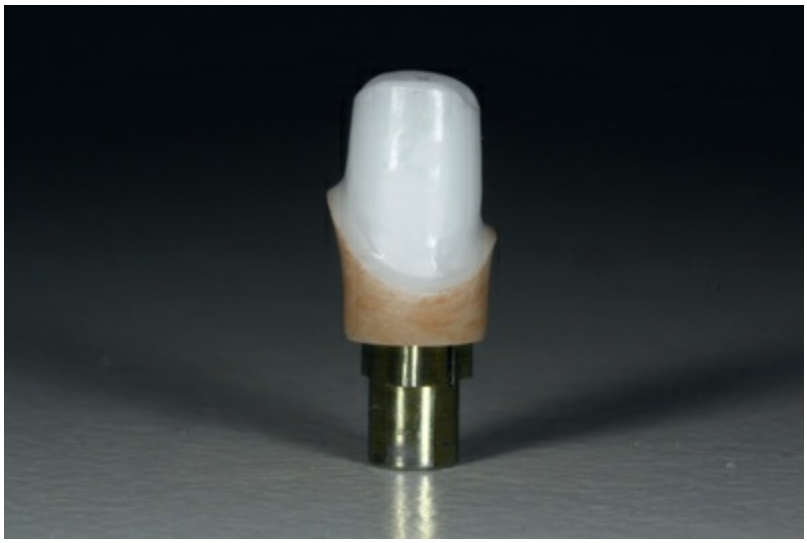

FIG. 77.7 Zirconia abutments are useful to minimize any changes to the color of the peri-implant tissues and allow the use of semitranslucent prosthetic materials. Most manufacturers have developed zirconia abutments, which have a titanium base as shown here. This may make the abutments stronger and will eliminate the failure of the zirconia *inside* the implant body. Such failures are difficult to resolve successfully.

The internal aspect of the implant is hollow to allow for the screw and the abutment connection. However, these spaces inside the implant can serve as a pathogenic reservoir if or when the IAJ leaks.[9,73,92] This internal chamber is anaerobic, body temperature, and when the IAJ leaks it will become filled with oral bacteria, saliva, and nutrients. The chamber is then fertile breeding ground for anaerobic bacteria and their by-products. Continued movement between the abutment and the implant will pump the bacterial exudate into the fragile peri-implant tissues. It appears that this is one of the primary causes of "normal" bone loss around implants. Excessive amounts of pumping may be culpable in idiopathic incidences of peri-implant mucositis and peri-implantitis. Therefore clinicians should opt for implants and abutments that have been shown (over extended periods of time) to reduce the micro-gap and leakage. This is best accomplished with a narrow tapered connection and abutments with titanium interfaces milled by the implant manufacturer. There are additional factors to consider in selecting the appropriate implant for any given scenario, but efforts

to minimize the loss of peri-implant tissues is best accomplished with this treatment modality.

The last type of implant connection to address is the "solid body" implant, or an implant in which the abutment and the implant are one contiguous piece. Such implants have been available for some time but have never gained significant popularity. The challenge with solid body implants is not surgical, and they may in fact be better for the peri-implant tissues because there is no microgap and no leakage. The problem is prosthetic. For these implants, there is no screw-retained option for the prosthesis, and the cement margin is determined at the time of placement. The abutment can be prepped to move the margin apically if absolutely necessary, but there is no reasonable way to move the margin coronally. This presents a serious problem when the gingiva has any significant papilla adjacent to the implant, as the cement margin that is placed perhaps 1 mm subgingival on the facial aspect may now be 3 to 7 mm subgingival at the mesial and distal aspect (Fig. 77.8). With no option for a screw-retained restoration, the restoring clinician is now tasked with fully removing cement far too deep subgingival and will inevitably leave cement behind. This residual cement is likely to induce inflammatory reactions and loss of bone, soft tissue, and perhaps the implant itself.[72,145]

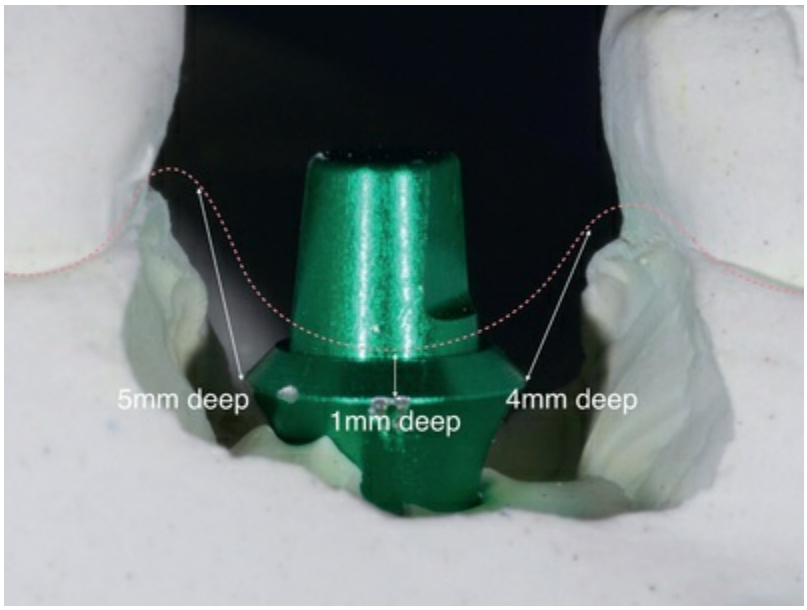

FIG. 77.8 Solid body (and tissue-level) implants present a unique prosthetic challenge due to the

margin being on the implant body itself. This often results in mesial and distal margins that are far too deep to reliably remove cement. As such, restorations for tissue-level implants should generally be screw retained. Unfortunately, restorations on solid body implants can only be cemented. Extreme care must be used with solid body implants.

The solid body implant offers no recourse should the abutment break. This is of particular concern as the use of solid body zirconia implants becomes more prevalent. Should the abutment on the solid body implant break, the implant must either be extracted or abandoned. Special care should be taken with solid body implants to avoid overprepping the abutment area, leading to weakness and increased risk of fracture.

There are a few esoteric implant-abutment connections on the market as well, including press-fit, cemented abutments (where the abutment is cemented *into* the implant), and others. These will not be discussed here due to space constraints and their relative obscurity at the current time.

Abutment/Prosthesis Considerations for Single Units

Retention Method for Partially Edentulous Treatment: Cemented Prostheses, Screw-Retained Porcelain-Fused-to-Metal Options, Screw-Retained Full Contour Zirconia, and Hybrid Designs

When treatment planning a partially edentulous case for restoration with an implant, one of the major prosthetic decisions to be made is whether to have a crown that is cemented to an abutment or a crown that is contiguous with the abutment and screwed directly to the implant. For the sake of discussion here, the screw-retained option will be defined as a cast gold alloy abutment with appropriate support of feldspathic porcelain that will be layered

directly on it (sometimes referred to as UCLA abutments). Variations of the screw-retained crown will be discussed later. Many clinicians have developed personal preferences for screw or cement-retained crowns based on their experiences and failures. Much of an individual clinician's anecdotal experience likely has much to do with the skill of his or her technician when considering screw-retained PFMs. Here we will consider the peer-reviewed evidence to determine the evidence-based advantages and disadvantages of each type of retention.

For *most* single tooth replacements, either screw or cement-retained crowns have proven to have very high levels of long-term success,[90,113,124,139] provided that the clinician and technician follow critical guidelines. In some clinical scenarios, one type of retention is the overwhelmingly superior choice, but this does not reflect the majority of cases.

It is important to understand the difference between *major* and *minor* complications (Table 77.1). Minor complications are issues that can be resolved with little effort or increased risk, such as loose screws, minor porcelain fracture, and reversible peri-implant mucositis. Major complications are loss of the implant, peri-implantitis, severe bone loss, fractured screws, significant porcelain failure, and loss of the prosthesis.

TABLE 77.1

Major Versus Minor Complications in Implant Prosthetics

Major Complications	Minor Complications
Implant failure	Screw loosening
Atypical peri-implant bone loss	Chipped porcelain not requiring prosthesis replacement
Persistent inflammation of the soft tissue	De-cementation of the prosthesis
Infection of the peri-implant tissues	
Failure of the porcelain requiring replacement of the prosthesis	
Loss of the prosthesis	
Fractured screws or abutments	

Screw-retained restorations have a long history of clinical success. Their introduction in 1988[78] allowed clinicians to create more aesthetic restorations than were possible with the available alternatives of the time, and in less vertical space. They can be used

in areas with limited interocclusal distances due to their construction design. They can be created with metal occlusal or palatal surfaces for patients with high functional demands. They can have the porcelain carried to within 1 mm of the head of the implant for improved aesthetics. The primary disadvantages of the screw-retained restoration are significantly more prosthetic complications[c]: porcelain fracture (Fig. 77.9),[68,94,113] screw loosening,[d] increased bone loss,[33,54,60,75,94] increased lab costs, and the need for ideal implant angulation. Minor areas of porcelain fracture can be predictably remedied with contouring and polishing. Larger fractures will require replacement of the entire prosthesis, as porcelain cannot be repaired after prolonged exposure to the oral environment. A dedicated technician could strip all the porcelain off the metal framework in an attempt to save the costs of a new abutment and alloy, but it may very well be that the reason for the fracture in the first place was a poorly designed framework. As such, it is advisable to fabricate an entirely new prosthesis should the porcelain fail. Screw loosening has been established repeatedly as significantly more common in screw-retained restorations, in spite of the fact that cemented restorations generally use the same screw and torque specifications. The reason for this phenomenon is not exactly known, though it is likely due to poorly casted abutment interfaces, increased preload due to nonpassive frameworks,[89,125,138] the historic use of weaker gold alloy screws, or damage to the interface during divestment (Fig. 77.10) or finishing. Technicians must exercise care when creating a screw-retained restoration to ensure the integrity of the abutment interface. The UCLA abutment should have a machined interface made by the manufacturer to ensure the integrity of the fit between the abutment and the implant. Because the screw access channel must exit the crown, this option is best reserved for when the implant angulation exits directly through the occlusal surface in posterior regions and through the palatal/lingual surface in the anterior regions.

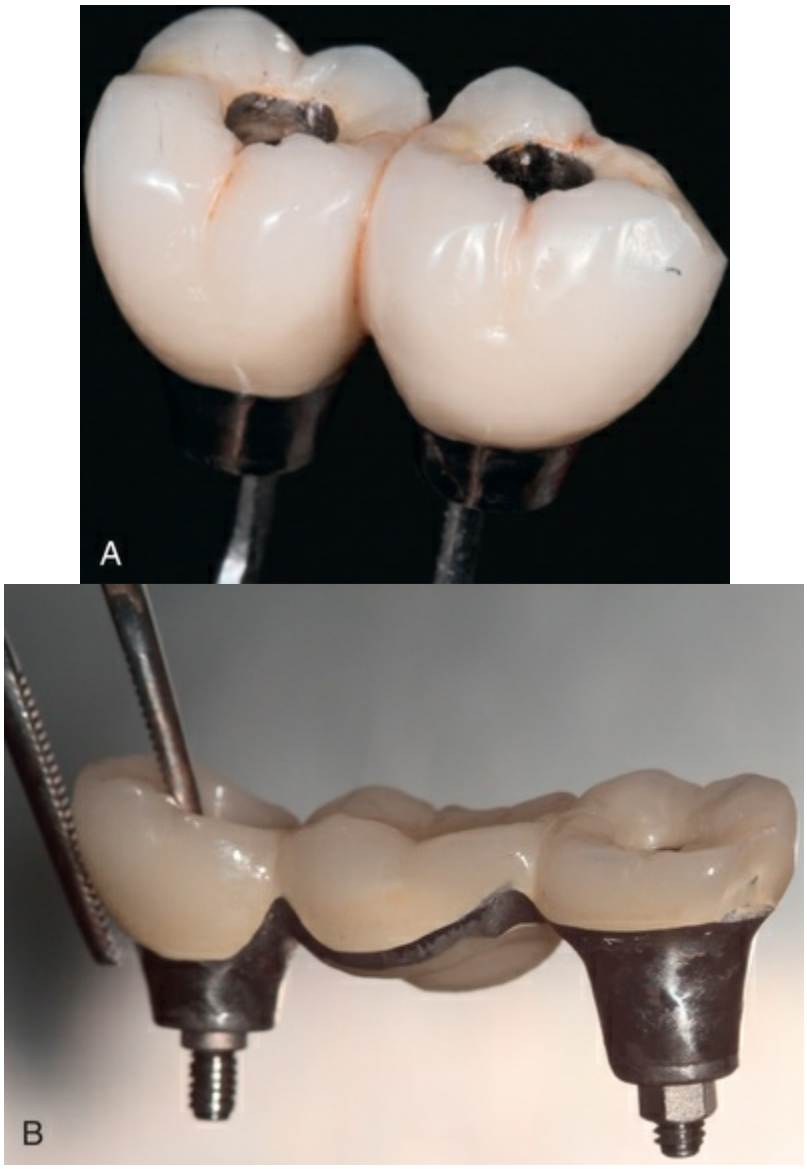

FIG. 77.9 Screw-retained PFM restorations have been shown to have significantly more prosthetic complications, most commonly failure of the porcelain and loose abutment screws. Failure of the porcelain is best addressed by replacement. The new prosthesis will need a more robust framework design or alternative materials. (A) Screw-retained PFM crowns with fractured porcelain. (B) Screw-retained PFM bridge being replaced after screws loosened.

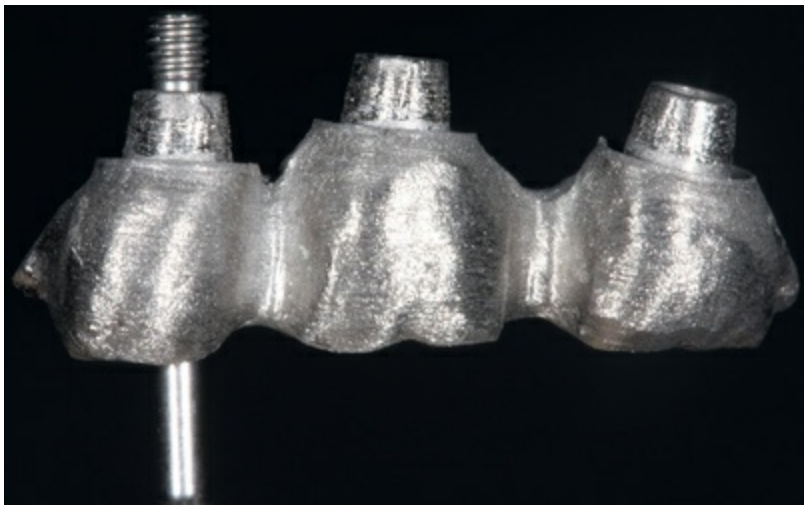

FIG. 77.10 During the fabrication of a screw-retained PFM, the technician must exercise extreme care in creation of the framework so as not to damage the interface area as shown here. The damaged interface will produce a poor-fitting prosthesis leading to increased leakage and screws that loosen more frequently.

Key Fact

For most single tooth implant crowns, both screw and cement-retained methods have proven to be highly successful over the long term provided that the clinician and technician follow critical guidelines. In some clinical scenarios, one type of retention is the overwhelmingly superior choice, but this does not reflect the majority of cases.

The common alternative to the screw-retained crown is the cement-retained crown. This system is made up of an abutment (titanium, gold alloy, or zirconia) that is screwed into the implant and a crown that will be cemented to the abutment. The cement-retained crown allows the restoration of implants that are not placed ideally without having to manage a screw access channel exiting through a crucial aesthetic or functional area. This situation is most common in the aesthetic zone. When implants are placed angled such that and their line of draw exits through the facial surface of the crown, it becomes aesthetically prohibitive to use a

"normal" screw-retained crown (Fig. 77.11). There are some workarounds that will be discussed briefly later.

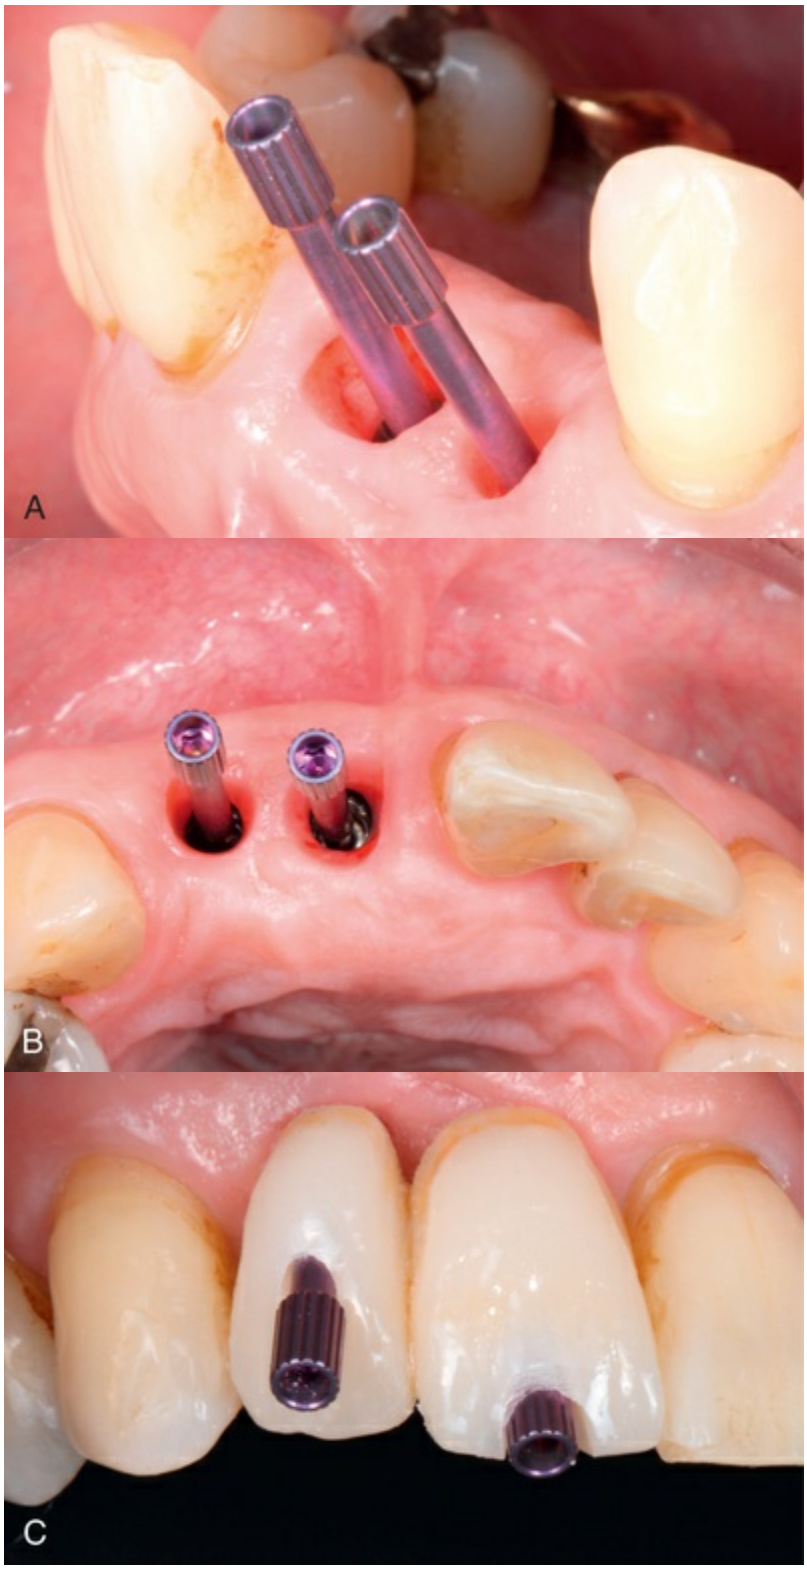

FIG. 77.11 In the aesthetic zone, ungrafted alveolar ridges may result in implants angled out to the facial.

This results in a relative contraindication to screw retention. With most implant systems, implants angled out through the facial surface will need to be restored with a cement-retained option. Lateral view (A) and occlusal view (B) of maxillary anterior implants with abutment screws showing long-axis projection toward facial surface. (C) Provisional restoration with abutment screws projecting through facial surface.

Some clinicians prefer cement-retained restorations because the cementation process is familiar and comfortable. However, the cementation process is not to be taken lightly, as residual cement is one of the major causes (but not the only cause) of peri-implantitis.[1,15,72,145] Cementation details will be discussed later, but note that no attempt should be made to cement an implant crown when margins are more than 1 mm subgingival (Fig. 77.12).[83,84] Cement-retained implant crowns have the main advantage of being far more durable than the screw-retained alternative, a fact confirmed in multiple reviews.[90,113,124,144,146] Porcelain failure of screw-retained crowns has been reported to be as high as 38%, compared with just 4% for cement-retained crowns at an average of 5 years.[94] For this reason cement-retained implant crowns are indicated in scenarios of higher loads (i.e., molars, patients with enlarged masseters). Should the patient break the cemented crown, retrieval of the remaining abutment is greatly simplified. Drilling through even an intact cemented crown to access the screw channel is a relatively simple matter, akin to endodontic access. Lastly, there is the issue of lab cost. The cemented restorations typically lead to far less expensive lab bills compared with the screw-retained PFM options, though the cost of the latter varies significantly with the market price for gold alloy.

FIG. 77.12 For cemented implant restorations, the abutment must be designed such that the cementation margin is no deeper than 1 mm below the gingival margin. In all but the flattest of ridges, this can only be accomplished with a custom-milled abutment.

One of the reasons cited for selecting a screw-retained restoration is the ease of retrievability. There is a valid concern that should something fail, the cemented crown is more difficult to remove. Although it may seem obvious, removal of the cemented crown is hardly more difficult than for a screw-retained crown (Fig. 77.13).[120] The differences are drilling the access through porcelain or metal instead of composite and the location of access may be difficult to discern. Most clinicians are fairly adept at cutting through porcelain, but locating the access channel can be a slight challenge. Most often, the access is fairly easy to locate based off simple radiographs. More sophisticated approaches to recording the location of the access have been proposed, from stents,[56] to guides,[141] to occlusal markings (Fig. 77.14).[116,122] During the era of weaker abutment screws and external connection implants, screw loosening was a common problem. As such, replacement of the screws was a common maintenance requirement and a screw-retained restoration was ideal. Modern implant connections rarely suffer from loose screws, even for single-unit implants.[90,105]

FIG. 77.13 Removal and replacement of failed cement-retained implant crowns are relatively straightforward procedures with most implant designs. The clinician estimates the long access of the implant with radiographs and by palpating the ridge and then simply drills into the screw access through the crown material. The abutments/crowns may still be cemented together and can be removed as one piece.

FIG. 77.14 Placement of an occlusal/palatal marker during fabrication of the crown can make finding the screw access more predictable should removal become necessary.

There are a few other crown retention variations that should be mentioned. One is the full-contour zirconia, screw-retained crown This crown is similar in design to the cast gold, screw-retained crown, but it has no feldspathic layering porcelain, and the substructure is zirconia. Though relatively new to market, these restorations may prove to maintain many of the advantages of the screw-retained system while eliminating its major complication—porcelain fracture. Not all manufacturers offer this restoration, and some variants do not offer a titanium insert to protect the implant from wear and zirconia failure. The titanium insert should be used whenever possible. Some manufacturers offer this restoration with a screw channel that can be angled up to 25 degrees to allow for screw-retained restorations even when the implant is not in the long access of the crown. The screw-retained zirconia option is relatively new and not fully tested in clinical trials. Implement with caution.

Another option is the hybrid crown (sometimes referred to as a screwmentable crown). This system consists of a crown that is cemented to a stock titanium abutment (Fig. 77.15), but the cementation is performed in the laboratory where excess cement can be easily removed. The screw access is predrilled into the crown. This system offers the advantages of minimal risk of retained cement, minimal risk of porcelain fracture when stronger ceramics are used, and a lower lab cost than cast gold alloys. This system is relatively new and not fully tested; in clinical trials implement with caution.

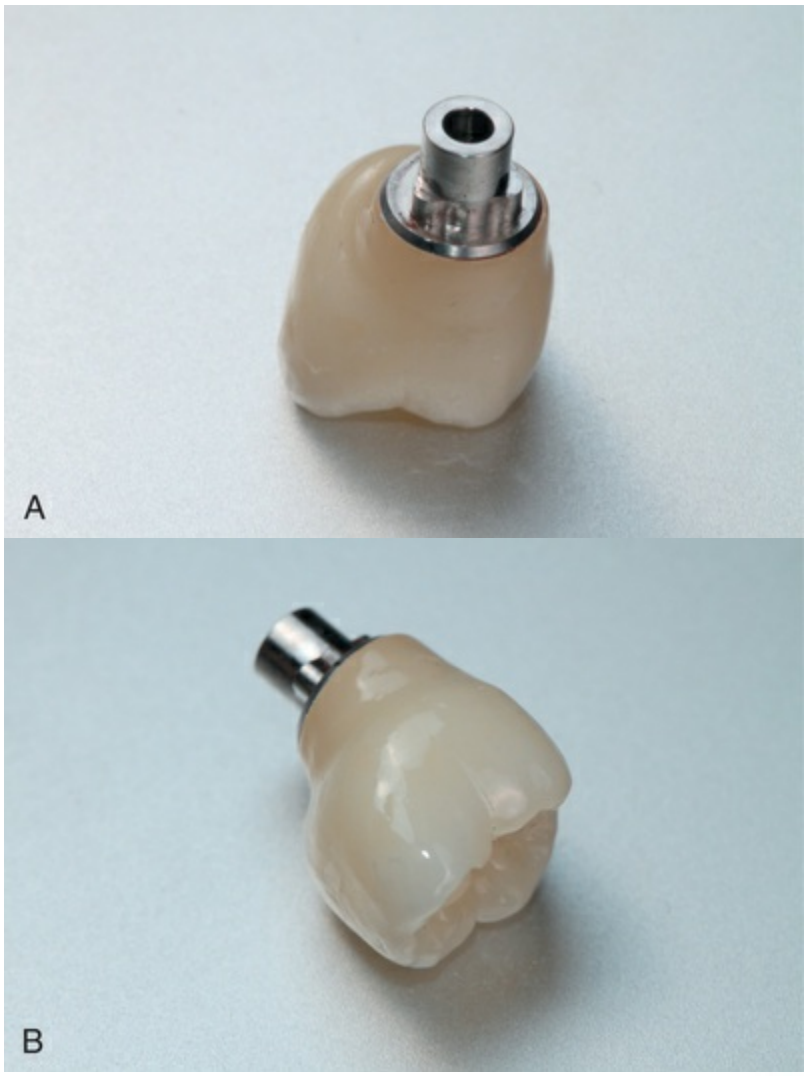

FIG. 77.15 The hybrid crown design consists of a titanium base that is connected to a full contour ceramic (generally zirconia) crown. In the laboratory, the technician follows a specific protocol to cement the titanium base to the ceramic crown. This design

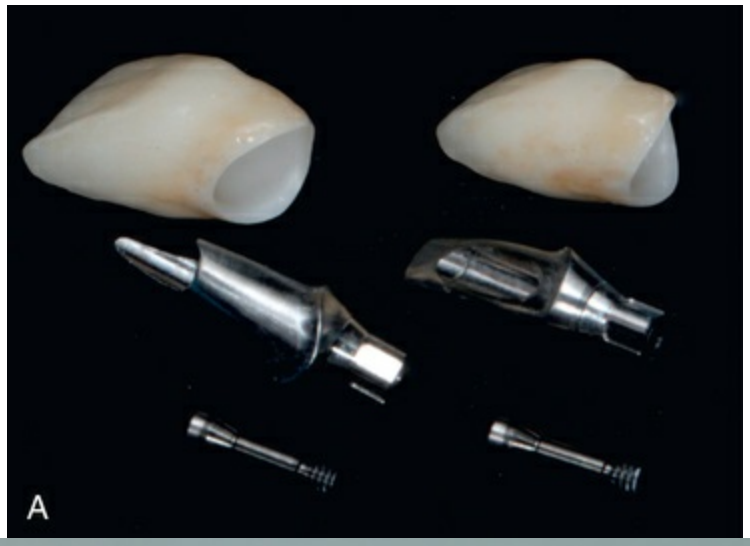
produces a screw-retained restoration that should be less prone to the problems of a PFM, though few long-term data are yet available. (A) Abutment view of titanium base crown. (B) Crown view of titanium base crown. (C) Titanium base crown in lab model.

Lastly, there is the option of lingual set screws. This system is most commonly employed in the anterior areas of the mouth when the implants are angled too far toward the facial for a traditional screw-retained restoration and the clinician is uncomfortable with a cemented option. The challenges with lingual set screws are increased lab costs, difficulty in locating technicians competent in the technique, leakage between the crown and the abutment, and challenging screw access.

Abutment Material Selection

In most bone-level implant designs, the junction between the abutment and the implant is near the crestal bone. In this area the connective tissue and the junctional epithelium may be in intimate contact with the abutment. As such, the abutment material and accuracy of the fit play a critical role in preserving the peri-implant bone and soft tissue. Some abutments better preserve the peri-implant tissues than others. The most relevant options for currently available definitive abutment materials are titanium, titanium with a titanium nitride coating, full-contour zirconia, zirconia with a titanium base, and gold alloy (Fig. 77.16). Other less common options include lithium disilicate and chrome-cobalt alloys.



A

B

C

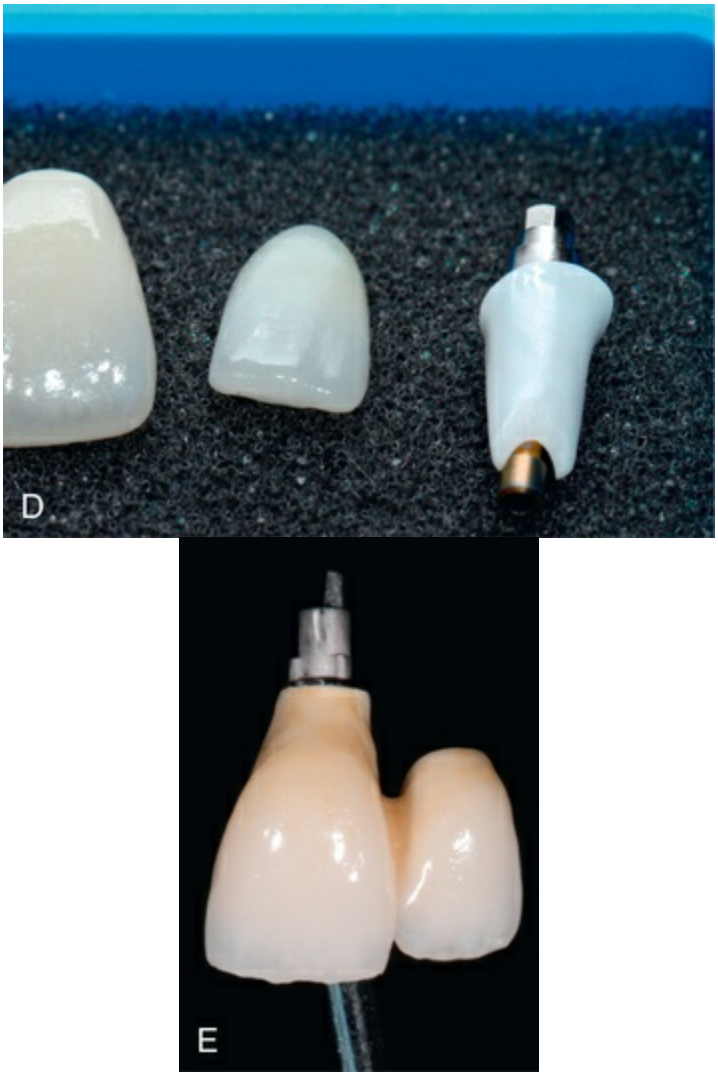


FIG. 77.16 Implant abutments are available in a variety of materials. (A) Titanium. (B) Titanium with a titanium nitride coating. (C) Full contour zirconia. (D) Zirconia with a titanium base. (E) Gold alloy.

The most rigorous study examining bone and soft tissue reactions to abutment materials found histologic evidence that titanium preserved 1.5 mm more soft tissue and 1 mm more bone compared with the fully cast gold alloy abutment.[2] However, it should be noted that this study was performed in the canine mandible and that when a titanium interface was used in conjunction with a cast gold abutment, there was less bone loss than with the gold alone. It stands to reason that some of the bone and soft tissue loss with gold abutments may have more to do with the less accurate fit of a cast restoration than to the influence of the material itself. More recent clinical studies and reviews have questioned these findings, with gold and titanium showing an equivalent biologic response.[79,137]

However, the latter were done with radiographic analysis rather than the histologic measurements of the former. As a whole, the data are not yet conclusive on the biocompatibility of the abutment material and its clinical effects on the tissues. Titanium has been repeatedly shown to perform better on a histologic level than gold alloys, but the difference may be of little clinical significance. What is clear is that the interface between the abutment and the implant must be as accurate as possible. This will ensure minimal leakage, minimal screw loosening, and better maintenance of the peri-implant tissues. Abutments that require casting of the implant interface portion cannot match the fit accuracy of the machined interface.[19]

The strength of the abutment is critical in maintaining long-term success with minimal technical complications. Titanium and gold alloy abutments have a long track record of outstanding strength. Some studies have even shown failure of the implant before failure of the titanium abutment.[131] The primary concern regarding strength is related to zirconia abutments.

Zirconia abutments can be used with little risk of fracture in many clinical scenarios,[91] but there are a few caveats. The zirconia abutment should have an implant interface component made of titanium (Fig. 77.17).[131] This minimizes the risk of wear to the implant body, and should the zirconia fracture, it is outside the implant where it is much easier to treat. The zirconia abutment should not be used in cases with extreme loads (i.e., molars, patients with enlarged muscles of mastication, long span FDPs). The zirconia abutments should be made by a reputable manufacturer. Evidence has shown that the manufacturer can have a huge impact on the strength of the material.[69] The abutment walls should be sufficiently thick, no less than 0.7 mm. Every effort should be made to avoid cutting the zirconia after it has been sintered.

FIG. 77.17 Zirconia implant abutments should be fabricated with a titanium base. This has multiple advantages: increased strength, less complicated failures, and less wear of the internal surface of the implant.

Lastly we must consider the effect of the abutment material on the color of the soft tissue. Gray-colored metallic abutments will darken the tissue more than zirconia abutments, but the effect is not as great as might be expected. Zirconia abutments still cause a significant and perceptible darkening of the soft tissue, confirmed in multiple studies.[17,70,82] Some manufacturers and clinicians have developed techniques to anodize or coat titanium abutments to create gold or pink shades. These may offer some improvement of soft tissue aesthetics. The gold-colored abutments (Fig. 77.18) allow predictable use of semi-translucent ceramics with minimal shade change. The thickness of the overlying tissue has been shown to have a greater influence on the perceived color of the gingiva over an implant than the material used. Thick tissues have an almost nonperceptible color shift, whereas with thin tissues the shift is always perceptible, even with zirconia abutments.[63]

FIG. 77.18 Gold color coating of titanium abutments produces less graying of the soft tissue. This coating is made from titanium nitride or titanium oxide.

Key Fact

It is clear that the interface between the abutment and the implant must be as accurate as possible. An accurate IAJ fit will ensure minimal leakage, minimal screw loosening, and better maintenance of the peri-implant tissues. Clinicians should understand and appreciate that abutments with casting of the implant interface portion cannot match the fit accuracy of the machined interface.

Abutment Design and Emergence Profile

The design and contours of the abutment play a key role in the shape and dimensions of the peri-implant tissues. If the abutment is overcontoured it will ultimately lead to a loss of bone and soft tissue. This is a common problem when technicians design and shape the abutment without the soft tissue mask on the model. Such overcontoured abutments may require surgery to deliver because the tissue prevents complete seating of the restoration. Alternatively, the restoration can be reshaped to reduce or eliminate impingement on tissues.

The emergence profile of the abutment is the area of the abutment between the head of the implant and the soft tissue

margins. More data are showing that undercontouring the emergence profile helps to protect and maintain the peri-implant bone and soft tissue.[111] The "platform switch" style implant helps to create the narrowed abutment design due to the smaller diameter of the connection interface. In most scenarios, the abutment should be designed to emerge from the implant in a narrowed hourglass shape. The narrowed design may allow for increased blood flow around the implant and provide sufficient room for the soft tissues without bone remodeling.[121,135]

Understanding the effects the emergence profile has on the shape and position of the soft tissue is critical for implant treatment in the aesthetic zone.[117,127] By selectively over- or undercontouring the emergence zone, the soft tissue can be positioned with a high degree of accuracy.[132] More on this technique will be described in the next section with the use of aesthetic zone provisional restoration.

For cement restorations, arguably the most critical aspect of the abutment design is the placement of the margins. The peri-implant soft tissue is never perfectly flat, and as such custom abutments are almost universally indicated to avoid deep subgingival margins with the risk of retained cement and the resulting peri-implantitis. The only way for a stock abutment to be used with minimal risk is to select one with completely supragingival margins, but this can be aesthetically unacceptable. If a common stock abutment is selected to hide the titanium, with a facial margin 1 mm subgingival, in most scenarios the margin at the mesial and distal papilla will be 4 mm or more subgingival. Both in vitro and in vivo studies have shown that for margins beyond 1 mm subgingival, significant amounts of cement will always be left behind.[83,84] No attempt should ever be made to cement restorations on implants with margins more than 1 mm subgingival (Fig. 77.19). A custom abutment can be easily designed to address the natural scalloping of the gingiva. It is fabricated by milling or casting, though casting of custom abutments for cement-retained crowns is no longer the best option due to increased costs, increased screw loosening,[e] and the less accurate fit at the implant.[19]

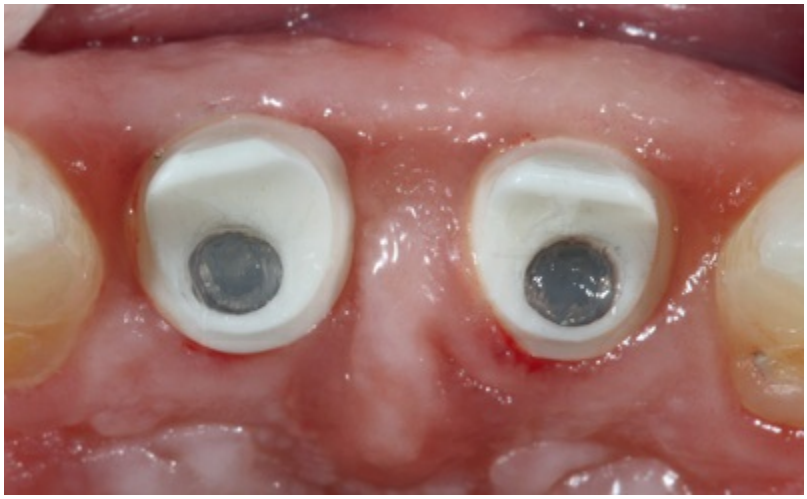

FIG. 77.19 Even in the aesthetic zone, the abutment margins should not be placed deeper than 1 mm subgingivally. The margins should be clearly visible circumferentially. This will minimize the risk of cement-induced peri-implantitis.

Clinical Correlation

The thickness of the overlying tissue has been shown to have a greater influence on the perceived color of the gingiva over an implant than the abutment/restorative material used. The color shift is almost imperceptible under thick tissues, whereas it is nearly always noticeable when covered by thin tissues, even with zirconia abutments.

Milled custom abutments can be made out of titanium or zirconia. When prescribing these abutments, it is critical to communicate to the technician where the margins should be placed. If left unstated, many technicians will opt to place them deep subgingivally. Several studies[83,84] have clearly shown that cement cannot be predictably removed at depths greater than 1 mm subgingival. If the margins are any deeper than 1 mm, significant amounts of cement will be left behind and will likely start the process of peri-implantitis (Fig. 77.20). It is common for clinicians and technicians to place the margins deeper than 1 mm subgignival in aesthetic cases in an attempt to hide the titanium abutment if recession should occur. This strategy is unwise and will inevitably

result in retained cement. The correct approach is to shape the tissue with a provisional, allow it to mature, and place the margin no deeper than 1 mm. The abutment could also be made of zirconia and stained to resemble the root surface. Clinicians should be aware of the significant strength variations in zirconia abutments based on the manufacturer.[69]

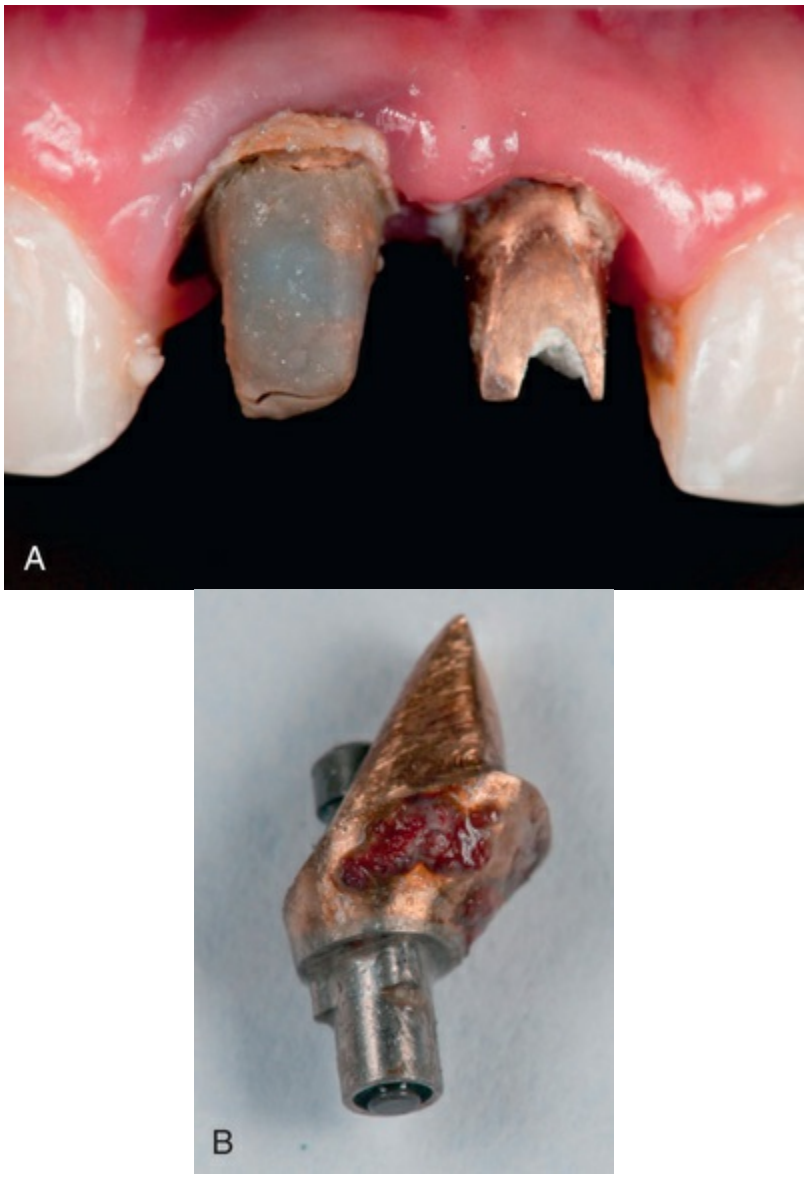

FIG. 77.20 When margins are placed deeper than 1 mm, it is inevitable that cement will be left subgingivally. Regardless of cement type, cement left subgingivally will result in significant loss of bone and soft tissue. Here, a large amount of residual cement has caused catastrophic loss of bone and soft tissue

(peri-implantitis). These implants ultimately required extraction and significant reconstruction to treat. (A) Clinical view. (B) Abutment removed.

Clinical Correlation

No attempt should ever be made to cement restorations on an implant abutment with margins more than 1 mm below the gingival margin. A custom abutment can be easily designed to address the natural scalloping of the gingiva. The probability of leaving (missing) excess cement trapped below the gingival margin is extremely high and problematic. Studies have clearly shown that cement cannot be removed at depths greater than 1 mm subgingival.

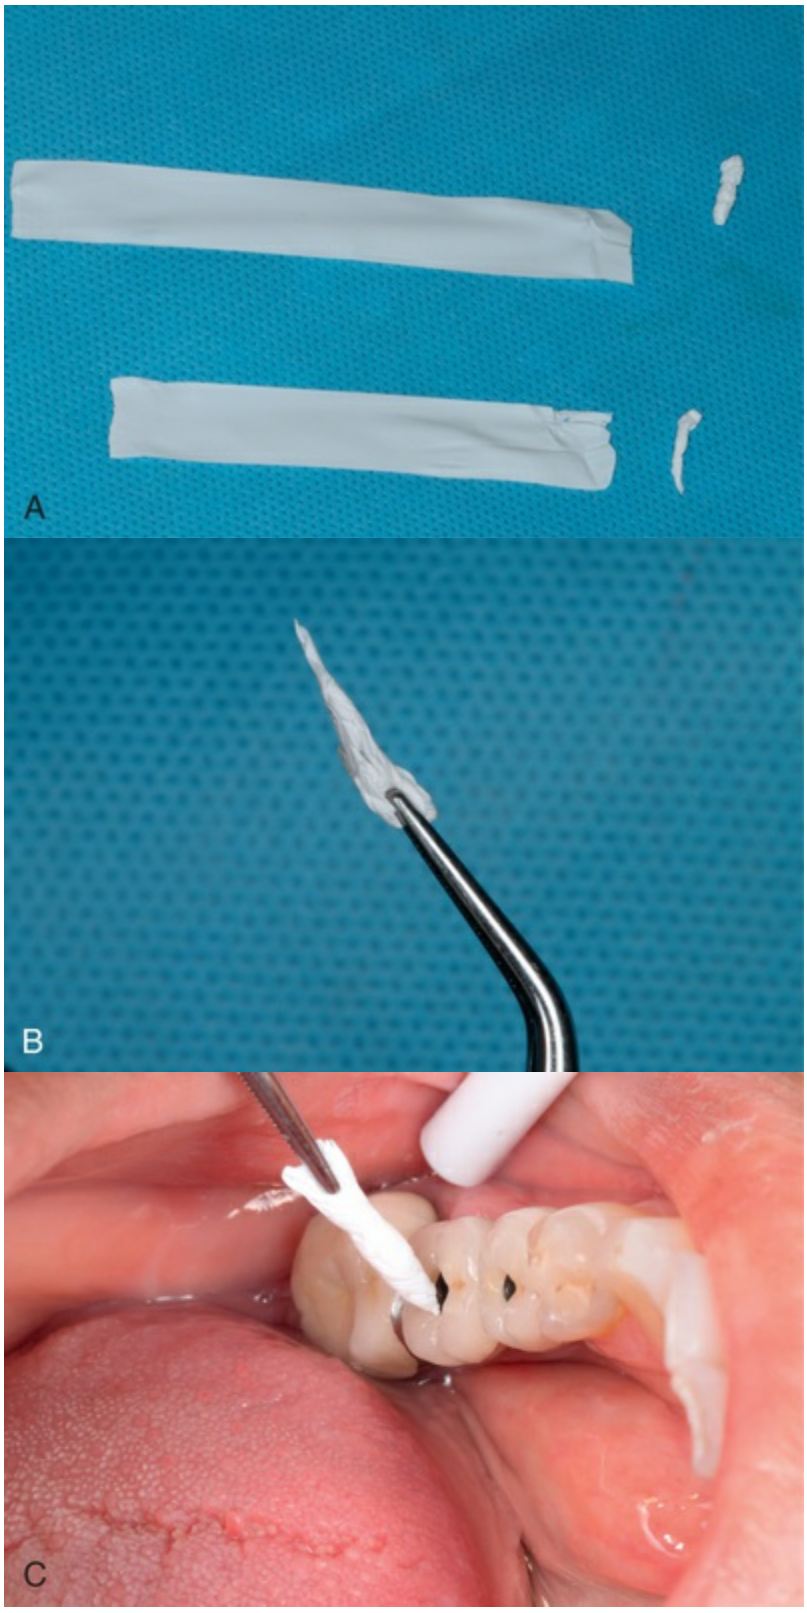
Covering the Screw Access

After placement and proper torquing of the abutment screw, there is the need to cover the screw access channel. The ideal material for this is one that does not inhibit future access to the abutment screw and provides a seal to inhibit leakage into the abutment. Traditionally this has been done with a cotton pellet, a technique adapted from the temporary procedure used in endodontics. However, unlike a root canal temporary, the screw cover in an implant abutment will be left in place for many years.

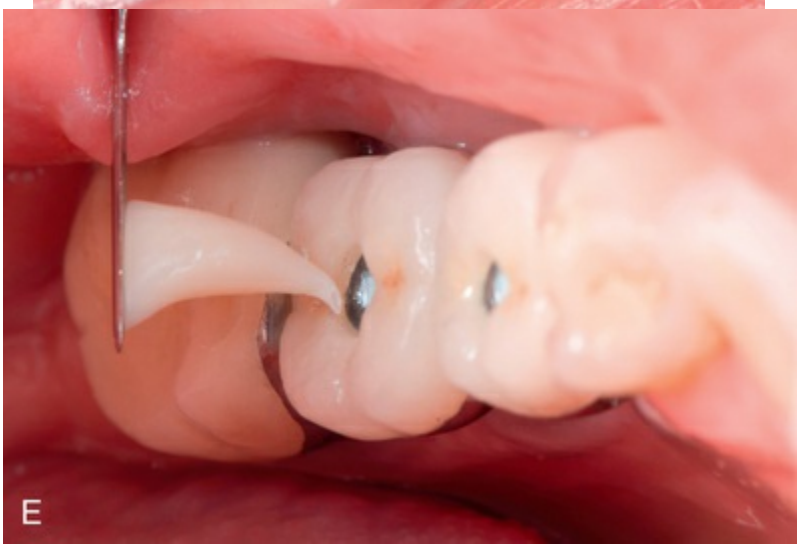
The challenge in implants is that the internal aspect of the implant and the abutment are hollow, body temperature, dark, and oxygen free. Upon functioning, the abutment will move slightly in the implant, and the fluids and bacteria from the oral environment will fill this hollow chamber. Ultimately, proliferation of certain bacterial strains *inside* the implant may play a role in the presence of peri-implantitis.[21-24] Obviously, placing a cotton pellet into this environment for any extended period of time is a poor idea. It provides no seal and is an ideal environment for the proliferation of pathogenic bacteria (i.e., *Parvimonas micra*) (eFig. 77.1).

EFIG. 77.1 Cotton has been a commonly used material to directly cover the abutment screw. However, the internal aspect of two-piece implants will have saliva and oral flora filling this area, leading to the proliferation of vast amounts of anaerobic bacteria. The cotton provides an ideal substrate for the bacteria and leads to foul odors and tastes coming from the implant under function.

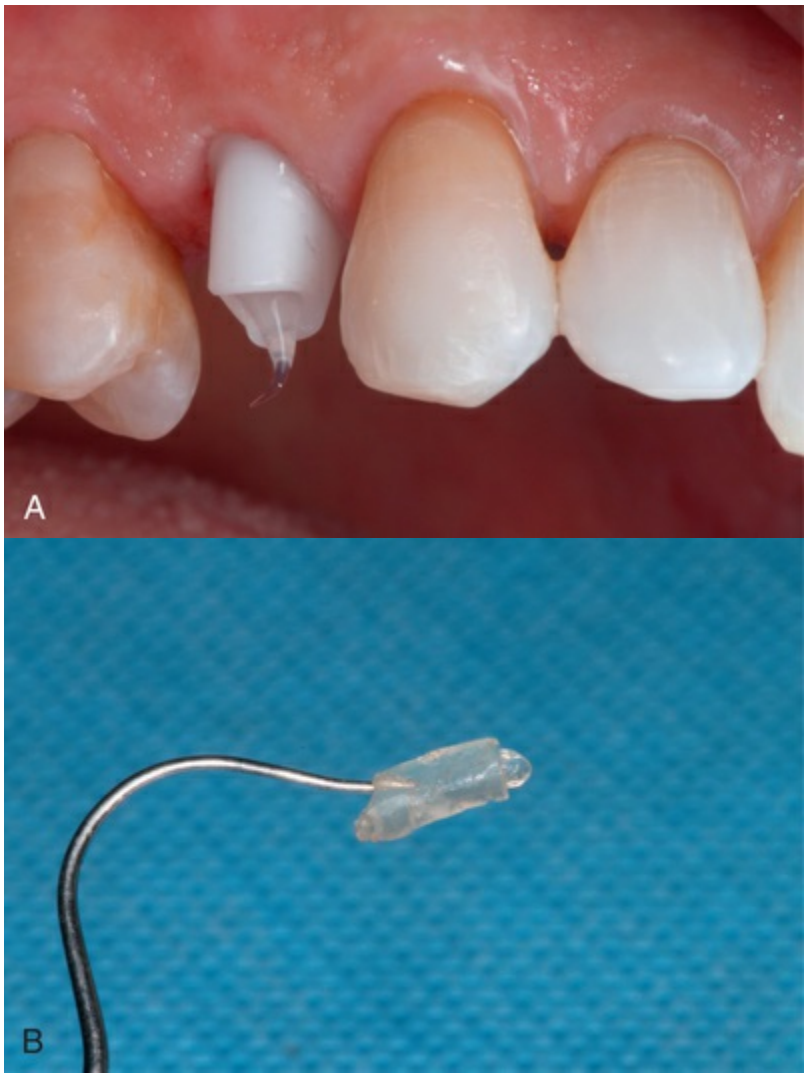
Reasonable and tested alternatives include gutta-percha, polytetrafluoroethylene (PTFE) tape (also known as Teflon or "plumber's" tape), and polyvinyl siloxane (PVS) impression material. Gutta percha has been shown to provide a good seal[27,93] but can be challenging to remove without the use of an endodontic heat instrument. PTFE tape and PVS look to be reasonable alternatives,[98,102,108] but further testing is needed to determine their long-term success and clinical effects. To use PTFE tape, a long portion (~10 cm) is sterilized then rolled up and condensed into the screw access (eFig. 77.2). Alternatively, light body PVS impression material can be injected into the screw access (eFig. 77.3). With either technique, 3-4 mm of space must be left coronally in screw-retained restorations to allow space for a robust composite seal. For cement-retained restorations, either material can be placed to the top of the abutment screw. It is advisable to clean the screw access beforehand with a strong chlorhexidine solution (eFig. 77.4) and dry thoroughly.



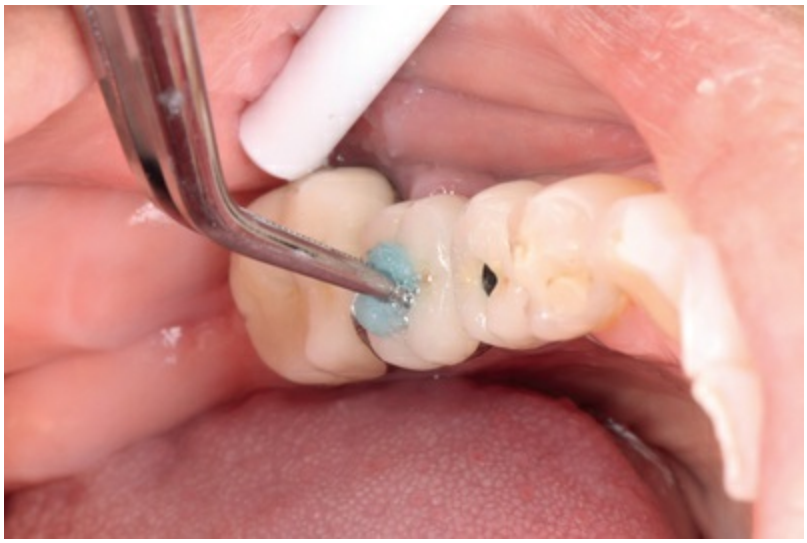
A
B
C



EFIG. 77.2 PTFE tape (“plumber's tape”) is a good alternative to cotton (A). It is easy to remove, protects the screw, and does not promote bacterial growth. It is rolled into rope or “cigar” shape and fully condensed into access after torquing the screw (B–D). A 2- to 4-mm space should be left above the condensed PTFE. (E) This is then covered with a bonded layer of opaque composite.



EFIG. 77.3 PVS impression material also works well to cover the abutment screw, though it is best suited for use with cemented restorations. The material is dispensed into the screw access starting at the bottom and back-filling to the top (A). The excess is then wiped off before setting and cementation of the crown. The PVS plus is easy to remove should the need arise (B).



EFIG. 77.4 Chlorhexidine-soaked pellets or brushes are used to clean prior to covering the screw access. Common chlorhexidine is made as a 0.12% solution, though 2% is preferable when available.

Splinting Adjacent Implants

The rational for splinting adjacent implants (Fig. 77.21) stems from various finite element analysis (FEA)[10,12,142,148] and photo-elastic gel (PEG) experiments.[51] These in vitro studies repeatedly confirm that multiple implants produce less acute forces in the peri-implant bone when splinted compared with multiple individual restorations. However, we do not have a clear notion of how much stress is acceptable for the peri-implant bone and at what threshold we might expect pathologic bone loss. The clinician must consider the length and diameter of the implants as well as the quality and quantity of the bone when determining if multiple implants should be splinted together.

FIG. 77.21 Many in vitro studies have shown that splinting of adjacent implants helps to share occlusal forces between the implants. However, several clinical trials have shown no clinically significant difference in bone levels between splinted and nonsplinted restorations at 3, 5, and 10 years of use.

Splinted restorations are advisable when the foundation is compromised (i.e., short or narrow implants, compromised bone).[87,147] This will allow the stronger or better supported implants to "assist" the others. The compromise here is that if the weaker implant fails, an entirely new prosthesis may need to be fabricated, usually at a significant expense.

The rationale for splinting adjacent implants involves the intention of "sharing the forces," a concept derived from the in vitro studies of the early 2000s cited earlier. The implication is that clinically we would see fewer implant failures and less bone loss over extended use with splinted restorations. Long-term in vivo randomized controlled trials (RCTs)[30,42,140] have tested this hypothesis in order to quantify the differences in bone loss and implant failure with splinted versus nonsplinted restorations. In the partially edentulous RCT, at 10 years the mean difference in bone loss between splinted and nonsplinted restorations for 132 implants was a mere 0.1 mm.[140] This could hardly be considered clinically significant under most scenarios. In the fully edentulous study with two mandibular implants retaining a full denture, the differences at 3 years were statistically insignificant at most sites and only about 0.5 mm at the most significantly different sites.[42] A prospective split

mouth, in vivo trial examining bone levels around splinted and not-splinted restorations showed no significant difference at 36 months.[30] Until better evidence shows otherwise, "sharing forces" in an attempt to reduce bone loss is not a proper consideration for whether or not adjacent implants should be splinted. These data are not necessarily in conflict with the early in vitro experiments, they simply illustrate that higher forces do not necessarily result in more bone loss and that it is difficult to extrapolate data from FEAs and PEGs to clinical realities. Depending on the type of bone and implant, there is likely a threshold below which increased forces will not result in significant bone loss over extended use. Conversely, despite the lack of significance found in these studies, there may be scenarios in which clinical judgment warrants splinting adjacent implants such as multiple implants placed in the posterior maxilla in type IV bone opposing an intact natural dentition or implants.

The downside to splinted restorations is largely related to long-term repair and replacement costs. With patients having implants that must maintain a prosthesis for 30, 40, or 50 years, it is appropriate to consider that the prosthesis will require replacement throughout its life. Most commonly, this is related to porcelain failure on screw-retained PFM FDPs.[94] After a PFM restoration has been in the mouth for any significant period of time, porcelain failure cannot simply be repaired. The restoration must be fully stripped or replaced. Practically speaking, it can be a challenge to find a laboratory willing and able to strip and restack porcelain, and most will opt for complete replacement of the prosthesis. Essentially this has doubled, tripled, or quadrupled the cost of replacement. If an individual unit suffers the same complication, only the unit affected needs to be replaced. Issues related to patient autonomy and desires need to be considered in the replacement of multiple adjacent missing teeth. Some patients may tolerate splinted restorations, whereas others may desire individual units. Oral hygiene techniques and ease of cleansibility will vary between restoration types as well.

Key Fact

Until evidence shows otherwise, "sharing forces" is not a valid reason to splint adjacent implants. These data are not necessarily in conflict with the early in vitro experiments, they simply illustrate that higher forces do not necessarily result in more bone loss and it is difficult to extrapolate data from finite element analysis and photo-elastic gel studies to clinical realities.

Indications for splinting adjacent implants include significant off-axis forces (i.e., canine replacement), multiple adjacent external hex implants, poor bone, and diminutive implants.[50]

Management of Partially Edentulous Implant Treatment in the Aesthetic Zone

Diagnosis and Treatment Planning

Treatment of the partially edentulous patient in the aesthetic zone is one of the more challenging prosthetic scenarios. The "aesthetic zone" is not simply canine to canine in the maxilla. Each patient must be individually evaluated for lip position and movement (Fig. 77.22) to determine the appropriate level of aesthetic consideration necessary.

FIG. 77.22 Implant treatment in the aesthetic zone is more challenging than in the functional zone. It is important to keep in mind that the aesthetic zone differs for each patient. It should be evaluated though a series of basic photos: right, center, and left at maximum smile (A–C), and with lips at rest (D). In this

patient the aesthetic zone clearly includes the anterior teeth and all premolars.

The primary challenge in this treatment is the peri-implant soft tissues.[18] If patients show soft tissue during lip movement, then particular attention should be paid to the creation and preservation of natural appearing gingiva. First, there must be sufficient thickness of the gingiva. Thin tissue biotypes are more prone to recession, peri-implant mucositis, papilla loss, and graying.[65,80,81,107,149] The surgical team may need to employ various techniques prior to, or at the time of, implant placement to increase the tissue thickness.

During the treatment planning phase, the clinical team should consider the shape and position of the soft tissue on all teeth or implants in the area. If any of these positions are planning to be modified, the corresponding implant position may change as well.

Management of potential changes to the tissue color can be challenging, as there is a shift in the gingiva around implants to a gray tone.[17] This can be somewhat managed with the use of UCLA or zirconia abutments, though research has clearly shown that there can still be a perceptible color shift with these more aesthetic materials (delta E >3.9).[62] Though zirconia abutments are weaker than titanium, they have shown comparable survival rates for single units in vivo.[150] Some technicians have begun experimenting with the use of fluorescing glazes over the emergence zone of zirconia abutments to decrease the color shift. Some manufacturers and clinicians have coated the titanium abutments with a gold or pink color, again in an attempt to mitigate color changes.

The greatest challenge of implants in the aesthetic zone is papilla management. Implants, even with contemporary designs (i.e., platform switch, conical connections), cannot maintain crestal bone height as much as a healthy tooth. The implant is very different than the natural tooth because it does not have periodontal ligament (and its blood supply) or supracrestal inserting connective tissue fibers. The clinical appearance (i.e., height and fullness) of the papilla between an implant and a tooth ultimately depends on the periodontal attachment level of the adjacent tooth and not the level of bone adjacent to the implant. Should the papilla fail to meet desires and expectations, the open gingival embrasure is generally

best managed through additional surgery or closing the space with restorations.[132] Although there have been good attempts to solve the problem of deficient papilla with pink prosthetics, it is all but impossible to resolve it in a manner that is both aesthetically convincing and hygienic in the partially edentulous patient.

Although there will be variations in papilla height adjacent to or between implants, the average papilla height adjacent to a single implant is 4.2 mm.[66] Between adjacent, unrestored natural teeth, the average papilla height is at least 5 mm.[130] Between adjacent (external hex) implants, the average papilla is only 3.4 mm (Table 77.2).[128]

TABLE 77.2
Anticipated Papilla Height

	Between Natural Teeth	Between Tooth and Implant	Between Adjacent Implants
Average expected papilla height (from crest of bone)	≥5 mm (Tarnow, 1992)[130]	4.2 mm (Kan, 2003)[66]	3.4 mm (Tarnow, 2003)[128]

The preceding figures are averages and do not represent the actual value for what is possible for any given patient. The key to predictable, successful treatment in the aesthetic zone is the implant-retained provisional restoration. This will allow the clinical team and the patient to truly test the four key criteria of aesthetics, phonetics, function, and hygiene. Revisions and alterations are much easier to accomplish with provisionals as compared with the definitive prosthesis.

« Flash Back

The greatest challenge of implants in the aesthetic zone is papilla management. Although there have been good attempts to solve the problem of deficient papilla with pink prosthetics, it is all but impossible to resolve it in a manner that is both aesthetically convincing and hygienic in the partially edentulous patient.

Implant-Retained Provisional Restorations

The implant-retained provisional restoration is a critical tool in the treatment of partially edentulous patients. It can be fabricated in the laboratory or directly in the mouth (eTable 77.1). As stated previously, the provisional restoration allows the clinical team and the patient to determine if the proposed treatment will meet expectations. Regardless of the definitive restoration design, the implant provisional should be screw retained because the use of cement should be avoided in fresh surgical sites, and the ability to remove, modify, and replace the restoration is essential. The emergence zone of the provisional must be smooth and well polished. The apical most 2 mm of the provisional should be clean titanium (not polyetheretherketone [PEEK], composite, or acrylic) (eFig. 77.5) due to its well proven effects on the soft tissues[2] and minimal risk of breakage.

eTABLE 77.1

Fabrication of the Implant-Retained Provisional Restoration

1. Clean the provisional abutment, apply opaquing composite resin; polymerize.
2. Attach titanium provisional abutment to the implant; verify complete seating.
3. Adjust the composite shell crown to fit over or around the abutment.
4. Apply bonding agent and flowable composite to the shell intaglio and the surface of the abutment.
5. Carefully place the shell onto the abutment in the correct position and polymerize.
6. Remove the abutment/shell from the implant; steam clean, dry, and apply bonding agent.
7. Use flowable composite to fill in the emergence area.
8. Most scenarios will benefit from the creation of an undercontoured emergence profile.
9. Finish and polish; ensure that the apical 2 mm portion of the provisional restoration is clean and polished titanium.
10. Deliver the provisional restoration to the implant and tighten to the appropriate setting.
11. Cover the screw access.

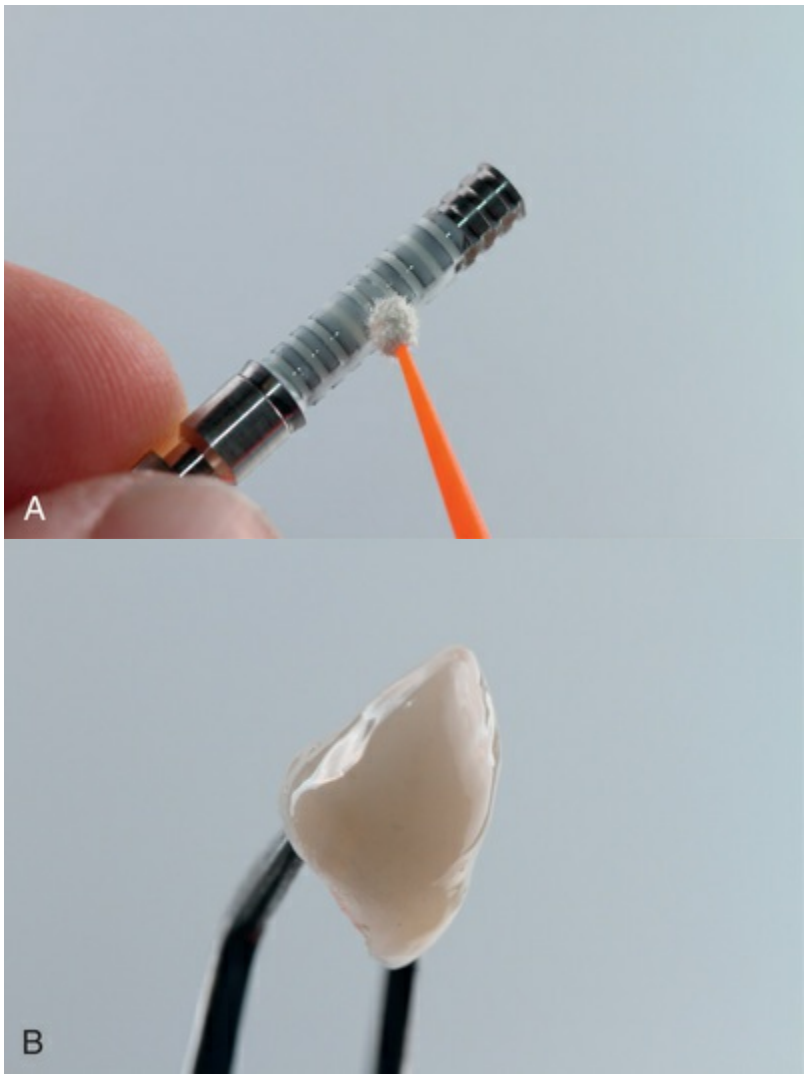
EFIG. 77.5 The screw-retained provisional restoration is a critical tool in the treatment of aesthetic zone implant cases. It will support and shape the soft tissue while allowing in vivo evaluation of function, hygiene, phonetics, and aesthetics. It should be designed such that the apical 1.5 to 2 mm portion of the restoration is in highly polished titanium.

The main advantage of the implant-retained provisional restoration is its use in *preserving* and supporting the peri-implant tissue contours.[11,126,133] This scenario presents itself when an implant is placed and restored with the provisional immediately at the time of extraction—a technique commonly called "immediate provisionalization" or "immediate loading." Immediate loading requires sufficient stability of the implant, the ability to keep the restoration out of occlusion/excursion, stable maximum intercuspal position (MIP), and patient cooperation. There appears to be little change in implant failure when these criteria are carefully followed. The main advantage of immediate loading is the preservation of the papilla[25,31,32,35] and decreased bone loss.[114] It is much easier to preserve papilla than to regenerate.

At the time of implant placement, the provisional should be designed with the goals of protecting the surgical site and maximizing the potential volume of the peri-implant tissues. To accomplish these goals, it should have a smooth, titanium emergence that is no wider than the implant itself. This will help to promote blood supply to the area and any graft that may have been placed. It should not blanch the tissue or compress the papilla at

this stage. It should emerge from the implant narrow and gradually transition to the contour of the crown near the gingival margin. Should the implants be angled to the facial, a screw-retained provisional can still be predictably used.

To fabricate the restoration, the following items are needed (eFig. 77.6):



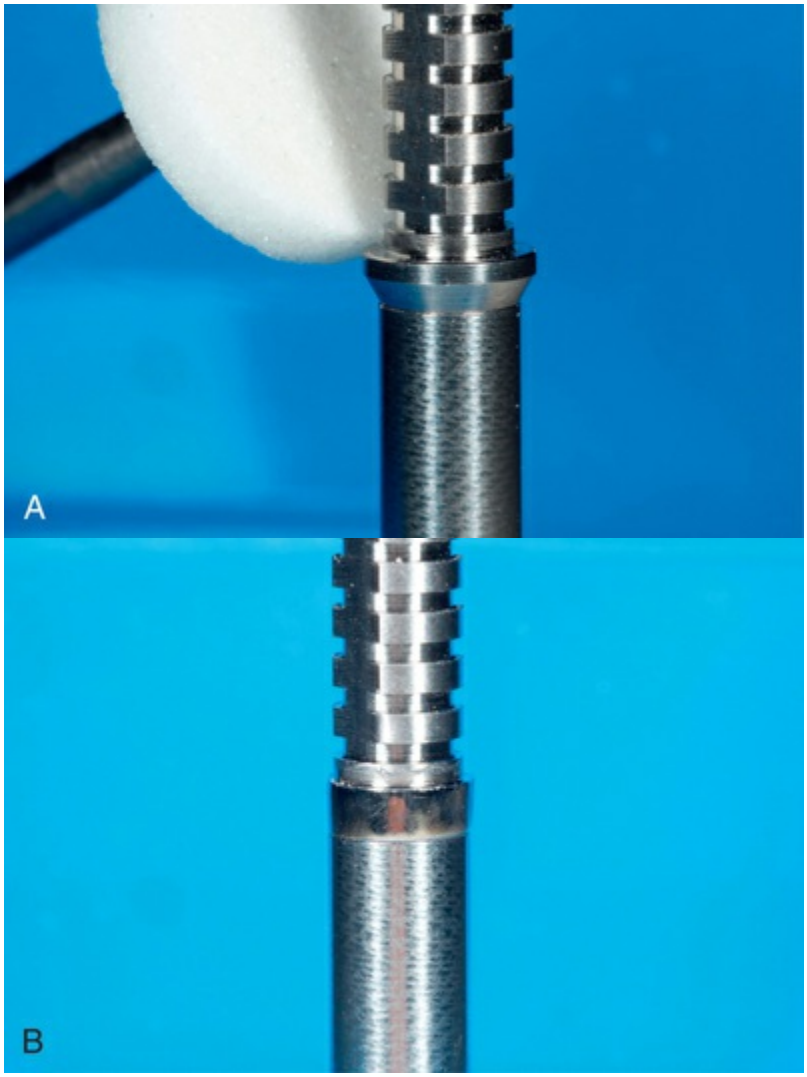
EFIG. 77.6 Prior to fabricating the provisional restoration in the mouth, the titanium (not PEEK) abutment should be coated with a layer of opaque composite resin (A). A provisional shell needs to be fabricated from composite resin as well (B).

- Titanium provisional abutment (not PEEK)

- Abutment screw
- Crown form (composite, natural tooth, or crown)

Prior to the appointment, the titanium abutment should be sandblasted with 50 micron aluminum oxide, covered with an appropriate opaquing resin (generally A1), and polymerized.

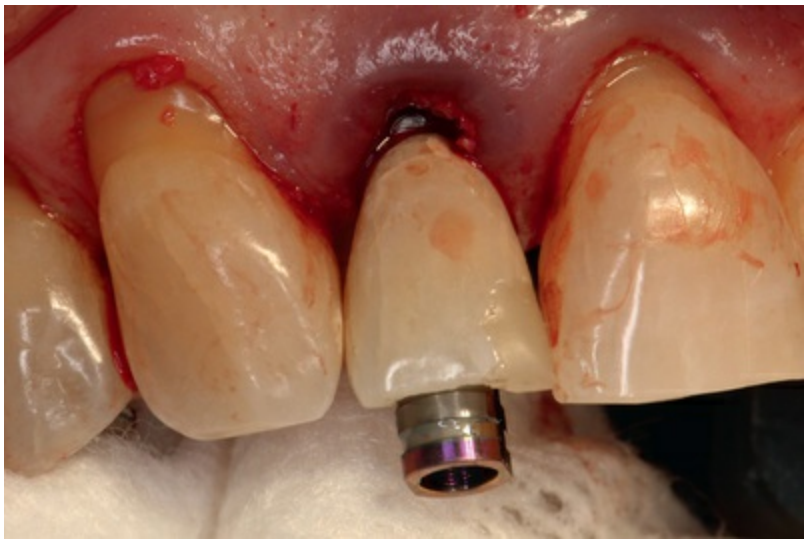
Some titanium temporary abutments are incorrectly designed with a flared portion directly exiting from the junction with the implant.[117] This puts unnecessary pressure on the per-implant tissues and will force the peri-implant bone to remodel to a more apical position.[121] This area of the abutment can and should be removed prior to the procedure (eFig. 77.7).



EFIG. 77.7 Temporary abutments from some manufacturers have a flared area that comes directly off the head of the implant. This is a flawed design and the flared area should be removed prior to use with a heatless stone (A). Once removed, the area should be no wider than the implant and must be polished (B).

The crown form can be fabricated from composite resin in the laboratory on a model. Alternatively, the patient's existing natural tooth or current crown may be used. Material-specific bonding procedures should be implemented to ensure adhesion. Acrylic materials could be used as well, but delivery and manipulation can be difficult in the surgical environment.

Following the placement and stability check of the implant, the provisional abutment is attached, checked for full seating, and hand tightened. The crown form is then adjusted to fit over or around the provisional abutment (eFig. 77.8). If the angulation is through the facial, the abutment itself must be marked, removed, cut, and repositioned. It is critical that the crown form easily fits into the exact desired position over or around the abutment. Both the crown and the abutment are cleaned, bonding agent applied, and both are lined with flowable composite (eFig. 77.9). The crown is then positioned and the composite polymerized. Upon removal, there will be sharp, unfilled, and undercut areas (eFig. 77.10). The provisional is thoroughly cleaned and fresh bonding agent applied. Composite is then used to fill and shape the emergence area (eFig. 77.11). It should now be placed back onto the implant to ensure there is no blanching and that there is some degree of open gingival embrasures to allow for swelling and papilla migration (eFig. 77.12). The provisional should be removed, polished, and carefully examined. At this stage, the surgeon may opt to complete the grafting procedure, prior to delivery of the provisional. It should be checked to ensure that there is absolutely no contact in MIP or throughout the excursive movements (eFig. 77.13).



EFIG. 77.8 To fabricate the provisional, the titanium abutment is connected to the implant, and the composite shell is adjusted to fit around/over it. For lateral incisors, the shell will often have to be made into a three-quarter crown form to fit around the abutment. Special care must be taken to ensure that the shell easily fits into the proper position.

EFIG. 77.9 Using composite bonding agent and flowable composite, the shell is positioned and bonded to the titanium abutment. In immediate placement sites, care must be given to ensuring that blood does not contaminate the bonding interface.

EFIG. 77.10 After polymerizing the flowable composite, the abutment and shell are removed together. They should be steam cleaned and thoroughly dried. The open and undercut areas are covered with bonding agent, and flowable composite is used to fill the emergence area.

EFIG. 77.11 The finished screw-retained provisional should have 2 mm of polished titanium at the base, and it should flow into a smooth, narrow emergence area.

EFIG. 77.12 The provisional restoration is delivered onto the implant and torqued to an appropriate value. The ideal provisional should produce little to no blanching of the peri-implant tissues and have open gingival embrasures to allow for papillary development.

EFIG. 77.13 The provisional restoration in immediate load cases should be designed to be fully out occlusion in maximum intercuspal position (MIP) and throughout the excursive range. Patients are instructed to not chew on the provisional.

Tissue Shaping and Management

Following integration of the implant and maturation of the soft tissue, there may be the need to correct slight malpositions of the peri-implant tissues. This can be done through modification of the implant abutment, but it should not be done repeatedly to avoid increased tissue changes that lead to bone loss. Significant deficiencies of tissue may be difficult to correct, whereas others may be able to be addressed with additional surgery.

The emergence profile of the provisional restoration can be added to or contoured back to manipulate the soft tissue position. Applying additional contour will move the gingiva apically, whereas undercontouring will allow the tissue to drape more coronally. The abutment can also be modified to apply pressure to the base of the papilla, thus forcing the tip coronally,[132] but this technique should be used with caution around implants due to a diminished blood supply and fragility of the soft tissue.[111] The clinician should minimize the number of reattachments to the head of the implant, as this will weaken the integrity of the tissues and create additional bone loss.[3,112]

Ideally all contours of the soft tissues should be designed in the patient's mouth, and the four keys (aesthetics, phonetics, function, and hygiene) should be tested and approved. If done correctly, the transition from the patient to the technician is seamless with the provisional serving as a blueprint for the definitive prosthesis.

Customized Impression Copings

To ensure that the technician is fabricating the definitive abutment and crown on a model that *exactly* replicates the current patient condition, a customized impression coping should be used (eTables 77.2 and 77.3

eTABLE 77.2

Fabrication of Indirect Custom Impression Copings

Custom impression copings can be fabricated indirectly in the lab.[57] The indirect technique is well suited for three or more units. Fabrication of indirect custom impression copings involves the following steps:
1. Remove and clean the provisional restoration.

2. Attach appropriate analogs.
3. Submerge in impression material.
4. Mark the orientation of the facial surfaces.
5. Remove the provisional restoration.
6. Attach narrow impression copings.
7. Fill the emergence zone with a low-shrinkage resin.
8. Mark the facial surface and tooth number for each coping.
9. Return to the patient and place the impression copings on the appropriate implant with the facial surface oriented correctly.
10. Verify seating with radiographs.
11. Make the impression.

eTABLE 77.3

Fabrication of Direct Custom Impression Copings

For one or two implant units, the custom impression copings can be fabricated directly in the mouth.[118] Fabrication of direct custom impression copings involves these steps:
1. Remove the provisional restoration. 2. Quickly attach narrow impression coping. 3. Fill the emergence zone with a dual-cure resin. 4. Polymerize. 5. Verify seating with radiographs. 6. Make the impression.

). The customized impression coping replicates or preserves the existing tissue contours in the final impression. Without the use of a custom impression coping, the soft tissue will collapse and deform during the impression, leaving the technician guessing about where to put margins or how to shape the emergence zone.

Fully Edentulous: Prosthetic Considerations

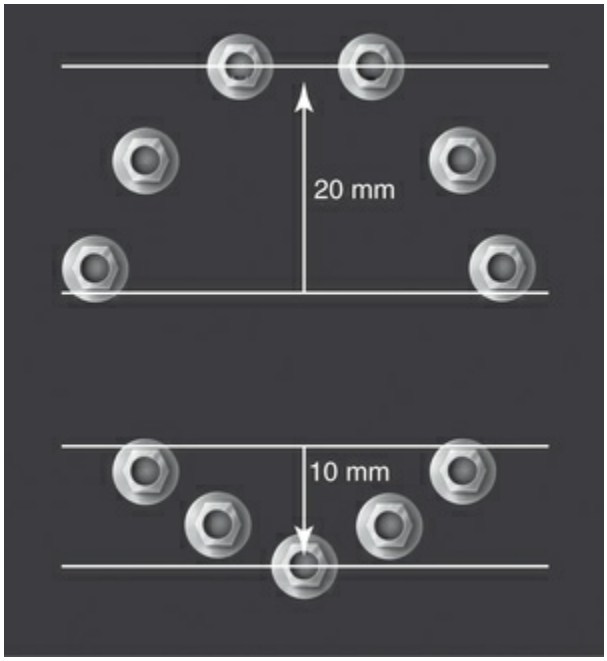
Edentulous Maxilla

Prosthetic options for the patient with an edentulous maxilla include a conventional complete denture, an implant-assisted denture, or an implant-supported fixed prosthesis. However, a conventional complete denture does not provide the comfort and quality of life that many patients desire. An implant-assisted or implant-supported prosthesis can provide stability, retention, and comfort, and can restore the patient's confidence, especially in patients with one or more of the following conditions:

1. *Poor ridge form with a marginally stable conventional maxillary denture.* Two or four implants provide greater stability and security of a maxillary denture in function when the maxillary ridge is severely resorbed and lacks resistance to lateral forces.
2. *Lack of posterior support with an intact mandibular anterior dentition.* Implants in the maxilla can offset the potentially destructive effects on the premaxillary region when a mandible with natural anterior teeth and missing posterior teeth opposes an edentulous maxilla. In this situation the lack of posterior support leads to a condition often referred to as *combination syndrome,* in which overclosure of the jaws with mandibular anterior teeth causes destruction of the edentulous anterior maxilla.
3. *Palatal coverage is not tolerated.* Some patients prefer a palateless denture, which may enhance their sensations of taste and texture or may simply provide a psychological advantage. Some patients prefer a palateless denture because the proximity of the denture with the soft palate induces a gag reflex. Patients with large palatal tori (see Fig. 58.19A) can also benefit from a palateless maxillary denture. A minimum of four implants with adequate anterior-posterior (A-P) spread allows the fabrication of an implant-assisted overdenture without palatal coverage.
4. *High functional expectations and strong preference on fixed prosthodontic tooth replacement treatment option.* Patients with a failing natural dentition, especially those who have never used a removable prosthesis, often strongly prefer the implant-supported fixed prosthesis treatment modality to meet their specific expectations and to allow a smoother transition. With modern rough surface implants and computer-aided design/computer-assisted manufacture (CAD/CAM) technology, immediate restoration of function and aesthetics with implant-supported fixed prostheses offers great benefits and patient satisfaction in carefully selected cases.[96]

The design of a maxillary implant-retained prosthesis is greatly

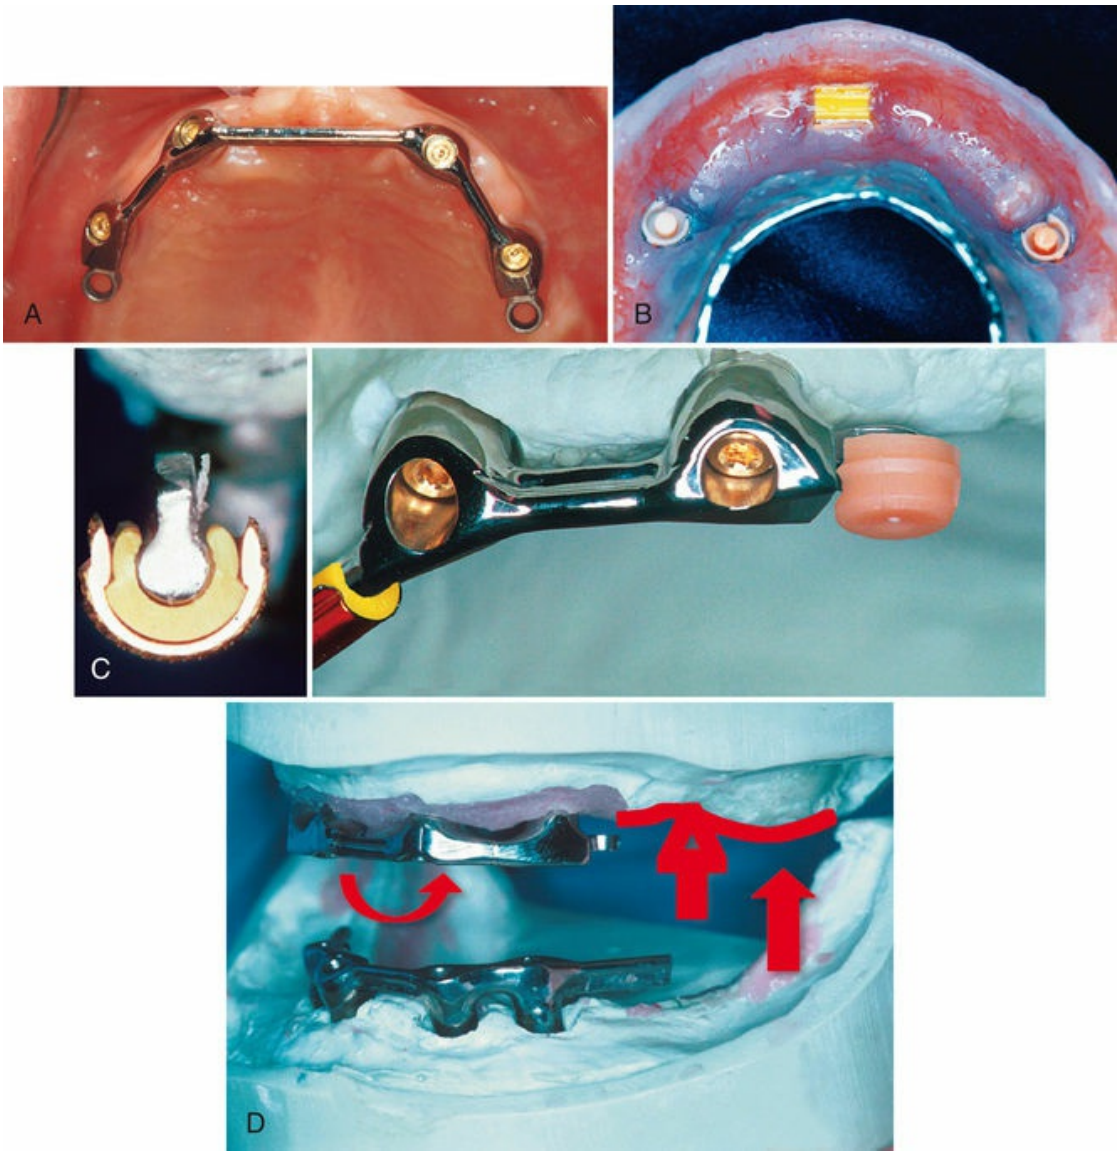
influenced by the anatomy of the maxilla. Most notably, the maxillary sinus limits the height of bone available for implant placement in the posterior region. As a result, implant placement is confined to the anterior region, and the A-P spread that can be achieved is often limited (eFig. 77.14). If the A-P spread is inadequate to provide support, a full-palatal-coverage overlay denture is recommended.



EFIG. 77.14 Diagram demonstrating the anterior-posterior (A-P) implant spread. It is defined as the distance from the middle of the most anterior implant to the distal edge of the most posterior implant.

Most edentulous patients are best served with an implant-assisted overlay denture. Lower cost, improved hygiene access, better lip support and predictable speech articulation are additional benefits that favor the use of an overlay denture in the edentulous maxilla over an implant-supported fixed prosthesis. The four-implant–assisted, palateless overlay denture ideally addresses the needs of most patients (eFig. 77.15). Many patients who are edentulous in the maxilla have lost a significant amount of structure in the premaxillary region resulting in a lack of support for the upper lip. An implant-assisted maxillary overdenture is preferred over an implant-supported fixed prosthesis for this

patient population because the labial flange can provide the needed lip support to optimize the aesthetic outcomes. The usual resorption pattern of the alveolus places the gingival margin of a fixed restoration too far superiorly, too far palatally, or both. Even if the patient has a low enough smile line to hide the appearance of long crowns and deficient soft tissue height, a lack of lip support just beneath the nose can be unsightly with fixed prostheses.



EFIG. 77.15 Implant-assisted overlay denture. (A) Clinical photograph of a four-implant bar in the maxilla designed to retain a palateless overlay denture. (B) Photograph of the clip and attachment design of a palateless overlay denture. Anterior Hader clip attaches to anterior bar, and posterior extracoronal

resilient attachments (ERAs) fasten to female connectors at posterior ends of the bar. (C) Cross section of Hader bar clip attached to the anterior bar *(inset).* View of overdenture bar with Hader clip *(left)* and ERA *(right)* attached. These plastic components will be embedded in the overdenture as in part B. (D) Axis of rotation and function of the resilient attachment. When posterior occlusal forces *(solid vertical arrow)* are applied, the denture rotates around the bar clip anteriorly *(curved arrow),* and resilient attachment *(arrow)* allows the denture to be compressed to primary denture-support areas posteriorly *(open arrow).*

For patients who prefer an implant-supported fixed prosthesis (and do not require additional lip support), six or more implants arranged in an appropriate arc of curvature with at least 2 cm of A-P spread are required (see eFig. 77.14). In this situation, the fixed prosthesis can be fabricated with distal extension cantilevers up to half the A-P spread provided it does not exceed 10 mm.

Transition from terminal dentition to complete edentulism always presents the biggest challenge for patients with failing remaining teeth. In the past, many patients were reluctant and unable to benefit from the dental implants due to multiple surgeries, lengthy treatment time, and the psychological fears of losing all their natural teeth and getting used to an immediate removable prosthesis. However, advances in modern implant designs, implant surfaces, and CAD/CAM technology have broadened the implant applications due to high primary stability, precision planning, and optimal implant placement. Emerging evidence showed high patient-reported satisfaction and a comparable implant success rate of immediate implant placement and immediate loading compared with the delayed loading protocols.[6,36,43,103,109,129] With careful patient selection and appropriate training, the experienced clinician can shorten the treatment time, provide immediate restoration of function and aesthetics, and mitigate the psychological impact of complete edentulism with immediate loading of implant-supported fixed prostheses[96] (eFig. 77.16A–B).

B
C

D

E

F

EFIG. 77.16 (A–E) *Pretreatment:* A 60-year-old male

patient presented with failing dentition due to rampant caries. This patient chose immediate implant placement and an immediate loading treatment option due to his specific expectations. Immediate restoration of aesthetics and function was his top priority. Notice the extensive caries, heavy plaque build-up, and severe occlusal plane discrepancy and crowding of remaining dentition. (F–H) *Post-op:* Full mouth extractions of 22 teeth, bone reduction, and immediate placement of 11 implants (six on the maxilla and five on the mandible) were completed in one surgery with CAD/CAM bone reduction guide and implant surgical guide. Then CAD/CAM PMMA fixed provisional prostheses were connected onto five maxillary implants and four mandibular implants, respectively, as shown on the post-op panoramic x-ray. Lower insertion torque values were noted on implants at #11 and 22 positions at the time of surgery, and the decision was made to exclude these two implants from the immediate loading protocol. (I and J) The patient was very satisfied with the transition from his terminal dentition to implant-supported fixed provisional prostheses.

That being stated, caution should be exercised in choosing immediate treatment until methods have proven successful, especially in the maxillary arch. Parel and Phillips[100] identified several common primary factors in maxillary implant failure scenarios based on a retrospective study of the all-on-four implant concept. They found the number of maxillary implant failures was about five to six times the number of failed mandibular implants. Through this process of patient profiling, they concluded that opposing natural dentition, male gender, lack of bone density, the distal implant site, and parafunctional habits were sufficiently frequent occurrences in failure situations to suggest that either the use of additional implants or delayed loading and the provision of a complete denture as an interim prosthesis may be more appropriate in the management of patients identified as being high risk. Secondary factors such as bone availability (volume) and smoking were less common in failure situations. These factors, when considered and evaluated presurgically, can be helpful in

treatment planning with regard to the appropriate number of implants necessary and the possible loading sequence for optimal integration and prosthesis success.

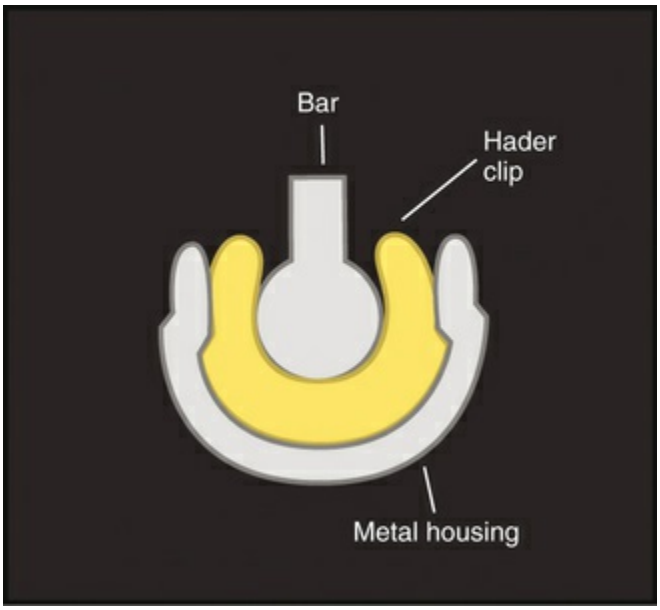
The use of CAD/CAM technologies for digital workflow from the virtual implant treatment planning, image-guided implant surgery, to the manufacturing prosthetic frameworks on dental implants is noticeably increasing. While embracing the exciting technology advancement in implant dentistry, clinicians must be mindful of the limitations, and the overall possible accuracy of the CAD/CAM technology depends on the accuracy of the individual steps of the production process. Flügge and colleagues[47] showed that the registration accuracy in commercial virtual implant planning software is significantly influenced by the preprocessing of imported data, by the user, and by the number of restorations resulting in clinically nonacceptable deviations encoded in image-guided implant surgery drilling guides. This study emphasized that the automatic segmentation in the implant planning software was significantly less accurate compared with the manual segmentation by the users, especially in patients with multiple preexisting dental restorations.

Edentulous Mandible

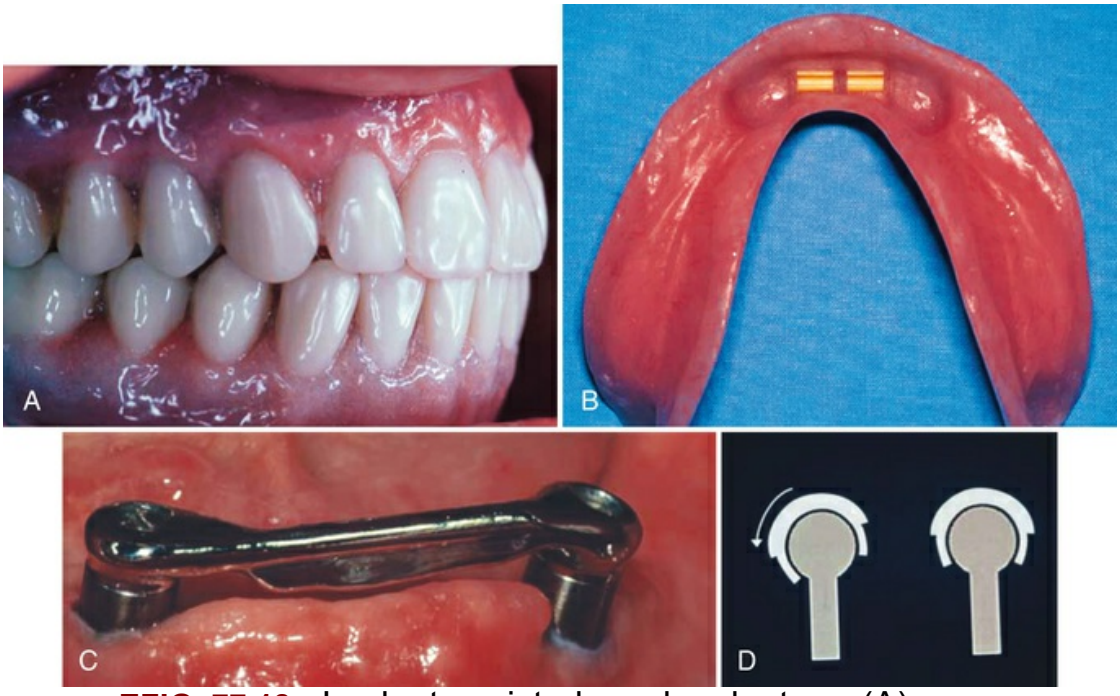
Similar to the edentulous maxilla, prosthetic options for patients with an edentulous mandible include a conventional complete denture, an implant-assisted denture, or an implant-supported prosthesis. A mandibular complete denture is more problematic for patients than a maxillary complete denture, especially for patients with a severely resorbed (atrophic) mandibular ridge. The lack of stability and retention makes it challenging for patients to control the denture. The addition of implants offers unprecedented control (i.e., stability and retention) for a complete, removable prosthesis.

Implant-assisted overlay dentures are designed so that most of the masticatory load is borne by the primary denture-support areas (i.e., retromolar pad, buccal shelf). A common practice is to place two implants in the anterior mandible with a connecting bar. One or two clips retain the denture to the bar (eFig. 77.17). When occlusal forces are applied, the denture rotates around the bar

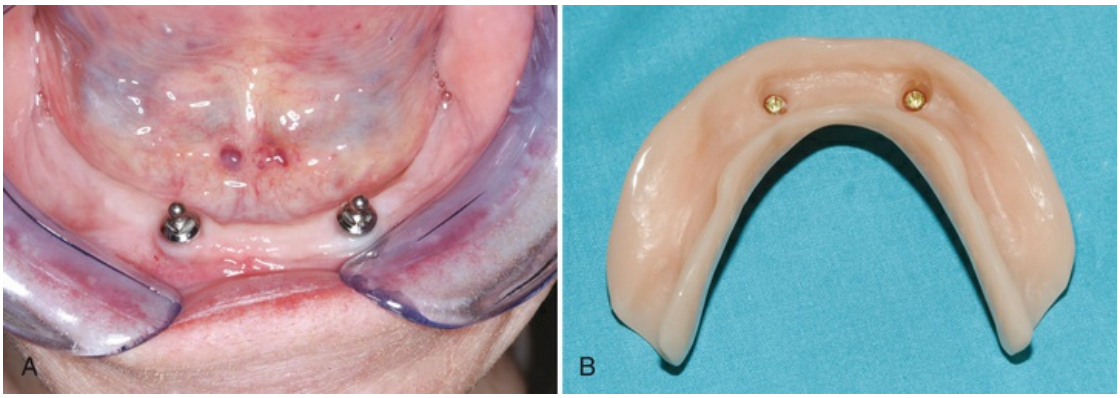
(anterior axis of rotation) and depresses slightly in the posterior aspect, directing the forces to the primary denture-bearing areas (eFig. 77.18). The implants provide stability and retention while bearing minimal stress from occlusal loads. Individual attachments secured to each implant can also offer a simple prosthetic alternative (eFig. 77.19) to the bar and clip design. However, it is more critical for implants with individual attachments to be parallel to one another to facilitate a proper path of insertion and to minimize stress during prosthetic seating and function.



EFIG. 77.17 Cross section of a Hader bar with clip. Note that the minimal height of the Hader bar is 2.5 mm and about 1.2 mm for the plastic clip and the metal housing. We should also allow room for acrylic for the retention of these components.



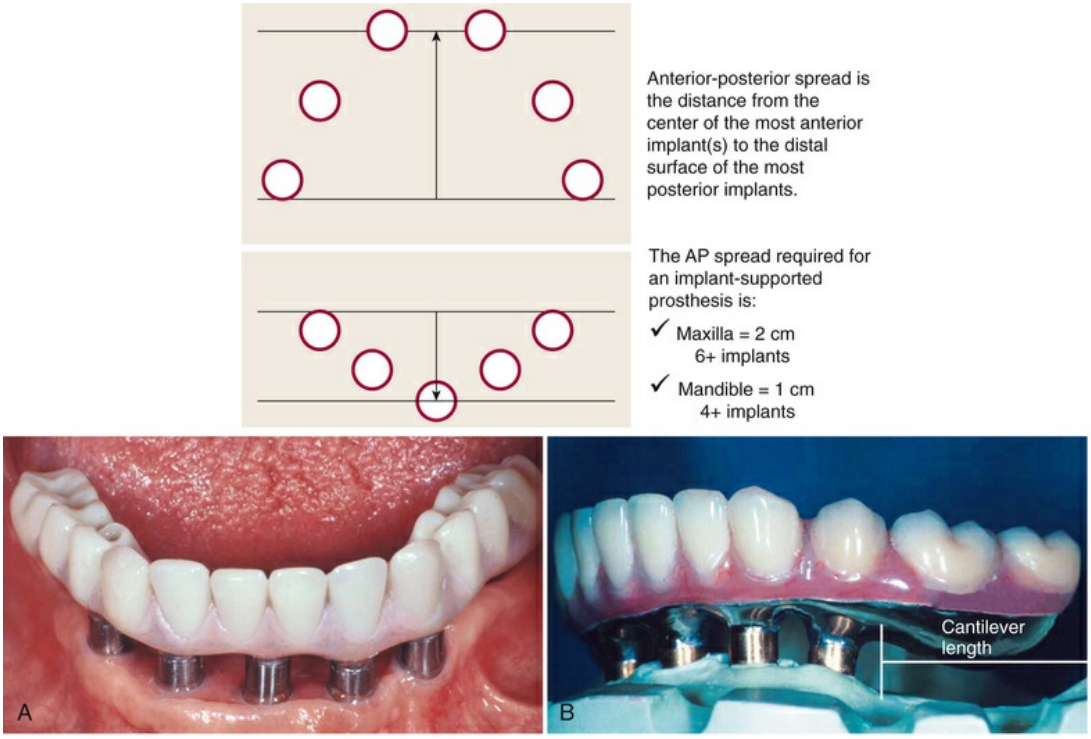
EFIG. 77.18 Implant-assisted overlay denture. (A) Clinical view of an overdenture in occlusion. (B) Photograph of a mandibular overlay denture (tissue-bearing surface) designed for an implant bar attached to two implants in the anterior mandible. Two Hader clips are embedded in the anterior acrylic. (C) Clinical view of a bar attached to two implants in the anterior mandible. (D) Illustration demonstrating how the axis of rotation allows denture to rotate around the bar. When the patient applies occlusal force posteriorly, the overlay denture rotates around the bar, and the load is absorbed by primary denture-bearing surfaces posteriorly.



EFIG. 77.19 Individual attachments can be used on

each implant to assist in retention of the mandibular overdenture. (A) Clinical view of the anterior mandible with individual ball attachments on two implants. (B) Tissue-bearing surface of the mandibular overdenture showing individual female attachments embedded in the denture. (Courtesy Dr. Sal Esposito, Beachwood, Ohio.)

For patients who prefer an implant-supported fixed prosthesis, four, five, or six implants arranged in an appropriate arc of curvature with at least 1 cm of A-P spread are required (see eFig. 77.14). In this situation, the fixed prosthesis can be fabricated with distal extension cantilevers up to twice the A-P spread (eFig. 77.20).



EFIG. 77.20 Cantilever length relative to A-P spread of implant distribution. (A) Clinical view of an implant-supported restoration replacing mandibular teeth. Notice that the restoration is supported by five implants in the anterior and has cantilever extensions in the posterior segments. (B) Study model view of a similar mandibular implant-supported restoration with posterior cantilever extensions. Cantilever length, in the edentulous mandible, should not exceed twice the A-P spread.

Many patients prefer a fixed option for psychological reasons, but the mastication efficiency provided by a fixed versus removable prosthesis does not appear to be significant.[67] Evidence suggests that such fixed restorations tend to stop resorption of the body of the posterior mandible and in some cases enable regeneration of the bone in this region.

Conclusion

Successful implant treatment requires a team of clinicians and technicians dedicated to excellence in surgical and prosthetic aspects. A thorough understanding of the prosthodontic restoration of implants from implant-abutment connections to hard and soft tissue interfaces and compatibility with the implant/abutment/restoration is essential. This chapter reviewed the critical aspects of prosthetic implant treatment proven to maximize long-term functional, biologic, and aesthetic success.

Case Scenario 77.1

Patient:

29-year-old Caucasian female, ASA 1.

Chief Complaint:

"I have pain and swelling around my implant."

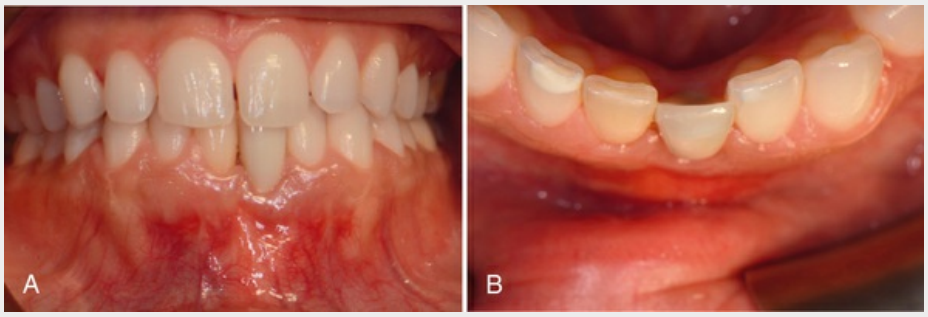
Background Information

Patient reports having the mandibular left central incisor replaced with an implant about 1½ years ago. She did not have symptoms until recently when the gum over the implant became tender and swollen.

Current Findings:

Exam reveals that probing depths range from 2 to 3 mm. Dentition is intact except for the mandibular left lateral incisor, which is replaced with an implant. There is a 7- to 8-mm pocket on the labial area with moderate erythema and edema. The tissues easily retract away from the implant revealing excess cement. The implant

crown is positioned facial to the adjacent teeth.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What is the diagnosis? A. Peri-implantitis B. Peri-implant mucositis C. Normal peri-implant health D. Periodontal abscess	**Answer: A** **Explanation:** There is attachment loss, bone loss, and peri-implant inflammation most likely precipitated by excess cement.
2. What are the etiologic factors? A. Smoking B. Poor oral hygiene C. Cementing an implant crown with margins that are more than 1 mm subgingival D. Unknown systemic disease	**Answer: C** **Explanation:** It has been well documented that excess cement cannot be detected or removed when >1 mm subgingival.
3. What prosthetic measures can be taken to avoid this problem? A. Use a screw-retained restoration B. Use a custom abutment that keeps the cement margins ≤ 1 mm from the gingival margin C. Both of the above D. This problem is unavoidable	**Answer: C** **Explanation:** Using a screw-retained restoration or using a custom abutment that creates crown margins within 1 mm of the gingival margin will avoid or minimize the likelihood of excess cement being extruded into the subgingival tissues.

CHAPTER OUTLINE

General Principles of Implant Surgery
Two-Stage "Submerged" Implant Placement
One-Stage "Nonsubmerged" Implant Placement
Conclusion

The surgical procedures for the placement of nearly all endosseous dental implants currently used are based on the original work of Professor Per-Ingvar Brånemark and colleagues in Sweden in the 1960s and 1970s.[4,5] Their landmark research evaluated the biologic, physiologic, and mechanical aspects of the titanium screw-shaped implant, subsequently known commercially as the Nobelpharma "Brånemark" implant system and currently manufactured by Nobel Biocare. The original Brånemark implant was a parallel-walled, cylindrically shaped, threaded implant with an external hex connection and a machined surface. Since their introduction, many

designs of root form implants have been developed, modified, and studied. The same fundamental principles of atraumatic, precise implant site preparation applies to all implant systems. Briefly, this includes a gentle surgical technique and progressive, incremental preparation of the bone for a precise fit of the implant at the time of placement.

This chapter outlines the basic surgical procedures for the placement of endosseous dental implants using either one-stage or two-stage protocols. The principles described here are intentionally generic and meant to serve as guidelines that are applicable to most common implant systems (Video 78.1). Each implant system is designed with specific armamentarium and recommendations for use (e.g., drilling speeds), and it is advisable to follow the detailed protocols provided by the manufacturer. For the presentation of a dental implant case, see Video 78.2.

General Principles of Implant Surgery

Patient Preparation

Most implant surgical procedures can be done in the office using local anesthesia. Conscious sedation (oral or intravenous) may be indicated (see Chapter 38) for some patients. The risks and benefits of implant surgery specific to the patient's situation and needs should be thoroughly explained prior to surgery. A written, informed consent should be obtained for the procedure.

Implant Site Preparation

Some basic principles must be followed to achieve osseointegration with a high degree of predictability[3,4,7] (Box 78.1). The surgical site should be kept aseptic, and the patient should be appropriately prepared and draped for an intraoral surgical procedure. Prerinsing with chlorhexidine gluconate for 1 to 2 minutes immediately before the procedure will aid in reducing the bacterial load present around the surgical site. Every effort should be made to maintain a sterile surgical field and to avoid contamination of the implant surface. Implant sites should be prepared using gentle, atraumatic surgical

techniques with an effort to avoid overheating the bone.

Box 78.1

Basic Principles of Implant Therapy to Achieve Osseointegration

1. Implants must be sterile and made of a biocompatible material (e.g., titanium).
2. Implant site should be prepared under sterile conditions.
3. Implant site should be prepared with an atraumatic surgical technique that avoids overheating of the bone during preparation of the recipient site.
4. Implants should be placed with good initial stability.
5. Implants should be allowed to heal without loading or micromovement (i.e., undisturbed healing period to allow for osseointegration) for 2 to 4 or 4 to 6 months, depending on the bone density, bone maturation, and implant stability.

Successful osseointegration occurs predictably for submerged[4] and nonsubmerged[11] dental implants when proven clinical guidelines are followed. Well-controlled studies of patients with good plaque control and appropriate occlusal forces have demonstrated that root form, endosseous dental implants show little change in bone height around the implant over years of function.[1] After initial bone remodeling in the first year (1 to 1.5 mm of resorption described as "normal remodeling around an externally hexed implant"),[1] the bone level around healthy functioning implants remains stable for many years afterward. The average annual crestal bone loss after the first year in function is expected to be 0.1 mm or less. Hence, implants offer a predictable solution for tooth replacement.

Regardless of the surgical approach, the implant must be placed in healthy bone with good primary stability to achieve osseointegration, and an atraumatic technique must be followed to avoid damage to bone. Drilling of the bone without adequate cooling generates excessive heat, which injures bone and increases

the risk of failure.[12] The anatomic features of bone quality (dense compact versus loose trabecular) at the recipient site influences the interface between bone and implant.[9] Compact bone offers a much greater surface area for bone-to-implant contact than cancellous bone. Areas of the jaw exhibiting thin layers of cortical bone and large cancellous spaces, such as the posterior maxilla, have lower success rates than areas of dense bone.[9] The best results are achieved when the bone-to-implant contact is intimate at the time of implant placement.

One-Stage Versus Two-Stage Implant Placement Surgery

Currently, most threaded endosseous implants can be placed using either a one-stage (nonsubmerged) or a two-stage (submerged) protocol. In the one-stage approach, the implant or the abutment emerges through the mucoperiosteum/gingival tissue at the time of implant placement, whereas in the two-stage approach, the top of the implant and cover screw are completely covered with the flap closure (Fig. 78.1). Implants are allowed to heal, without loading or micromovement, for a period of time to allow for osseointegration. In two-stage implant surgery, the implant must be surgically exposed following a healing period. Some implants, referred to as "tissue level," are specifically designed with the coronal portion of the implant positioned above the crest of bone and extending through the gingival tissues at the time of placement in a one-stage protocol (Fig. 78.1A). Other implant systems, referred to as "bone level," are designed to be placed at the level of bone and require a healing abutment to be attached to the implant at the time of placement to be used in a one-stage approach[8] (Fig. 78.1B).

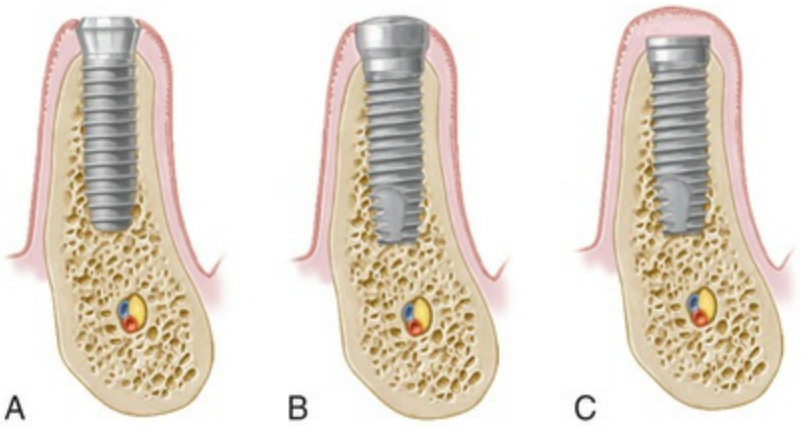

FIG. 78.1 One-stage implant versus two-stage implant surgeries. (A) One-stage surgery with the implant designed so that the coronal portion of the implant extends through the gingiva. (B) One-stage surgery with implant designed to be used for two-stage surgery. A healing abutment is connected to the implant during the first-stage surgery. (C) In the two-stage surgery, the top of the implant is completely submerged under gingiva.

A one-stage surgical approach simplifies the procedure because a second-stage exposure surgery is not necessary. The two-stage, submerged approach is advantageous for situations that require simultaneous bone augmentation procedures at the time of implant placement because membranes can be submerged, which will minimize postoperative exposure. Mucogingival tissues can be augmented if desired at the second-stage surgery in a two-stage protocol or as part of the one-stage protocol. Fundamental differences in flap management for these two surgical techniques are described separately.

Two-Stage "Submerged" Implant Placement

In the two-stage implant surgical approach, the first-stage or implant placement surgery ends by suturing the soft tissues together over the implant cover screw so that it remains submerged and isolated from the oral cavity. In areas with dense cortical bone and good initial implant support, the implants are left to heal

undisturbed for a period of 2 to 4 months, whereas in areas of loose trabecular bone, grafted sites, and sites with lesser implant stability, implants may be allowed to heal for periods of 4 to 6 months or more. Longer healing periods are indicated for implants in sites with less bone support. During healing, osteoblasts migrate to the surface and form bone adjacent to the implant (osseointegration).[6] Shorter healing periods are indicated for implants placed in good quality (dense) bone and for implants with an altered surface microtopography (e.g., acid etched, blasted, or etched and blasted). Readers are referred to online material and other resources for more information about implant surface microtopography.

In the second-stage (exposure) surgery, the implant is uncovered and a healing abutment is connected to allow emergence of the abutment through the soft tissues. Once healed, the restorative dentist then proceeds with the prosthodontic aspects of the implant therapy (impressions and fabrication of prosthesis).

The following paragraphs describe the steps for osteotomy preparation and the first-stage implant placement surgery of the two-stage protocol. Figs. 78.2 and 78.3 illustrate the procedures via diagrams, and Fig. 78.4 depicts the procedures with clinical photographs.

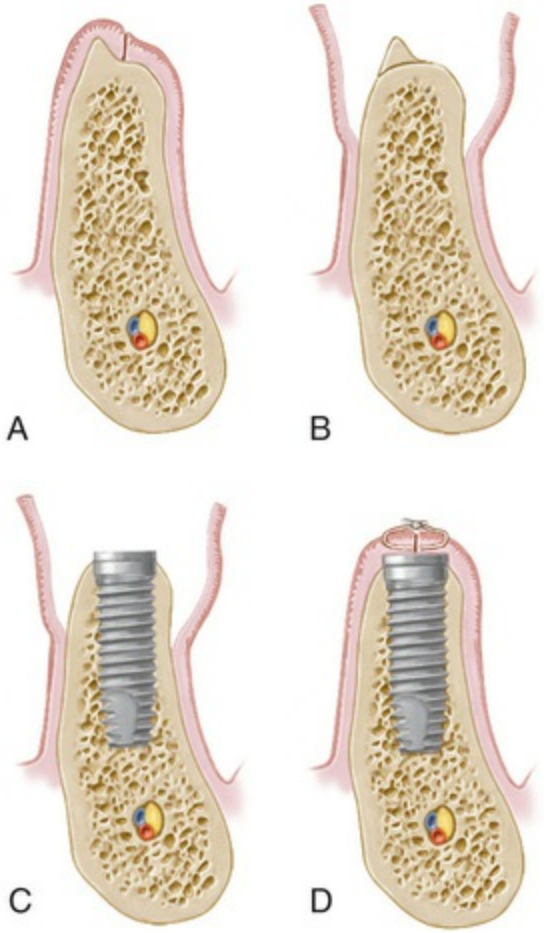

FIG. 78.2 Tissue management for a two-stage implant placement. (A) Crestal incision is made along the crest of the ridge, bisecting the existing zone of keratinized mucosa. (B) Full-thickness flap is raised buccally and lingually to the level of the mucogingival junction. A narrow, sharp ridge can be surgically reduced/contoured to provide a reasonably flat bed for the implant. (C) Implant is placed in the prepared osteotomy site. (D) Tissue approximation achieves primary flap closure without tension.

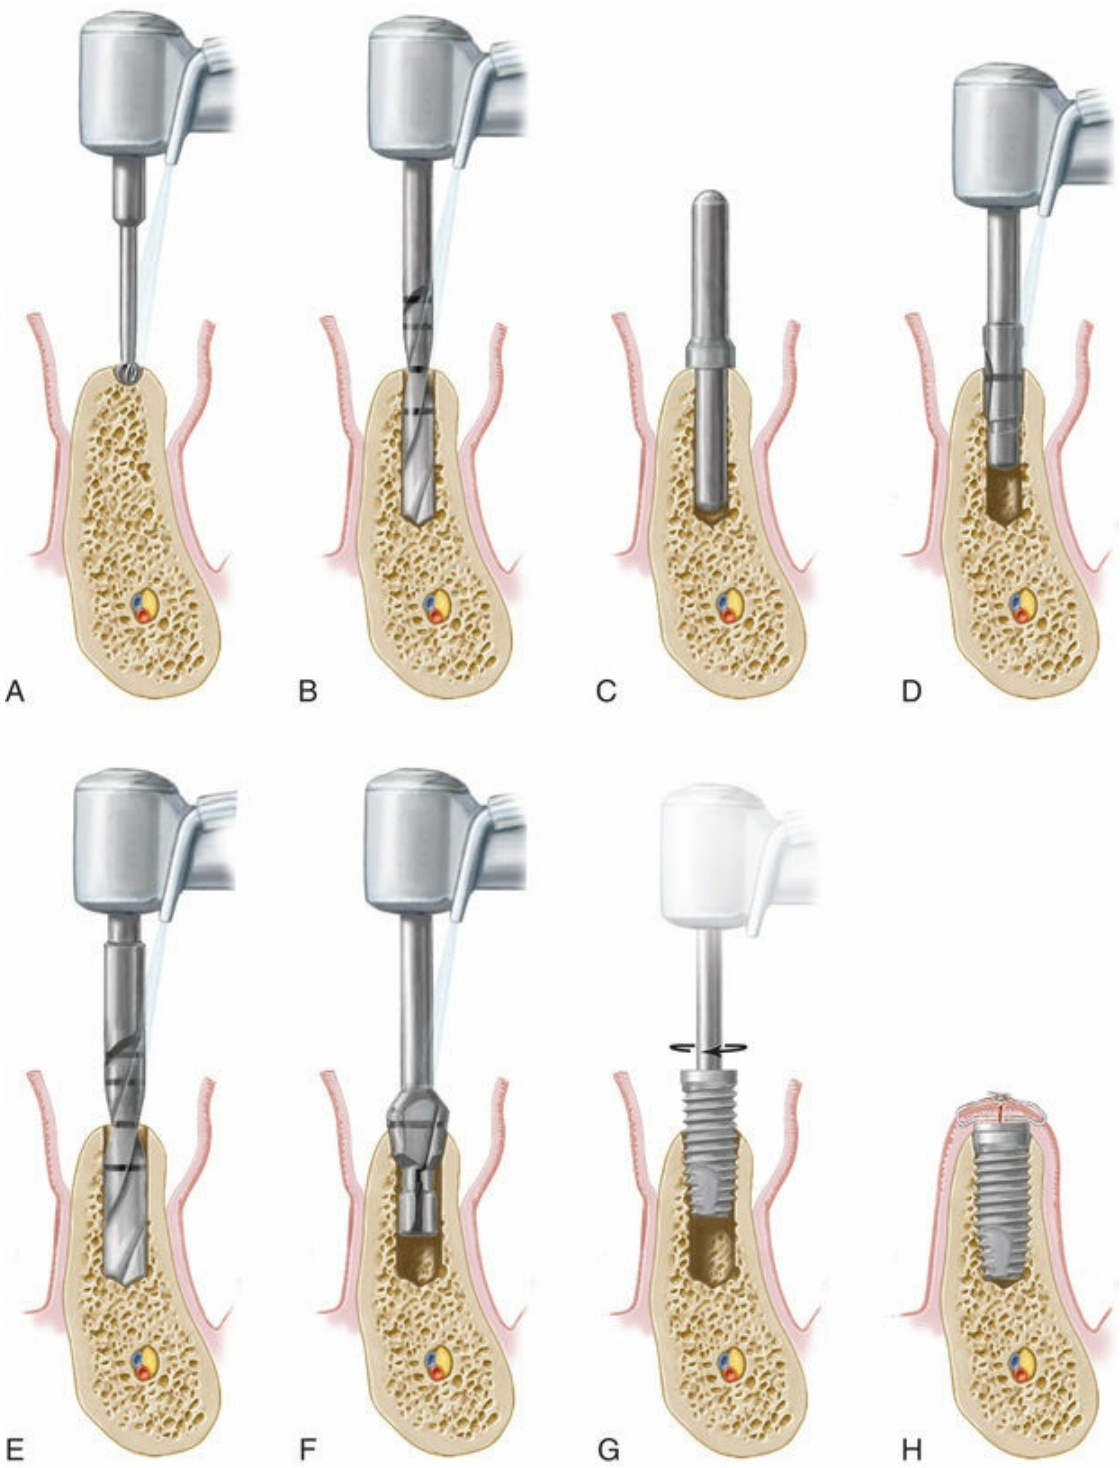

FIG. 78.3 Implant site preparation (osteotomy) for a 4-mm diameter, 10-mm length screw-type, threaded (external hex) implant in a subcrestal position. (A) Initial marking or preparation of the implant site with a round bur. (B) Use of a 2-mm twist drill to establish depth and align the implant. (C) Guide pin is placed in the osteotomy site to confirm position and angulation. (D) Pilot drill is used to increase the diameter of the coronal aspect of the osteotomy site. (E) Final drill

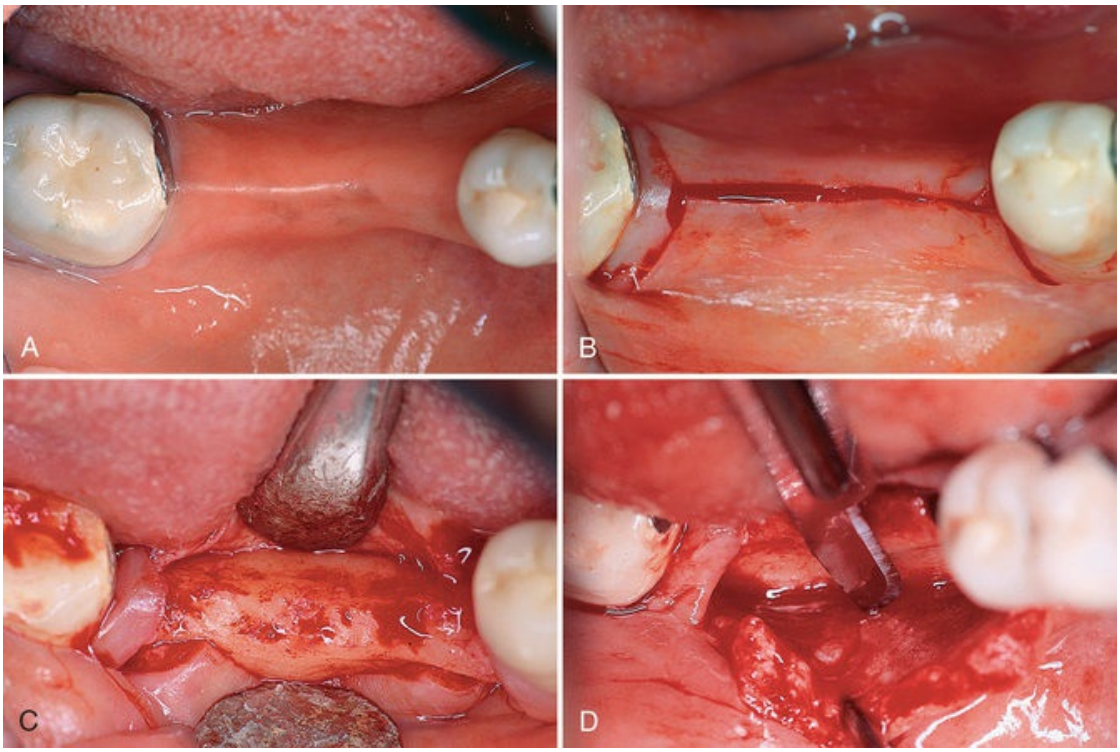
used is the 3-mm twist drill to finish preparation of the osteotomy site. (F) Countersink drill is used to widen the entrance of the recipient site and allow for the subcrestal placement of the implant collar and cover screw. Note: An optional tap (not shown) can be used following this step to create screw threads in areas of dense bone. (G) Implant is inserted into the prepared osteotomy site with a handpiece or handheld driver. Note*:* In systems that use an implant mount, it is removed prior to placement of the cover screw. (H) The cover screw is placed and soft tissues are closed and sutured.



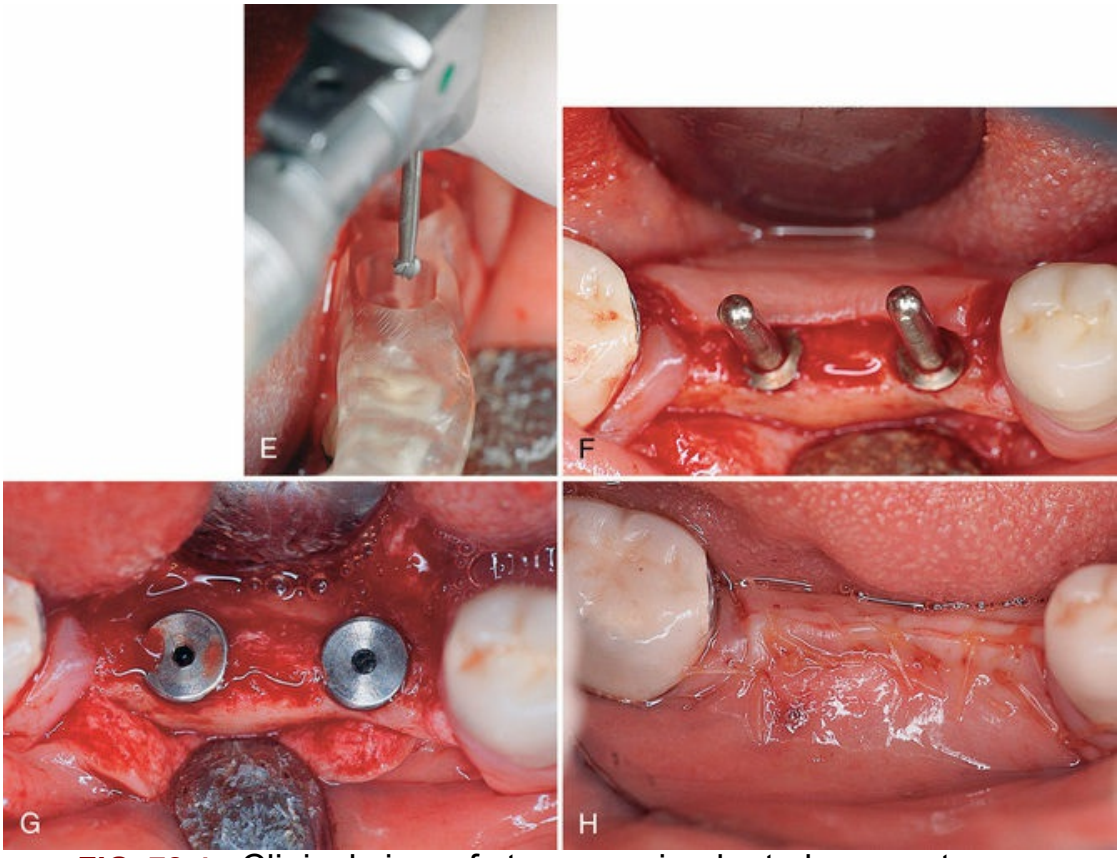


FIG. 78.4 Clinical view of stage-one implant placement surgery. (A) Partial edentulous ridge; presurgical and prosthodontic treatment has been completed. (B) Mesial sulcular and distal vertical incisions are connected by a crestal incision. Notice that bands of gingival collars remain adjacent to the distal molar tooth. (C) Minimal flap reflection is used to expose the alveolar bone. Sometimes a ridge modification is necessary to provide a flap recipient bed. (D) Buccal flap is partially dissected at the apical portion to provide a flap extension. This is a critical step to ensure a tension-free closure of the flap after implant placement. (E) It is important to use the surgical stent to determine the mesial-distal and buccal-lingual dimensions and proper angulation of the implant placement. (F) Frequent use of the guide pins ensures parallelism of the implant placement. (G) After placement of two Nobelpharma implants, the cover screws are placed. The cover screws should be flush with the rest of the ridge to minimize the chance of exposure. This is especially important if the patient will wear a partial denture during the healing phase. (H) Suturing completed. Both regular interrupted and inverted mattress sutures are used intermittently to

ensure tension-free, tight closure of the flaps.

Flap Design, Incisions, and Elevation

Flap management for implant surgery varies slightly, depending on the location and objective of the planned surgery. There are different incision/flap designs, but the most common is the crestal flap design. The incision is made along the crest of the ridge, bisecting the existing zone of keratinized mucosa (see Figs. 78.2A and 78.4B).

A remote incision with a layered suturing technique may be used to minimize the incidence of bone graft exposure when extensive bone augmentation is planned. The crestal incision, however, is preferred in most cases, because closure is easier to manage and typically results in less bleeding, less edema, and faster healing.[10]

A full-thickness flap is raised (buccal and lingual) up to or slightly beyond the level of the mucogingival junction, exposing the alveolar ridge of the implant surgical sites (see Figs. 78.2B and 78.4C). Elevated flaps may be sutured to the buccal mucosa or the opposing teeth to keep the surgical site open during the surgery. The bone at the implant site must be thoroughly debrided of all granulation tissue.

For a "knife-edge" alveolar process with sufficient alveolar bone height and distance from vital structures (e.g., inferior alveolar nerve), a large round bur is used to recontour or flatten the bone to provide a wider, level surface for the implant site preparation (see Fig. 78.2B). However, if the vertical height of the alveolar bone is limited (e.g., <10 mm), the knife-edge alveolar bone height should be preserved. Bone augmentation procedures can be used to increase the ridge width while preserving alveolar bone height (see Chapter 79).

Implant Site Preparation

Once the flaps are reflected and the bone is prepared (i.e., all granulation tissue removed and knife-edge ridges flattened), the implant osteotomy site can be prepared. A series of drills are used to prepare the osteotomy site precisely and incrementally for an

implant (Fig. 78.5). A surgical guide or stent is inserted, checked for proper positioning, and used throughout the procedure to direct the proper implant placement (see Fig. 78.4E).

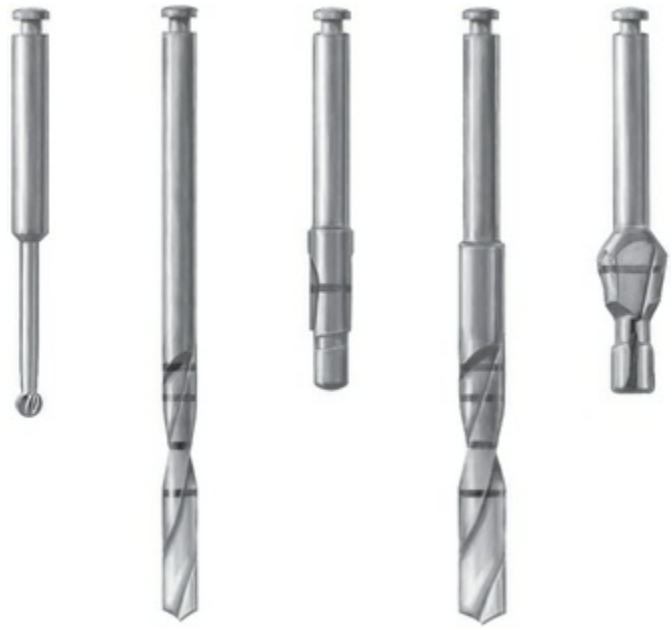

FIG. 78.5 Sequence of drills used for standard-diameter (4-mm) implant site osteotomy preparation: round, 2-mm twist, pilot, 3-mm twist, and countersink. Bone tap (not shown here) is an optional drill that is sometimes used in dense bone before implant placement.

Round Bur

A small round bur (or spiral drill) is used to make the initial penetration into bone for the implant site. The surgical guide is removed, and the initial marks are checked for their appropriate buccal-lingual and mesial-distal location, as well as the positions relative to each other and adjacent teeth (see Fig. 75.9). Slight modifications may be necessary to adjust spatial relationships and to avoid minor ridge defects. Any changes should be compared with the prosthetically driven surgical guide positions. Each marked site is then prepared to a depth of 1 to 2 mm with a round drill, breaking through the cortical bone and creating a starting point for the 2-mm twist drill (see Fig. 78.3A).

The 2-mm Twist Drill

A small twist drill, usually 2 mm in diameter and marked to indicate various lengths (i.e., corresponding to the implant sizes), is used next to establish the depth and align the long axis of the implant recipient site (see Fig. 78.3B). This drill may be externally or internally irrigated. In either case, the twist drill is used at a speed of approximately 800 to 1500 rpm, with copious irrigation to prevent overheating of the bone. Additionally, drills should be intermittently and repeatedly "pumped" or pulled out of the osteotomy site while drilling to expose them to the water coolant and to facilitate clearing bone debris from the cutting surfaces. In other words, clinicians should pump the drill (up and down) intermittently and avoid using a constant "push" of the drill in the apical direction only.

When multiple implants are being placed next to one another, a guide pin should be placed in the prepared sites to check alignment, parallelism, and proper prosthetic spacing throughout the preparation process (see Fig. 78.3C). The relationship to neighboring vital structures (e.g., nerve and tooth roots) can be determined by taking a periapical radiograph with a guide pin or radiographic marker in the osteotomy site (see Fig. 76.15). Implants should be positioned with approximately 3 mm between one another to ensure sufficient space for interimplant bone and soft-tissue health and to facilitate oral hygiene procedures. Therefore the initial marks should be separated by at least 7 mm (center to center) for 4 mm standard-diameter implants. Incrementally more space is needed for wide-diameter implants (see Fig. 75.9).

The 2-mm twist drill is used to establish the final depth of the osteotomy site corresponding to the length of each planned implant. The clinician should also evaluate the bone quality (density) with this drill while preparing the osteotomy to assess the need for modifying subsequent drills used (Box 78.2). If the vertical height of the bone was reduced during the initial ridge preparation, this must be taken into account when preparing the site for a predetermined implant length. For example, if it appears that the implant will be too close to a vital structure, such as the inferior alveolar nerve canal, the depth of the implant osteotomy site and length of the implant may need to be reduced.

Box 78.2

Clinical Advice to Enhance Precision of Final Implant Site Preparation

Clinical Situation 1

If the final drill stops advancing in the apical direction before reaching the desired depth, the added hand pressure necessary to achieve the proper depth can cause wobbling and funneling of the recipient site. This is especially true with "cannon" drills (used for cylindrical implants). To minimize this effect, a smaller-diameter drill should be used to prepare the site slightly deeper (e.g., 0.5 mm or less). This narrower drill allows the desired depth to be reached without affecting the side walls and facilitates a more precise osteotomy preparation with the final drill. It is also important to use drills that are sharp, especially for dense bone.

Clinical Situation 2

If the final drill is inserted at an inaccurate angle, the result is funneling of the coronal portion of the implant site. To minimize this potential problem, when drilling multiple implant sites, the operator should always keep a direction indicator in an adjacent site. For single-implant sites, the adjacent teeth and surgical guide should serve as direction indicators. When dealing with dense bone, a precise recipient site can be achieved more predictably if there is minimal diameter change from drill to drill. For example, switching from 3 to 5 mm is much less precise than proceeding from 3 to 3.3 to 4.2 to 5 mm.

Clinical Situation 3

If the bone is "soft" (e.g., loose trabecular bone), it may be advantageous to underprepare the osteotomy site. A slightly underprepared site can be accomplished by using the final drill to a shallower depth than the previous drill (e.g., half the depth of the osteotomy site). This avoids removing too much bone and increases the implant stability or tightness at the time of placement. Another method to achieve an underprepared site is to use a drill

with a slightly smaller diameter as the final drill in the preparation (e.g., a 2.75-mm drill as the final drill rather than a 3-mm or a 3.25-mm version as the final drill for a 4-mm implant).

The next step is to use a series of drills to incrementally increase the width of the osteotomy site to accommodate the planned implant diameter. The styles, shapes, and final diameter of the drills will differ slightly among different implant systems, but their general purpose is to prepare a recipient site with a precise diameter (and depth) for the selected implant without unduly traumatizing the surrounding bone. It is important to use copious irrigation and a "pumping" action for all drilling.

Key Fact

A series of drills will be used (speeds determined by manufacturer) sequentially to prepare osteotomy sites. It is essential to prepare sites with copious irrigation to prevent overheating of the bone. Additionally, drills should be intermittently and repeatedly "pumped" or pulled out of the osteotomy site while drilling to expose them to the water coolant and to facilitate clearing bone debris from the cutting surfaces.

Pilot Drill

Following the 2-mm twist drill, a pilot drill with a noncutting 2-mm–diameter "guide" at the apical end and a cutting 3-mm–diameter (wider) midsection is used to enlarge the osteotomy site at the coronal end, thus facilitating the insertion of the subsequent drill in the sequence (see Fig. 78.3D).

The 3-mm Twist Drill

The final drill in the osteotomy site preparation for a standard-diameter (4 mm) implant is the 3-mm twist drill. It is the last drill used to widen the site along the entire depth of the osteotomy from the previous diameter (2 mm) to final diameter (3 mm). This final drill in the sequence finishes preparing the osteotomy site and consequently is the step that dictates whether the implant will be

stable or not (see Fig. 78.3E). It is critically important that the final diameter drilling be accomplished with a steady hand, without wobbling or changing direction so that the site is not overprepared. Finally, depending on bone density, the diameter of this final drill may be slightly increased or decreased to enhance implant support (see Box 78.2).

Countersink Drill (Optional)

When it is desirable to place the cover screw at or slightly below the crestal bone, countersink drilling is used to shape or flare the crestal aspect of the osteotomy site allowing the coronal flare of the implant head and cover screw to fit within the osteotomy site (see Fig. 78.3F). As with all drills in the sequence, copious irrigation and gentle surgical techniques are used.

Bone Tap (Optional)

As the final step in preparing the osteotomy site in dense cortical bone, a tapping procedure may be necessary (not shown on Fig. 78.3). With self-tapping implants being almost universal, there is less need for a tapping procedure in most sites. However, in dense cortical bone or when placing longer implants into moderately dense bone, it is prudent to tap the bone (create threads in the osteotomy site) before implant placement to facilitate implant insertion and to reduce the risk of implant binding (see Fig. 78.3G).

Clinical Correlation

When faced with a very soft, poor-quality bone (e.g., loose trabecular bone in the posterior maxilla), tapping is not necessary or recommended (see Box 78.2). It is better to allow the threaded implant to "cut" its own path into the osteotomy site.

Bone tapping and implant insertion are both done at very slow speeds (e.g., 20 to 40 rpm). All other drills in the sequence are used at higher speeds (800 to 1500 rpm).

It is important to create a recipient site that is accurate in size and angulation. In partially edentulous cases, limited jaw opening or

proximity to adjacent teeth may prevent appropriate positioning of the drills in posterior edentulous areas. In fact, implant therapy may be contraindicated in some patients because of a lack of interocclusal clearance, lack of interdental space, or a lack of access for the instrumentation. Therefore a combination of longer drills and shorter drills, with or without extensions, may be necessary. Anticipating these needs before surgery facilitates the procedure and improves the results.

Clinical Correlation

In areas with loose trabecular bone, such as the posterior maxilla, it may not be necessary to tap the site. If bone is especially loose, it may be beneficial to underprepare the site. For example, the final drill could be omitted to increase the implant stability.

Implant Placement

Implants are inserted with a handpiece rotating at slow speeds (e.g., 25 rpm) or by hand with a wrench. Insertion of the implant must follow the same path or line as the osteotomy site. When multiple implants are being placed, it is helpful to use guide pins in the other sites to have a visual guide for the path of insertion.

Flap Closure and Suturing

Once the implants are inserted and the cover screws secured (see Fig. 78.4G), the surgical sites should be thoroughly irrigated with sterile saline to remove debris and clean the wound. Proper closure of the flap over the implant is essential. One of the most important aspects of flap management is achieving good approximation and primary closure of the tissues in a tension-free manner (see Fig. 78.3H). This is achieved by incising the periosteum (innermost layer of full-thickness flap), which is nonelastic. Once the periosteum is released, the flap becomes very elastic and is able to be stretched over the implant without tension. One suturing technique that consistently provides the desired result is a combination of alternating horizontal mattress and interrupted sutures (see Fig.

78.4H). Horizontal mattress sutures evert the wound edges and approximate the inner, connective tissue surfaces of the flap to facilitate closure and wound healing. Interrupted sutures help to bring the wound edges together, counterbalancing the eversion caused by the horizontal mattress sutures.

The clinician should choose an appropriate suture for the given patient and procedure. For patient management, it is sometimes simpler to use a resorbable suture that does not require removal during the postoperative visit (e.g., 4-0 chromic gut suture). However, when moderate-to-severe postoperative swelling is anticipated, a nonresorbable suture is recommended to maintain a longer closure period (e.g., 4-0 monofilament suture). These sutures require removal at a postoperative visit.

Postoperative Care

Simple implant surgery in a healthy patient usually does not require antibiotic therapy. However, antibiotics (e.g., amoxicillin, 500 mg three times a day [tid]) can be prescribed if the surgery is extensive or if the patient is medically compromised. Postoperative swelling is likely after flap surgery. This is particularly true when the periosteum has been incised (released). As a preventive measure, patients should apply cold packs over the first 24 to 48 hours. Chlorhexidine gluconate oral rinses can be prescribed to facilitate plaque control, especially in the days after surgery when oral hygiene is typically poorer. Adequate pain medication should be prescribed (e.g., ibuprofen, 600 to 800 mg tid).

Patients should be instructed to maintain a relatively soft diet after surgery. Then, as healing progresses, they can gradually return to a normal diet. Patients should also refrain from tobacco and alcohol use after surgery. Provisional restorations, whether fixed or removable, should be checked and adjusted to minimize trauma to the surgical area.

Second-Stage Exposure Surgery

For implants placed using a two-stage "submerged" protocol, a second-stage exposure surgery is necessary. Box 78.3 lists the objectives for second-stage implant exposure surgery. The need for

a zone of keratinized tissue surrounding implants is desirable, as one long-term study indicated that the presence of keratinized tissue is strongly correlated with soft- and hard-tissue health.[2]

Box 78.3

Objectives of Second-Stage Implant Surgery

1. To expose the submerged implant without damaging the surrounding bone
2. To control the thickness of the soft tissue surrounding the implant
3. To preserve or create attached keratinized tissue around the implant
4. To facilitate oral hygiene
5. To ensure proper abutment seating
6. To preserve soft-tissue aesthetics

Simple Circular "Punch" or Crestal Incision

In areas with sufficient zones of keratinized tissue, the gingiva covering the head of the implant can be exposed with a circular or "punch" incision (Fig. 78.6). Alternatively, a crestal incision through the middle of the keratinized tissue and full-thickness flap reflection can be used to expose implants.

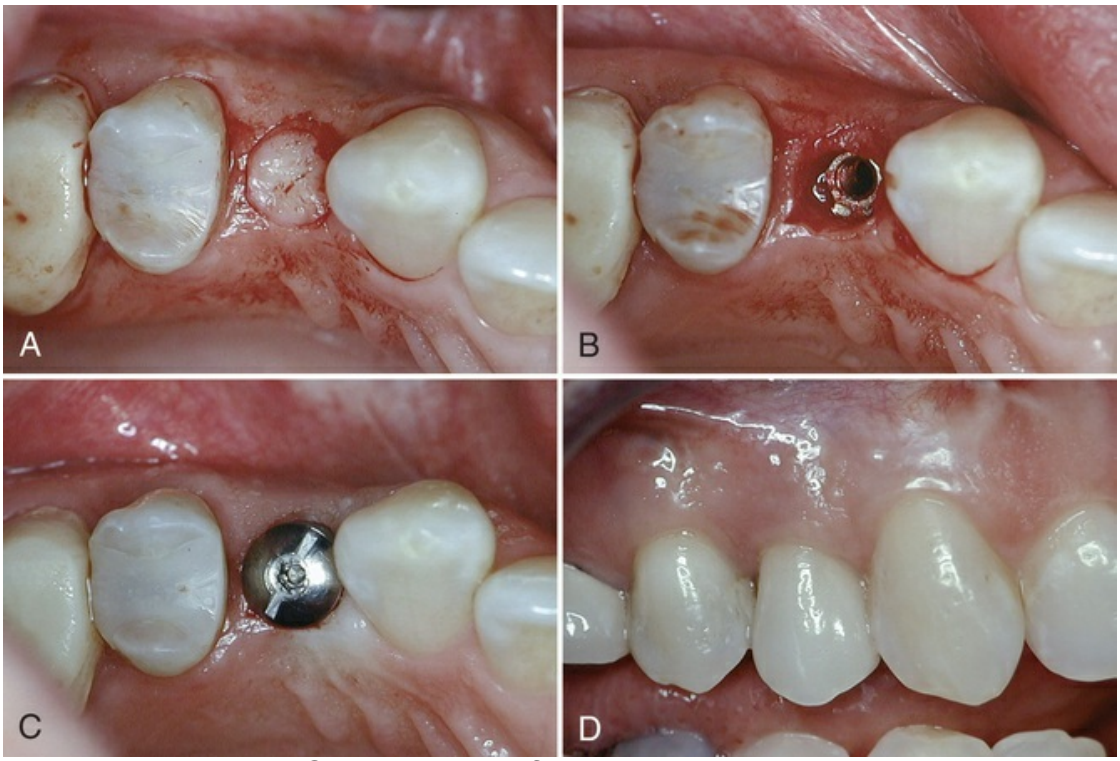

FIG. 78.6 Clinical view of second-stage implant exposure surgery in a case with adequate keratinized tissue. (A) Simple circular "punch" incision used to expose implant when sufficient keratinized tissue is present around the implant. (B) Implant exposed. (C) Healing abutment attached. (D) Final restoration in place, achieving an aesthetic result with a good zone of keratinized tissue.

Partial-Thickness Repositioned Flap

If a minimal zone of keratinized tissue exists at the implant site, a partial-thickness flap technique can be used to fulfill the objective of the second-stage surgery (exposing the implant) while increasing the width of keratinized tissue. The initial incision is made within the zone of keratinized tissue so that it becomes the outer edge of the reflected split-thickness flap. Vertical releasing incisions are used on both the mesial and the distal end of the flap (Fig. 78.7A–B). A partial-thickness flap is then raised in such a manner that a nonmobile, firm periosteum remains attached to the underlying bone. The flap, containing a narrow band of keratinized tissue, is then repositioned to the facial side of the emerging head of the implant and sutured to the periosteum with a fine needle and

resorbable suture such as a 5-0 gut suture (Fig. 78.8). If the initial amount of keratinized tissue is less than 2 mm, the flap may be started at the labial edge of the keratinized tissue allowing that zone to remain on the lingual aspect of the implant. A partial-thickness flap is apically displaced and sutured to the periosteum without exposing the alveolar bone (see Fig. 78.7C). A free gingival graft may be harvested from the palate and sutured to the periosteum on the labial surface of the implants to increase the zone of keratinized tissue (not shown).

FIG. 78.7 Clinical view of second-stage implant exposure surgery in a case with inadequate keratinized tissue. (A) Two endosseous implants were placed 4 months previously and are ready to be exposed. Note the narrow band of keratinized tissue. (B) Two vertical incisions are connected by crestal incision. If facial keratinized tissue is insufficient, it is necessary to locate the crestal incision more lingually so that there is at least 2 to 3 mm of keratinized band. (C) Buccal partial-thickness flap is sutured to the periosteum apical to the emerging implants. (D) Gingival tissue coronal to the cover screws is excised using the gingivectomy technique. (E) Cover screws are

removed, and heads of the implants are cleared. (F) Abutments are placed. Visual inspection ensures intimate contact between the abutments and the implants. (G) Healing at 2 to 3 weeks after second-stage surgery. (H) Four months after the final restoration. Note the healthy band of keratinized attached gingiva around the implants.

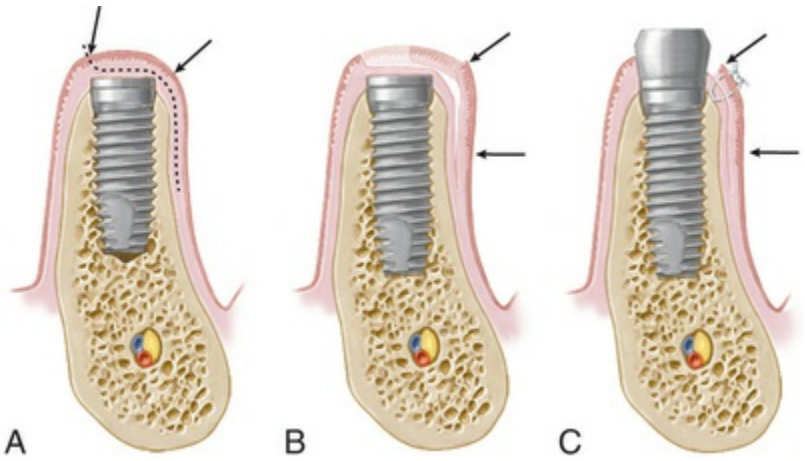

FIG. 78.8 Illustration depicting the use of a split-thickness flap that is repositioned to the labial surface to preserve and increase the amount of keratinized tissue. (A) Partial-thickness flap is created from the lingual aspect of the crest toward the labial surface to preserve the keratinized tissue on the crest (over the implant). Note: This tissue might be excised in a simple implant exposure. (B) The split-thickness flap is repositioned to the labial surface. (C) The flap is sutured to the periosteum at a more apical position preserving the amount of keratinized tissue *(arrows).* Finally, the remaining connective tissue over the cover screw (B) is excised with a sharp blade to expose the implant. Care should be taken to avoid removing keratinized tissue from the lingual aspect of the implant.

After the flap is repositioned and secured with periosteal sutures, the excess tissue coronal to the cover screw is excised, usually with a surgical blade (see Fig. 78.8B). However, if removal of this tissue would jeopardize the amount of remaining keratinized tissue around the lingual aspect of the implant, a similar partial-thickness

flap can be elevated and repositioned on the lingual side as well. Extra care must be taken when creating a split-thickness flap on the lingual surface of mandibular sites because the tissue is often very thin. Alternatively, a full-thickness lingual flap will be safer and will serve a similar purpose of preserving keratinized tissue on the lingual surface of the implant.

A sharp blade is used to eliminate all tissues coronal to the cover screw (see Fig. 78.7D). The cover screw is then removed, the head of the implant is thoroughly cleaned of any soft- or hard-tissue overgrowth, and the healing abutments or standard abutments are placed on the implant (see Fig. 78.7E–F). The fit of the healing abutments to the implants can often be visually evaluated. However, if it is not possible to visualize clearly the intimate connection between the implant and the abutment, an intraoral periapical x-ray film should be taken to confirm complete seating. Bone may need to be removed around the top of the implant to get the abutment to seat properly. Readers are referred to online material for a discussion of bone profiling.

Key Fact

In sites with limited keratinized tissue, a partial-thickness flap can be utilized to preserve and reposition the keratinized tissue. A partial-thickness flap is apically displaced and sutured to the periosteum. In cases without keratinized tissue, a free gingival graft may be harvested from the palate and sutured to the periosteum on the labial surface of the implants to increase the zone of keratinized tissue.

Postoperative Care

Once the implant is exposed and soft tissues are sutured, it is important to remind the patient of the need for good oral hygiene around the implant and adjacent teeth. Care should be taken during oral hygiene procedures to avoid dislodging any repositioned or grafted soft tissues. Direct pressure or movement directed toward the soft tissue from a provisional prosthesis can delay healing and should be avoided. Tissues should be monitored regularly, and the

provisional prosthesis should be adjusted as needed. Impressions for the final prosthesis fabrication can begin about 2 to 6 weeks after implant exposure surgery, depending on healing and maturation of soft tissues. Fig. 78.7 (parts G and H) shows the postoperative results in a clinical case after 2 to 3 weeks and 4 months, respectively.

One-Stage "Nonsubmerged" Implant Placement

In the one-stage implant surgical approach, a second implant exposure surgery is not needed because the implant is exposed (per gingival) from the time of implant placement (Fig. 78.9). In the standard (classic) implant protocol, the implants are left unloaded and undisturbed for a period similar to that for implants placed in the two-stage approach (i.e., in areas with dense cortical bone and good initial implant support, the implants are left to heal undisturbed for a period of 2 to 4 months, whereas in areas of loose trabecular bone, grafted sites, or minimal implant support, they may be allowed to heal for periods of 4 to 6 months or more).

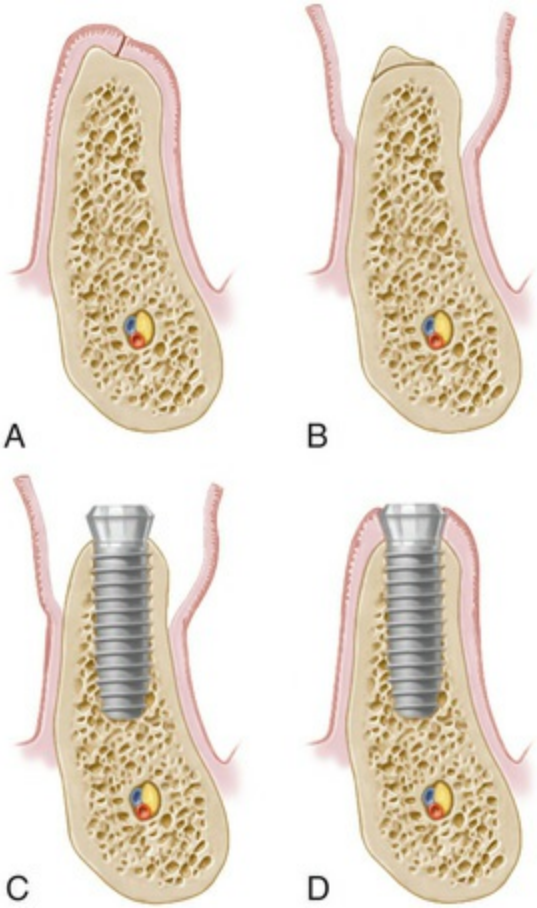

FIG. 78.9 Tissue management for a one-stage implant placement. (A) Crestal incision made along the crest of the ridge, bisecting the existing zone of keratinized mucosa. (B) Full-thickness flap is raised buccally and lingually to the level of the mucogingival junction. A narrow, sharp ridge can be surgically reduced or contoured to provide a reasonably flat bed for the implant. (C) Implant is placed in the prepared osteotomy site. (D) Tissues are adapted around the neck of the implant to achieve flap closure with the implant protruding through the soft tissues.

In the one-stage surgical approach, the implant or the healing abutment protrudes approximately 2 to 3 mm from the bone crest, and the flaps are adapted around the implant/abutment. As with the second-stage surgical procedures described, the soft tissues may be thinned, repositioned, or augmented at the implant placement surgery to increase the zone of keratinized tissue surrounding the implant.

Flap Design, Incisions, and Elevation

The flap design for the one-stage surgical approach is always a crestal incision bisecting the existing keratinized tissue (see Fig. 78.9). Vertical incisions may be needed at one or both ends to facilitate access to the bone or osteotomy site. Tissues can be thinned in posterior areas if desired but are generally not thinned in anterior aesthetic areas. Full-thickness flaps are elevated facially and lingually.

Implant Site Preparation

Implant site preparation for the one-stage approach is identical in principle to the two-stage implant surgical approach. The primary difference is that the coronal aspect of the implant or the healing abutment (two-stage implant) is placed approximately 2 to 3 mm above the bone crest and the soft tissues are approximated around the implant/implant abutment.

Flap Closure and Suturing

The keratinized edges of the flap are sutured with single interrupted sutures around the implant. Depending on the clinician's preference, the wound may be sutured with resorbable or nonresorbable sutures. When keratinized tissue is abundant, scalloping around the implant provides better flap adaptation.

Postoperative Care

The postoperative care for the one-stage surgical approach is similar to that for the two-stage surgical approach except that the cover screw or healing abutment is exposed to the oral cavity. Patients are advised to avoid chewing in the area of the implant. Prosthetic appliances should not be used if direct chewing forces can be transmitted to the implant, particularly in the early healing period (first 4 to 8 weeks). When removable prosthetic appliances are used, they should be adequately relieved and a soft-tissue liner should be applied.

Conclusion

It is essential to understand and follow basic guidelines to predictably achieve osseointegration. Fundamental protocols must be followed for implant placement (stage one) and implant exposure surgery (stage two). These fundamentals apply to all implant systems.

Case Scenario 78.1

Patient:

60-year-old Hispanic female

Chief Complaint:

"I'm ready for my implant."

Background Information

The patient has controlled hypertension. She is currently taking Atenolol. She is a nonsmoker. Tooth #3 was extracted with socket preservation 1 year ago. A sinus lift/bone augmentation procedure was completed 4 months after extraction due to a limited (4-mm) vertical height of native bone. Now, 8 months later, the patient presents for implant placement.

Current Findings:

Generalized healthy gingiva with history of moderate chronic periodontitis. Edentulous site #3 has adequate ridge width, mesial-distal dimension, and interocclusal space. There is a good zone of keratinized, attached tissue. Cone beam computed tomography (CBCT) scan reveals good healing and consolidation of bone grafted sinus. The native bone is type 3, with a loose trabecular pattern.

CASE-BASED QUESTIONS	SOLUTIONS AND EXPLANATIONS
1. You plan to place a 5 × 10 mm implant in site #3. How should the osteotomy be prepared?	**Answer: C** **Explanation:** The posterior maxilla has softer, loose trabecular bone, which reduces bone-to-implant contact. Overpreparing the osteotomy will remove an unnecessary amount of bone, making it more difficult to achieve primary implant stability. Bone tapping should only be performed in dense cortical bone. Additionally,

A. Overprepare the osteotomy site by using a 5-mm drill as the final drill. B. Complete the osteotomy site with a 4-mm drill, but perform bone tapping to facilitate implant insertion. C. Underprepare the osteotomy site by using a 3.75-mm drill as the final drill. D. Prepare the osteotomy site with reduced speeds (< 800 rpm) to avoid overheating the bone.	osteotomy sites should be prepared at 800 to 1500 rpm with a pumping motion and copious water irrigation to prevent overheating the bone.
2. Which of the following promotes bone-to-implant contact? A. Machined surface implant B. Roughened surface implant C. Bone-level implant D. Tissue-level implant	**Answer: B** **Explanation:** Implants with roughened surface topography (e.g., sandblasted or acid etched) increase the surface area of the implant to promote increased implant-to-bone contact and may result in shorter healing time.
3. If the patient did not have adequate keratinized tissue, when could soft tissue augmentation be performed? A. Prior to implant placement B. During the second stage of the procedure	**Answer: D** **Explanation:** Soft tissue augmentation can be performed at any time. However, the need for bone augmentation prior to or during implant placement may dictate that a free gingival graft be performed first to provide adequate keratinized tissue for flap management and suturing.

C. Following delivery of final prosthesis D. All of the above

CHAPTER 79

Localized Bone Augmentation and Implant Site Development

Perry R. Klokkevold

CHAPTER OUTLINE

Guided Bone Regeneration *(e-only)*
Localized Ridge Augmentation
Alveolar Ridge Preservation/Management of Extractions
Conclusion

One of the most critical aspects of creating an aesthetic implant restoration is surgical placement of the implant in a "prosthetically driven" position; doing so will restore the tooth in a natural position and emulate the natural emergence of the tooth from the

soft tissues. Implants placed without regard for prosthetic position often leave patients with dental restorations that are functionally and aesthetically compromised. To place implants in an aesthetically and functionally optimal position that is properly surrounded with bone, it is often necessary to reconstruct (or preserve) the alveolar ridge.

Periodontal bone loss, gingival recession, tooth loss, and long-term use of removable appliances typically result in alveolar defects that prevent the placement of implants in an optimal prosthetic position. It also leads to soft-tissue deficiencies that are aesthetically unacceptable. Fortunately, continuous innovations in regenerative materials and advances in surgical techniques have led to advanced implant procedures and an increased predictability in the reconstruction of alveolar ridge defects.[32,43]

Standard implant placement surgery, as described in Chapter 78, is based on adequate bone volume and quality in the desired implant location. The time-tested standard protocol allows for adequate remodeling and maturation of bone, with healing periods of 3 to 6 months. In recent years, the implant procedures have challenged these original conventions by placing implants in areas with inadequate bone volume, simultaneous with bone augmentation, and restoring or loading implants after shorter healing periods. This chapter presents an overview of surgical bone augmentation procedures used to correct or to prevent alveolar ridge deficiencies for the optimal placement of dental implants.

Guided Bone Regeneration

Much of what can be achieved with implant surgery and specifically with bone augmentation procedures is directly related to the fundamental concept of guided bone regeneration (GBR). Historically, augmentation or "regeneration" of alveolar bone that was lost following tooth removal, or from alveolar bone resorption or traumatic injury, presented a significant challenge for clinicians. Allowed to heal without the intervention of regenerative procedures, extraction site defects (especially those lacking a self-supporting bone structure) heal with fibrous connective tissue or scar formation and may not fill completely with bone. The

surrounding soft tissues collapse into the bone defect, leaving an alveolar ridge deficiency. Over time, the alveolar ridge continues to resorb, especially when removable prosthetic appliances are used.

Periodontal studies during the last several decades have led to new techniques and a new treatment approach referred to as guided tissue regeneration (GTR). Briefly, this concept is based on the principle that specific cells contribute to the formation of specific tissues. Exclusion of the faster-growing epithelium and connective tissue from a periodontal wound for a minimum of 6 to 8 weeks allows the slower-growing tissues to occupy the space adjacent to the tooth. Osteoblasts, cementoblasts, and periodontal ligament cells are then afforded the opportunity to regenerate a new periodontal attachment (defined by new bone and new connective tissue fibers inserted into newly formed cementum) on the previously diseased root surface. Chapter 63 includes a discussion on the concepts of GTR as related to periodontal regeneration.

The same basic principle of GTR has been applied to alveolar bone defects to regenerate new bone.[16] Using a canine model, Schenk and colleagues[52] demonstrated with histology that bone regeneration in membrane-protected defects healed in a sequence of steps that simulated bone formation after tooth extraction. They found that after blood clot formation, bone regeneration was initiated by the formation of woven bone initially along new blood vasculature at the periphery of the defect. The new vascular supply emanated from the existing bone bed (recipient site). Cortical perforations surgically created in the recipient site are thought to enhance the blood supply and cellular access to the bone grafted area. The woven bone, which is formed quickly with a disorganized, immature structure, was subsequently replaced by lamellar bone with an organized, mature structure. Over time, bone remodeling continued with new, secondary osteons being formed.

This concept employed the same principles of specific tissue exclusion but was not associated with teeth. Rather, it was bone that was being isolated from the surrounding soft tissues. Thus the term applied to this technique was guided bone regeneration. Because the objective of GBR is to regenerate a single tissue, namely bone, it is theoretically easier to accomplish than GTR, which strives to

regenerate multiple tissues simultaneously in a complex relationship.

Interestingly, long before the current concepts of GBR were introduced, Murray and coworkers[45] demonstrated that when a cavity with a source of osteoblasts and a blood supply was isolated from adjacent soft tissues, it could fill with bone, whereas if the space were not protected, it would fill with fibrous connective tissue. In addition to this observation, they suggested that a bone graft placed in the space might interfere with bone formation because the graft would need to be resorbed before bone could occupy the space.

Bone is a unique tissue that has the capacity to regenerate itself completely. Because of its rigid calcified structure, however, bone has specific requirements that must be respected to achieve regeneration. Because the calcified structure of bone is not conducive to perfusion, new bone formation is critically dependent on establishing an adequate blood supply through the ingrowth of new vasculature while maintaining rigid fixation or stabilization for bone formation. Any movement of the segments of bone relative to one another (even micromotion) during healing results in disruption of the blood supply and a change in the type of tissue formed in the site from mineralized bone to fibrous connective tissue. eTable 79.1 lists the biologic requirements for bone regeneration and the associated component of GBR surgical procedures needed to accomplish it.

eTABLE 79.1

Biologic Requirements for Bone Regeneration

Requirement	Surgical Procedure
Blood supply	Cortical perforations
Stabilization	Fixation screws, membrane tacks
Osteoblasts	Autogenous bone (graft or recipient site)
Confined space	Barrier membrane
Space maintenance	Tenting screws, bone graft materials
Wound coverage	Flap management, tension-free suturing

Barrier Membranes

Barrier membranes are biologically inert materials that protect the

blood clot and prevent soft-tissue cells (epithelium and connective tissue) from migrating into the bone defect, allowing osteogenic cells to be established. Membranes have been manufactured from biocompatible materials that are either nonresorbable or resorbable. The ideal properties of a barrier membrane are (1) biocompatibility, (2) space maintenance, (3) cell occlusiveness, (4) good handling properties, and (5) resorbability or ease of removal (nonresorbable). Advantages and disadvantages of the resorbable versus nonresorbable membranes are outlined next.

Nonresorbable Barrier Membranes

Various nonresorbable materials have been used as barrier membranes, including latex and Teflon. Teflon, an expanded polytetrafluoroethylene membrane (ePTFE, Gore-Tex Periodontal and Bone Regenerative Membranes, Gore and Associates, Flagstaff, Arizona), has been used extensively as a barrier membrane in both GTR and GBR procedures. A variety of shapes and sizes have been designed to be custom-fit around teeth and osseous defects. These barrier membranes are nonresorbable and thus require a subsequent surgical procedure to remove them. The advantage of a nonresorbable barrier membrane is its ability to maintain separation of tissues over an extended time. Unless the barrier is exposed, it can remain in place for several months to years. Typically, GBR membranes are removed after 6 to 12 months.

The disadvantage of a nonresorbable barrier membrane is that if it becomes exposed, it will not heal (i.e., wound will remain open) spontaneously and may become progressively more exposed. Exposed membranes become contaminated with oral bacteria, which may lead to infection of the site and result in bone loss. Therefore, exposed membranes must be removed. Contamination or early removal may also result in less bone regeneration.

Space can be maintained under a barrier membrane with bone graft material or tenting screws, thereby facilitating the regeneration of increased bone volume. Stiffer or titanium-reinforced (TR) membranes (Gore and Associates, Flagstaff, Arizona) with space-maintaining capabilities can regenerate bone without the need for bone grafts or a tenting apparatus.[41,52] Stiffer membranes are able to promote significant amounts of new bone

and maintain sufficient space without the addition of supportive devices. Ridge augmentation can be enhanced with a TR membrane in conjunction with implant placement in localized bone defects.[29]

Resorbable Barrier Membranes

The use of resorbable membranes continues to attract widespread interest, primarily because it eliminates the need for an additional surgery to remove them. Copolymers of polylactide and polyglycolide have been used to construct biodegradable membranes. Today, collagen-based resorbable barrier membranes are used extensively. The primary advantage of a resorbable membrane is the elimination of surgical reentry for membrane removal. In the case of a subsequent implant placement procedure (or exposure surgery), this may not be a significant advantage. The other advantage is that resorbable membranes are less likely to become exposed and are less problematic if they do become exposed.

A possible disadvantage is that many resorbable membranes degrade before bone formation is completed, and the degradation process may produce varying degrees of inflammation.[68] Developments include cross-linking of collagen to increase resistance to biodegradation and thus increase longevity of the barrier function.[21] Fortunately, the mild inflammatory reaction caused by bioresorbable membranes does not seem to interfere with osteogenesis. Another disadvantage is that resorbable barrier membranes are quite pliable. The lack of stiffness often results in collapse of the membrane into the defect area.[51] Thus resorbable membranes are best suited for situations that allow the graft material or hardware (tenting screws, plates) or the adjacent alveolar bone to maintain the desired dimensions.

Human histology has demonstrated that resorbable barrier membranes support the growth of new bone when used in GBR procedures for horizontal, vertical, sinus, and extraction socket defects.[22,24,42] They have also been shown to reduce bone resorption when used over a monocortical bone block to augment horizontally deficient ridges.[63] Geurs and colleagues[24] demonstrated that a bioabsorbable barrier membrane, used in a GBR procedure along with an allograft, was able to facilitate new bone formation. At

present, it can be stated that biodegradable membranes have the potential to support bone formation if they are supported by bone graft material to resist collapse and if they are long lasting enough to maintain their barrier function for extended periods in small to moderate bone defects.[33,34]

Bone Graft Materials

Unlike other tissues, bone has the unique capacity to completely regenerate itself. The major limiting factors are maintenance of space and structure for bone formation. Bone graft materials have been used to facilitate bone formation within a given space by occupying that space and allowing the subsequent bone growth (and graft replacement) to take place on the structure. The biologic mechanisms that support the use of bone graft materials are osteoconduction, osteoinduction, and osteogenesis.

Osteoconduction is the formation of bone by osteoblasts from the margins of the defect on the bone graft material. Materials that are osteoconductive serve as a scaffold for bone growth. They neither inhibit nor induce bone formation. They simply allow the normal formation of bone by osteoblasts into the grafted defect along the surface of the graft material. Osteoconductive bone graft materials facilitate bone formation by bridging the gap between the existing bone and a distant location that otherwise would not be occupied by bone.

Osteoinduction involves new bone formation through stimulation of osteoprogenitors from the defect (or from the vasculature) to differentiate into osteoblasts and begin forming new bone. This induction of the bone-forming process by cells that would otherwise remain inactive occurs through cell mediators that "turn on" these bone-forming cells. The most widely studied of these mediators is the family of bone morphogenic proteins (BMPs). See Chapter 80 for a review of BMP use in bone augmentation.

Osteogenesis occurs when living osteoblasts are part of the bone graft, as in autogenous bone transplantation. Given an adequate blood supply and cellular viability, these transplanted osteoblasts form new centers of ossification within the graft. Thus in addition to the bone formation from osteoblasts that already exist in the

defect, osteoblasts added as part of the bone graft also form ossification centers and contribute to the total capacity for bone formation.

Numerous bone graft materials have been used to aid in the reconstruction of bone defects. These range from allografts (derived from the same species) to xenografts (derived from a different species) and alloplast or synthetic graft materials. At a minimum, bone graft materials should be osteoconductive. Bone graft materials that are also osteoinductive are believed to be more advantageous than those that are only osteoconductive. eTable 79.2 lists the properties of different classes of bone graft materials.

eTABLE 79.2

Biologic Properties of Various Bone Graft Materials

Source	Osteoconductive	Osteoinductive	Osteogenic
Alloplast	Yes	No	No
Xenograft	Yes	No	No
Allograft	Yes	Yes/no?	No
Autograft	Yes	Yes	Yes

Demineralized freeze-dried bone allograft (DFDBA) is thought to have osteoinductive effects because viable BMPs within the donor tissue matrix are exposed by the decalcification process.[62] In contrast to this view, more recent reports suggest that bone augmentation with DFDBA is not osteoinductive because it does not contain the BMPs necessary to induce bone formation.[5,9] Schwartz and coworkers[53] reported that variations in the amount of bone formation induced by BMPs in DFDBA may be related to the source (i.e., donor tissue) of the bone and the techniques used to process it. In addition to processing variations, it has been demonstrated that young donor bone results in significantly greater quantities of BMPs retained in the bone allograft matrix compared with older donor bone.[54] Therefore the source of donor bone can greatly influence its osteoinductive capacity.

Bone graft materials help maintain space under a barrier membrane to facilitate the formation of bone within a confined space. Perhaps more important, bone graft materials should facilitate neovascularization and the migration of osteoprogenitors. Because the size of the bone graft particles determines the resultant

space available (between particles) for osseous formation, particle size has been carefully selected according to this concept. The typical size of bone graft particles ranges from 100 to 1000 μm, which is conducive to neovascularization and the ingrowth of bone. Bone forms in cones called osteons with a central blood supply. The dimension of these cones (100-μm radius) is determined by nutrient perfusion from the central vasculature supply of the osteon.

Autogenous Bone

Compared with other bone graft materials, autogenous bone is thought to be the best bone graft material because, in addition to being osteoconductive, it is osteoinductive and osteogenic. Furthermore, barring contamination, there is no risk of rejection or adverse reaction to the autogenous graft material. Intraoral sources of autogenous bone include edentulous spaces, maxillary tuberosity, mandibular ramus, mandibular symphysis, and extraction sites. Bone harvested from a recent extraction site (e.g., approximately 6 to 12 weeks healing) may have the advantage of increased osteogenic activity compared with other sites, which are more static and undergoing little or no osteogenesis. The maxillary tuberosity provides a more cellular source of autogenous bone compared with other sites. However, the trabecular nature of this site provides a lesser quantity of mineralized matrix, and the resultant total volume of bone available for grafting is often inadequate. For greater amounts of bone, it is more desirable to harvest bone from the mandibular ramus or symphysis. This bone, which is typically more cortical, can be harvested and used as a monocortical block graft or it can be ground or shaved into small fragments and used as a particulate graft.

Although the mandibular ramus and symphysis offer good sources of bone for grafting, clinicians are sometimes reluctant to harvest bone from these sites because of an increased risk of morbidity from the surgical procedure. Risks of surgery in the mandibular symphysis region include postoperative bleeding, bruising, wound dehiscence, damage to lower incisors, disfigurement, and injury to nerves. Nerve injury may be the most significant concern because it can be a long-term (possibly

permanent), annoying alteration in sensation of the lower lip, chin, anterior teeth, and gingiva for the patient. A more serious risk is the alteration of facial appearance, particularly when the facial muscles are completely elevated from the bone beyond the inferior border of the mandible. A condition referred to as "witch's chin" can occur when the facial muscles and overlying skin of the chin fall, causing a disfiguring sag of facial tissues after surgery.

A retrospective analysis of 48 chin graft–harvesting procedures suggests that maintaining a 5-mm margin of safety between graft harvest sites and vital structures (e.g., lower incisors, the inferior border of the chin, and the mental foramen) will minimize postoperative complications.[25] In the 48 procedures, postoperative sequelae included bruising of the lower face (48/48), bruising of the upper neck (6/48), and paresthesia of the lower lip and incisors (6/48). No patient experienced facial disfigurement or muscle prolapse (chin droop). Three of the six patients with paresthesia experienced transient symptoms and recovered completely within 2 months, whereas symptoms persisted longer than 6 months in the other three patients. Not surprisingly, the larger harvest defects (trephined six-ring sites) resulted in a higher incidence of paresthesia, which was longer lasting than that of the smaller defects (trephined four-ring sites). Harvesting bone in a custom-shaped "block" did not result in paresthesia, presumably because these harvest sites were smaller than the four-ring and six-ring trephine-harvested sites.

Observation of the following basic principles can minimize the risk of postoperative morbidity:

1. Carefully evaluate the harvest site for potential risks. A critical radiographic evaluation before surgery can identify individuals with inferior alveolar nerve branches that extend anterior beyond the mental foramen.
2. Use extreme care in making incisions laterally toward the mental nerve, and dissect the area with blunt instruments to locate the foramen.
3. Do not elevate and reflect muscle attachments beyond the inferior border of the mandible.
4. Limit bone cuts to an area at least 5 mm away from the tooth

apices, the inferior border of the mandible, and the mental foramen. Do not extend cuts or harvest bone deeper than 6 mm, and do not include both labial and lingual cortical plates.

5. Suture the wound in layers (muscle and overlying mucosa separately) to prevent postoperative wound separation.

When harvesting autogenous bone, regardless of site or method used, it is important to use techniques that prevent overheating and maintain viability of the bone cells. Exceeding 47° C (116.6° F) is known to cause bone necrosis.[19] Thus the use of drills, trephines, or saws to cut bone should always be done with profuse irrigation to keep instruments and bone cooled. Precision of osseous cuts can be facilitated with new technologies such as piezoelectric bone surgery (see Chapter 83).

Localized Ridge Augmentation

Patients often present with a request for implants after the tooth or teeth have already been lost, sometimes for years, and the alveolar ridge has resorbed. In these cases, the clinician is obligated to perform augmentation procedures to reconstruct lost alveolar bone dimensions so that implants can be placed in the proper (prosthetically driven) position.

Surgical reconstructive procedures for the preparation and placement of dental implants have become more numerous and complex. Depending on the size and morphology of the defect, various augmentation procedures can be used. These procedures are categorized according to the deficient dimension: horizontal or vertical. The fundamental bone grafting methods used to augment alveolar deficiencies include particulate bone grafts and monocortical block grafts. Barrier membranes can be used with bone grafts to reconstruct all types of alveolar bone defects. See Chapter 80 for a review of procedures used to achieve vertical augmentation. The proven principles of guided bone regeneration (GBR) and flap management must be followed to achieve good results. These include an adequate blood supply; maintaining a stable, protected space for bone growth; and achieving tension-free

flap wound closure.

Flap Management

Soft-tissue management is a critical aspect of bone augmentation procedures. Incisions, reflection, and manipulation should be designed to optimize blood supply and wound closure. The design and management of mucoperiosteal flaps must consider the increased dimensions of the ridge after augmentation as well as aesthetics and approximation of the wound margins. The surgical procedure must be executed with the utmost of care to preserve the vascularity of the flap and to minimize tissue injury.[1]

Several flap techniques maintain a "submerged" position of bone grafts and barrier membranes during the entire healing process, including a remote or displaced incision.[11,30] The advantage of a remote incision is that the wound opening is positioned away from the graft. On the other hand, a conventional crestal incision can be used, even in large supracrestal defects, as long as a periosteal releasing incision and coronal advancement of the flap achieve a tension-free closure.[35] Most reports suggest removing sutures approximately 10 to 14 days after surgery. It is also highly advisable to abstain from using removable prosthesis for several weeks (longer is better) after surgery to avoid placing pressure over the wound during the early healing phase.

General concepts for flap management associated with ridge augmentation include the following:

1. It is desirable to make incisions remote relative to the placement of barrier membranes (e.g., vertical releasing incisions at least one tooth away from the site to be grafted). In the anterior maxilla, keeping vertical incisions remote is also an aesthetic advantage.
2. Full mucoperiosteal flap elevation at least 5 mm beyond the edge of the bone defect is desirable.
3. The use of vertical incisions, although often required for surgical access, should be minimized.
4. Use of a periosteal releasing incision to give the flap elasticity and permit tension-free suturing is essential. This

permits complete closure without stress on the wound margins.

5. Removable appliances should not be inserted over the wound for 2 to 3 weeks or more to avoid postoperative trauma to the surgical site.
6. Wound closure should incorporate a combination of mattress sutures to approximate connective tissues and interrupted sutures to adapt wound edges.

Horizontal Bone Augmentation

A deficiency in the horizontal dimension of bone may be minimal, such as a dehiscence or fenestration of an implant surface, or it may be more significant, such that the implant would have more than one axial surface exposed while having some bone along the entire vertical length. Dehiscence or fenestration defects can usually be managed during implant placement because most of the implant is covered and stabilized by native bone. If the horizontal deficiency is large and the implant placement would result in significant exposure (i.e., implant body is significantly outside the alveolar bone), it may be better to reconstruct the bone first, in a staged approach, with a subsequent surgery for implant placement.

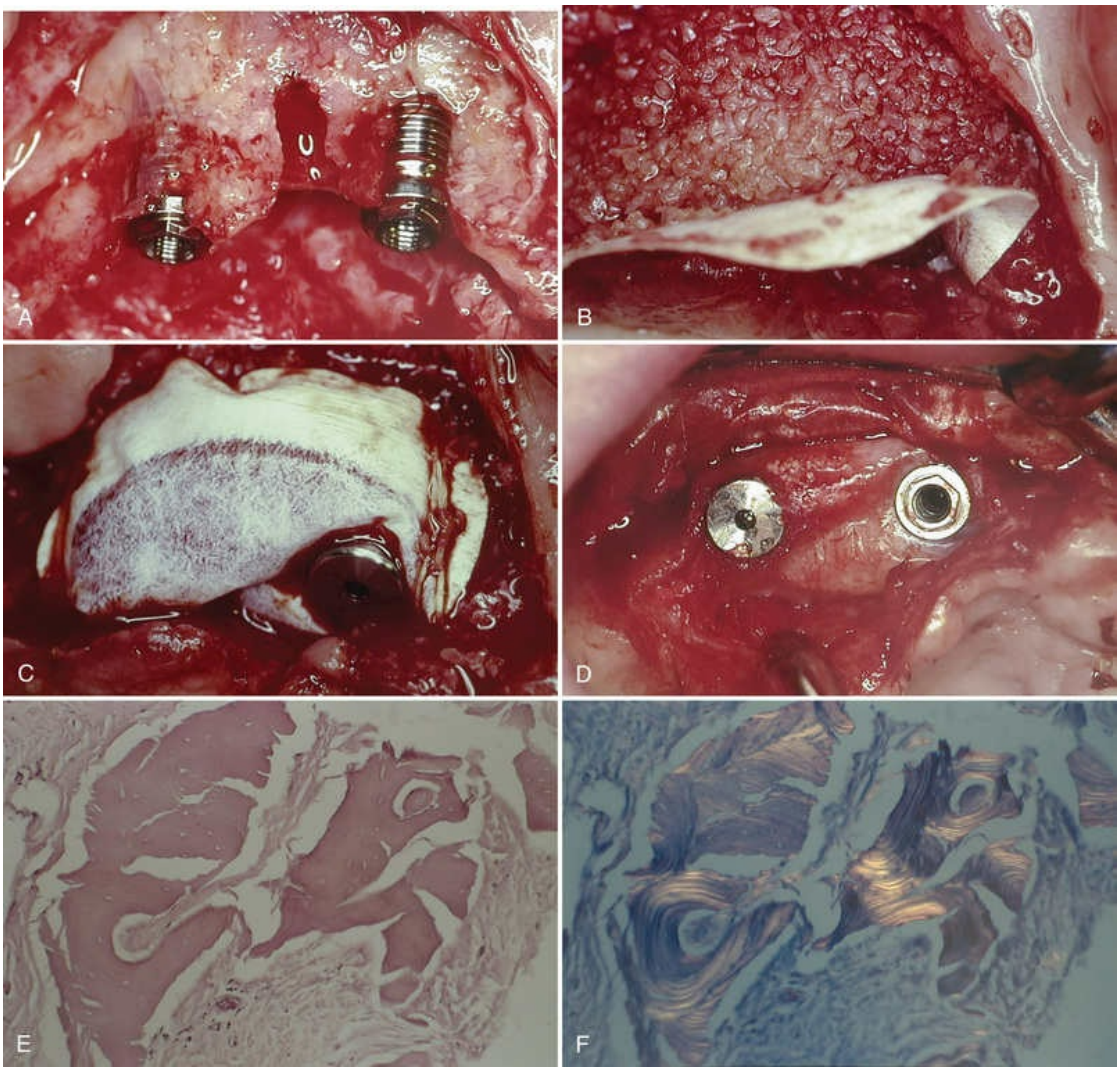
Although reconstruction of deficient ridges with bone grafts alone (i.e., without barrier membrane) has proved to be effective, variable resorption of the grafted bone has been reported. Preliminary results in a 1- to 3-year study using autografts harvested from the maxillary tuberosity showed an increased ridge width, but resorption of 50% of the graft volume was also noted.[60] Buser and colleagues[11] investigated the lateral ridge augmentation procedure using an autograft from the retromolar or symphysis area covered by a membrane in 40 consecutively treated patients and noted no clinical signs of resorption of the block graft. The researchers emphasized a remote incision technique, perforation of the cortex, stable placement of corticocancellous autografts, precise adaptation and stabilization (with miniscrews) of the polytetrafluoroethylene (ePTFE) membranes, and a tension-free primary soft-tissue closure. After 7 to 13 months, the sites were reopened for membrane removal and implant placement. Of the 40

patients, 38 exhibited excellent ridge augmentation, whereas two sites showed some soft-tissue encapsulation of the grafted bone.

Nevins and Mellonig[47] and Doblin and colleagues[17] reported an increased amount of new bone using freeze-dried bone allografts (FDBAs) with membranes, even in the presence of membrane exposure. The biopsies showed viable bone cells and visible osteocytes in lacunae, and a 9-month specimen showed no remaining allograft material.

On the other hand, there are some contradictory results using demineralized freeze-dried bone allograft (DFDBA) and membrane combinations.[3,8,9] In a human study, seven paired extraction sockets were grafted with either DFDBA or autologous bone. Sites were reentered and biopsied after 3 to 13 months to evaluate bone formation. Histologic specimens revealed dead particles of DFDBA with no evidence of bone formation on the surface and no evidence of osteoclastic resorption. Conversely, the autogenous sites revealed vascular channels with woven and lamellar bone. Some nonvital, cortical bone chips were observed with osteoclastic resorption.

eFig. 79.1 (online) shows an example of the lack of bone formation around DFDBA particles used in a ridge augmentation procedure after more than 20 months of healing under a nonresorbable ePTFE barrier membrane.



EFIG. 79.1 (A) Clinical view of the maxillary alveolar ridge after removal of a failed implant (center defect) and placement of two implants in the bone adjacent to this site. (B) The narrow ridge was grafted with decalcified freeze-dried bone allograft (DFDBA) particulate bone graft material. The graft material was completely covered by a nonresorbable, expanded polytetrafluoroethylene (ePTFE) barrier membrane. (C) The ePTFE barrier membrane was secured with the cover screw of one implant and sutures that were secured to the periosteum. (D) Clinical view of DFDBA-augmented ridge after more than 20 months of healing under a nonresorbable ePTFE barrier membrane. The membrane remained submerged throughout the healing period. (E) Hematoxylin-eosin (H&E) light microscopic view of a specimen harvested from the DFDBA-augmented ridge. Note there are no bone cells (osteoblasts, osteoclasts, or osteocytes), no bone

formation, and no osteoclastic resorption of DFDBA particles. There is no evidence of inflammation. Fibroblasts and connective tissue surround the “dead” DFDBA particles. (F) Polarized light microscopic view of the same specimen shown in (E) harvested from the DFDBA-augmented ridge. Note the appearance of lamellar layers demonstrating the presence of the DFDBA particles.

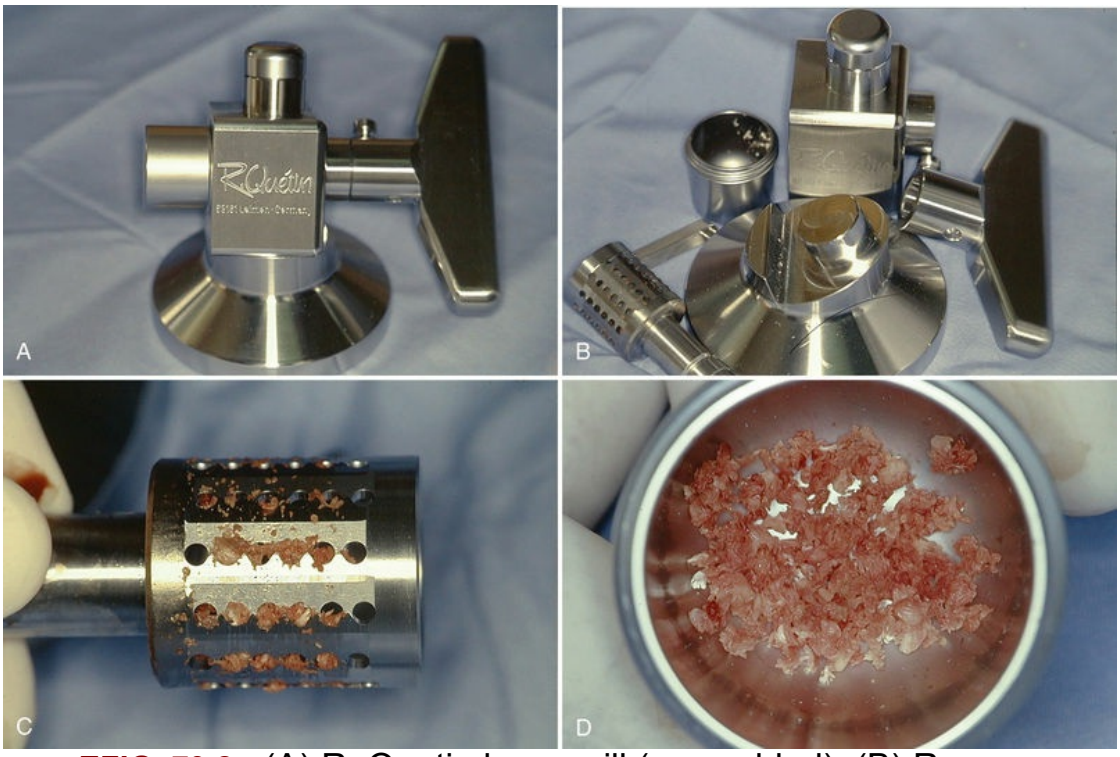
Key Fact

Dehiscence defects can usually be managed with simultaneous bone grafting during implant placement because most of the implant is covered and stabilized by existing native bone. If the horizontal alveolar deficiency is large such that the implant would be positioned with significant exposure (i.e., more than half of the implant diameter placed outside the alveolar bone), it may be better to reconstruct the bone first, in a staged approach, with a subsequent surgery for implant placement.

Particulate Bone Graft

Advantages of particulate bone grafts (or bone chips) are that the smaller pieces of bone demonstrate more rapid ingrowth of blood vessels (revascularization), larger osteoconduction surface, more exposure of osteoinductive growth factors, and easier biologic remodeling compared with a bone block for reconstruction of large defects. However, particulate grafts often lack a rigid, supportive structure and are therefore much more easily displaced as compared with monocortical block grafts.

Autologous particulate bone grafts can be harvested from any edentulous jaw site, either in smaller “particle” or in a larger “block” of bone. If the bone has been harvested in a block, a bone mill is necessary to grind or “particulate” the bone and prepare it for transplantation into the bone defect (eFig. 79.2, online).



EFIG. 79.2 (A) R. Quetin bone mill (assembled). (B) R. Quetin bone mill (disassembled). (C) Ground bone observed in blades of bone mill. (D) Autogenous block bone ground into evenly sized particulate bone with bone mill suitable for bone grafting.

Particulate grafts are indicated (1) in defects with multiple osseous walls that will contain the graft, or (2) in dehiscence or fenestration defects when implants are placed during the bone augmentation procedure. If a bone defect does not have sufficient osseous walls to contain the graft, the barrier membrane (placed in contact with the native bone) should be secured along the periphery with tacks, screws, or sutures. This bone graft and secured barrier membrane combination becomes an environment that is stable and supports new bone formation. Fig. 79.1 depicts the use of a barrier membrane in combination with a particulate bone graft to treat a mandibular horizontal defect.

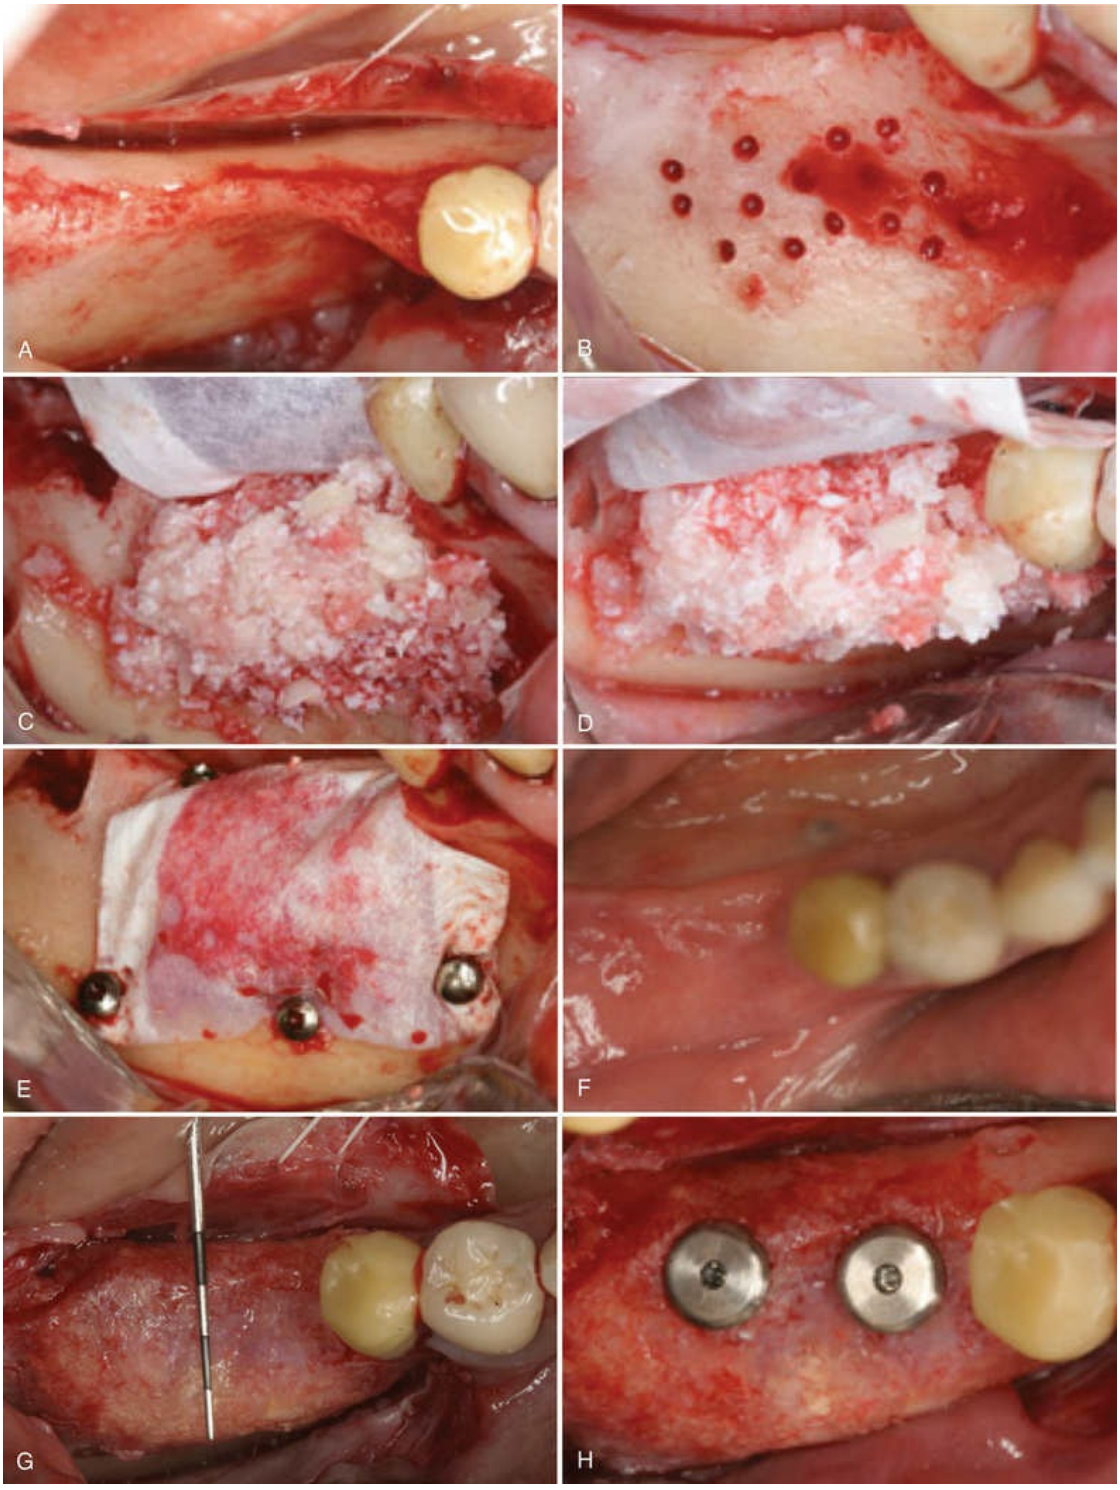


FIG. 79.1 Horizontal bone augmentation with expanded polytetrafluoroethylene (ePTFE) barrier membrane. Bone graft consists of a mixture of autogenous particles harvested from the alveolar ridge and Bio-Oss (Osteohealth Company, Luipold Pharmaceuticals, Inc., Shirley, New York). (A) Partially edentulous posterior mandible with narrow

buccolingual dimensions. (B) Cortical perforations made in buccal bone with small round bur to enhance blood supply to the grafted area. (E) Barrier membrane secured to native bone with fixation screws. (F) Clinical photograph of healed site prior to membrane removal. Soft-tissue closure maintained throughout healing without membrane exposure. (G) Clinical photograph of healed ridge after membrane removal. Dimensions of alveolar ridge are significantly wider as demonstrated with periodontal probe. (H) Two standard-diameter implants placed in a "prosthetically driven" ideal position. Notice there are no implant exposures. (Images courtesy Dr. Istvan A. Urban, Budapest, Hungary.)

Monocortical Block Graft

Horizontal alveolar deficiencies that might be challenging to reconstruct with particulate grafts can easily be reconstructed with a monocortical block bone graft. The technique uses a cortical block of bone harvested from a remote site and used to increase the width of bone. The block graft taken from an intraoral (e.g., mandibular symphysis or ramus) or extraoral (e.g., iliac crest or tibia) site is fixated to the prepared recipient site with screws. The overlying soft tissues can be separated from the bone graft with a barrier membrane or simply covered with the mucoperiosteal flap. Fixation hardware (screws and plates) should be removed after an adequate period of healing (approximately 6 months). The disadvantage of this technique is the biologic limitation of revascularizing large bone blocks. It therefore is crucial to have sufficient osteogenic cells in the residual surface of the surrounding bone and to limit this technique to horizontal augmentation and only minimal vertical defects.

Fig. 79.2 shows the use of a monocortical block graft to reconstruct a horizontal deficiency in the posterior right mandible. The patient presented with a loss of the buccal cortical plate of bone after a traumatic extraction of endodontically treated tooth #29. The

surgical extraction also resulted in an iatrogenic cut into the mesial root of tooth #30, rendering the tooth nonrestorable. The recommended treatment included extraction of tooth #30, monocortical block graft reconstruction of the buccal defect at site #29, and bone augmentation of the extraction socket #30. The procedure for this case follows.

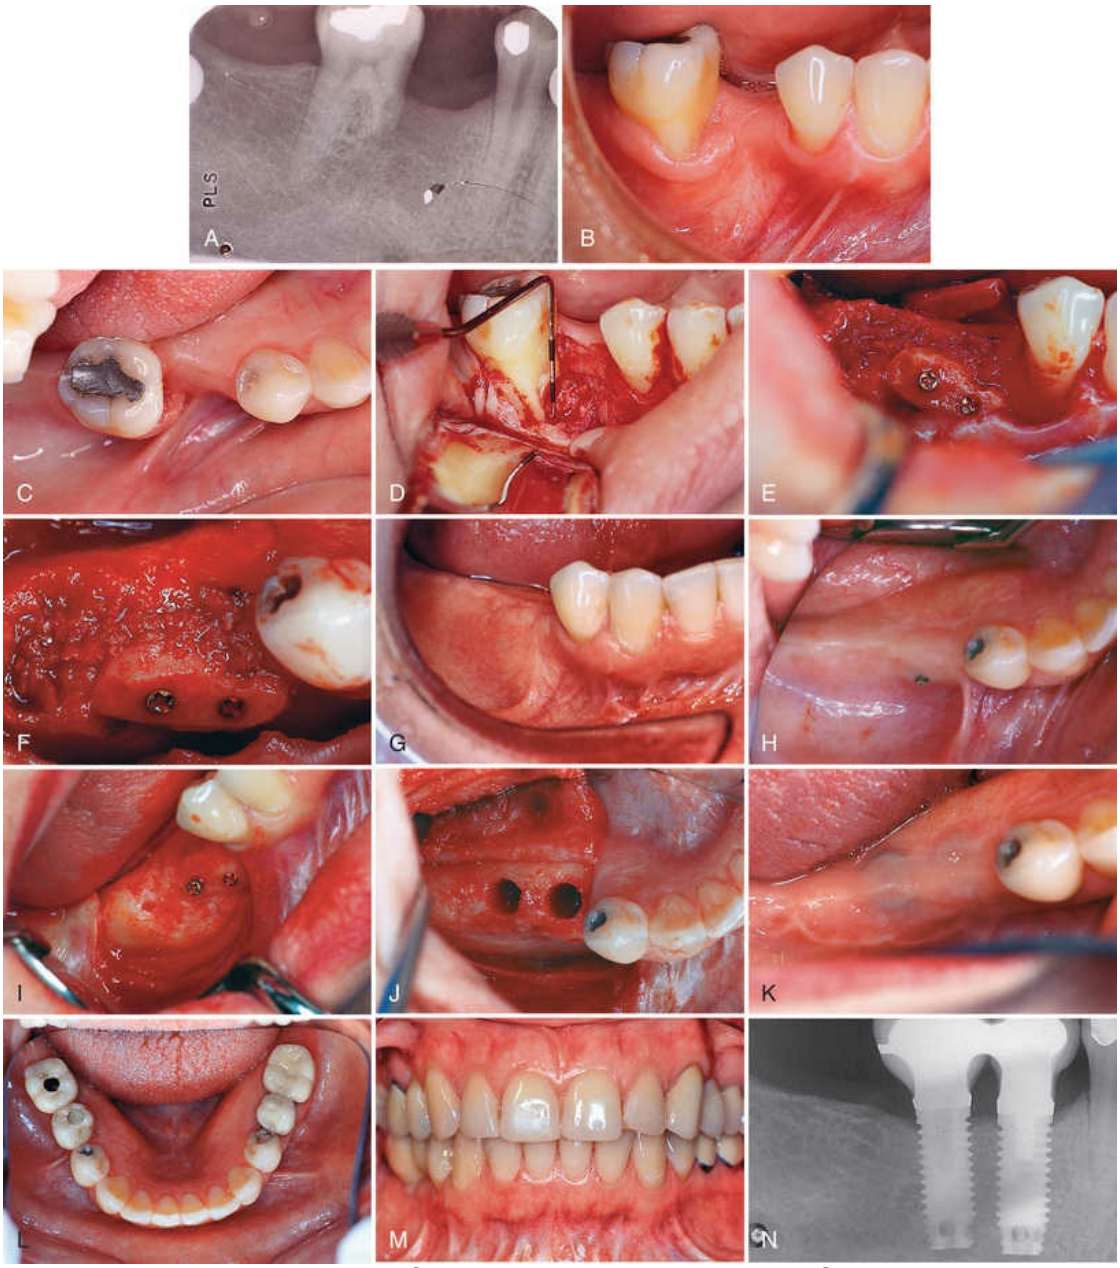

FIG. 79.2 Use of a monocortical block graft to reconstruct a horizontal deficiency in the posterior right mandible. (A) Periapical radiograph shows missing tooth #29 and damaged (i.e., cut) mesial root #30. (B–

C) Labial and occlusal views, respectively, of site reveal deficient alveolar ridge on buccal side of #29. (D) Full-thickness flap reflection reveals the extent of missing bone in the buccal aspect of site #29, as well as the periodontal defect and damaged mesial root #30. (E–F) Autogenous monocortical bone block graft secured to native alveolar bone with fixation screws. (G) Good tissue healing after block graft, with evidence of a widened alveolar ridge. (H) After 6 months of healing, posterior fixation screw is observed protruding through the mucosa. (I) Full-thickness flap reveals that bone resorption has resulted in exposure of part of the fixation screw. (J) Osteotomy prepared for wide-diameter implants, taking care to avoid making the labial bone "graft" too thin. (K) Complete closure and good healing of wound after implant placement. (L–M) Clinical photographs of completed restorations. (N) Final radiograph shows good restoration contours on wide-diameter implants.

Key Fact

Large horizontal alveolar deficiencies can be challenging to reconstruct with particulate grafts. In such a situation, it may be more manageable to use a monocortical block bone graft to reconstruct the area. The technique uses a cortical block of bone harvested from a remote site (e.g., mandibular symphysis or ramus) and fixated to the prepared recipient site with screws.

Procedure

Following local anesthesia, an incision was made in keratinized tissue along the crest and around the molar tooth (#30) with a vertical releasing incision mesial to the first bicuspid (#28). A full-thickness flap was elevated to expose the alveolar bone (see Fig. 79.2D). All soft tissues were thoroughly removed from the recipient site before bone grafting. After simple forceps delivery of tooth #30, the defect to be grafted was measured to determine the size of block graft to harvest from the mandibular symphysis. Several bleeding points were created using a small round bur.

The autogenous monocortical block graft was harvested from the mandibular symphysis. It was cut to an appropriate size and mortised to intimately fit the recipient defect site. Once properly positioned, the graft was fixated with two fixation screws (Leibinger, Kalamazoo, Michigan) that passed through the graft and into the existing native alveolar bone. A periosteal releasing incision was used to sever the periosteum from anterior to posterior and facilitate coronal advancement of the mucogingival flap.

After 6 months of healing, a full-thickness mucoperiosteal flap was elevated to expose the alveolar bone sites #29 and 30. Mild resorption of the monocortical block graft is evident. Notice that the position of the head of the fixation screws (especially the posterior screw) is more protruded than the grafted bone as a consequence of bone remodeling and resorption (see Fig. 79.2H–I).

The fixation screws are removed, and the sites are prepared in the usual manner for the placement of two-screw type, wide-diameter implants (Implant Innovations, Palm Beach Gardens, Florida). Care is taken to avoid preparing into the grafted site too wide or too far to the buccal surface because the grafted bone may be vulnerable to fracture or additional resorption (Fig. 79.2J).

Simultaneous Implant Placement

Large alveolar bone defects need to be augmented before implant placement and require a healing period of 6 months or longer. In selected cases, it is possible to perform a bone augmentation procedure simultaneously with the implant placement. It is essential to achieve good implant stability in the existing native bone so that endosseous integration can occur.

A predictable osseous defect to manage with simultaneous implant placement is the implant dehiscence or fenestration defect. *Fenestration* defects are exposures of the implant's axial surface that do not include the coronal aspect of the implant (Fig. 79.3). *Dehiscence* defects expose a part of the axial surface, including the coronal aspect of the implant, while maintaining sufficient bone volume around all remaining implant surfaces (Fig. 79.4). In a dehiscence defect, the implant remains within the confines of the existing bone.

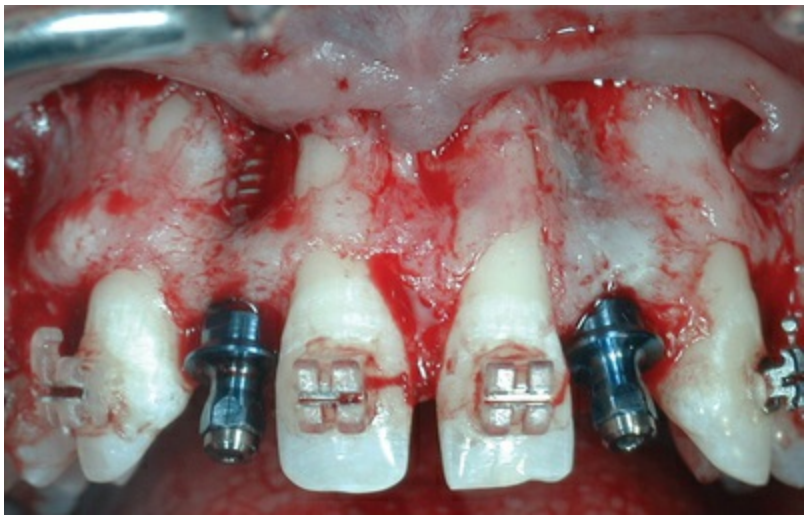

FIG. 79.3 Fenestration defect observed in very thin maxillary anterior sites. Implants placed in the maxillary lateral incisor positions demonstrating fenestration defects caused by the concavities in the apical area. Notice that the natural teeth (centrals and cuspids) also demonstrate fenestrations. Bone will grow across this type of defect in a predictable manner because the implants are stable; the defect is small and surrounded by bone.

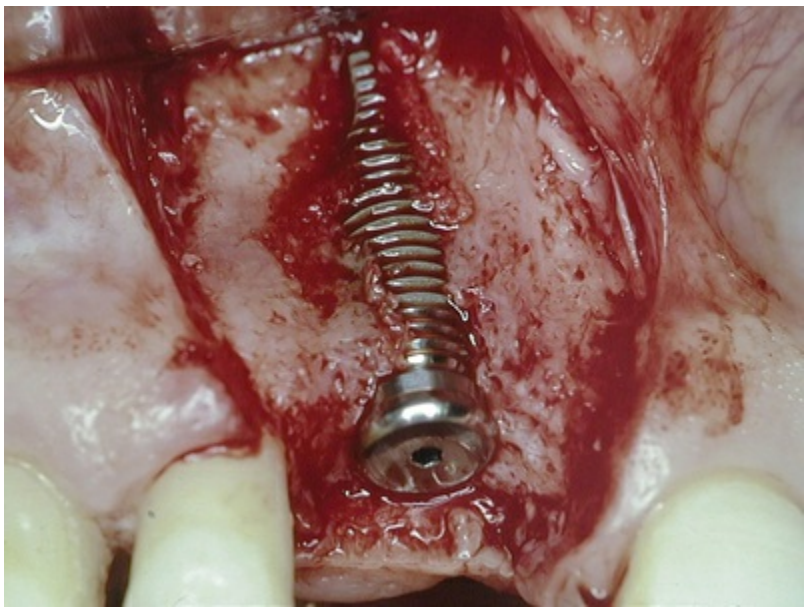

FIG. 79.4 Dehiscence defect observed during placement of an implant in the maxillary central incisor position. Note that the implant is completely surrounded by existing native bone except for the

facial surface, which is exposed. Bone will grow across this type of defect in a predictable manner because the implant is stable and the exposed surface is relatively flat with bone on all surfaces.

Fenestration and dehiscence defects have been managed with barrier membranes or simply with flap closure. Bone grafts have also been used. The only controlled comparison studies between membrane treatment and periosteal flap coverage of exposed implant surfaces in humans demonstrated that the membrane treatment was far superior with regard to bone fill.[14] Another controlled study in humans showed better results in the membrane groups; four of six sites (67%) treated with a membrane resulted in 95% to 100% elimination of the dehiscence and total coverage of the threads. In the control sites, only two of six sites (33%) showed moderate-to-complete bone fill.[48] All other clinical studies are in the form of case reports.[43] Fig. 79.5M demonstrates coverage of an implant dehiscence using a barrier membrane. Admittedly, without a biopsy it cannot be determined whether the tissue covering the implant is bone or firm connective tissue.[27,31]

(H) Atraumatic extraction of tooth #10 without tissue incision or tissue elevation. Palpation reveals no facial bone present, and dehiscence is expected. (I) Two months after extraction, the implant is placed with dehiscence defect. (J) Guided bone regeneration accomplished with ePTFE barrier membrane positioned over the dehiscence. (K) Final restoration. (L) Periapical radiograph of tooth #7 with a large radiolucent lesion around the apex and periodontal bone loss along the distal interproximal area. (M) Final radiograph of delayed implant placement. (N) Periapical radiograph of tooth #10. (O) Final radiograph. (A, B, C, F, G, J, M, N, and O from Klokkevold PR, Han TJ, Camargo PM: Aesthetic management of extractions for implant site development: delayed versus staged implant placement, *Pract Periodontics Aesthet Dent* 11:603, 1999.)

A 1-year multicenter study evaluating 55 Brånemark implants (i.e., machined-surface, external hex) with bone dehiscence in 45 patients, treated by ePTFE membrane alone, demonstrated an average bone fill of 82%.[15] The average initial defect height was 4.7 mm. The 1-year follow-up of these implants demonstrated a favorable response to loading. Of the 55 implants, a total of 6 failed, corresponding to a cumulative survival rate of 84.7% in the maxilla and 95% in the mandible, which is similar to previously published results for this implant design.

A clinical report on the use of titanium-reinforced (TR) membranes demonstrated the biologic potential to fill a large protected space in four patients.[29] Bone dehiscence at implant sites ranged from 5 to 12 mm (mean: 8.2 mm). They were covered with a TR membrane alone (no graft). Reentry after 7 to 8 months of submerged healing found complete bone coverage over all implants. Radiographic evaluation demonstrated the implants functioning with normal crestal bone support after 1 year.

No clinical comparisons are available in the literature evaluating the placement of bone grafts with or without barrier membranes on implant dehiscence defects. Most evidence supports the use of graft materials in conjunction with membrane treatment, especially the use of FDBA in conjunction with GBR. In a study with 40 patients, 110 implants were placed in conjunction with barrier membranes

and FDBA; a success rate of 96.8% was achieved with complete bone fill (defined as >90% fill of dehiscence).[50] This study reported a membrane exposure rate of 29% but noted little adverse effect on the bone regeneration.

With respect to ridge preservation, Becker and colleagues[7] reported the effect of barrier membranes and autogenous bone grafts on the preservation of ridge width around implants. They evaluated the ridge width around 76 implants in 61 patients from a case series database. Three groups were compared, including 34 implants treated with GBR (barrier membranes), 27 implants treated with autogenous bone grafts, and 15 implants placed without the need for ridge preservation/augmentation procedures (control group). The results revealed that implant sites treated with barrier membranes and autogenous bone grafts lost an average of 0.1 mm and 0.8 mm, respectively, more than the no-augmentation group.

Another study evaluated the possibility of regenerating bone around implants placed in extraction sockets.[35] Bone augmentation was achieved with human DFDBA particles mixed with tetracycline packed around the exposed implant surfaces. Implants and graft material were covered with ePTFE barrier membranes with complete flap closure for 4 to 6 months. The results demonstrated complete bone regeneration in all cases except when barrier membranes were prematurely exposed and removed. One-year posttreatment histologic evaluation of regenerated bone revealed remnants of the DFDBA graft particles in direct contact with vital bone tissue (woven and lamellar bone). Osteoblasts were observed and appeared to be actively engaged in bone formation adjacent to graft particles. Fig. 79.5 (parts L and M) demonstrates a simultaneous GBR and implant placement in a dehiscence defect.

Complications

Bone augmentation procedures used to increase the bone volume in deficient alveolar ridges have been successful and have enabled the placement of implants into prosthetically driven positions.[56] Unfortunately, these augmentation procedures carry an increased risk of morbidity and can require secondary surgeries to correct

problems resulting from the procedure.[67] The subsequent corrective surgeries required to correct problems add surgical time and complexity to the implant therapy.

Surgical complications are reported for a variety of bone reconstructive techniques.[18] A review assessed the number and types of complications associated with bone reconstructive procedures for endosseous implants.[61] The review of the literature (1976–1994) included 2315 implants in 733 autogenous block, particulate, and various other bone graft materials. Complications reported included bleeding, postoperative infection, bone fracture, nerve dysfunction, perforation of the mucosa, loss of a portion of the bone graft, pain, decubital ulcers, sinusitis, and wound dehiscence. Wound dehiscence seemed to have the most deleterious effect on implant survival. This finding emphasizes the importance of flap management.

Typical findings include less bone fill with early exposure and membrane removal versus retaining the membrane without exposure for 6 to 8 months.[30,58] Buccolingual ridge deficiencies were treated in a prospective study involving 19 patients using ePTFE membranes and miniscrews as fixation and tenting devices.[37] The group of defects, which healed uneventfully, yielded on reentry a 90% to 100% bone regeneration compared with the maximal volume of the space defined by the membrane placement. In the exposed-membrane group, the percentage of regenerated bone ranged from 0% to 62%. When a late membrane removal was performed (3 to 5 months after surgery), the regeneration varied between 42% and 62%. The authors concluded that the length of membrane healing and size of the defect played a significant role in the amount of new bone formation.[37]

Clinical Correlation

Bone is a unique tissue that has the capacity to regenerate itself completely. Bone augmentation procedures have been shown to be an effective way to increase the bone volume in deficient alveolar ridges, allowing the placement of implants in a proper, "prosthetically driven" position. Clinicians must appreciate that bone augmentation procedures have an increased risk of

complications, which may add procedures and complexity to the implant therapy.

A retrospective review of 233 patients treated with a variety of bone augmentation procedures to correct 331 alveolar ridge defects reported the incidence of soft-tissue dehiscence, infection, sensory disturbance, the need for additional augmentation procedures, and early implant failure.[26] Augmentation procedures included GBR, staged horizontal ridge augmentation, staged vertical ridge augmentation, and sinus floor elevation. Soft-tissue dehiscence occurred in 1.7% after GBR and 25.9% after staged horizontal augmentation. Infections were diagnosed in 2% of cases after GBR, 11% after staged horizontal augmentation, and 9% after staged vertical ridge augmentation. The need for additional bone augmentation was identified in 2% following GBR, 37% following staged horizontal ridge augmentation, and 9% after staged vertical ridge augmentation. Early implant failures occurred in 1.6% after GBR and in 12% after staged vertical augmentation. One patient experienced a temporary sensory disturbance following a staged horizontal ridge augmentation procedure.

Other authors have reported successful bone fill in situations in which membranes were removed early due to premature exposure.[47,57] A significantly greater fill of the osseous defect at the grafted sites was noted. The authors concluded that the regeneration of bone around the implants appeared most dependent on the anatomy of the bony defect at the time of implant placement.

Although the effect or amount of regenerated bone with regard to membrane exposure is somewhat contradictory, the goal should be to keep the membranes covered during the healing period so that the risk of infection and soft-tissue and aesthetic problems can be minimized or eliminated. Again, the importance of flap management for ridge augmentation procedures should be stressed. See Chapter 85 for more information and details regarding surgical complications and failures.

Alveolar Ridge

Preservation/Management of Extractions

Because tooth extraction (or loss) often results in alveolar ridge resorption or collapse, preservation of bone volume at the time of extraction is a desirable goal. Most bone loss after extraction occurs in the first 6 to 24 months.[12] Therefore when clinicians are afforded the opportunity to intervene at the time of extraction, preservation of alveolar bone should be initiated. A conservative approach to the management of extraction sites can eliminate or significantly reduce the necessity of advanced bone augmentation procedures.

When extracting a tooth and preparing for implant placement, alveolar bone resorption should be prevented or at least minimized. Experimental animal studies show that the use of a barrier membrane enhances the predictability of bone fill in the extraction site and therefore maintains original bone volume when compared with mucoperiosteal flap coverage alone.[8] Clinical studies also demonstrate the benefits of a regenerative approach to tooth extraction.[39,40,46] These authors found that a nonresorbable barrier membrane results in minimal resorption of alveolar ridge size and shape.

Although earlier studies have proposed the concept of treating extraction sites without flap closure (i.e., an exposed membrane used to cover the graft), more recent studies conclude that complete wound closure over the physical barrier might be associated with greater bone fill.[6,58] The decision about whether to advance a flap to achieve wound closure must be weighed against the soft-tissue changes that will be created (i.e., mucogingival junction discrepancies and aesthetic problems) and that may require subsequent surgical correction.

The histologic assessment of allograft healing in extraction sockets has been reported.[2,10,13,20,64,66] In a series of clinical studies, the authors evaluated the quality of bone as well as the dimensions of alveolar ridge preservation with various comparison of allograft properties. Extraction sockets were nonmolar sites that were grafted and allowed to heal for a prescribed amount of time. The alveolar dimensions were measured at the time of extraction and again at the time of implant placement. A core biopsy was harvested to

assess the percentage of new bone formation, residual bone graft particles, and connective tissue/nonmineralized tissue. In a study[64] evaluating the timing of bone formation in sites grafted with DFDBA, it was determined that more new bone (47.41% vs. 32.63%) was formed in sites allowed to heal for a long term (18–20 weeks) as compared with sites that healed for a short term (8–10 weeks), respectively. Another study[2] evaluating new bone formation with mineralized allograft found no greater new bone formation (45% vs. 45.8%) by waiting longer (27 weeks) as compared with the shorter healing period (14 weeks), respectively. When demineralized allograft was compared with mineralized allograft, there was significantly more new bone formation in sites grafted with DFDBA (38.42%) than in sites grafted with FDBA (24.63%).[66] The DFDBA group also had a significantly lower mean percentage of residual graft particles (8.88% vs. 25.42%). Finally, in another clinical study[20] comparing cortical versus cancellous FDBA, the authors found no difference in the percentage of new bone formation. There was a significantly greater percentage of residual bone graft particles in the cortical FDBA compared with the cancellous FDBA. Except for a great loss of lingual bone crest in the cancellous group of the latter study, none of the other studies found significant differences in clinical measurements between groups.

The timing of implant placement relative to the time of extraction has been widely debated. Depending on the quantity, quality, and support of existing bone, as well as the preferences of the clinician and patient, the placement of implants after tooth extraction can be immediate, delayed, or staged. By definition, *immediate* implant placement occurs at the time of extraction. Delayed implant placement is performed approximately 2 months after extraction to allow for soft-tissue healing. *Staged* implant placement allows for bone healing within the extraction site, which typically requires 4 to 6 months or longer.

Tooth extraction is managed with an atraumatic surgical technique that uses a narrow, flat instrument (e.g., Periotome, Hu-Friedy, Chicago) directed apically into the sulcus to sever the periodontal ligament and slightly expand the adjacent periodontal tissues. The tooth is elevated and removed with forceps using a gentle, rotational movement. Chapter 83 describes new techniques

for atraumatic extraction. Buccolingual forces are avoided to prevent damaging the integrity of the labial bone. No incisions are made, and care is taken to avoid soft-tissue reflection. In this manner, soft tissues maintain their structural anatomy, and the periosteum (blood supply to the bone) remains intact. If the tooth has multiple roots, curved roots, or other anatomic features that make removal difficult, it may be necessary to cut the tooth using a high-speed rotary drill or other cutting device and remove it in smaller pieces. It is important to cut only tooth structure and avoid cutting (overheating) bone when using high-speed rotary drills. The bone within the extraction site is completely debrided of soft tissue with surgical curettes. After debridement, the extraction site is thoroughly irrigated with sterile saline. Finally, the clinician can evaluate the bone level and socket anatomy to determine whether to bone graft the site and when to place the implant (immediate, delayed, or staged placement).

« Flash Back

The timing of implant placement relative to the time of extraction has been widely debated. Historically, during the early period of osseointegrated implants, immediate or early implant placement was discouraged. Today, these early tenents are being challenged with immediate implant placement and immediate provisionalization.

Delayed Implant Placement

Delayed implant placement shares some advantages of immediate implant placement, including extraction site preservation, and offers additional advantages. Unlike immediate implant placement, which is deficient of soft tissue for coverage, the delayed implant placement technique allows time for soft-tissue healing to close the wound.[28] The delayed placement technique still reduces the length of treatment by a few months because it is not necessary to wait for complete bone healing. Furthermore, because bone formation is active within the first few months after tooth extraction, the delayed technique may facilitate more osteogenesis adjacent to the implant.

The primary advantage of delayed implant placement is that, by allowing for soft-tissue healing and closure of the extraction site, mucogingival flap advancement is not necessary. This alleviates the need for additional surgeries to correct mucogingival discrepancies. Delayed implant placement also allows time for the resolution of infections that may have been present within the extraction site.

As with immediate implant placement, similar limitations of bone support and implant stability exist for delayed placement. The normal osseous healing that occurs within the first 2 months does not significantly affect the anatomy of the alveolar bone. Therefore limitations in bone support after 2 months of healing are similar to those that exist at the time of extraction.

Staged Implant Placement

Staged implant placement allows adequate time for osseous healing. This may be complete osseous healing of an extraction site without a bone graft (if circumferential bone support is good) or with a bone graft. Staged implant placement, by definition, allows for complete hard- and soft-tissue healing and permits the placement of implants into healed bone sites with adequate coverage by hard and soft tissues.[56] This eliminates the necessity of mucogingival flap advancement, allows for the resolution of preexisting infections, and prevents soft-tissue invasion. Furthermore, by using an extended healing period, the grafted bone also has the opportunity to become vascularized. Bone grafts performed simultaneously with implant placement do not share this advantage. The primary disadvantage of staged implant placement is the length of time required for bone healing.

Delayed Versus Staged Technique

Delayed and staged techniques for implant placement are demonstrated here in one individual using two extraction sites with similar bone morphologies in the anterior maxilla (see Fig. 79.5). Both techniques facilitate the aesthetic placement of implants into prosthetically driven positions. Delayed and staged approaches maintain alveolar bone volume, reduce the need for advanced bone augmentation, and eliminate the need for subsequent mucogingival

surgery. The timing and management of delayed versus staged implant placement are described in the next section.

To decide which implant placement method to use, the quantity and location of bone surrounding the tooth should be assessed. Once the patient has been anesthetized, a periodontal probe can be used to "sound" for the level of bone support through the soft tissue. Using this method, the bone levels surrounding the tooth can be mapped. Bone support that surrounds the extraction site can also be evaluated and confirmed after tooth removal by palpation, probing, and direct (internal) visualization.

If the tooth to be extracted has sufficient bone support on all surfaces, the extraction site can be expected to fill with bone without additional augmentation procedures, except when the labial bone is very thin. A simple extraction followed by a healing period of 4 to 6 months could be sufficient for complete osseous healing. Subsequently, an implant could be placed in the usual manner without the need for bone augmentation. Conversely, if little or no bone exists on the labial surface, it should be anticipated that the site would require bone augmentation to facilitate placement of the implant. In this case, bone grafting at the time of extraction can be used to maintain the alveolar ridge dimensions occupied by the tooth.

Immediate Implant Placement

The primary advantage of immediate implant placement is the reduction of the healing time, which translates to an earlier restorative time (i.e., shorter time to completion for the patient).[38,44,55,65] Because the implant is placed at the time of extraction, the bone-to-implant healing begins immediately with extraction site healing. Another advantage is that the normal bone healing, which generally occurs within the extraction site, takes effect around the implant. This bone-forming activity may enhance the bone-to-implant contact compared with an implant placed in a site with less osteogenic activity.

Possible disadvantages of immediate implant placement include the need for subsequent mucogingival surgeries to correct tissues moved by repositioned flaps and the need for bone grafting to fill

extraction site defects around the implant. If inadequate bone exists to stabilize the implant, immediate implant placement is not recommended.

When a two-stage implant is placed at the time of tooth extraction, the mucogingival flap is advanced, with releasing incisions, to cover the implant completely (an exception would be a one-stage implant). It may also be necessary to graft bone into the extraction site in areas that do not contact the implant to avoid soft-tissue invasion around the implant.[55] A 1-year study of 49 immediate extraction site implants treated by a membrane alone demonstrated a 93.6% bone fill. After 1 year (postloading), the implant success rate was 93.9%.[6]

Although some have advocated submerging implants placed in extraction sockets with flap advancement,[28] others have demonstrated success with a nonsubmerged approach. Implants may be placed in extraction sockets along with bone augmentation without flap advancement using a one-stage implant placement approach. Clinical studies evaluating the outcome of bone augmentation around implants placed in extraction sockets reveal good bone fill.[36] The placement of 21 transmucosal implants in immediate extraction sites treated with a barrier membrane were tested for the implant success rate and the percentage of bone fill. Twenty of the twenty-one transmucosal implants yielded complete bone fill and coverage of the entire plasma-coated implant surface.

A clinical report on the use of resorbable collagen membranes around extraction site implants demonstrated a variable degree of bone fill in nine patients.[49] More clinical review of the use of resorbable membranes for GBR is required because evidence is insufficient to evaluate the predictability.

In a study of 30 patients, the use of autografts alone in 54 extraction sites was highly effective for simultaneously placed implants completely within the envelope of bone.[4] The study showed that extraction sites, including those with a buccal dehiscence, could be treated with autografts alone. However, because nongrafted sites were not included, the absolute need to graft small defects adjacent to implants was not ascertained by this study. In another study, implants placed in extraction sockets were tested for their potential to regenerate bone with allograft alone, a

membrane alone, and a combination treatment.[23] Reentry confirmed 100% thread coverage in all but one implant in the "no-wall" group treated with DFDBA alone. A clinical study of five patients evaluated different treatment modalities for extraction site implants together with bone graft combinations.[59] This small study supported the concept that "non–space-making defects" are best treated with a combination of barrier membrane and an autograft or allograft as compared with treatment with a nonreinforced membrane alone (without a graft).

Immediate placement of an implant into the extraction socket in a one-stage approach along with immediate provisionalization is perhaps the best way to manage the hard and soft tissues following extraction (Fig. 79.6). The immediate placement of a provisional restoration is the best way to support the soft tissues (papilla and marginal gingiva) following tooth extraction.

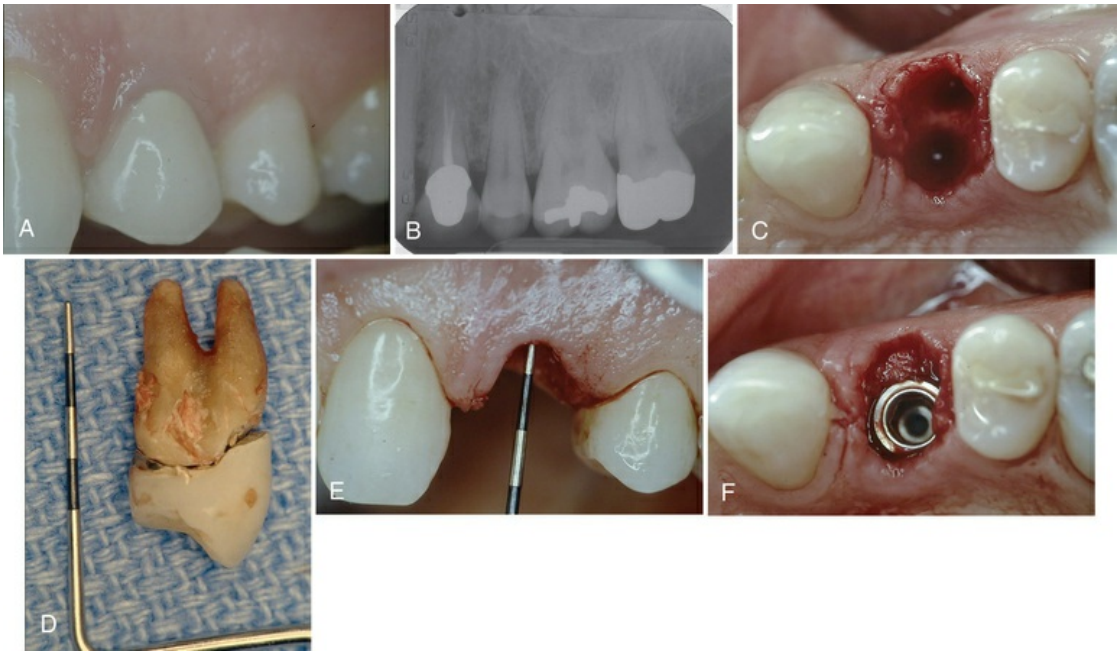

FIG. 79.6 Immediate implant placement after extraction of a maxillary first premolar. (A) Preoperative clinical photograph of tooth #12, which fractured and was deemed nonrestorable. (B) Periapical radiograph of tooth #12. It is root canal–treated and has a full-coverage porcelain-fused-to-metal crown. (C) Atraumatic extraction of tooth #12 without incisions or tissue elevation. (D) Extracted tooth. (E) Palpation and examination with probe reveals intact bony walls around the extraction socket. The facial bone wall is observed to be about 2 mm below the facial gingival margin. (F) The palatal aspect of the extraction socket is prepared, and a tapered implant is placed to emerge through the central fossa. Autogenous bone chips (harvested from the maxillary tuberosity) are condensed into the labial aspect of the extraction socket to support the facial bone and soft-tissue contours. (G) An immediate provisional restoration is fabricated (indirectly in the laboratory) and delivered at the time of implant placement. The palatal cusp is not replaced in this provisional to avoid function and the occlusion is checked for light centric contacts only. (H) Facial view of provisional restoration at the time of delivery. Notice how the interdental papilla and facial gingival margin are well supported by the contours of the provisional restoration. (I) Final restoration at time of delivery (approximately 4 months

after implant placement). (J) Final radiograph of definitive restoration.

Conclusion

Localized bone augmentation procedures allow clinicians to reconstruct horizontal alveolar ridge deficiencies and replace missing teeth with dental implants in a prosthetically driven position with natural appearance and function. In many cases, implants can be placed simultaneously with the bone augmentation procedure. In cases of advanced bone resorption, ridge augmentation before implant placement may be a better choice. Bone grafting procedures can also be used to preserve alveolar dimensions following tooth extraction. If adequate bone exists around the extraction socket to stabilize an implant, it may be possible to combine immediate implant placement and bone grafting in a simultaneous procedure. The predictable outcome of these procedures depends on several biologic principles that must be followed. Diagnosis, treatment planning, careful execution of the surgical treatment, postoperative follow-up, and appropriate implant loading are all important factors in achieving success.

Case Scenario 79.1

Patient:

55-year-old female

Chief Complaint:

"My front tooth is loose. It bothers me, and I would like an implant."

Background Information:

Patient is healthy. She does not smoke. She is not taking any medications. She reports a history of root canal treatment and crowns for two front teeth many years ago. Now the left central incisor is loose.

Current Findings:

Tooth #9 has class 2 mobility. There is no significant increase in probing pocket depth measurements. There is a fistula in the mucosa on the labial surface over tooth #9. The radiograph reveals an apical radiolucency and a large radiolucent lesion along the mesial aspect of tooth #9. Teeth #9 and #10 both have root canal treatment and crowns. Tooth #10 does not have any notable lesions.

CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. How should extraction site #9 be addressed? A. It should be allowed to heal without intervention. B. It should be bone grafted to preserve alveolar dimension. C. It should receive an immediate implant and simultaneous bone graft.	**Answer: B** **Explanation:** Alveolar bone dimensions, especially in the anterior maxilla, will diminish following tooth extraction. Thus it is important to preserve alveolar dimensions with bone grafting. Immediate implant placement may not be advisable depending on available bone to stabilize the implant.

D. None of the above.	
2. Bone grafting of the extraction site with mineralized allograft is superior to grafting with demineralized allograft. A. True B. False	**Answer: B** **Explanation:** Both clinical measurements (i.e., alveolar dimensions) and histologic assessment of extraction sites grafted with FDBA compared with DFDBA showed no significant differences.

CHAPTER 80

Advanced Implant Surgical Procedures

Perry R. Klokkevold, Istvan A. Urban, David L. Cochran

CHAPTER OUTLINE

Maxillary Sinus Elevation and Bone Augmentation
Supracrestal/Vertical Bone Augmentation
Growth Factors in Bone Augmentation *(e-only)*
Conclusion

The high predictability of endosseous dental implants has led to routine use and an expectation for success. Yet the ultimate success for any individual patient or any particular implant relies on a multitude of factors, the most important of which is the *availability of bone.* The loss of teeth, whether caused by disease or trauma, frequently results in severe deficiency of the alveolar bone. Horizontal bone deficiencies are managed quite predictably with localized bone augmentation procedures (see Chapter 79). However, vertical bone deficiencies can be much more challenging and less predictable. The posterior maxilla is challenging due to a

general lack of bone volume and the omnipresent poor bone quality of the area; that is, posterior maxillary bone often consists of a thin cortical shell filled with sparse trabecular bone. Edentulous sites, in any anatomic location, that suffer from significant vertical alveolar bone loss are especially challenging to reconstruct.

This chapter reviews advanced surgical procedures used to treat the most challenging type of bone loss, which is *a deficiency in vertical bone height.* Maxillary sinus elevation and bone augmentation, vertical bone augmentation, and distraction osteogenesis are reviewed. The role of growth factors in bone augmentation procedures is also discussed.

Maxillary Sinus Elevation and Bone Augmentation

Rehabilitation of the edentulous posterior maxilla with dental implants often represents a clinical challenge due to insufficient bone volume resulting from *pneumatization* of the maxillary sinus along with a loss of alveolar crestal bone from disease or remodeling. Prior to the utilization of bone augmentation procedures, patients with missing teeth and deficient bone in the posterior maxilla could only be rehabilitated with removable prostheses, short implants, or cantilevered restorations (i.e., supported by adjacent teeth). Historically, the failure rate for implants in the posterior maxilla has been significantly higher than failure rates for implants in other anatomic locations.[23] Consequently, procedures such as the maxillary sinus elevation and bone augmentation are needed to increase the amount of vertical bone height in the posterior maxilla for the placement of implants.

In 1980, Boyne and James[4] first described a procedure to graft the maxillary sinus floor with autogenous marrow and bone for placing an implant (blade type). Access to the maxillary sinus was gained through a "Caldwell-Luc" procedure (i.e., an opening into the maxillary sinus created at the anterior-superior aspect). Since then, several other techniques have been described, including variations on the lateral window osteotomy and a variety of techniques to lift the sinus floor from a crestal approach.

Various bone graft materials have been used to augment the maxillary sinus. The 1996 Consensus Conference on Maxillary Sinus Bone Grafting reviewed available data and concluded that allografts, alloplasts, and xenografts, alone or in combination with autogenous bone, can be effective as bone substitute graft materials for sinus bone augmentation.[24] More important, it was concluded that the sinus graft procedure with implant placement is a highly predictable and effective therapeutic modality for the rehabilitation of the posterior maxilla. Sinus floor elevation with bone augmentation is now a well-accepted procedure used to increase bone volume in the posterior maxilla. Numerous reports have validated the safety and efficacy of this procedure.[7,13,18,50] Implant success rates are equal to or better than that of implants placed in nongrafted maxillary bone (i.e., areas of the posterior maxilla with adequate height of existing native bone).[50] Thus bone augmentation of the maxillary sinus is a viable option for the vertically deficient posterior maxilla in which the interocclusal dimension is normal or only moderately increased.

Clinical Correlation

The normal process of pneumatization of the maxillary sinus often results in inadequate bone height to place implants in the posterior maxilla. The lack of bone height is further exacerbated by alveolar bone loss from periodontal disease or tooth loss.

Indications and Contraindications

As with any therapeutic procedure, treatment success depends on appropriate patient selection, careful evaluation of the anatomy, identification and management of any pathology, sound surgical procedures, and appropriate postsurgical management. The primary indication for maxillary sinus elevation and bone augmentation, specific for the placement of endosseous dental implants, is an alveolar bone height in the posterior maxilla that is deficient (e.g., less than 7 mm of existing vertical bone height). Other factors that must be considered include the health of the patient, the condition of the remaining dentition, and the likelihood

of a beneficial outcome. A thorough evaluation of the patient and the clinician's assessment will ultimately determine whether the procedure is indicated for any particular individual.

Contraindications to maxillary sinus elevation and bone augmentation are similar to contraindications for other surgical procedures, with the added consideration of contraindications specific to the maxillary sinus (Box 80.1). Patients must be in good general health and free of diseases that affect the maxilla or maxillary sinus. Local factors that are considered contraindications to maxillary sinus elevation and bone augmentation include the presence of tumors, maxillary sinus infection, severe chronic sinusitis, scar or deformity of the sinus cavity from previous surgery, dental infection, severe allergic rhinitis, and chronic use of topical steroids. Systemic contraindications to treatment include radiation therapy, uncontrolled metabolic disease (e.g., diabetes), excessive tobacco use, drug or alcohol abuse, and psychological or mental impairment.

Box 80.1

Contraindications for Maxillary Sinus Elevation and Bone Augmentation

Local Factors

Tumors or pathologic growth in the sinus
Maxillary sinus infection
Severe chronic sinusitis
Surgical scar/deformity of sinus cavity
Dental infection involving or in proximity to sinus
Severe allergic rhinitis/sinusitis
Chronic topical steroid use

Systemic Factors

Radiation therapy involving the maxillary sinus
Metabolic disease (e.g., uncontrolled diabetes mellitus)

Excessive tobacco use
Drug/alcohol abuse
Psychologic/mental impairment

Surgical Procedures for Sinus Elevation

The goal of sinus elevation and bone augmentation is to lift the schneiderian membrane from the floor of the sinus, raising it up into the sinus cavity to create a new, more superiorly located sinus floor with a space between it and the deficient alveolar ridge. The newly created space can then be filled with bone (or a suitable bone substitute material) to increase the total vertical height of bone in the posterior maxilla for implant placement.

The maxillary sinus bone augmentation procedure was first described in the 1960s by Boyne (unpublished oral presentations to United States [US] Navy Dental postgraduates, 1965–1968) and originally used as a preprosthetic surgical procedure for patients with large tuberosities and pneumatized sinuses.[3] To reduce the size of the tuberosity without creating an oral-antral defect, bone was grafted into the sinus cavity to increase the volume of bone within the maxillary tuberosity. After a period of healing, the tuberosity was reduced surgically from the alveolar ridge crest. As stated previously, Boyne and James[4] (1980) were the first to describe the use of the maxillary sinus bone-grafting procedure for placement of an implant (blade type) to retain a dental prosthesis. Greater use and further development of this procedure evolved along with the success of endosseous dental implants and the desire to replace missing posterior maxillary teeth with implant-retained restorations.

The variety of techniques used for sinus elevation and bone augmentation are defined by the anatomic location of the osteotomy used to gain access to the maxillary sinus. Specifically, four different anatomic locations have been described: (1) the superior lateral wall, or "Caldwell-Luc," opening, which is located high on the lateral wall of the maxilla just anterior to the zygomatic arch; (2) the middle lateral wall opening, which is located midway between the alveolar ridge and the zygomatic arch; (3) the inferior lateral wall opening, which is located at the level of the alveolar

ridge; and (4) the crestal osteotomy approach, which is an opening through the alveolar bone crest superiorly toward the floor of the sinus. At present, the most common procedure used for sinus elevation and bone augmentation is the lateral wall antrostomy (middle or inferior approach). The crestal approach osteotomy is also fairly common.

« Flash Back

Sinus augmentation is the most commonly performed procedure to overcome the problems associated with the pneumatized sinus. Several different approaches have been used to access the maxillary sinus for bone augmentation. Currently, the lateral window approach is the most frequently used technique. The crestal approach is popular as well.

Presurgical Evaluation of Maxillary Sinus

Presurgical evaluation of the maxillary sinus is primarily accomplished using radiographic examination techniques (Fig. 80.1). Several observations about the anatomy can be made with a periapical or panoramic projection, but the internal anatomy is more accurately assessed with a three-dimensional scan, such as computed tomography (CT) or cone beam CT (CBCT) scan. The maxillary sinus should be evaluated for any pathology, masses, or the presence of septa. If three-dimensional scans are available, the lateral wall should also be evaluated for the presence of medium or large intraosseous vascular channels (see Fig. 58.15). Medium- to large-sized vessels occasionally traverse the lateral wall of the maxillary sinus, and identifying them prior to surgery helps to avoid a bleeding problem during surgery (see Chapter 58).[31]

from cone beam scan. Note the presence of maxillary septa in the premolar region. (C) Cross-sectional image in premolar region showing about 6 mm of bone height and the presence of maxillary septa. (D) Cross-sectional image in molar region showing about 2 mm of bone height.

Simultaneous Implant Placement

Simultaneous implant placement is possible with sinus elevation and bone augmentation procedures as long as the implant can be stabilized in the desired location with the existing native bone (eFig. 80.1).

(C) Preoperative, cross-sectional image in molar region demonstrating 5.3 mm of vertical bone height. (D) Postsurgical radiograph of graft and implants in place.

It has been suggested that a minimum of 5 mm of existing native bone in the alveolar crest is required for simultaneous implant placement. However, some clinicians claim that it is possible to place implants simultaneously with as little as 1 mm of remaining bone.[29,58] The most important factor in determining whether implants can be placed at the time of sinus bone augmentation is the ability to achieve implant stability in the existing bone rather than any predetermined measure of bone height. Factors that influence implant stability include bone height, bone quality, precision of osteotomy preparation, and the surgeon's skill. If the amount and quality of existing native bone is not sufficient to place and stabilize implants at the time of bone augmentation, then implants should be placed at a subsequent surgery after an appropriate healing period (Fig. 80.2).

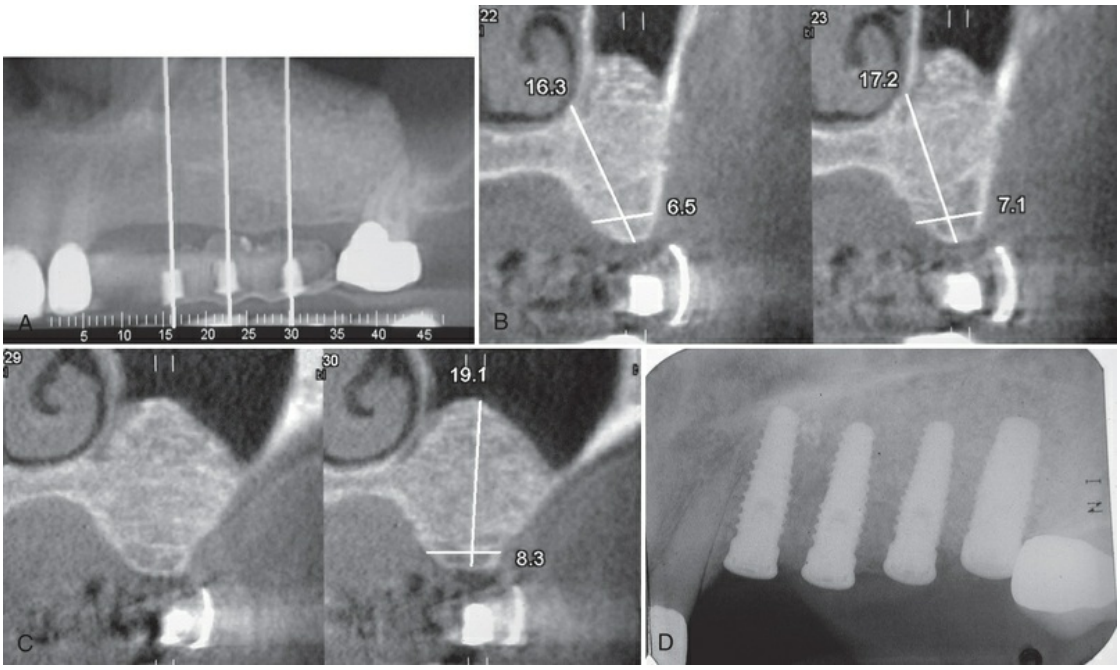

FIG. 80.2 Staged implant placement after sinus elevation and bone augmentation procedure. Same patient as in Fig. 80.1. See preoperative radiograph and preoperative cross-sectional images. (A) Postsurgical panoramic view of bone-augmented maxillary sinus. The maxillary left cuspid has been extracted because of a vertical fracture. (B) Postsurgical cross-sectional image in premolar region demonstrating more than 17-mm vertical bone height. (C) Postsurgical cross-sectional image in molar region demonstrating 19.1-mm vertical bone height. (D) Postsurgical radiograph of implants placed in the previously grafted maxillary sinus (and cuspid site).

Bone Graft Materials

Autogenous bone is often referred to as the gold standard for bone augmentation because of its osteoconductive, osteoinductive, and osteogenic properties.[4] However, harvesting autogenous bone from intraoral or extraoral locations creates a second surgical site with additional morbidity. Numerous studies have demonstrated clinical success using many variations of bone graft materials and combinations.[24,50]

Several clinical studies and reports have attempted to evaluate the maxillary sinus augmentation procedures using a variety of bone-grafting materials, including autogenous bone from the iliac

crest or oral cavity and bone substitutes such as freeze-dried demineralized bone, resorbable and nonresorbable hydroxyapatite, and xenografts. However, only a few studies have critically evaluated the long-term clinical outcome of this procedure, and most have used a small study population. Short- to long-term clinical studies of dental implants placed into grafted sinuses demonstrate an equivalent or higher survival rate as compared with implants placed in native maxillary bone (i.e., without the need of sinus augmentation).[24,50] The results of these studies support the clinical predictability of maxillary sinus augmentation procedures for the rehabilitation of the edentulous posterior maxilla with implant-supported prostheses (Fig. 80.3).

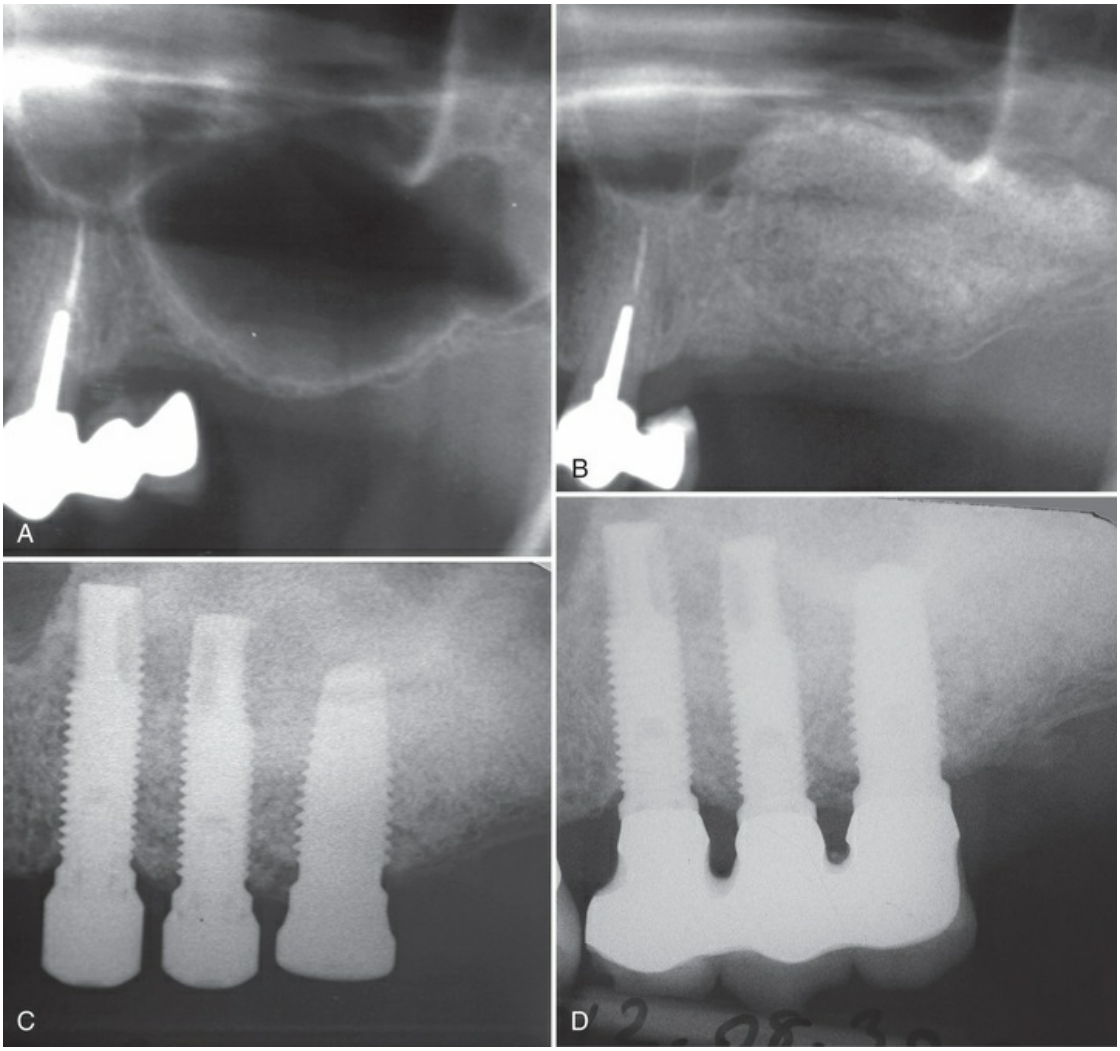

FIG. 80.3 Long-term follow-up of patient presenting with minimal residual crestal bone height. (A) Preoperative radiograph demonstrates minimal

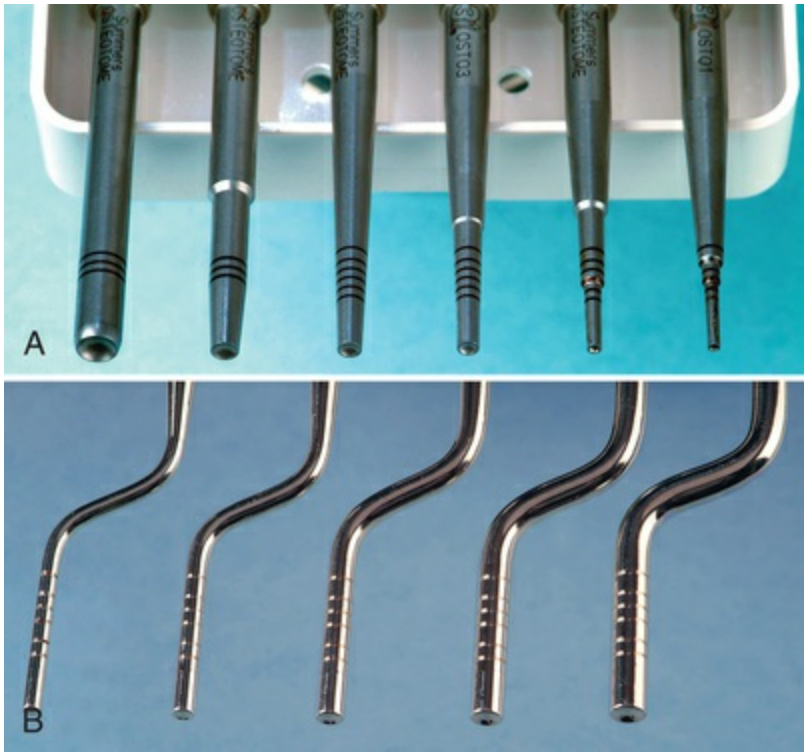
residual crestal bone height. (B) Postoperative radiograph demonstrates sinus graft healing after 6 months. (C) Abutment connection of implants after 6 months of submerged healing. The three distal implants were placed into augmented bone. (D) Periapical radiograph demonstrates stability of crestal bone around implants at 10 years loading. (From Urban IA, Lozada JL: A prospective study of implants placed in augmented sinuses with minimal and moderate residual crestal bone: results after 1 to 5 years, *Int J Oral Maxillofac Implants* 25:1203–1212, 2010.)

The use of bone-substitute graft materials can reduce the morbidity introduced by a second surgical site while maintaining equally good implant success rates.[24] Anorganic bovine bone-derived mineral (ABBM) (Bio-Oss, Geistlich Pharma AG, Wolhusen, Switzerland) has also been utilized successfully for sinus augmentation.[55] (ABBM has also been referred to in the literature as *deproteinized bovine bone mineral, deproteinized anorganic bovine bone,* and *anorganic bovine bone.*) This graft material has demonstrated good dimensional stability and high implant survival rates.[13] These bone-substitute graft materials form an osteoconductive scaffold for bone growth but do not have any osteoinductive properties. A possible exception is demineralized freeze-dried bone allograft (DFDBA). This material has demonstrated osteoinductive potential but has not proved to be particularly advantageous in the maxillary sinus bone augmentation.[24,54] In fact, the bone volume gained with the use of DFDBA is less than that achieved with mineralized graft materials. Presumably the lesser bone volume achieved with DFDBA is a result of moderate postoperative shrinkage of this material.

Crestal Osteotomy Technique

In cases with moderate bone height (e.g., 7–9 mm) that require limited sinus bone augmentation, a crestal approach to elevation may be desirable. The osteotome technique is a procedure that uses osteotomes (eFig. 80.2) to compress bone (internally from the alveolar crest upward) against the floor of the sinus, ultimately leading to a controlled "inward fracture" of the sinus floor bone along with the schneiderian membrane, creating a "tented" space

for grafting.



EFIG. 80.2 Osteotome instruments. (A) Straight osteotomes. (B) Offset osteotomes.

The osteotome sinus floor elevation (OSFE) technique was described by Summers.[42,43] It is considered to be a conservative approach to sinus elevation, but it is also a "blind" technique because it does not allow the operator to visualize the schneiderian membrane during the osteotomy. For this reason, it is a technique-sensitive procedure as well (i.e., the operator must "feel" the bone fracture and the membrane elevation). The increased vertical bone height can only be observed with radiographs that, if successful, will show a raised radio-opaque dome at the treatment site within the sinus cavity. Radiolucent graft materials such as DFDBA will not be apparent in the immediate postoperative radiograph.

Procedure

An osteotomy site is prepared with a series of drills (e.g., initial drills used for implant site preparation) to a depth that is approximately 1 to 2 mm from the floor of the maxillary sinus.

Osteotomes are used to increase compressive forces gradually against the floor of the sinus by adding incremental quantities of graft material until the floor of the sinus fractures inward (Fig. 80.4). The impact force needed to fracture the sinus floor is typically achieved with careful tapping of the osteotome with a mallet. Care must be taken to prevent over-insertion of osteotomes beyond the level of existing sinus floor bone to avoid instrument perforation through the schneiderian membrane. After the controlled inward fracture of the maxillary sinus floor, bone graft materials continue to be slowly introduced, through the osteotomy site and into the maxillary sinus, which continues to elevate the membrane and thus allows a vertical expansion of the bone height in a localized area of the maxillary sinus. This latter elevation of the membrane is achieved by simply pushing graft material into the site with the osteotome alone (i.e. without using the mallet). Once the sinus membrane is elevated with bone graft material to the desired height, the implant osteotomy can be completed. The final implant osteotomy drill is used to finish preparing the lateral walls to a depth of the native bone only (i.e., full depth drilling is not necessary) and the implant is inserted. Multiple individual sites can be elevated and prepared simultaneously through separate osteotomy sites.

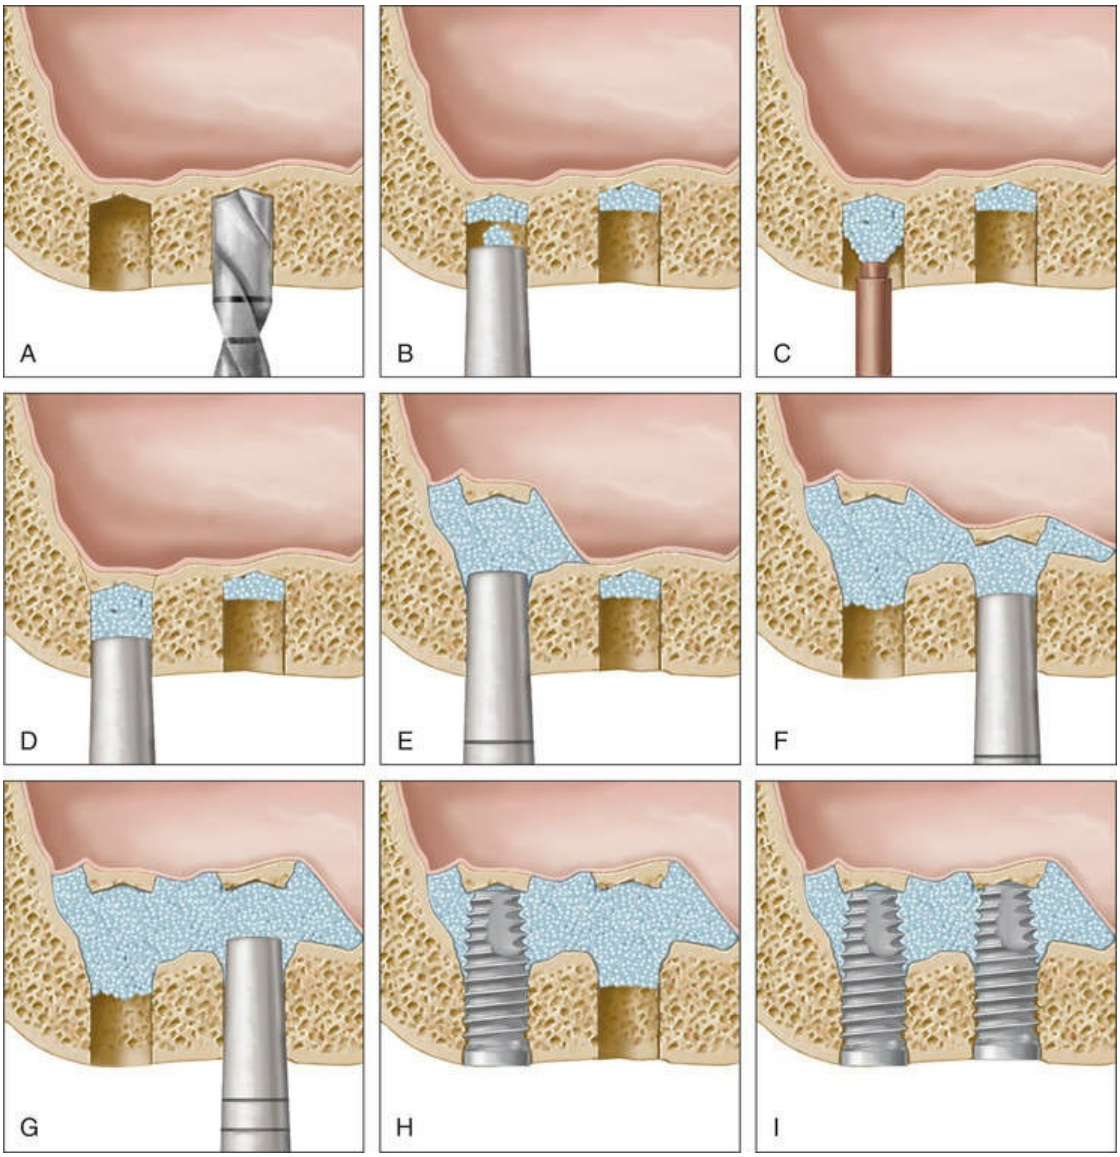


FIG. 80.4 Illustration of the osteotome sinus floor elevation (OSFE) technique. (A) Osteotomy prepared with drills to a depth that is near the maxillary sinus floor. (B) Graft material introduced into osteotomy and condensed with osteotome. (C) Additional bone graft material is added to the osteotomy. (D) Bone graft continues to be condensed by osteotomes. (E) This process is continued until floor of sinus is “fractured” up internally and the floor is lifted with the bone graft material. (F) Continuation of process shown in E for second site. (G) Bone graft material continues to be added gradually to both sites with osteotome condensation to elevate the schneiderian membrane away from the bone (maxillary sinus walls) until sufficient height and volume are created for the placement of implants. (H) The coronal aspect of the

osteotomy is carefully prepared for the placement of implants (instrumentation not shown), and the implant is placed. (I) Final view of two implants placed in the grafted maxillary sinus using the OSFE technique.

Published reports of this technique have demonstrated increased bone height from 2 to 7 mm (average, 3.8 mm).[47] Thus the crestal approach is a useful technique for increasing the vertical height of bone up to approximately 4 mm. If more vertical bone height is needed, the lateral wall osteotomy approach may be more advantageous. In addition to the usual precautions and contraindications for sinus elevation and bone augmentation procedures, the osteotome technique may be contraindicated for sinuses that have an acutely sloped floor or septa in the location of the planned osteotomy. An acutely sloped sinus floor will tend to deflect the osteotome in an undesirable direction rather than allowing the osteotome to penetrate into the sinus space, and the presence of septa makes it virtually impossible to fracture the sinus floor inward. Box 80.2 provides additional precautions and clinician comments on using the osteotome technique. Several new instruments and techniques have emerged that improve the ability to create a crestal approach osteotomy while avoiding trauma or injury to the schneiderian membrane. These instruments/techniques vary from selective rotary drill systems to piezoelectric bone surgery. See Chapter 83 for a description of piezoelectric bone surgery.

Box 80.2

Clinician Comments on Use of the Osteotome Technique

Clinical Perspective 1

The osteotome procedure involves repeated tapping of osteotomes with a mallet to create the necessary pressure to fracture the floor of the maxillary sinus. This tapping can be bothersome to some individuals, especially patients who are not sedated for the procedure. The tapping procedure tends to be more bothersome for

patients with dense cortical bone and for those with loose trabecular bone. In fact, a specific postoperative complication, called *benign paroxysmal positional vertigo* (BPPV), has been associated with the osteotome sinus elevation technique. During the osteotomy preparation and sinus floor elevation, the trauma induced by percussion of the osteotome with the surgical hammer, along with hyperextension of the neck during the operation, can displace otoliths in the inner ear and induce BPPV.

Clinical Perspective 2

The osteotome technique requires that the osteotome be properly aligned in the direction of the long axis of the planned implant. Thus patients must be able to open wide enough to allow a direct insertion of the osteotome into the osteotomy site. Offset osteotomes are available that can facilitate the correct angulation (see eFig. 80.2B, online).

Key Fact

Published reports of the crestal osteotomy technique have demonstrated increased bone height from 2 to 7 mm (average, 3.8 mm). Significantly more bone height increase is typically possible with the lateral window approach. When more than 4 mm of bone height increase is desired, the lateral window approach may be advantageous.

Lateral Window Technique

The lateral window technique is probably the most effective and efficient way to access the maxillary sinus for bone augmentation. In this procedure, an opening into the maxillary sinus is created in the lateral wall to elevate the schneiderian membrane and to place bone graft in the space immediately superior to the existing alveolar bone. The lateral wall osteotomy can be prepared with a high-speed drill (carbide or diamond) or a piezoelectric bone surgery device (see Chapter 83). It is also possible to prepare the lateral wall osteotomy with rotary instruments that are designed to selectively cut bone. Some clinicians will prepare the lateral window outline

only, leaving the center bone attached to the membrane as it is elevated and rotated into the sinus, thus becoming the superior wall of the space created for bone grafting (Fig. 80.5A–C). Other clinicians prefer to eliminate the bony window entirely by reducing or removing it completely (Fig. 80.5D–F). With the former technique, it is important to create a window that is small enough, relative to the mediolateral width of the maxillary sinus, to allow the "window" to be pushed completely into the sinus cavity without prematurely hitting the medial wall. If the window cannot be inserted completely, it must be carefully separated from the membrane and removed. The bone removed from the lateral window osteotomy can be harvested and incorporated into the bone graft.

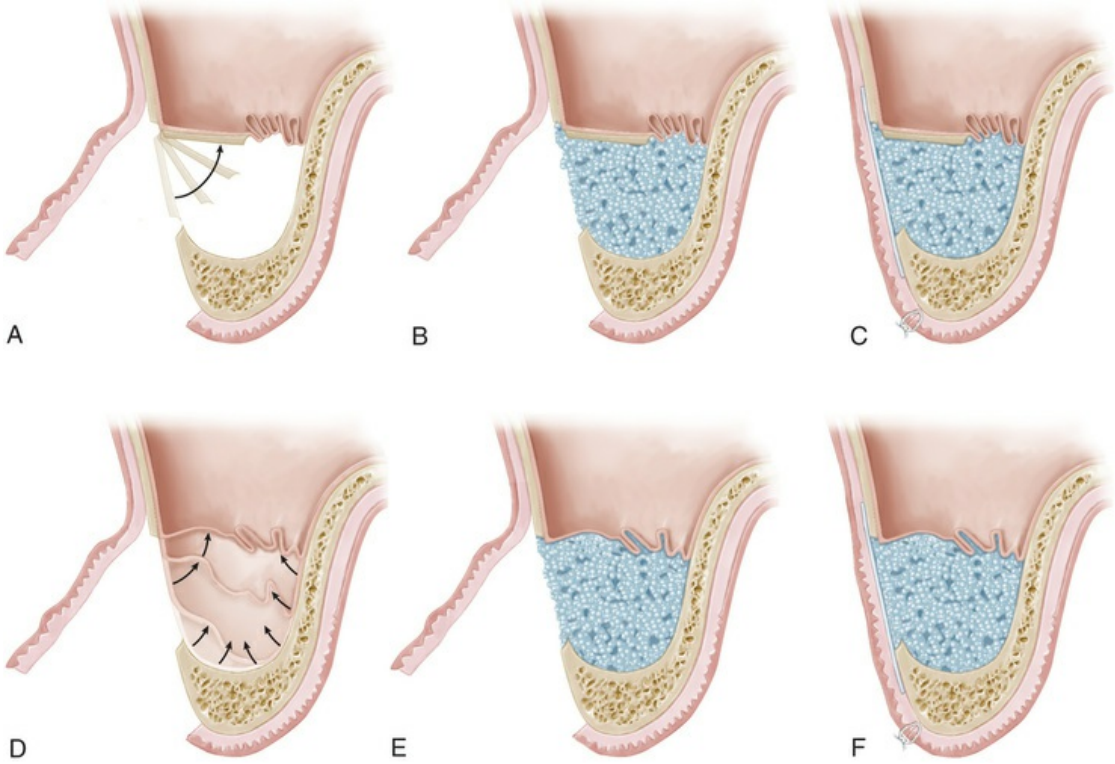

FIG. 80.5 Illustrations showing two techniques for the lateral window procedure to access the maxillary sinus for bone augmentation. The first technique (A–C) preserves the bone of the lateral window, elevating it up into the sinus cavity to create a new sinus floor. The second technique (D–F) completely removes the lateral window as part of the preparation. (A) Lateral window is cut at the periphery of the access window,

leaving the lateral bony wall in the center of the window intact. The bony window is then pushed inward to become the new, elevated sinus floor/superior wall of the grafted maxillary sinus space. (B) Bone graft material is packed into the newly created space. (C) A barrier membrane is placed over the lateral window and bone graft material. The full-thickness flap is sutured over the barrier membrane. (D) Lateral window is removed entirely during the preparation of the osteotomy. The schneiderian membrane is elevated inward and upward to become the superior containment of the grafted maxillary sinus space without a superior bony wall. (E) Bone graft material is packed into the newly created space. (F) A barrier membrane is placed over the lateral window and bone graft material. The full-thickness flap is sutured over the barrier membrane.

Once the lateral window osteotomy is created, elevation of the schneiderian membrane is accomplished with hand instruments that are inserted along the internal aspect of the bony walls of the sinus (eFig. 80.3). Great care is taken to avoid perforation of the membrane. Small instruments (e.g., De Marco curette) are introduced along the inferior, anterior, posterior, and superior aspects of the prepared window, gradually inserting further along the bone until the membrane begins to separate and lift away from the bone. Subsequently, larger instruments (e.g., Gracey curette) are gently introduced along the bone to continue lifting the membrane to the desired levels (height, width, and depth). Instruments must always be kept in contact with the bone surface while elevating the schneiderian membrane to avoid perforation. An implant surgical guide should be used to estimate the planned anterior-posterior implant positions and to assess the dimensions of needed sinus augmentation. Once elevated, the space can be grafted with bone (autogenous, bone substitute, or a combination). If implants will be simultaneously placed, the implant osteotomy sites should be prepared, and implants placed after the medial, anterior, and posterior aspects of the sinus are filled with bone graft, thereby supporting the schneiderian membrane up and away from the drills and implants. After implant placement, the remaining lateral aspect

is packed with bone graft. Finally, the lateral window and bone graft are covered with a barrier membrane (e.g., resorbable membrane) and the flap is sutured. Covering the lateral window osteotomy with a barrier membrane has been shown to increase the amount of vital bone and has a positive effect on implant survival.[45,56]

Risks and Complications

The maxillary sinus elevation and bone augmentation procedure is technique sensitive, requiring meticulous surgical skills. Risks and complications of the procedure include tearing or perforation of the schneiderian membrane, intraoperative/postoperative bleeding, postoperative infection, and loss of bone graft or implants (see Chapter 85).

The reported incidence of perforation or tearing of the schneiderian membrane varies greatly (up to 60%) and depends largely on the anatomy of the sinus as well as the skill and experience of the operator.[9,26,30,36] The presence of septa in the maxillary sinus increases the likelihood of membrane perforation.

Positioning of the sinus window within 2 to 4 mm from the anterior and inferior borders of the sinus makes it easier to get direct access to the bony walls. This may lessen the amount of membrane perforation during the elevation of the sinus membrane.

If the perforation is small, it can often be managed with a resorbable barrier membrane placed over the opening, followed by careful packing of the bone augmentation material. If a perforation or tear is extensive (see Fig. 85.18), it may be necessary to abort the procedure, close the wound, and attempt it again at a later date.

Infections have been reported in a small but significant number of cases (up to 10%) after maxillary sinus elevation and bone augmentation procedures.[36,53] Prevention of infection is crucial for bone augmentation procedures. Surgery should always be performed using sterile techniques. Patients should use a presurgical antimicrobial mouth rinse (e.g., chlorhexidine), and postoperative antibiotics should be prescribed. The signs and symptoms of sinus graft infection as well as a detailed protocol for its treatment was described in a clinical study.[53]

Opening a window through the lateral wall is accomplished by completely cutting through the bone of the lateral wall up to the schneiderian membrane. The membrane is highly vascularized and may bleed significantly.[1,31] However, a more serious bleeding problem can arise if an intraosseous artery is severed in the process. Bone wax and topical hemostatic agents must be available to manage such an urgent surgical complication. If a medium-to-large intraosseous vascular channel is identified presurgically via three-dimensional imaging such as a cone beam scan (CBCT), the surgical approach can be modified to minimize the risk of a bleeding complication.

Key Fact

Maxillary sinus augmentation is a predictable technique to gain vertical bone height in the posterior maxilla. However, despite the high success rates, various intraoperative and postoperative complications have been reported. Patient selection, patient preparation, and precise surgical techniques are the key factors for reducing the incidence of sinus complications.

Supracrestal/Vertical Bone Augmentation

Supracrestal or vertical bone augmentation presents one of the greatest challenges of bone regeneration in implant dentistry. This is primarily due to difficulty of the surgical procedure and the potential for postoperative complications. Because vertical augmentation can be a challenging procedure with a relatively high rate of complications, it is necessary to justify this particular treatment for each patient. The rate of complications associated with vertical bone augmentation procedures, including membrane exposure or postoperative infection, is reported to range from 2.87% to 17%.[40,41,46,49] Alternative treatment options, albeit with limited outcomes, need to be considered. For example, regenerating a vertically deficient ridge may not be necessary if (1) implants can be placed in adjacent sites, (2) short implants can be used, (3) cantilevers or conventional bridges can be used, or (4) in the case of vertical deficiencies in aesthetic areas, pink ceramic can be used to create an illusion of "normal" soft tissue anatomy.

Historical attempts to vertically increase alveolar bone height using modalities such as onlay bone grafting have failed. More recent treatment modalities developed for vertical bone growth include vertical guided bone regeneration (GBR) and distraction osteogenesis. The techniques and evidence of success are presented.

Guided Bone Regeneration

The surgical technique of GBR for supracrestal regeneration was described in the 1990s.[43] Although available evidence is limited, both animal and human studies demonstrate successful vertical bone augmentation with histologic evidence.[25,41] Some studies have evaluated the effect of space creation by a membrane alone, whereas others have used an autogenous bone graft to maintain space under the membrane. Using titanium-reinforced (TR) membranes without bone graft (space filled with blood clot only) in a canine model, Jovanovic and colleagues[25] demonstrated a gain of 1.82 mm of vertical bone height around simultaneously placed implants. In a clinical study, Simion and coworkers[41] treated five

patients with GBR to gain vertical bone height around 15 implants placed in a supracrestal position with 4 to 7 mm of the implant exposed. Titanium miniscrews were placed distal to the implants in a supracrestal position with 3 to 4 mm exposed. The implants and miniscrews were covered with a titanium-reinforced expanded polytetrafluoroethylene (e-PTFE) barrier membrane. Clinical evaluation at implant exposure surgery revealed an average of 3 mm (range from 1 to 4 mm) of vertical bone gain after 9 months. Histomorphometric evaluation of harvested miniscrews showed good bone-to-implant contact (42.5% ± 3.6%) with the regenerated bone. These studies suggest that supracrestal bone formation up to 3 mm is predictable using the GBR technique with a titanium-reinforced barrier membrane–blood clot combination.

Studies showed that supracrestal bone formation is more predictable using a bone graft filler material placed under the TR membrane.[39] Therefore at present, advanced surgical GBR augmentation for vertical bone gain should be achieved with a nonresorbable TR membrane that is supported by a bone graft (Fig. 80.6). The long-term results of vertical GBR after 1 to 5 years of prosthetic loading were examined in a retrospective multicenter study evaluating 123 implants.[39] Three treatment modalities (nonresorbable regenerative membranes in combination with blood clot only, DFDBA, and autogenous bone chips) were studied, and the results from this investigation revealed that vertical bone regeneration greater than 4 mm could only be achieved with the use of autogenous bone chips. These authors reported an overall success rate of 97.5%, leading them to conclude that vertically augmented bone using GBR techniques supports implant placement in a fashion similar to native, nonregenerated bone.

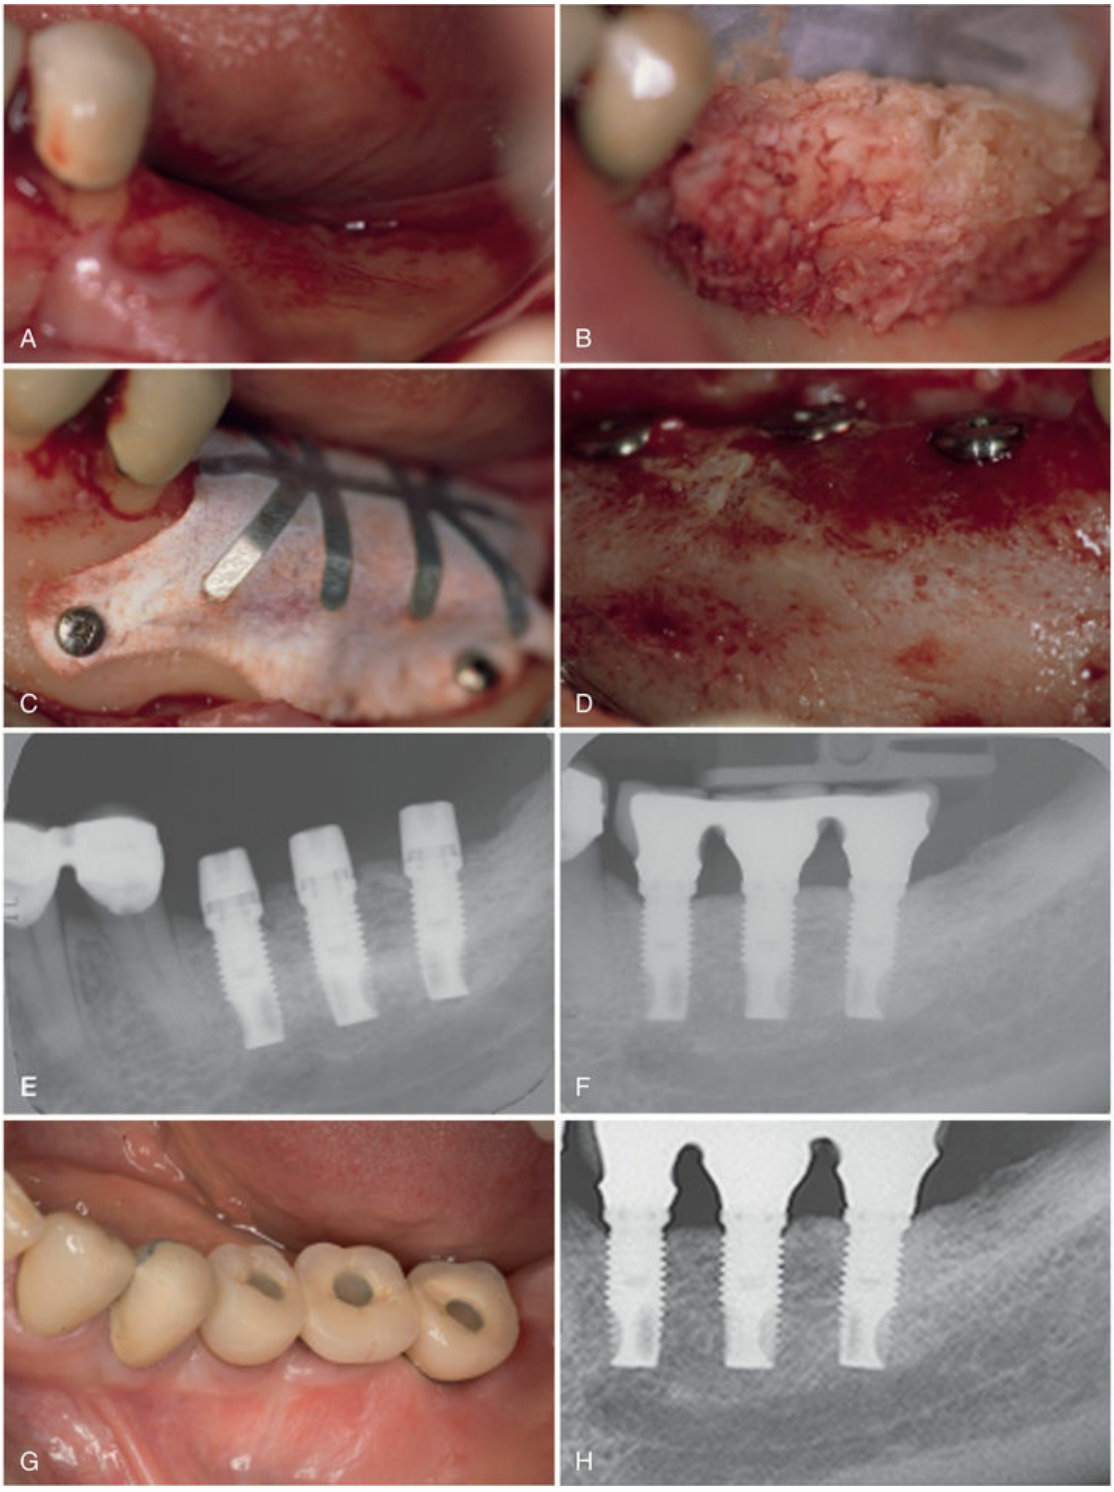

FIG. 80.6 Representative case of a posterior mandibular vertical ridge augmentation. (A) Atrophic posterior mandibular area. (B) Particulated chin bone graft is placed on the ridge. Cortical bone was perforated, and guided tissue regeneration membrane/titanium-reinforced (GTRM-TR) membrane was secured on the lingual side before applying bone

graft. (C) GTRM-TR membrane is secured over the graft with titanium pins. (D) Three implants are in place in the newly formed posterior mandibular ridge. Note the well-integrated bone graft. (E) Periapical radiograph at abutment connection. (F) Periapical radiograph at 8-year follow-up with implants in function. (G) Clinical picture demonstrates healthy peri-implant mucosa. (H) Periapical radiograph at 13-year follow-up with implants in function. (A–G from Urban IA, Jovanovic SA, Lozada JL: Vertical ridge augmentation using guided bone regeneration (GBR) in three clinical scenarios prior to implant placement: a retrospective study of 35 patients 12 to 72 months after loading, *Int J Oral Maxillofac Implants* 24:502–510, 2009.)

Urban and colleagues[49] used TR membranes with autogenous particulated bone for vertical bone augmentation before implant placement. The study included 35 patients with 36 vertical bone defects. Eighty-two implants were placed in a staged approach, and a resorbable collagen membrane (Bio-Gide Resorbable Bilayer Membrane, Osteohealth, Shirley, New York) was placed over the newly formed crestal bone during the implant placement surgery to protect the graft from early resorption after removal of the ePTFE membrane. Implants were followed from 1 to 6 years after prosthetic loading. Treatment groups included single and multiple tooth sites, as well as vertical defects in the posterior maxilla. Vertical bone augmentation of the posterior maxillary ridge was done simultaneously with sinus bone augmentation (eFig. 80.4). At membrane removal, the mean vertical bone augmentation was 5.5 mm (±2.29 mm). The mean combined crestal remodeling was 1.01 mm (±0.57 mm) at 12 months, which remained stable through the 6-year follow-up period. There were no statistically significant differences between the treatment groups in mean marginal bone remodeling. The overall implant survival rate was 100% with a cumulative success rate of 94.7%.

(C–D) Remote full thickness flap is elevated, exposing the facial bone of the posterior maxillary region. Buccal and occlusal views of aesthetically and functionally demanding vertical defect. (E) The lateral window of the sinus is outlined and fractured inward. The schneiderian membrane is carefully elevated until the correct vertical height is reached. (F–G) Anorganic bovine-derived bone mineral (ABBM) and autogenous bone were applied and packed to the subantral space of the elevated sinus. Guided tissue regeneration membrane/titanium-reinforced (GTRM-TR) membrane was fixated on the palatal bone, and a titanium tenting screw is placed protruding to the desired vertical position. Autogenous particulated bone was applied to the vertical defect. (H–I) Buccal and occlusal views of GTRM-TR membrane secured over the graft with titanium pins. (J) After 9 months of uneventful healing, the GTRM-TR membrane has maintained its position. (K–L) Buccal and occlusal views of the regenerated alveolar bone crest. (M) The final reconstruction demonstrates a functional and aesthetic outcome. (N) Stable crestal bone around the implants after 10 years of loading. (O) Stable crestal bone around the implants after 13 years

of loading.

The efficacy of a 1 : 1 mixture of ABBM and autogenous particulated bone graft using ePTFE membranes was evaluated histologically and histomorphometrically in 8 patients (10 ridge defects).[38] After a healing period of 6 to 9 months, a mean vertical gain of 3.15 mm (SD ±1.12 mm) was achieved. A clinical and histologic study evaluating the same graft material and using dense-PTFE membranes in 19 patients achieved an average bone gain of 5.45 mm (SD 1.93).[51] In both studies histologic evaluation showed that ABBM was surrounded by a dense network of newly formed bone at varying degrees of maturation.

Simion and coworkers reported the long-term results of machined surface implants placed in vertically augmented bone achieved with GBR. Patients were followed from 13 to 21 years with a mean follow-up of 16 years. The average marginal bone loss between baseline (1-year postloading) and the final evaluation was 1.06 mm.[37]

There are limited clinical data on the outcomes of simultaneous GBR for horizontal or vertical bone gain for the reconstruction of severely atrophic edentulous maxilla. Urban and colleagues[52] evaluated 16 consecutively treated patients (mean age: 64 years) for vertical and/or horizontal bone augmentation with GBR in combination with bilateral sinus augmentation utilizing a mixture of autologous and anorganic bovine bone. Implant survival, bone gain, intraoperative/postoperative complications, and peri-implant bone loss were calculated up to the last follow-up exam. One hundred and twenty-two dental implants were placed into augmented sites and have been followed for up to 15 years (average follow-up of 6.5 years). The vertical bone gain was 5.1 mm; horizontal bone gain was 7 mm. The mean peri-implant bone loss values were consistent within the standards for implant success (1.4 ± 1 mm). At the patient level, only one patient who had three implants presented with severe peri-implant bone loss (Fig. 80.7).

Key Fact

Vertical ridge augmentation is one of the most challenging clinical procedures in reconstructing alveolar ridges. Despite the potential for complications with this treatment approach, high success and good long-term implant survival rates have been documented.

Distraction Osteogenesis

Distraction osteogenesis is a surgical technique that has been developed to increase vertical bone height in the deficient jaw site and contrasts with the more conventional method of bone grafting with or without membranes. Under the proper circumstances, most cells in bone can differentiate into osteogenic (or chondrogenic) cells needed for repair. Ilizarov popularized the concept of distraction osteogenesis in the 1980s by developing a protocol for

"cutting" long bones and "stretching" them during the healing process.[20-22]

Based on experimental and clinical studies over 35 years, distraction osteogenesis can provide a surgeon with the ability to treat small bones in the hands and feet using external fixation devices. New intraoral devices for vertical bone growth of the alveolar process have been developed and applied in preparation for dental implant placement. One advantage of distraction osteogenesis is the ability to increase bone height in an area using the native autogenous bone without the need for a second surgical site to harvest bone.

A significant disadvantage of distraction osteogenesis for intraoral applications is the unidirectional limitation of current devices. The application of distraction osteogenesis for vertical bone growth has been demonstrated, but there are limitations in achieving horizontal bone growth with this method. Secondary bone grafting is frequently needed following vertical distraction osteogenesis, especially for the extremely resorbed (narrow) ridge. Consequently, distraction osteogenesis cannot be expected to solve vertical ridge defects without the use of additional augmentation procedures.

Growth Factors in Bone Augmentation

Current research is exploring the use of various growth factors to induce bone formation.[5,6] These bone-inductive mediators are powerful modifiers of the healing process. Incorporation of osteoinductive mediators into bone graft material or other carriers can be applied to sites in conjunction with conventional bone augmentation procedures to enhance the outcome.

Most of the clinical techniques available for delivering growth factors to augmentation sites utilize some type of bone replacement graft, including autograft, allograft, xenograft, or alloplast. These bone graft materials have both advantages and limitations. Consequently, attempts have been made to improve bone grafting by using either growth factors alone or growth factors combined

with a bone replacement graft.[2,34,35] The rationale is that bone formation can be further enhanced when a growth factor is used to stimulate osteoblast precursors and osteoblasts pushing the bone formation/resorption balance in favor of bone formation.[33]

Bone Morphogenetic Proteins

Perhaps the most studied of all the osteoinductive growth factors are the bone morphogenetic proteins (BMPs), which belong to the transforming growth factor beta (TGF-β) superfamily. Of this family, *recombinant human bone morphogenetic protein-2* (rhBMP-2) has shown significant signs of bone-enhancing potential.

One commercial bone growth factor product has been approved by the Food and Drug Administration (FDA) for use in the oral cavity to stimulate bone formation. As noted in the discussion on the use of growth factors for periodontal regeneration (see Chapter 63), the growth factor protein must be combined with a carrier to facilitate clinical activity. The commercially available bone growth product contains rhBMP-2 combined with a bovine type I collagen sponge. This product has been cleared for oral cavity use in both sinus lift augmentation therapy and for ridge augmentation in maxillary anterior extraction sites with bone loss.[3,6,17,19,48]

The BMPs are a group of related proteins that are found in the body and are important for skeletal development.[8,12,59] Each of the proteins has relatively specific functions, and BMP-2 has been shown to have some of the strongest bone-producing activity. BMP-7 (also called *osteogenic protein-1* [OP-1]) and BMP-3 (also known as *osteogenin*) have also been shown to stimulate bone formation. The BMPs were originally isolated from bovine bone by Marshall Urist.[54] As a growth factor, the BMPs induce the differentiation of mesenchymal stem cells to become bone-producing osteoblast cells. Thus unlike proliferation factors that increase the number of cells, the BMPs are differentiation factors that stimulate cells to produce bone tissue. Many carriers have been tested with the BMPs, but the binding and release kinetics using bovine type I collagen have proved to be the most useful clinically. BMP binds tightly to the collagen within minutes and has been shown to be released over time for 2 to 3 weeks at the defect site. The extended release kinetics

likely allow the undifferentiated mesenchymal cells migrating into the wound site over time to be exposed to the growth factor. These BMPs have been extensively studied and have been shown to stimulate bone formation in many animal models and in humans under a variety of conditions and indications.[57] In fact, the same product approved for use in the oral cavity had previously been approved by the FDA for use in single-level spine fusion procedures and in open tibial fractures in humans.

The BMPs have specific receptors on the surfaces of cells.[32,44,60] Binding of the BMP causes dimerization of the receptor proteins, which in turn stimulates a cascade of events intracellularly involving a set of proteins called *SMADs.* The result of the intracellular cascade is the activation of genetic activity and bone cell differentiation.

The preclinical results of using rhBMP-2 in animals with critical-sized defects have reported rapid new bone formation. The inductive capacity of rhBMP-2 was demonstrated by impregnating a polymer carrier and placing the substrate in critical-sized rat mandibular defects with or without a barrier membrane.[27] The study evaluated 12- and 24-day healing times and showed a bony union of the defects for rhBMP-treated sites. The control sites were not closed at the same intervals.

The clinical results of using rhBMP-2 and collagen in patients are remarkable considering that only one bone differentiation agent is being delivered to the bone site and it is only delivered at the time of the surgical procedure. Relatively high doses of the protein are often used in some sites, however, possibly as the result of the need to release effective doses at later times. Future research directions will likely focus on more targeted delivery of the bone growth factor at specified times during the wound-healing process.

The use of growth factors for bone augmentation has the potential to completely eliminate the need for bone harvesting or any bone filler materials, and preliminary results are encouraging. However, the clinician must recognize that there is limited clinical information available on these new modalities, and no information on resorption of the regenerated bone, implant survival, or bone remodeling around implants. Further documentation from long-term, randomized controlled clinical studies are necessary.

Autologous Platelet Concentration

A new approach to enhance the vitality of bone grafts has been introduced by using platelet concentrate or platelet-rich plasma (PRP).[28] PRP is an autologous source of platelet-derived growth factors and transforming growth factors that is obtained by sequestering and concentrating platelets by centrifugation. The patient's own blood is withdrawn and separated into platelet-rich and platelet-poor components. The PRP is the important content, containing a high-level mixture of platelets and a concentration of growth factors. This PRP mixture is added to the autologous bone graft and has been shown to increase the quality of and reduce the time needed for bone regeneration. Clinical and experimental studies are scarce but suggest that this technique holds promise for large bone defects and bone defects with low osteogenic potential. Extrapolation to the possible effect of PRP on other bone-filler materials cannot be made at this time.

A more recent variation of platelet concentration techniques is the preparation of leukocyte and platelet-rich fibrin (L-PRF).[10,11,14-16] The technique is simplified and does not require the application of thrombin. See Chapter 66 for a detailed description of the biologic properties and the applications of L-PRF.

Conclusion

Bone augmentation and advanced implant surgery procedures allow clinicians to reconstruct vertical alveolar bone deficiencies and replace missing teeth with endosseous dental implants. Diagnosis, treatment planning, careful execution of the surgical treatment, postoperative follow-up, and appropriate implant loading are all important factors in achieving a predictable outcome and success with these procedures. Sinus elevation and bone augmentation has become a widely used and predictable procedure to augment the deficient posterior maxilla (i.e., pneumatized maxillary sinus). Reconstruction of vertically deficient ridges remains a significant challenge despite the reported progress and success of new techniques.

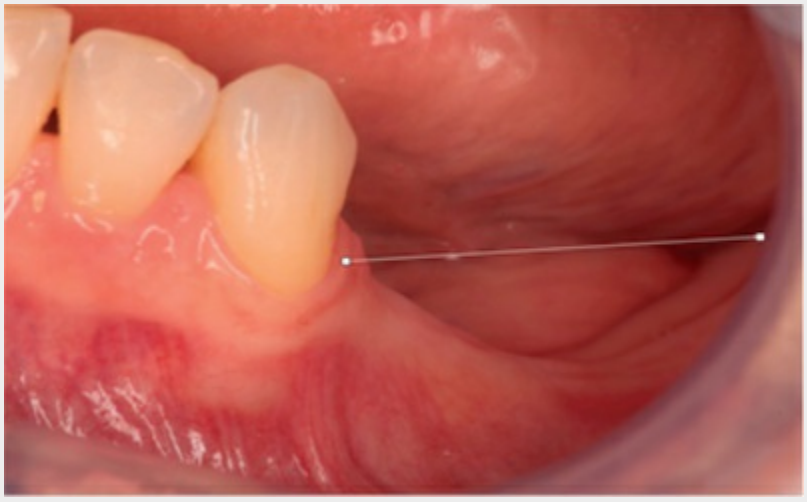
Case Scenario 80.1

Patient:
50-year-old male

Chief Complaint:
“My lower left teeth have been missing for several years. I don't like my removal partial denture and I would like a fixed solution.

Background Information
Patient reports that he is healthy. He is not taking any medications. He denies any tobacco use. He has been missing the mandibular left posterior teeth for more than 10 years.

Current Findings:
Exam reveals a severe vertical ridge deficiency in the posterior mandible. The CBCT scan shows that the distance between the inferior alveolar nerve and the alveolar crest in this area is 5 mm. Additionally, the alveolar ridge width is only 2 mm. The remaining dentition is intact. Oral hygiene is good.



CASE-BASED QUESTIONS	SOLUTION AND EXPLANATION
1. What treatment option will address the patient's chief complaint? A. New removable	**Answer: B** **Explanation:** A new removable prosthesis is an option, but it will not address the patient's chief complaint. Vertical and horizontal ridge augmentation will allow placement of

prosthesis B. Vertical and horizontal ridge augmentation followed by implant placement and restoration with an implant-supported prosthesis C. Nerve lateralization procedure with implant placement and restoration with an implant-supported prosthesis D. Fixed tooth-borne partial denture on the remaining teeth with several cantilevers replacing the premolars and at least one molar	implants to restore his posterior dentition with an implant-supported fixed prosthesis. The other options pose significant risk of morbidity or failure.
2. What complications are associated with supracrestal vertical bone augmentation procedures? A. Membrane exposure B. Postoperative infection C. Both of the above D. Neither of the above	**Answer: C** **Explanation** The rate of complications associated with vertical bone augmentation procedures are relatively high, ranging from 2.87 to 17%. The most common complications include membrane exposure and postoperative infections.

CHAPTER 81

Aesthetic Management of Difficult Cases (Minimally Invasive Approach)

Thomas J. Han, Kwang-Bum Park, Perry R. Klokkevold

CHAPTER OUTLINE

Surgical Strategy for Predictable Aesthetics
Immediate Implant Placement for Predictability and Aesthetics
Surgical Management of Difficult Cases (Minimally Invasive Approach)
Conclusion

In recent years, implant dentistry has been increasingly influenced by aesthetic considerations. In addition to successful osseointegration, harmonious soft and hard tissues must surround the implant restorations so that they look natural and healthy. A major challenge in implant dentistry is that, in many instances, dental implants need to be placed in an aesthetic zone with extensive alveolar bone deficiency from tooth loss, dentoalveolar infection, or other disorders (Fig. 81.1). Gingival morphology follows the shape of the underlying bone, and it is difficult to build aesthetically acceptable gingiva in areas with deficient supporting bone. Furthermore, using conventional surgical approaches to accomplish the goal in a patient-friendly manner with minimal trauma and clinical predictability is an extremely demanding task.

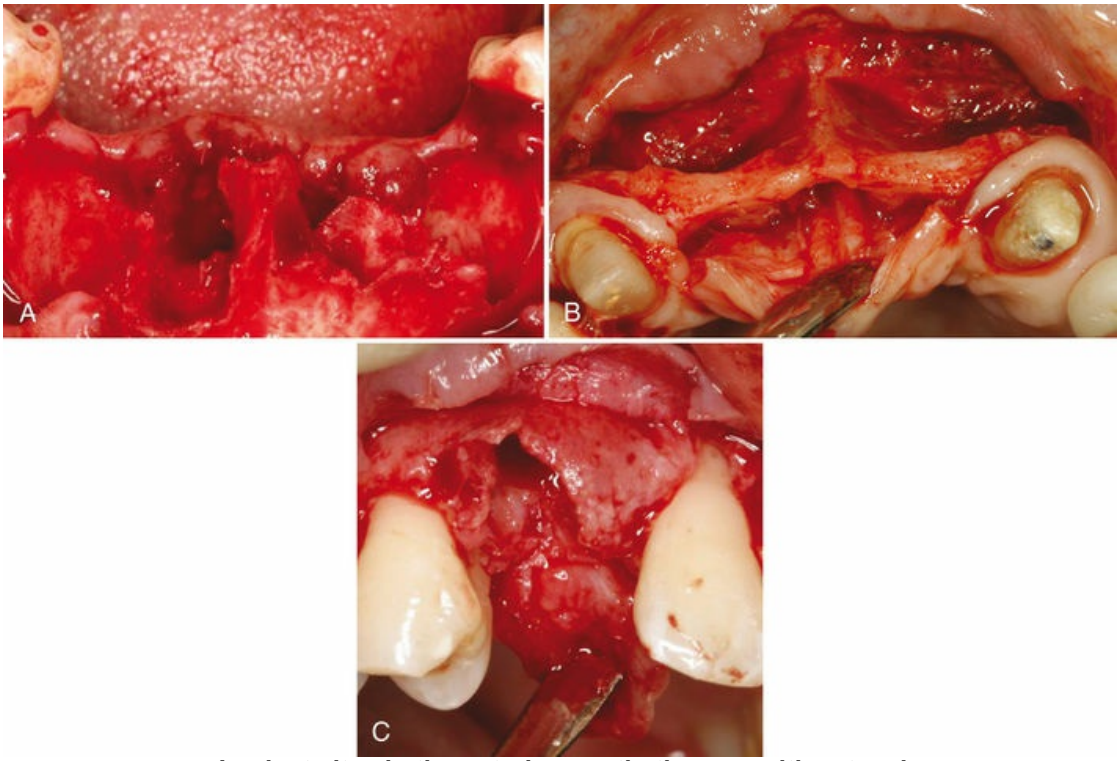

FIG. 81.1 Implant sites in the anterior, aesthetic zone with extensive bone loss. (A) Anterior mandibular site showing extensive bone loss following extraction of hopelessly infected mandibular incisors. (B) Extremely narrow (labial-palatal) ridge width in the anterior maxilla that was missing central and lateral incisors for many years. (C) Moderate bone loss associated with the extraction socket of a maxillary cuspid.

Treatment planning in a complex implant case today is often confusing because of the many different surgical and restorative

approaches to solve the same problem. Many times these procedures seem to conflict. When considering the surgical placement of implants, clinicians must consider the approach (conventional two-stage approach versus a one-stage approach) and the timing of implant placement (immediate versus delayed or staged placement). For bone augmentation procedures, the clinician may choose the more conventional approach of augmenting the ridge first and placing the implant or implants after healing, or the simultaneous implant placement technique with bone augmentation approach in which bone grafting is done at same time as implant placement. All of these approaches can provide a successful outcome if patient selection is appropriate and techniques are performed properly.[9,22,24,32] However, depending on the situation, some of these techniques are more advantageous than others in achieving aesthetic results with better predictably and less patient discomfort.

It is easy for a clinician "dogmatically" to choose one approach, usually the one that the clinician feels most comfortable with, and to treat all patients with the same approach. However, with heightened expectations of aesthetics pushing the art and science of dentistry, it is necessary more than ever for clinicians to understand fully all the available options of treatment and decide appropriately which, where, when, and how to use these options for each patient.

An important clinical development in dental implant surgery is the concept of a "minimally invasive" approach to treatment. Specifically, the drive is toward minimally invasive implant placement. With advances in technologies, materials, and biologic sciences in dentistry, this approach to implant surgery is becoming more popular among clinicians and will most likely dominate the way dental implants will be placed in the near future.

Minimally invasive surgery in implant dentistry implies a surgical approach that minimizes the extent and number of surgical procedures while providing aesthetics, predictability, and longevity with minimal surgical morbidity and discomfort to patients. The surgical approach most often required to achieve these goals for anterior implant therapy involves immediate implant placement, a one-stage surgical approach, with or without flap, and simultaneous bone grafting. Furthermore, these surgical techniques

need to be guided by a consistent surgical strategy that provides predictable aesthetic results in implant dentistry. A minimally invasive approach to implant therapy in posterior sextants in which aesthetics is not a major concern can be predictably achieved with the use of short, wide implants.[2,15,16,27]

This chapter introduces surgical strategies that enhance the aesthetic predictability in implant dentistry. The minimally invasive surgical approach to manage difficult aesthetic and anatomically deficient cases is discussed with examples. The one-stage, immediate implant placement technique, which is the foundation of a patient-friendly approach to aesthetic implant dentistry, is presented in detail. The thought processes involved in case selection, their scientific rationale, and proper techniques of soft and hard tissue management are described with cases.

Key Fact

Minimally invasive surgery is an approach that minimizes the extent of surgical invasiveness, as well as the number of surgical procedures, while providing aesthetics and predictability with minimal surgical morbidity and discomfort to patients. The surgical approach most often required to achieve these goals for anterior implant therapy involves immediate implant placement, a one-stage surgical approach, with or without flap, and simultaneous bone grafting.

Surgical Strategy for Predictable Aesthetics

Adherence to the following surgical strategies enhances predictability and outcomes for aesthetic dental implant surgical procedures with minimal discomfort to patients (see the online description of the following key points):

1. Determine the level of surgical aesthetic goal to be achieved.
2. Visualize the final outcome.
3. Preserve existing tissues important for aesthetics.

4. Always overbuild bone and soft tissue in augmentation surgical procedures.

Determine the Level of Surgical Aesthetic Goal

In dental implant therapy, it is important to determine from the onset the level of surgical aesthetic goal. To determine the treatment needs, it is important to assess the patient's aesthetic expectations and to consider the patient's age, medical condition, time constraints, and finances, as well as the status of existing soft and hard tissues. The ability and experience of the clinician must also be factored into the determination.

The surgical aesthetic goal can be ideal, acceptable, or compromised. An ideal surgical aesthetic goal (eFig. 81.1) implies an ideal, complete surgical reproduction of peri-implant tissue around an implant restoration. An acceptable surgical aesthetic goal (eFig. 81.2) implies that the aesthetics of the final implant restoration and the peri-implant tissue is not ideal, but both the patient and the clinician accept it. In this case, the hygiene and the long-term health of the implant and restoration should not be compromised. A compromised surgical aesthetic goal (eFig. 81.3) implies that the aesthetics, hygiene, and long-term health of the implant are less than what is acceptable in today's clinical standard.

EFIG. 81.1 Ideal surgical aesthetic goal. Clinical photograph of an implant-supported crown replacing a maxillary right cuspid in a 20-

year-old female patient with a high smile line. Soft tissues are full, and contours appear natural.

EFIG. 81.2 Acceptable surgical aesthetic goal. Clinical photograph of implant-supported crowns replacing multiple missing maxillary anterior teeth in a 63-year-old female patient with a low smile line. Soft tissues are nearly full, and contours appear fairly normal but not ideal.

EFIG. 81.3 Compromised surgical aesthetic goal. Severe ridge deficiency resulted in long implant-supported fixed restoration and difficult oral hygiene access. Notice the pink porcelain used to mask the increased length of the crowns. Soft tissues are obviously compromised and completely lack any semblance of normal.

In general, more surgical procedures are required to achieve aesthetic results that are close to ideal. The treatment time is usually much longer, and the cost is much higher. The patient has more surgical morbidity, and the ideal aesthetic outcome remains elusive and may not be achieved.

Due to the logistical consequences of this decision, the level of the aesthetic goal should be determined at the beginning of treatment

so that the patient is well informed about expectations including treatment costs and time requirements. Many clinicians believe that it is overtreatment to attempt ideal aesthetics for all patients.

Visualize the Final Outcome

Once the level of the aesthetic goal is determined, the next step is to visualize the final outcome. Determination of the vertical position of the implant, the quantity and quality of the soft and hard tissue augmentation needed, the components of the alveolar tissue that need to be preserved in surgery, and what surgical approach is most appropriate for the patient cannot be accomplished without first visualizing the final aesthetics of the implant restoration or restorations involved. In simple cases, the visualization can be done mentally or with the aid of computer graphic simulation. In more complex cases, a diagnostic wax-up may be necessary.[38]

Preserve Existing Tissues Important for Aesthetics

Once what needs to be accomplished surgically is decided through visualization of the aesthetics of the final restorations, the next step is determining what aspects of the soft and hard tissues need to be preserved for a predictable aesthetic result. For example, if the initial vertical position of the interdental papillae is aesthetically compatible with the image of the final restorations, it is prudent to preserve them rather than needing to rebuild them after they are lost. Knowing what needs to be preserved will aid in the choice of an appropriate surgical approach.

Always Overbuild Bone and Soft Tissue in Augmentation Surgery

Many studies have shown rapid labial and vertical bone loss after extractions,[3,26,30] and immediate implant placement does not stop the resorption process.[10,12,35] Furthermore, it has been demonstrated that soft and hard tissues grafted in augmentation procedures to enhance aesthetics undergo extensive shrinkage within 3 to 6

months.[1,36] Therefore the deficient ridge needs to be overbuilt by approximately 30% to 40% at the time of surgery to be aesthetically sufficient after the expected primary and secondary tissue shrinkage.

Immediate Implant Placement for Predictability and Aesthetics

Immediate implant placement in a one-stage approach, in which a healing abutment or provisional restoration is attached to the implant and remains exposed, provides more predictable preservation of the interproximal peri-implant gingival tissue with less patient discomfort and treatment time.[21,22] This approach to implant placement is the foundation of a minimally invasive approach to aesthetic implant dentistry. However, as with any surgical technique, it takes learning and practice to perform it properly. The criteria and techniques for proper immediate implant placement have previously been established and reported with successful long-term outcomes.[18,32]

One of the more difficult aspects of immediate implant placement is positioning the implant with sufficient primary stability in an extraction socket, often without elevating a flap. The alveolar architecture in relation to the angle of the implant to be inserted, the presence or absence of a bone concavity apical to the extracted tooth, the amount of existing bone apical and palatal to the extraction socket that can provide primary stability for the immediate implant, and the quality of the bone and soft tissues of the ridge should all be thoroughly evaluated clinically and radiographically before surgery.[18,32] Many clinicians perform successful immediate implant placement without the aid of three-dimensional scans (e.g., computed tomography [CT] or cone beam CT [CBCT]). However, if the tooth involved is long and large or if the patient has an alveolar concavity or other anatomic variations, the use of a CT or CBCT scan is advised.

A major disadvantage of placing implants immediately in the changing alveolar bone of an extraction socket is that it may result in progressive recession of the gingival labial margin over the

implant restoration.[4,17] Therefore, when placing an immediate implant with a one-stage surgical approach in an aesthetic zone, a prudent strategy would be to improve the quality and quantity of labial gingival tissue, which seems to be vital for the stability of the labial gingival margin involving immediate implants.[19,31] One of the most effective ways to keep the implanted socket from collapsing and improve the labial gingival biotype is simultaneously to fill the labial socket void with particulate bone and augment the labial gingival tissue with soft tissue.[3,23,26,30,32]

An effective bone and gingival tissue augmentation technique used with flapless immediate implant placement in a one-stage approach is the bone and crescent-shaped free gingival grafting technique.[18] In this technique, the space between the inner surface of the labial bony wall and the labial surface of the implant is filled with slow-resorbing mineralized, freeze-dried particulate bone allograft or particulate xenograft to help preserve the horizontal dimension of the ridge (Fig. 81.2A). Then, a crescent-shaped soft tissue graft is harvested from the ipsilateral palate (Fig. 81.2B) and is transplanted into the labial recipient site coronal to the particulate bone graft (Fig. 81.2C). To provide or maintain the blood supply to the donor tissue, it is important that the outer surface of the crescent graft fits in intimate contact with the bleeding lamina propria of the labial gingiva. Proper suturing ensures good proximity and prevents the graft from being displaced coronally out of the recipient site (Fig. 81.2D).

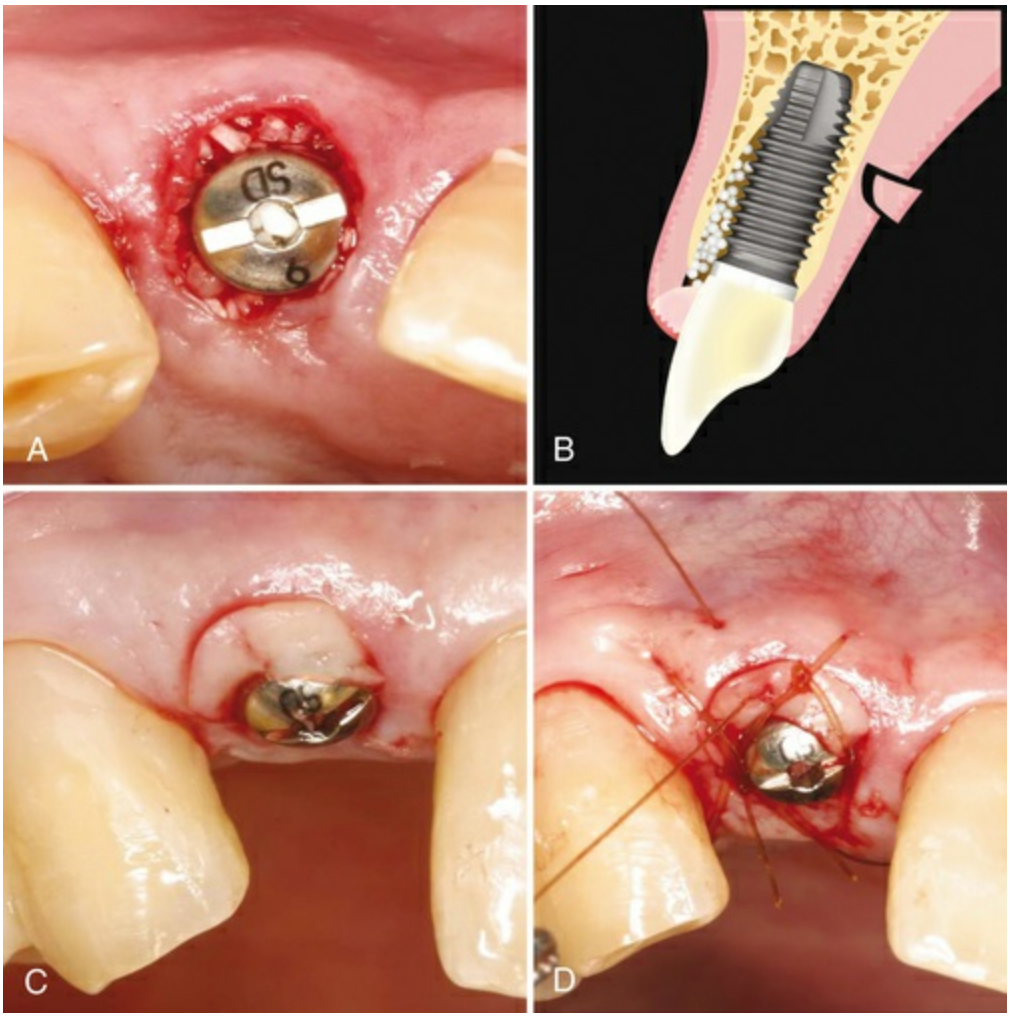

FIG. 81.2 (A) Bone graft material is lightly packed into the extraction socket gap between the labial wall and the implant surface. (B) Diagram of crescent-shaped, free gingival graft tissue being harvested from the palate. (C) Clinical photograph of crescent-shaped, free gingival graft tissue positioned over the bone graft to fit snugly in the gap between the gingival wall and the implant surface. (D) Crescent-shaped, free gingival graft is sutured in place using 5-0 gut sutures. The sutures pass through the gingival graft toward the labial gingival margin and are tied. Then, without cutting the ends, the suture is passed over the graft and tied to the palatal gingival tissue. Three sutures are needed to keep the graft in position.

The advantages of this approach to gingival augmentation are simplicity and minimal surgical morbidity. In addition to providing a sealed protection for the bone graft, it prevents resorption of the sensitive labial crestal bone. Preparation of the recipient site

involves no surgical manipulation other than de-epithelialization, as described. Gingival walls are completely intact with a full blood supply. The donor site wound is small (approximately 3 mm depth × 3 mm height at the widest point) with intact epithelium around the wound, which epithelializes within a week and causes minimal discomfort for the patient. Because each donor tissue graft is small, multiple grafts can be harvested from a single palate, so that multiple immediate implants can be augmented at same time. Furthermore, this gingival augmentation technique frequently improves an unfavorable initial gingival margin because the grafted gingival margin is always coronal to the existing gingival margin. This minimizes a need for other time-consuming techniques, such as orthodontic extrusion, or a delayed approach to implant placement when the initial gingival margin is not aesthetic or ideal, as recommended by many investigators.[5,33]

The risk-to-benefit ratio of the crescent grafting technique is favorable enough that if the graft does not survive, or if more than expected horizontal resorption of the ridge occurs, traditional techniques (e.g., subepithelial connective tissue graft) can be performed to augment the results. This is usually possible without refabrication of the implant restoration because the vertical height of the interdental papilla is sufficiently preserved with immediate implant placement in a one-stage approach.

Key Fact

An effective bone and gingival tissue augmentation technique used with flapless immediate implant placement in a one-stage approach is the bone and crescent-shaped free gingival grafting technique. To provide and maintain the blood supply to the donor tissue, it is important that the outer surface of the crescent graft fits in intimate contact with the bleeding lamina propria of the labial gingiva. Proper suturing ensures good proximity and prevents the graft from being displaced coronally. The crescent graft technique enhances gingival thickness following extraction and immediate implant placement.

Surgical Management of Difficult Cases (Minimally Invasive Approach)

The failure to satisfy the aesthetic needs of a patient frequently starts with an inadequate examination of the soft and hard tissues surrounding the surgical site and the natural dentition. This can result in an incorrect diagnosis, which leads to an incorrect treatment plan. The wrong treatment plan combined with selection of inappropriate surgical approaches or techniques can result in a disastrous aesthetic outcome and unnecessary patient suffering. The first two case presentations describe the examination and thought processes involved in determining the diagnosis and treatment planning of complex anterior cases with extensive alveolar bone loss. The proper application of the surgical strategies and the minimally invasive techniques, previously described, are illustrated. The final case presentation illustrates the minimally invasive approach to posterior implant therapy with the use of short, wide implants, in which aesthetics is not the major concern.[2,15,16,27]

Components of Aesthetic Examination

The patient's chief complaint, aesthetic zone, tooth positions, gingival form, osseous crest position, biotype, tooth shape, horizontal and vertical ridge deficiency, and occlusal status all play important roles in deriving an accurate aesthetic treatment plan for the patient. Therefore developing the necessary skill and knowledge to examine and recognize problems of these components is an essential first step to clinical success.

Case Presentation 1

The first case presented is in a patient with a simultaneous bone and soft tissue augmentation with multiple maxillary anterior immediate implants placed in a one-stage, flapless approach.

Patient Dental History and Chief Complaint

The patient is a 70-year-old woman with severe mobility and

discomfort of the maxillary four incisors. Except for a generalized feeling of weakness, she is healthy and does not have any medical contraindications to dental treatment. She presented with a desire to replace her maxillary incisors with dental implants, but she is very concerned about the physical discomfort she may experience from the implant surgery. She does not want to wear a removable prosthesis at all, not even for a short time. She is content with her present dental aesthetics.

Examination and Diagnosis

The maxillary incisors exhibit moderate to severe periodontitis with 4- to 7-mm periodontal probing depths. They exhibit severe (2+) mobility with fremitus. The periodontal and restorative prognosis of these teeth is poor. She has an excessive overbite with evidence of moderate mandibular incisor wear, indicating possible parafunctional habits. Her incisors are slightly elongated, but the dentogingival symmetry is acceptable (Fig. 81.3A). The shape of the incisors is slightly triangular with sufficient interdental papilla volume and height. Interproximal gingival tissue is not swollen or edematous. Her gingival biotype appears to be on the thin side with slight marginal inflammation, and the position of the labial gingival margins is already high (i.e., maximal apical position). Any further recession will be unaesthetic.

FIG. 81.3 (A) Clinical photograph of periodontally compromised maxillary anterior teeth with long clinical crowns. The presenting aesthetic status is not ideal. However, the dentogingival symmetry is fair because the gingival margin is approximately the same for all incisors (cuspid, lateral, and central). (B) Periapical radiographs of the maxillary anterior teeth reveal moderate to severe horizontal periodontal bone loss with vertical intrabony defects. (C) Simple, atraumatic

extraction of the maxillary incisors reveals sockets with unsupported interdental tissues. Note the absence of incisions or flap reflection, which has preserved the blood supply and integrity of the interdental soft tissues. (D) Guide pins placed in prepared implant sites reveal good position within the extraction sockets achieving good primary stability from the palatal aspect of the socket. (E) Implants with temporary abutments and crescent-shaped, free gingival grafts (not yet sutured). (F) Implant provisional abutments are prepared, and provisional restorations are fabricated using conventional methods. (G) One-year postloading results show nearly complete preservation of the interproximal papilla height and improved labial gingival biotype. Labial gingival margins are substantially coronal in position as compared with the initial levels. (H) The final restorations have a more normal length, offering the patient a much more youthful smile. Preexisting moderate to severe attrition is noted on the incisal edges of the mandibular anterior teeth. (I) Periapical radiographs at 1 year of the implants with final restorations reveal good preservation of interproximal bone height with minimal saucerization. The platform-switched implant restorations likely contribute to the preservation of bone.

Radiographic evaluation demonstrates moderate to severe vertical and horizontal periodontal bone loss. The osseous crest position, in relation to the gingival margins, appears too apical to provide adequate gingival support (see Fig. 81.3B). The restorative and periodontal status of the canines is healthy.

Treatment Objectives

Considering her age, reasonable aesthetic expectation, concern for surgical morbidity, and a lack of willingness to wear a removable provisional prosthesis, the treatment objective for this patient would be to use a surgical approach that minimizes the extent and number of surgical procedures while providing predictability, longevity, and acceptable aesthetics. Recommending orthodontic extrusion or multiple surgical procedures to achieve ideal aesthetics

on this patient would be considered an excessive treatment plan and would not provide any additional value or benefits for her.

Treatment Options

Considerations for extracting four maxillary incisors include the need to remove sound porcelain-fused-to-metal crowns from the canines to replace them as part of a six-unit fixed prosthesis. This option has a questionable long-term functional and aesthetic prognosis. Her dentition exhibits evidence of excessive overbite and parafunctional habit, which may have contributed to the alveolar bone loss of the incisors in the first place. The convex shape of the ridge and the lack of osseous support will most likely result in substantial horizontal and vertical resorption of the edentulous ridge under the pontics of the fixed bridge, even with extraction socket grafting and ovate provisionalization. This will compromise the long-term aesthetics.

Even if this patient can tolerate the temporary removable partial denture, which she said she cannot, this option poses a considerable aesthetic challenge. The ridge surrounding the extraction sockets will rapidly lose vertical and horizontal dimensional soon after the extractions.[3] The loss of vertical height in the interproximal gingival areas creates an aesthetic problem that is very difficult to correct. It often requires multiple surgical procedures that have a high incidence of surgical morbidity and rarely achieve the desired ideal aesthetic result. This is especially true in a case such as this in which the patient has extensive periodontal vertical and horizontal bone loss. The anticipated vertical ridge collapse after the extraction is substantial, even with bone grafting of the extraction sockets. More important, the need for multiple surgical procedures to achieve "acceptable" aesthetic results for this patient may be too traumatic for her.

Extracting four maxillary incisors, immediately placing two implants, and replacing the teeth with a 4-unit provisional fixed partial denture supported by two implants is an acceptable but risky treatment option. Immediate provisionalization of the two immediately placed implants, with her occlusion and suspected parafunctional habit, carries the risk of early excessive loading and implant failure. Additionally, it will be challenging to maintain the

vertical and horizontal ridge dimensions in the edentulous area under the pontics. Most likely it will require additional soft tissue augmentation procedures to achieve "acceptable" aesthetics in the pontic area (i.e., missing central incisor area).

Clinical Correlation

A common cause of aesthetic failure is inadequate examination of the soft and hard tissues surrounding the surgical site and the natural dentition. If the examination is incomplete or findings are misinterpreted, an incorrect diagnosis will be made, which in turn will lead to an incorrect treatment plan. The judgment to formulate an appropriate treatment plan depends on making an accurate diagnosis!

Extracting four maxillary incisors, immediately placing four implants in the sockets, and replacing the missing teeth with a four-unit provisional fixed partial denture supported by four implants is another acceptable option. Splinting four provisionals together should provide sufficient resistance and protection to the implants from early excessive loading. Some clinicians do not recommend placing implants next to each other in the lateral and central incisor positions because they are often positioned too close and it is very difficult to create or maintain an interdental papilla that emulates an interdental papilla between an implant and a tooth or between two natural teeth.[39] However, the more recent use of implants with a platform-switching design may change the spatial requirements for achieving an interdental papilla between implants. The bone between implants appears to be better protected, and as a result the vertical height of the interproximal tissue may be better preserved.[8,25] If procedures are carried out properly, this option can provide a long-term functional and aesthetic result, with minimal discomfort to the patient.

1. Extract four maxillary incisors and replace them with a conventional (six-unit) fixed prosthesis supported by the canines.

2. Extract four maxillary incisors and wait for healing of the sockets and ridge while temporarily replacing the missing teeth with a removable partial denture. Plan to place two or four implants after 3 to 6 months of healing by using either a one- or two-stage approach.
3. Extract four maxillary incisors, immediately place two implants in the lateral positions, and replace the missing teeth with a four-unit provisional fixed partial denture supported by two implants.
4. Extract four maxillary incisors, immediately place four implants in the sockets, and replace the missing teeth with a four-unit provisional fixed partial denture supported by four implants.

Surgical Strategy for Predictable Aesthetics

Because of the patient's age and reasonable expectation, the level of the aesthetic goal determined for this patient is not ideal but is acceptable. This level of aesthetics can be predictably achieved in a minimally invasive, patient-friendly manner. By mentally visualizing the surgical and prosthetic goal, an acceptable aesthetic outcome can be achieved for this patient if the existing heights of the interproximal gingival tissues can be maintained. Additionally, if the existing biotype and the level of the labial gingival margin can be overbuilt with hard and soft tissue augmentation, the final aesthetic outcome will be enhanced. If this can be accomplished with simultaneous implant placement, it will minimize the number of surgical procedures required. In this case, especially because the patient appears to have parafunctional habits, it is desirable to place more implants and use them to support the immediate provisionalization.

Considering all of these treatment options, the treatment that is most compatible with this patient's surgical strategy for predictability, acceptable aesthetics, and long-term results is treatment option 4, extraction of the incisors followed by immediate placement of four implants with an immediate provisional restoration supported by the implants.

Treatment Plan and Rationale

Four maxillary incisors are to be extracted and four implants placed immediately in a one-stage approach with simultaneous bone and soft tissue grafting. The bone and crescent-shaped free-gingival grafting technique will be used to overbuild labial gingival biotype.[18] A tapered implant with platform-switching design is to be used. The tapered design has been shown to promote primary stability in sockets, and the platform-switching design better maintains the interimplant bone.[8,25] An immediate provisional restoration without centric contacts will be attached to the implants.

Treatment Sequence

In complex treatment involving dental implants, the treatment plan must be sequenced and coordinated between the restorative dentist and the surgeon before starting the treatment. This is especially true when immediate provisionalization is planned. This will enhance success and help make the treatment more patient friendly.

Surgical Procedure

Once the patient is anesthetized, the incisors are extracted atraumatically, thus ensuring that gingival tissues, especially the interdental papilla, are not damaged (see Fig. 81.3C). The sockets are prepared to receive implants by removing the sulcular epithelium and by completely and thoroughly removing all granulation tissue. Immediately placed implants must have complete primary stability at the time of placement. Proper vertical position, buccolingual position, and mesiodistal position, as well as buccolingual angulation, are all critical factors for a successful outcome. Implants in anterior sockets are prepared and placed toward the palate (see Fig. 81.3D) to ensure sufficient labial bone thickness for labial margin stability.[9] Once the provisional healing abutments are accurately seated (may require bone profiler), the labial void of the sockets is grafted with particulate bone, and a crescent-shaped free gingival tissue graft is harvested and placed over the graft (see Fig. 81.3E), as described previously and in the literature.[18] By using this technique, all four teeth can be augmented in one surgical procedure with minimal discomfort to the patient. Once the soft tissue crescent grafts are secured with sutures, the provisional abutments are prepared for provisional crowns. The

provisional crowns (splinted) are fabricated using conventional methods (see Fig. 81.3F). Contours of the provisional crowns may need to be modified as healing and remodeling occurs. Impression taking for the final restoration is relatively easy because the provisional abutments placed at the time of surgery and modified during healing nicely shape the tissues for an optimal prosthetic emergence profile.

Results

The 1-year result shows nearly complete preservation of the interproximal papilla height and an improved labial biotype with labial gingival margins that are substantially coronal to the original gingival margin level (see Fig. 81.3G). The final result consists of crowns with a more normal incisor length and a more youthful smile (see Fig. 81.3H). Some gingival irregularity is noted, and it appears to be a result of the soft tissue grafting. These areas could easily be smoothed with gingivoplasty, but the patient refused. Radiographs reveal preservation of interproximal bone with minimal saucerization around the implants with a platform-switch design (see Fig. 81.3I).

After the surgical strategies described and with the use of minimally invasive surgical techniques, this 70-year-old patient received immediate implant-supported replacement of severely compromised maxillary incisors with an acceptable (or better) aesthetic result and minimal treatment discomfort. With one surgery, including the extractions, she was provided with a fixed implant restoration on four implants. In the same surgery, the bone and soft tissue were augmented while preserving the interdental papilla. She experienced very little postoperative pain and was pleased with her new, more youthful-looking smile. The treatment time was only 6 months from extraction to final restoration. She was never without teeth and never wore a removable prosthesis. The improvement of the labial gingival margin was achieved without orthodontic extrusion or multiple surgical procedures.

Case Presentation 2

Case presentation 2 is a simultaneous extensive bone augmentation

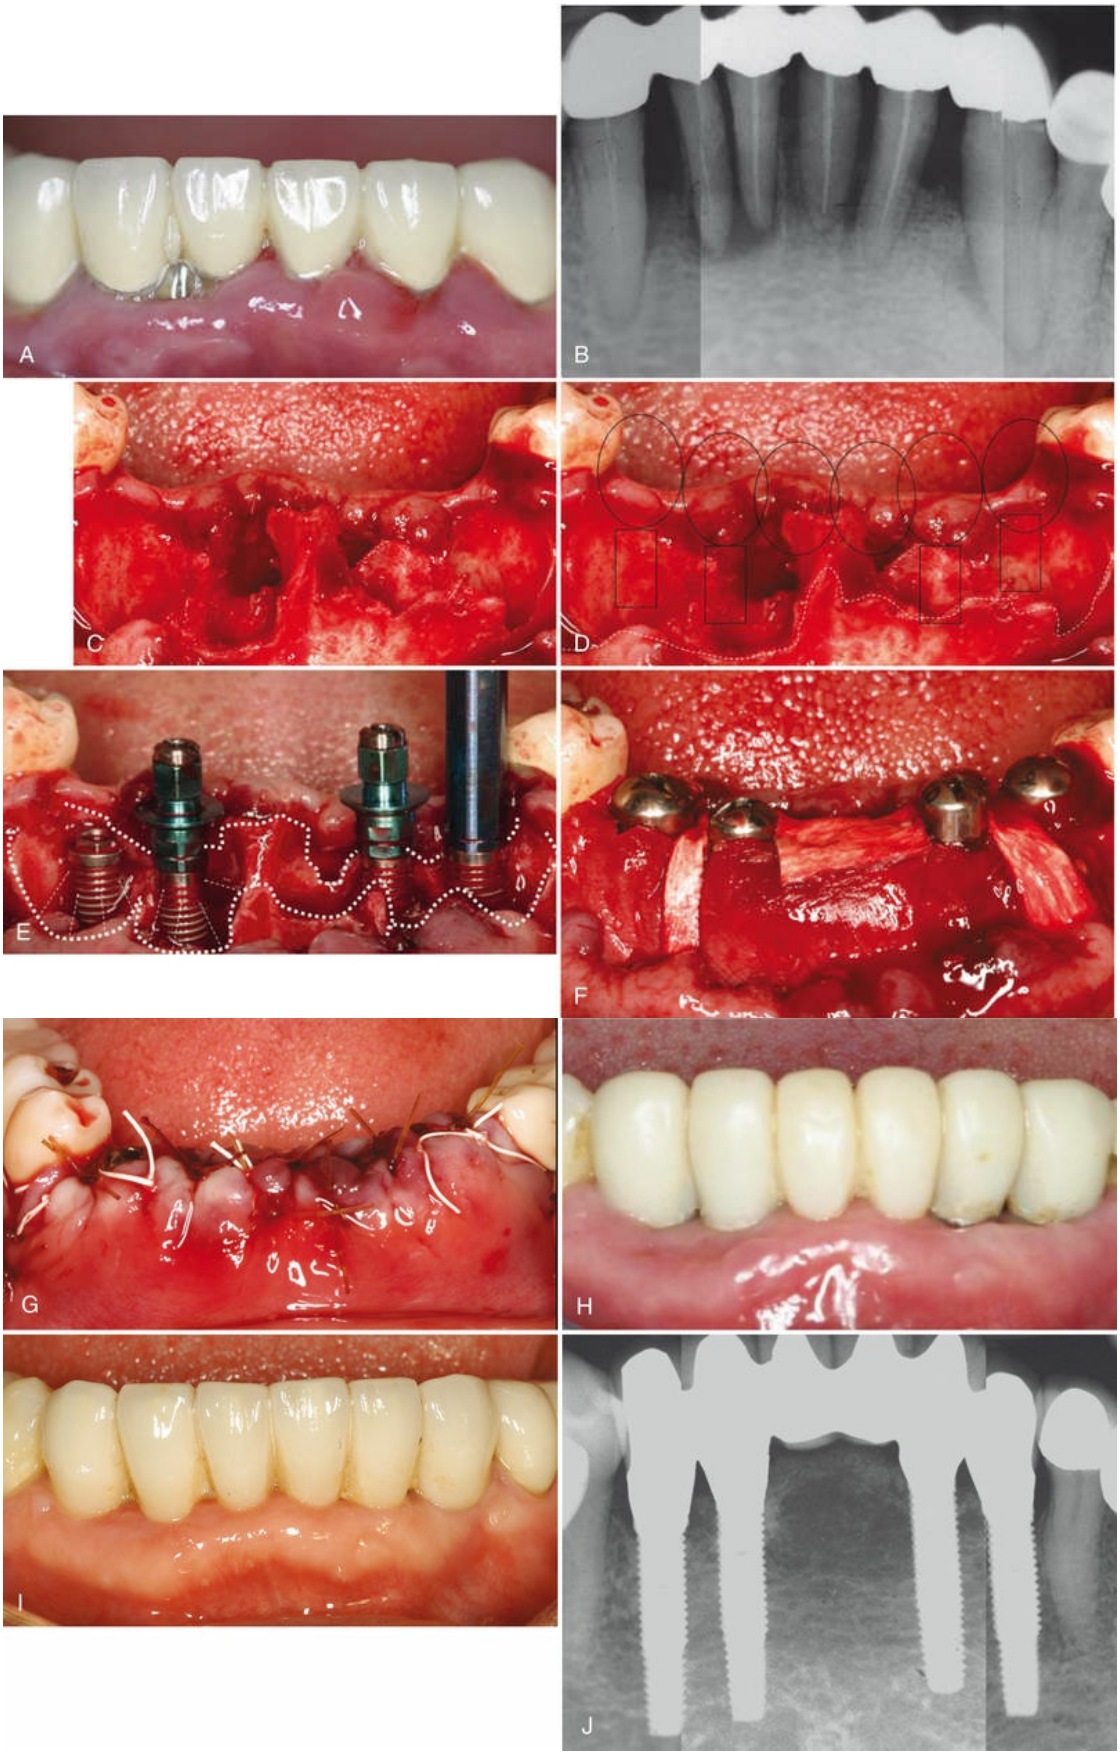
with multiple mandibular anterior immediate implants placed in a one-stage approach with labial flap reflection.

Dental History and Chief Complaint

The patient is a 41-year-old woman with severe periodontal and endodontic infection affecting her mandibular anterior teeth. She is experiencing pain, halitosis, and a bad taste in her mouth. She is healthy and does not present with any medical contraindications to dental treatment. She is frustrated by her current dental condition because she recently replaced the crowns on the involved teeth. She understands the hopeless condition and would like to replace the teeth with dental implants, but she is apprehensive about the surgical procedures and concerned that the procedures will interfere with her busy schedule. She prefers a fixed provisional during the healing period if possible.

Examination and Diagnosis

The patient's mandibular incisors exhibit severe periodontal and endodontic infections with periodontal pockets extending to the apex on several of her teeth. Porcelain-fused-to-metal crowns with overhanging margins are splinted together. The gingival tissue is swollen and erythematous, and heavy exudation is expressed from the gingival margins with palpation (eFig. 81.4A). She has a difficult time brushing because of the pain from the infection. Radiographic evaluation reveals severe generalized vertical and horizontal periodontal bone loss around the incisors with endodontic involvement. Existing endodontic treatment showed inadequate obturation and apical seal (eFig. 81.4B). These mandibular incisors have a poor periodontal and endodontic prognosis. The remaining dentition is stable. She is not overtly concerned with aesthetics, but desperately wants relief from pain, halitosis, and the bad taste in her mouth.



EFIG. 81.4 (A) Splinted porcelain-fused-to-metal crowns with overhanging margins on mandibular

incisors that are infected. The gingival tissues are swollen with moderate to severe inflammation. (B) Radiograph reveals severe generalized vertical and horizontal bone loss from periodontal and endodontic infections. (C) Alveolar bone shows extensive destruction from periodontal and endodontic infections. (D) With a surgical stent, the proposed implant sites are visualized and the surrounding bone is evaluated. (E) Visualizing how the adjacent bone topography (socket walls) will contribute to bone formation around the implants, it is evident that even without grafting, most of the implant surface will become integrated with bone. (F) Layers of resorbable collagen membrane cover the bone graft material. (G) Full-thickness periosteal flaps are released, adapted around the healing abutments, and sutured. (H) Three months after surgery, the provisional restoration shows healing gingival tissues with sufficient ridge height and volume. (I) Four-year results show acceptable aesthetic implant restorations in a stable ridge with a wide zone of keratinized, attached gingiva. (J) Periapical radiographs at 4 years demonstrate good bone regeneration and maintenance with osseointegration of all implants.

Treatment Objectives

The immediate focus for this patient is to make her comfortable by eliminating the source of infection as soon as possible. However, considering her aesthetic requirements, concern for surgical morbidity, and preference for a fixed provisional, an important treatment objective for this patient would be to identify a surgical approach that minimizes the extent and number of surgical procedures while providing predictability, longevity, and acceptable aesthetics. A situation in which multiple extensive surgical procedures are necessary to achieve acceptable aesthetics would be difficult for both the clinician and the patient.

Treatment Options

1. Extracting six mandibular incisors and replacing missing

teeth with a removable provisional prosthesis immediately addresses the patient's chief complaints, but because of the anticipated severe ridge collapse after the extractions, this approach will most likely result in a situation in which multiple extensive surgical procedures will be necessary to achieve acceptable aesthetics.

- It is common to expect a loss of vertical height ranging from 5 to 10 mm after extraction of multiple mandibular incisors with severe bone loss. Surgical procedures used in an attempt to regain the vertical height of the ridge for acceptable aesthetics in this region carry substantial risk and morbidity. Once the ridge collapses, any vertical ridge augmentation procedure requires extensive labial flap releasing to close over the grafting material and membrane. These large flaps often dehisce from the tension caused by the lower lip muscle movements and require more time to heal by secondary intention with a potentially compromised outcome.
- Even when flap closure is maintained, extensive labial flap releasing frequently results, obliterates the vestibular space, and creates mucogingival problems, which may require additional surgery to correct. The ridge augmentation procedure can be done on an incremental basis to minimize surgical complications, but the patient is subjected to multiple surgical procedures and prolonged treatment time. Distraction osteogenesis is an option to gain back the lost ridge height, but other problems are associated with this approach, and it also requires multiple patient visits with extended use of a removable provisional prosthesis.[11,20] However, the greatest disadvantage of this direction of treatment is that whichever ridge augmentation procedure is used to reconstruct the ridge, it is extremely difficult to gain back the vertical ridge height that was lost. The final

aesthetic result is usually disappointing.

2. Extracting six mandibular incisors and augmenting the ridge or sockets with particulate bone graft using a labial flap approach to remove granulation tissues completely and expose healthy alveolar bone is better than the first option, but it still requires considerable labial flap releasing to close over the grafting material and barrier membrane.

    A risk of flap dehiscence during healing is present for the reason mentioned previously. Because of the postoperative swelling and ridge dimensional changes, maintaining flap closure under a removable provisional prosthesis is difficult. Complete bone regeneration will take 6 to 10 months, depending on the type of bone grafting material used, and the total treatment time will be prolonged. Most often, multiple surgical procedures are required, with several provisional modifications to obtain the desired aesthetics. However, the greatest disadvantage of this treatment option is the inability to reconstruct the lost vertical ridge height predictably. The final aesthetic result is typically disappointing, especially considering the enormous time and effort invested in treatment.

3. Extracting six mandibular incisors, immediately placing four implants, augmenting the alveolar defects with particulate bone graft and resorbable membranes, and replacing the missing teeth with a six-unit provisional fixed partial denture supported by four implants is the third option. (*Note:* It is preferable to place implants in a one-stage approach and to restore them with a provisional restoration, but the decision depends on the relationship of the implants with the surrounding bone.)

    If implants are placed immediately using a two-stage approach (i.e., flap release with primary closure), the surgical risks and aesthetic limitations will be similar to those described for treatment option 2. However, this option has some advantages over

treatment option 2. The implants placed at the time of extractions will function as tent poles to support the bone graft materials and membrane and will be osseointegrated and able to support a fixed provisional restoration in approximately 6 months. This will minimize the required time that the patient will have to endure a removable provisional prosthesis. If the implant–bone relationship is favorable enough to place the implants in a one-stage approach (i.e., the implant will be positioned in an intraosseous location or within the bony envelope and not supracrestally or outside the bony envelope), the surgical risks and morbidity will be less, and an immediate fixed provisional restoration can be delivered at the time of the surgery. This treatment option more predictably preserves the vertical height of the ridge and avoids the likelihood of severe ridge collapse following extractions. Only this treatment option offers a reasonable possibility of providing an aesthetic implant restoration; it is accomplished with a minimal number of surgical procedures and less surgical risk.

Surgical Strategy for Predictable Aesthetics

Because of the patient's reasonable expectation, the level of the aesthetic goal selected for this patient is not an ideal level but an acceptable level. This level of aesthetics can be predictably achieved in a minimally invasive, patient-friendly manner. Mentally visualizing the final result with clinical and radiographic data, an acceptable aesthetic outcome can be achieved for this patient if the existing heights of the lingual and interproximal bone can be preserved with grafting. If the implants can be placed immediately, they will assist in preserving the alveolar bone height by acting as tent poles to support the grafting material and membrane. The ridge will be overbuilt in anticipation of augmentation tissue or material shrinkage. If the implant–bone relationship is favorable, a one-stage approach can be used, and an immediate fixed

provisional restoration can be delivered at the time of surgery.

Considering all of these treatment options, the treatment that is most compatible with this patient's surgical strategy for predictability, acceptable aesthetics, and long-term results is treatment option 3, extraction of the mandibular incisors, immediate placement of implants (provided the implant–bone relationship is favorable), bone augmentation with particulate bone graft and barrier membrane, and immediate fixed provisional restoration supported by the implants (again, provided the implant–bone relationship is favorable).

Treatment Plan and Rationale

To decrease the infectious process, alleviate symptoms, and improve tissue quality, initial therapy consists of patient education, oral hygiene instructions with an ultrasoft toothbrush, chlorhexidine rinses, and 1 week of antibiotic therapy (e.g., Augmentin [combination of amoxicillin and clavulanate] 500 mg/125 mg by mouth every 8 hours for 7 days). Six mandibular incisors will be extracted using a labial full-thickness flap reflection to ensure complete removal of the granulation tissue and to visualize the bony architecture. If the implant–bone relationship is favorable for bone regeneration around the restoratively determined implant positions (canines and laterals), implants are to be immediately placed in a one-stage approach with simultaneous bone augmentation, which allows immediate provisionalization of these implants. Because the bone in the anterior mandible is dense, sufficient primary stability for immediate provisionalization can be easily achieved. If the bone architecture is unfavorable for a one-stage approach, the implants will be placed in a two-stage approach with simultaneous bone grafting, barrier membrane, and primary flap closure. If a one-stage implant placement is achieved, the implant position will be recorded (i.e., indexed) at the time of surgery for the purpose of laboratory provisional fabrication, and the provisionals will be delivered within 1 to 2 weeks after surgery. The bulk of the surgical swelling should have subsided at that time. An Essex provisional will be delivered at the time of surgery for temporary aesthetic replacement of the missing teeth. The patient will be in provisional restoration for 6 months to ensure implant

integration and peri-implant tissue stabilization. A final restoration can be fabricated and delivered at that time.

Treatment Sequence

Impressions are taken at the initial oral hygiene appointment and used to fabricate a surgical guide and an Essex provisional restoration.

During the surgical appointment, the anterior mandibular teeth are extracted, and the surgical treatments are carried out as outlined in the treatment plan. The Essex provisional is delivered, and patient is dismissed. If all goes as planned and implants will be immediately placed in a one-stage approach, the fixed provisionals will be delivered in 1 to 2 weeks. The fixed provisional restoration is replaced with the final restoration in approximately 6 months.

Surgical Procedure

Once the patient is anesthetized, the incisors are extracted with minimal damage to the delicate gingiva. The interdental papillae are severed at the crest, and a full-thickness labial flap is reflected. The flap is designed with divergent vertical incisions at the mesial line angles of the first premolars to facilitate surgical access and wound closure. A lingual full-thickness flap is reflected just enough to expose the crest of the lingual bony wall. Granulation tissue is thoroughly debrided to prepare the bone for implant placement and bone augmentation (see eFig. 81.4C).

The initial impression of the extensive bony destruction observed after complete debridement suggests that immediate implant placement may not be possible and certainly immediate implant placement in a one-stage approach is doubtful. However, when the surgical guide is put in position, the bony architecture surrounding the proposed implant sites indicates a favorable implant–bone relationship (see eFig. 81.4D) and a good potential for bone regeneration around the immediately placed implants, even in a one-stage approach. Mentally visualizing the final result again with the bone exposed confirms that an acceptable aesthetic result can be achieved for this patient because the existing heights of the lingual and interproximal bone can be preserved with immediate implant placement and bone augmentation.

It has been documented in the literature and confirmed with clinical cases that if implants are placed within the bony envelope of the ridge (i.e., in an intraosseous relationship with the surrounding bone), the bone regeneration potential around immediately placed implants is favorable even in the presence of labial dehiscence.[40] Furthermore, when the implant head is positioned at or below the crest of bone in an intraosseous relationship with the surrounding bone and bone grafts are used with barrier membranes, bone will predictably fill to the top of the implant and integrate with the implant surface.[34]

Therefore the four implants are placed according to these principles, in the sites determined by the surgical guide. The apical-coronal position of the implant is partially dictated by the adjacent level of the bony wall, but care is taken to avoid placing them more than 4 mm below the anticipated labial gingival margin of the final restorations. The implants are placed as far lingual as reasonably possible to maximize the distance from the implant to the labial envelope of the residual ridge to enhance the likelihood of achieving an intraosseous relationship with the surrounding bone. Imagining how the adjacent bone topography (socket walls) contributes to bone formation around the implants, it is evident that even without grafting, most of the implant surfaces will become integrated with bone (see eFig. 81.4E). Once a favorable potential for bone regeneration around the implants is ascertained, the decision to proceed with a one-stage implant placement approach is confirmed. Long implants (15 mm in length) are placed to ensure sufficient primary stabilization that, when splinted together, will be capable of withstanding occlusal loads. A rapid setting registration material is used to register the implant position for provisional fabrication. Healing abutments (5 mm tall) are lightly secured to the implants for the initial postoperative healing phase.

For more complete bone regeneration around the implants and to overbuild the ridge dimensions, the site is augmented with particulated autogenous graft and mineralized allograft. A thin layer of particulated autogenous bone harvested from the ramus area is placed directly on the implant surfaces to enhance integration, and the allograft is layered to overbuild the ridge. Because only a small piece of the ramus bone was harvested, the

donor surgical site is minimized, and postoperative discomfort is minor. The grafted material is covered with two layers of resorbable collagen membrane (Bio-Gide, Osteohealth, Shirley, NY) to isolate and protect the graft material (see eFig. 81.4F). The labial flap periosteum is adequately released to minimize flap tension during closure and healing. The flaps are adapted around the healing abutments and sutured with interrupted 4-0 chromic gut sutures (see eFig. 81.4G). The mucogingival junction and the vestibular depth are not appreciably altered because it was not necessary to advance the flap significantly. The Essex provisional is delivered to the patient while making sure that the apical edges do not cut the sutures or impinge on the wound during the postoperative healing and probable swelling. The patient is dismissed with postoperative instructions.

Ten days after the surgery and after the postoperative swelling has mostly subsided, the lightly secured healing abutments are removed. The laboratory-fabricated provisionals are carefully placed, making sure to avoid tissue impingement. Provisional bridges should be sectioned before placing and rejoined after the placement on the implants. The joined contacts should be strong enough to avoid being separated during mastication. The patient should be seen on a monthly basis to enforce good oral hygiene and to evaluate tissue healing and provisional stability (see eFig. 81.4H). The provisional restoration is replaced with a final restoration in approximately 6 months.

Results

The 4-year result demonstrates an acceptable aesthetic implant restoration in a stable ridge with sufficient vertical height and horizontal volume. A wide zone of keratinized, attached gingiva is noted (see eFig. 81.4I). A periapical radiograph (at 4 years) indicates bone regeneration and maintenance at the top of the implants. All implants are stable and appear to be osseointegrated (see eFig. 81.4J).

By following the surgical strategies described and using minimally invasive techniques, this 41-year-old patient was provided with aesthetic dental implant restoration with a minimal number of surgical procedures and treatment time. Her immediate

complaints were addressed without the need for multiple extensive surgical procedures. She did experience some postoperative pain and swelling, but her entire treatment required only one surgery, and the total treatment time was only 6 months from extractions to the final restoration. She was provided immediately with an Essex provisional restoration, which was replaced with a laboratory-fabricated fixed provisional restoration attached to the implants 10 days after surgery. She was comfortable throughout the duration of the treatment.

This surgery may appear very extensive and at first impression not minimally invasive. However, any treatment option other than this approach would most likely require multiple, more extensive surgical procedures with higher surgical morbidity and a much longer treatment time. More critically, because it is difficult to reconstruct vertical ridge height after it is lost, the greatest disadvantage of the other treatment options is that the final aesthetic result is more often than not disappointing. Therefore, even with the extensive bone loss observed in this case, immediate implant placement in a one-stage approach with simultaneous bone augmentation and immediate provisionalization is considered by many clinicians to be a minimally invasive and patient-friendly approach to providing aesthetic dental implant therapy.

Case Presentation 3

Case presentation 3 illustrates the use of short, wide-diameter implants to treat a severely resorbed mandibular posterior ridge.

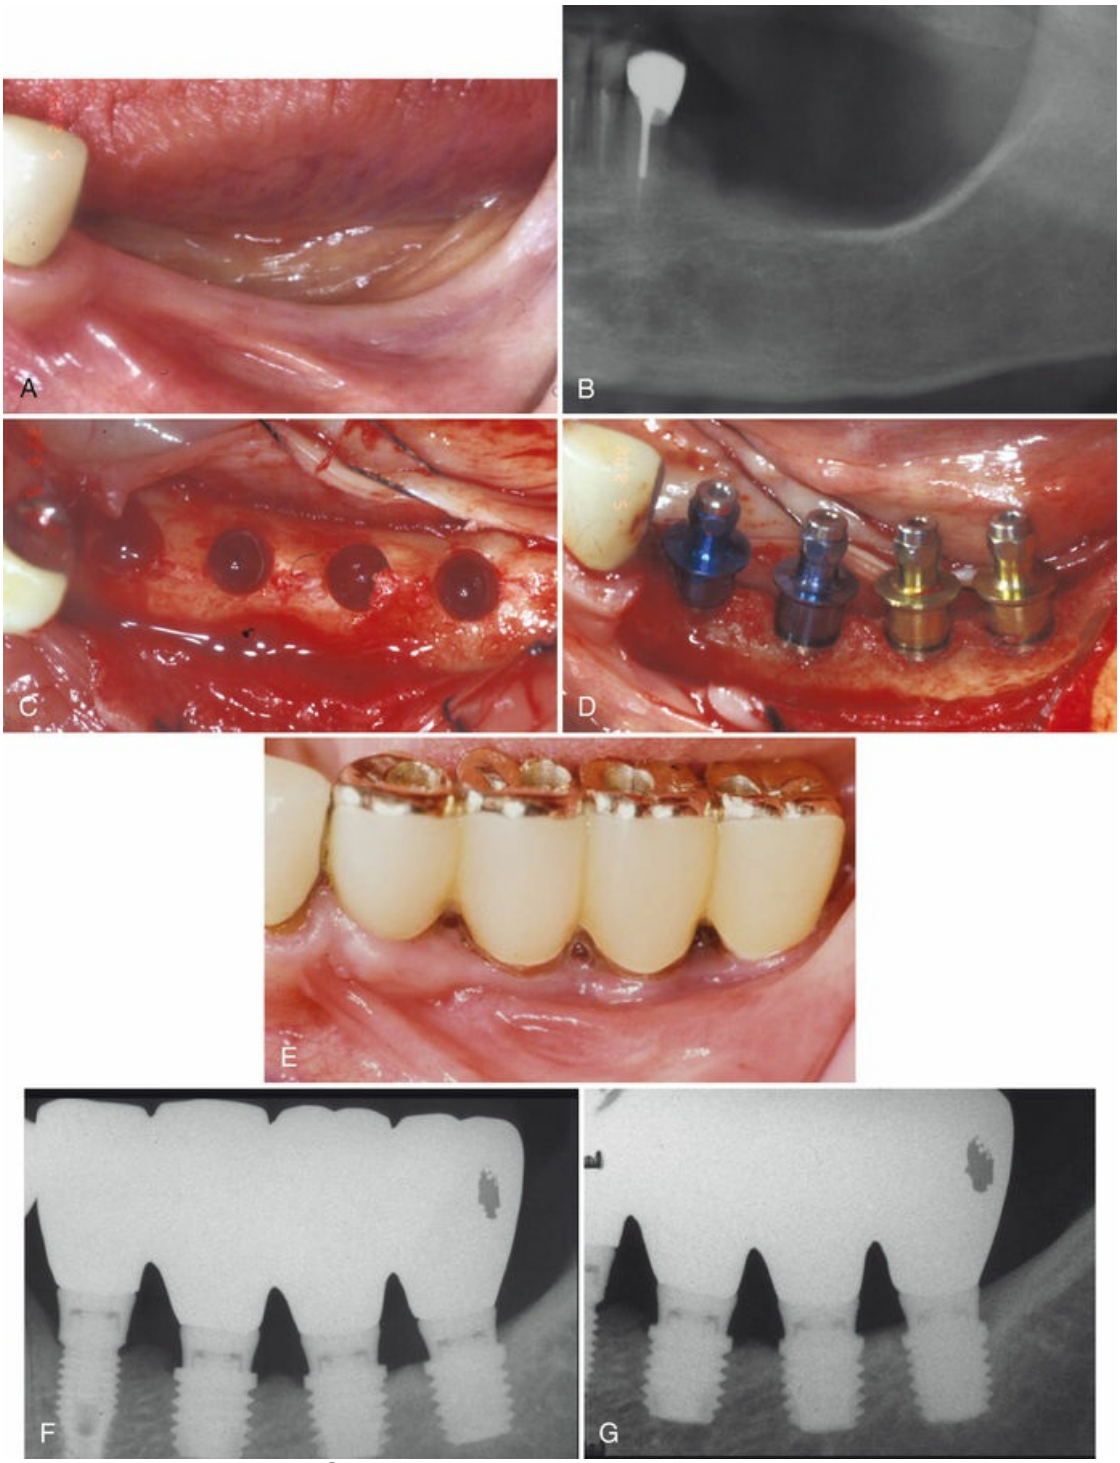
Dental History and Chief Complaint

The patient is a 65-year-old woman with a severely resorbed mandibular posterior ridge. She is frustrated with her partial denture and wants dental implants to give her better “chewing” ability. She does not present any medical contraindication to dental treatment, but she is anxious about extensive dental surgical procedures. The aesthetic outcome is not a concern for her.

Examination and Diagnosis

The patient's posterior ridge of the mandible shows extensive

vertical ridge resorption with a narrow band of keratinized gingiva at the crest. The ridge height is near the floor of the mouth, with frenum and muscle pull on the buccal side (eFig. 81.5A). The radiographic vertical height of the ridge measured from the crest to the mandibular canal is approximately 7 mm (eFig. 81.5B). Clinical examination shows what appears to be a narrow ridge, but the horizontal width of the ridge measured at the bony crest with a caliper is approximately 8 mm. A three-dimensional scan (e.g., CT or CBCT) can confirm this finding. The typical anatomy of mandibular and maxillary posterior segments after severe vertical resorption often has sufficient ridge width for implant placement.



EFIG. 81.5 (A) Severely resorbed ridge in the posterior mandible in a 65-year-old female patient. Examination reveals a narrow band of keratinized, attached gingiva at the ridge crest. (B) Panoramic radiograph of patient in (A) showing a limited vertical height of bone above the inferior alveolar nerve of approximately 7 mm. (C) Clinical view of prepared implant osteotomy sites in the posterior mandible. Despite the severe vertical ridge resorption, most of the time ridge width in posterior

sites is sufficient to accommodate wide-diameter implants. (D) One 4-mm–diameter short (7-mm) implant and three 5-mm–diameter short (5-mm) implants were placed with good initial stability. The bone width was adequate, with no implant thread exposures. (E) The final implant restorations were fabricated with gold occlusal surfaces and splinted together. Adequate interproximal spaces were created for oral hygiene access. (F) Periapical radiograph (13 months after loading) reveals stable crestal bone height despite the long crown-to-implant ratio. (G) Another follow-up periapical radiograph (30 months after loading) reveals continued stability of the crestal bone height. Platform-switched abutment or restorations, adequate biomechanical support, and careful occlusal design contribute to bone preservation and maintenance.

Treatment Objectives

Considering her concerns about surgical morbidity, the treatment objective would be to identify a surgical approach that minimizes the extent and number of surgical procedures while providing predictability and longevity. Attempting to reconstruct the vertical height of the deficient posterior ridge with multiple extensive surgical procedures would be difficult for both the clinician and the patient.

Treatment Options

1. Distraction osteogenesis can provide sufficient vertical height for normal implant placement, but it most likely requires multiple surgical procedures, may be associated with high surgical morbidity, and certainly increases treatment time.[11,20] Furthermore, performing this procedure in a severely resorbed posterior mandible area is challenging, technique sensitive, and skill dependent.
2. Interpositional bone augmentation can provide sufficient vertical height for normal implant placement, but as with the distraction osteogenesis approach, it requires multiple

surgical procedures, longer treatment time, and high surgical morbidity of both the donor and recipient sites. Performing this procedure in a severely resorbed posterior mandibular area is challenging, technique sensitive, and skill dependent.[13] Furthermore, the ridge height initially gained using interpositional grafts has been shown to decrease during healing, and often the resulting ridge is insufficient to place implants with longer lengths.

3. Vertical ridge augmentation with autogenous monocortical bone block can provide vertical ridge height gain, but as with the other two options, surgical morbidity of both the donor and recipient sites is increased.[28,29] It will require multiple surgical procedures and longer treatment time. This surgical approach often requires extensive reshaping of the recipient site to maximize bone contact between it and the donor bone. Even in the cases in which the graft has survived, substantial vertical height loss results from postsurgical resorption. As with the other two options, the final ridge height is often insufficient to place implants with longer lengths.
4. Vertical ridge augmentation with particulate bone and membrane (see Chapter 80) has provided vertical height gains up to several millimeters, but depending on the type of bone graft used, it can increase treatment time substantially.[6,7,37] If autogenous bone graft is used, postoperative surgical morbidity will be increased as the result of the donor site wound. Maintaining the flap closure over the grafted ridge and membrane is difficult, and clinicians have experienced increased surgical complications. It is a technique-sensitive and skill-dependent procedure. Furthermore, the vertically augmented bone can be unstable, and the resulting ridge is often insufficient to place implants with longer lengths.
5. Vertical augmentation using bone morphogenetic proteins (BMPs) and space-maintaining membrane or titanium mesh has the advantage of limiting or eliminating the need for donor sites to harvest autogenous bone. However, many clinically important questions related to the predictability of

augmentation with biologic mediators such as BMPs remain unanswered. As with other vertical augmentation procedures, the surgical challenge of maintaining flap closure over the grafted ridge and membrane or titanium mesh is difficult. A commercially available biologic mediator such as BMP is expensive, and the surgical procedure is technique sensitive and skill dependent.

6. Implant placement with mandibular nerve repositioning can provide the opportunity for placement of longer implants by repositioning the inferior alveolar nerve, but it is associated with increased surgical morbidity and complications.[14] It is also a technique-sensitive and skill-dependent procedure.
7. Placing multiple, short, wide-diameter implants is another option. Because examination of the alveolar dimensions reveals an 8-mm width and a 7-mm height, it is possible to plan for the placement of four short, wide-diameter implants. To increase the biomechanical stability, the restorations are splinted together. Because bone dehiscence is not anticipated, these implants can be placed using either a one-stage or a two-stage approach, depending on the clinician's preference. A one-stage approach would further reduce the number of required surgical procedures and treatment time. Preparation of precise osteotomy sites is important for short implants to ensure good stability. A mild to moderate amount (e.g., two threads) of bone loss around short implants is more significant than the same amount of bone loss around longer implants because it results in a greater percentage of lost support relative to the implant length.

Treatment Plan and Rationale

Because the patient has an 8-mm width and only a 7-mm ridge height at the three distal implant sites, three 5-mm–diameter × 5-mm–long implants will be placed; 4-mm–diameter × 7-mm–long implants will be placed in the most anterior site because the ridge is narrower (≈6 mm) and taller (≈9 mm). These implants will be placed in a two-stage approach to accommodate the clinician's preference,

but with precise surgery, they could be placed in a one-stage approach. This surgery does not require special skills, and if the restorative treatment plan is properly executed, the use of short implants will provide predictability and longevity.[2,15,16,27]

Treatment Sequence

No special treatment sequencing is necessary. This procedure is facilitated, as are all implant surgeries, by using a surgical stent and following a proper restorative treatment plan.

Surgical Procedure

Once the patient is anesthetized, a crestal incision is made, bisecting the existing band of crestal keratinized tissue. Buccal and lingual full-thickness flaps are reflected to visualize the full width of the ridge clearly. Sutures can be used to keep the flaps away from the surgical site. Properly spaced osteotomy sites are prepared to accommodate one 4-mm–diameter and three 5-mm–diameter implants (see eFig. 81.5C). Implants are placed with very good primary stability and no bone dehiscence (see eFig. 81.5D). The flaps are closed with a combination of mattress and interrupted sutures. Exposure of the implants and fabrication of the restorations are done 3 months after the implant placement. Because aesthetics is not the major concern of the patient, the clinician elected to use gold metal occlusal–surfaced implant restorations (see eFig. 81.5E). The restorations have a platform-switching configuration to enhance crestal bone preservation, and they are splinted together with sufficient embrasure for proper oral hygiene.

Results

A periapical radiograph, taken 13 months after loading, shows a stable crestal bone level despite the long crown-to-implant ratio of the restorations (see eFig. 81.5F). The implant abutments have a platform-switching design, which has been shown to preserve crestal bone. A periapical radiograph, taken 30 months after loading, shows long-term crestal bone stability without further bone loss around the short, wide-diameter implants (see eFig. 81.5G).

This patient was provided with a very functional, stable implant restoration in just 3 months by using short, wide-diameter implants. The other possible treatment options for this patient would have required multiple surgical procedures and would have increased the risk of surgical morbidities and complications. Treatment time would have been much longer, and the results may have fallen short of the treatment goal. This case offers a sound example of how patients with extensive vertical bone loss in posterior regions can be treated using short, wide-diameter implants with a minimally invasive, patient-friendly surgical approach, without sacrificing predictability and longevity.

Conclusion

The clinical science in dentistry has evolved to where placement of dental implants and restoring them require sufficient knowledge in several disciplines of dentistry. In addition to mastering surgical objectives and techniques, periodontists must be able to evaluate and accurately diagnose (and treat or refer) a wide range of related "restorative" issues including but not limited to aesthetics, occlusion, temporomandibular joint function, vertical dimension, and dental–skeletal relationships. These "other" aspects of diagnosis are essential for the development of an appropriate treatment plan, which is necessary for a successful outcome in aesthetic implant dentistry.

In addition, with heightened expectations of aesthetics pushing the art and science of dentistry, it is necessary more than ever for clinicians to understand fully all the available treatment options and to be able to determine appropriately which option to choose, when to use certain techniques, and how to apply them for each patient's scenario.

The minimally invasive approach and techniques presented in this chapter are not the only ways to manage difficult aesthetic cases, and some clinicians may consider them controversial. Certainly, these techniques require learning and practice to make them effective in each clinician's hands. However, they present a sound approach to what is possible in hard and soft tissue management for aesthetic implant surgery and provide effective

strategies and techniques for solving many difficult aesthetic cases in a patient-friendly manner.

Case Scenario 81.1

Patient:
A 52-year-old Hispanic female patient

Chief Complaint:
"My front tooth is loose and it hurts."

Background Information:
Patient reports a history of periodontitis. Her front teeth were traumatized initially 3 years ago and then again 2 weeks ago. She has porcelain-fused-to-metal crowns on several anterior teeth. She was informed by her general dentist that tooth #8 has a "hopeless" prognosis. It was deemed nonrestorable due to severe bone loss and horizontal root fracture sustained from the most recent traumatic injury. She was referred for evaluation and treatment to replace tooth #8 with an immediate implant. She is concerned about the aesthetic appearance.

Clinical Findings:
The patient has a high smile line. Periodontal examination revealed pocket depths in the range of 3 to 4 mm except in the upper anterior area, where the probing pocket depth is 6 to 9 mm on #8. Localized areas of gingival inflammation are noted on #8. Evaluation of the alveolar ridge in areas #8 revealed severe facial bone resorption.

CASE-BASED QUESTIONS	SOLUTIONS
1. What factors make this case aesthetically demanding? A. Moderate to severe bone loss B. High smile C. Thin periodontal biotype D. Lack of labial bone E. All of the above	**Answer: E** **Explanation:** Several factors make this case aesthetically challenging and difficult to manage, including but not limited to the factors listed in options A to D. In addition, the patient's expectations are demanding. This case requires both hard and soft tissue augmentation to address horizontal and vertical deficiencies.
2. What are treatment options for this patient? A. Single tooth implant #8 B. Fixed partial denture #7 to #9 C. Fixed partial denture with multiple abutments D. Removable partial denture E. All of the above	**Answer: E** **Explanation:** Although more information is needed about the remaining bone support and attachment levels of adjacent teeth, all options are potentially viable. Because several teeth already have porcelain-fused-to-metal crowns, it would be reasonable to consider a fixed bridge with pontic to replace tooth #8. The edentulous site would be augmented to improve aesthetics.

CHAPTER 82

Dental Implant Microsurgery

Immediate Placement

Dennis A. Shanelec, Leonard S. Tibbetts

CHAPTER OUTLINE

Implant Microsurgery
Conclusion

The success of dental implants in extraction sites combined with immediate provisionals for newly placed dental implants has brought a convergence in restorative and surgical practice for treatment planning of dental implants. This convergence reaches its summit in the approach to failing teeth in the maxillary aesthetic zone. For anatomic reasons, maxillary anterior teeth are at high risk for traumatic injury[13,14] (Fig. 82.1). Traumatized teeth frequently receive endodontic treatment that may be followed by horizontal or vertical root fracture.[1,2,15] Dentistry's historic answer to tooth loss

has been the fixed bridge. Tooth preparation necessary for a fixed bridge often results in significant reduction of tooth structure.[22] Inherent aesthetic limitations of fixed bridges include loss of gingival papillae and resorption of the buccal alveolar plate. For these reasons, dental implants are a preferred choice for tooth replacement in the maxillary aesthetic zone.

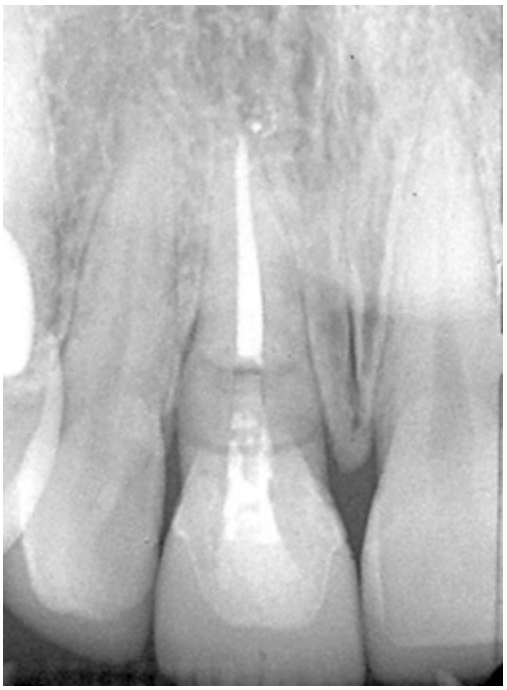

FIG. 82.1 **Periapical radiograph of typical fractured central incisor.**

Implant Microsurgery

Microsurgery is associated with enhanced soft tissue procedures and fine suturing. This is part of the scope of implant microsurgery, but additional benefits include dental implant drilling precision. The ability to discern minute dimensional differences permits implant osteotomy preparations centered exactly between reference points such as adjacent teeth, adjacent implants, or buccal and lingual ridge anatomy. More profoundly, the microscope allows immediate detection of subtle changes in drill position so appropriate feedback corrections can be applied to the handpiece. Enhanced angular perception is also important. The drill's angular position can be oriented relative to small landmarks such as the

implant platform surface level or the angle of adjacent implant healing caps. This permits optimal parallel positioning and depth of adjacent implants. The implant drill angle can also be accurately oriented to root surface angulation using just 3 to 4 mm of root anatomy exposed between the cementoenamel junction and the osseous crest. These reference points are simply not visible without a microscope. The detection of subtle angulation reference points and changes in drill position permit feedback correction, which is important for osteotomy preparation in extraction sockets. The microscope-enhanced accuracy of osteotomy microsurgery permits socket implant placement in an ideal position followed by an aesthetic implant-supported provisional (Fig. 82.2). As a flapless procedure, this is accomplished with minimal patient morbidity.[22]

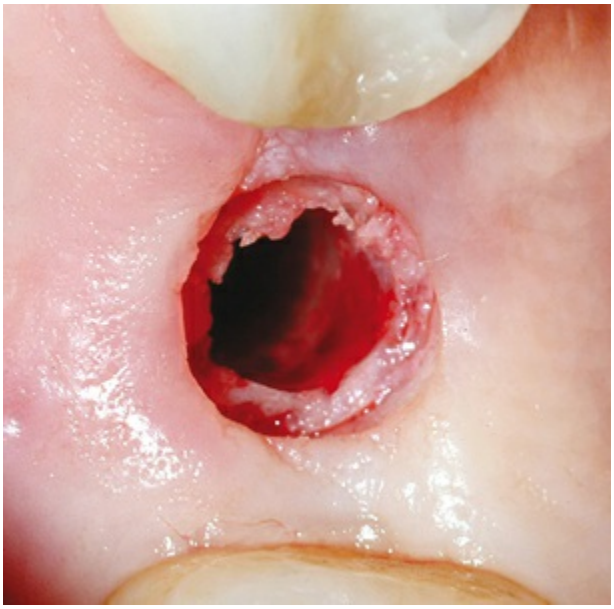

FIG. 82.2 **Flapless dental implant microsurgery.**

Key Fact

The microscope facilitates detection of subtle changes in drill position. Enhanced angular perception is possible by focusing on small landmarks such as the implant platform or healing abutment surface of an adjacent implant. This permits optimal parallel positioning of the drill angle. These reference points are not visible

without a microscope. Detection of subtle angulation reference points and changes in drill position permit feedback correction, which is important for osteotomy preparation in extraction sockets.

Microsurgical Tooth Extraction

Tooth extraction has been traumatic for centuries. Conventional tooth extraction may require mucogingival flaps and bone removal, resulting in compromised aesthetics. Using a microscope with minimally invasive principles reduces trauma and results in predictable aesthetic outcomes.[6] Instrument selection influences the trauma of tooth removal. Periotome luxation or leveraged mechanical extraction using tapped root anchorage systems can carefully separate a tooth from its surrounding ligament and lift it vertically from the socket. This limits injury to papillae and preserves natural gingival anatomy (Fig. 82.3). Subtle nuances in luxation direction can be microscopically detected for root removal in a proper anatomic path of extraction. Increased visibility under the microscope permits most extractions without mucogingival flaps. Greater visibility also permits atraumatic sectioning of ankylosed roots to leave alveolar bone and soft tissue uninjured. Apical granulomatous lesions can be completely debrided with full visibility. Such minimally invasive microsurgical techniques translate into reduced patient morbidity with enhanced healing.

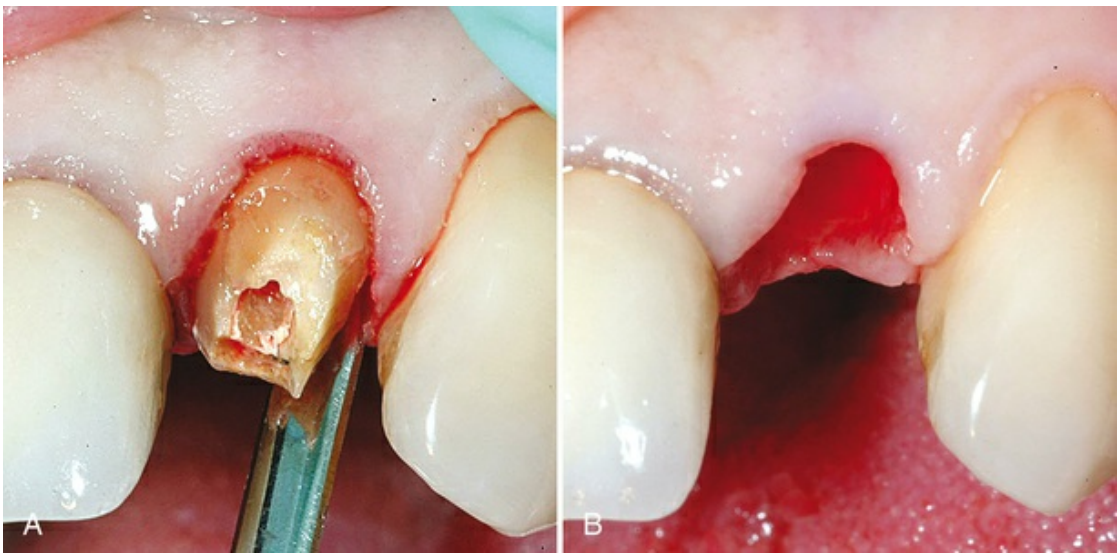

FIG. 82.3 (A) Periotome extraction of lateral incisor.

(B) Noninvasive extraction of lateral incisor. Tissue contours are preserved.

Implant Drilling in the Extraction Site

Microsurgical implant drilling in the extraction socket is unique. Under the microscope, a socket appears as large as a room, with its apex and walls clearly visible. A different set of skills is required for socket drilling. For placement of maxillary anterior implants, the most favorable bone lies to the palatal (Fig. 82.4). Drilling therefore must be done at an angle to the palatal socket wall. Twist drills innately track toward the direction of less dense bone and into the open socket. Drilling of sockets under a microscope utilizes visual feedback to constantly redirect the drill to the correct position and angulation. This avoids the common mistake of placing an implant too far toward the buccal. With the magnification and lighting a microscope provides, implants can be placed in the palatal socket wall with good initial stability and ideal aesthetic position. Microscope-enhanced dimensional and angular perceptions allow adjustments to correct drilling speed. Too little or too much drill pressure or excessive drill speed causes frictional heat. This adversely affects implant osteointegration. Detecting micromovement of the advancing drill ensures that proper pressure and rotational speed are applied to varying bone densities encountered in the socket. The angular velocity at the cutting edge of a 4-mm drill is several times faster than the velocity at the cutting edge of a 2-mm drill. For this reason, pressure and rotation of larger diameter drills must be decreased to compensate for their faster cutting speed. Enhanced visual feedback for speed and pressure correction is accomplished through directly viewing the advancing drill under the microscope.

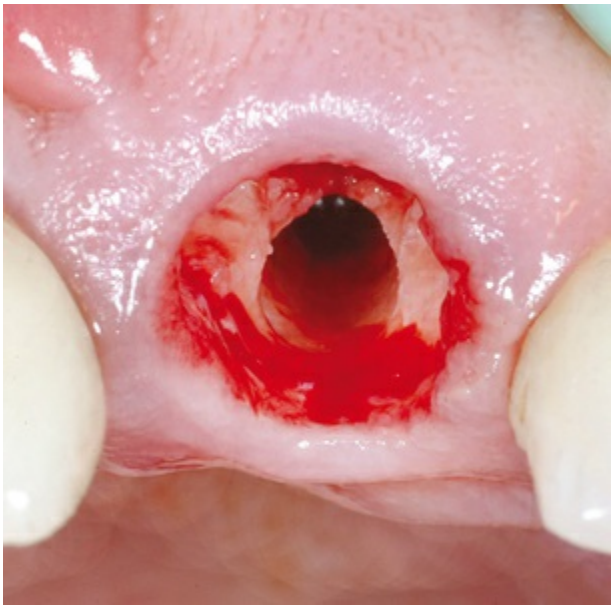

FIG. 82.4 **Palatal wall socket osteotomy.**

Bone Grafting

The osteotomy in an extraction socket is prepared in the palatal wall. This placement results in a gap between the implant and the buccal socket wall. To avoid displacing a particulate graft, the provisional is finished before a socket bone graft is placed. The socket is filled with xenograft to within a millimeter of its crest. Xenograft is selected to reduce remodeling resorption of the buccal bone. Filtered bone from the osteotomy preparation is rinsed with 3% tetracycline solution and then condensed on the top of the xenograft. Finally, it is covered with a layer of microfibrillar collagen to contain the graft.

Buccal Gingival Grafting

Recession on the buccal gingival margin around anterior implants placed in extraction sockets has been well documented.[11,17] Multiple factors, such as the periodontal biotype, presence or absence of the buccal cortical plate, surgical trauma, implant position, and the emergence profile of both the provisional and final restorations, are associated with such recession.[9,12,16,18–20] A subepithelial connective tissue graft is therefore harvested from the palate and transferred into a split-thickness envelope incision on the buccal of the implant. A connective tissue graft is done to maintain or augment gingival

height and thickness that may have been lost as the result of injury (Fig. 82.5). Even gingival tissue at a normal height can be expected to recede as much as 1.5 mm unless gingival grafting is performed. Placing a subepithelial connective tissue graft concurrent with implant placement ensures stability of the postoperative gingival level.[7,21]

FIG. 82.5 **Facial connective tissue graft placed under gingival margin and secured with a fine suture.**

Immediate Provisional Fabrication

To preserve natural aesthetics and provide support for gingival anatomy, an implant provisional must emerge from the surrounding gingival tissue in exactly the same way as the extracted tooth.[4,23] The surgical microscope gives dentists the visibility necessary to fabricate ideal anatomy for implant provisional crowns The provisional crown on the implant serves a number of functions, as follows:

1. It provides optimal aesthetics and function.
2. It minimizes tissue collapse by supporting the gingival tissue.
3. It obturates the surgical extraction socket to contain particulate and soft tissue grafts.

Creating an implant provisional crown begins before the tooth is removed.[8] A clear silicone impression captures the dentogingival junction and its proximal tooth contours (Fig. 82.6). Tooth color matching is done, and a light-cured flowable composite resin duplicate of the tooth is created using the impression (Fig. 82.7). The duplicate crown is trimmed to the exact location of the dentogingival junction and then hollowed to create a shell crown. It is fitted to a screw-retained titanium provisional abutment that is opaque for a color match (Fig. 82.8). Great attention is paid to the incisal edge position of the shell crown before luting it to the abutment with flowable composite resin. Screw access for removal of the provisional is accomplished by drilling through the incisal one-third of the provisional crown.

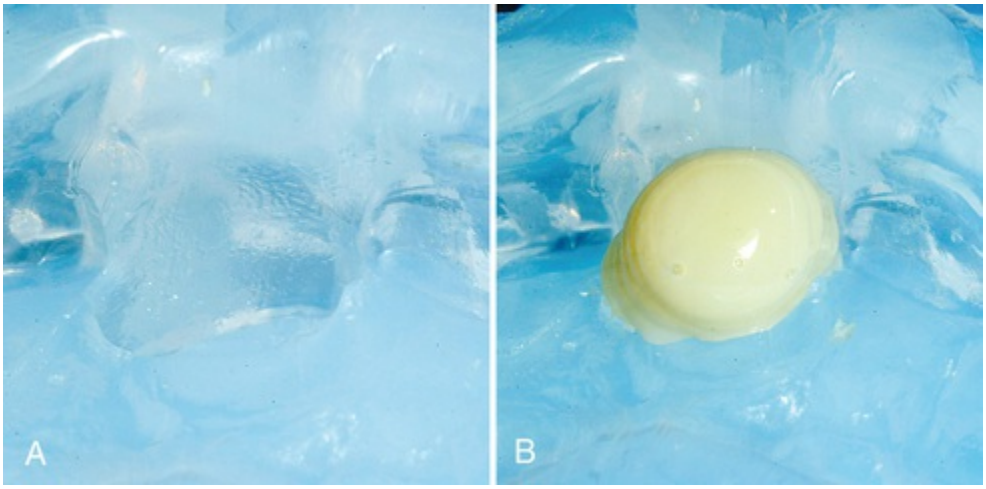

FIG. 82.6 (A) Clear silicone impression of failing tooth crown. (B) Clear silicone impression filled with composite.

FIG. 82.7 **Shell composite crown created from impression.**

FIG. 82.8 (A) Opaque titanium temporary abutment. (B) Composite crown luted to opaque titanium temporary abutment.

The luted abutment and crown are removed and placed on a laboratory handle to facilitate shaping and polishing (Fig. 82.9). Subgingival provisional contours created under the microscope provide tissue support and well-finished margins. Each provisional crown has a uniquely shaped subgingival emergence profile that duplicates the original tooth. Voids and rough edges are eliminated, and the provisional is carefully shaped under the microscope to provide gingival support (Fig. 82.10). Shaping the provisional is accomplished with a 12-fluted finishing bur, glass nail file, and a prophylaxis cup with pumice. Attention to detail is critical. As a

final step, the provisional crown is glazed and thoroughly cured. Light curing the composite ensures that no free monomer is present to irritate soft tissue or bone. The machined titanium provisional abutment ensures good marginal fit and reduces the possibility of loosening.

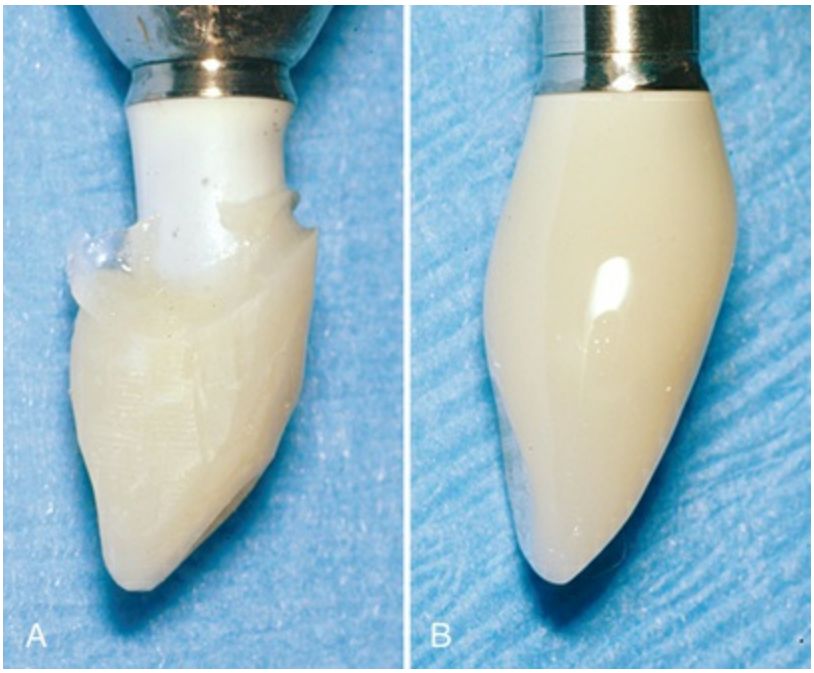

FIG. 82.9 (A) Screw-retained provisional before finishing. (B) Screw-retained provisional after finishing.

FIG. 82.10 **Provisional restoration supporting gingival tissue.**

Clinical Correlation

An immediate provisional restoration delivered with the immediately placed implant provides optimal aesthetics and function, minimizes tissue collapse by supporting the gingival tissue, and helps to obturate the surgical extraction socket to contain particulate and soft tissue grafts.

Immediate Implant Occlusion

Early loading bone trauma is minimized in multiple immediate implant provisional cases by splinting. Early loading bone trauma in single implant cases is reduced by lessening occlusal forces. Symmetric and light mesial and distal proximal contacts are established, and the provisional is taken out of centric and lateral occlusal contact by using 1-mm green occlusal indicator wax. This technique allows patients to leave the dental office with a nonloaded aesthetic provisional tooth securely anchored to the implant (Fig. 82.11).

FIG. 82.11 Provisional 1 week after implant microsurgery.

Custom Impression Transfer Coping

A custom impression transfer coping is necessary to preserve and communicate gingival supporting contours to the ceramicist. The

chairside-created provisional anatomy must be precisely reproduced for the dental laboratory via the custom impression transfer coping.[5,10] To make the custom transfer coping, an impression of the gingival third of the provisional crown is made with an implant analog attached (Fig. 82.12). This registers the implant platform orientation and preserves the provisional anatomy. The crown is removed, and a standard impression coping is attached to the implant analog. Acrylic powder fills the gap between the impression coping and the clear silicone impression. Monomer liquid is then infused into the powder to create a hard acrylic copy of provisional anatomy (Fig. 82.13).[3,5] Using a 25-gauge needle to apply monomer to the powder from the base upward minimizes inclusion of air bubbles in the custom transfer coping. For orientation, a mark is initially applied to the labial surface of the provisional impression. It is transferred to the custom transfer coping to provide orientation for the restorative dentist during final impressions. This technique allows precise communication from the surgeon to the restorative dentist to the ceramicist of the anatomy required for a final restoration that aesthetically supports gingival tissue.

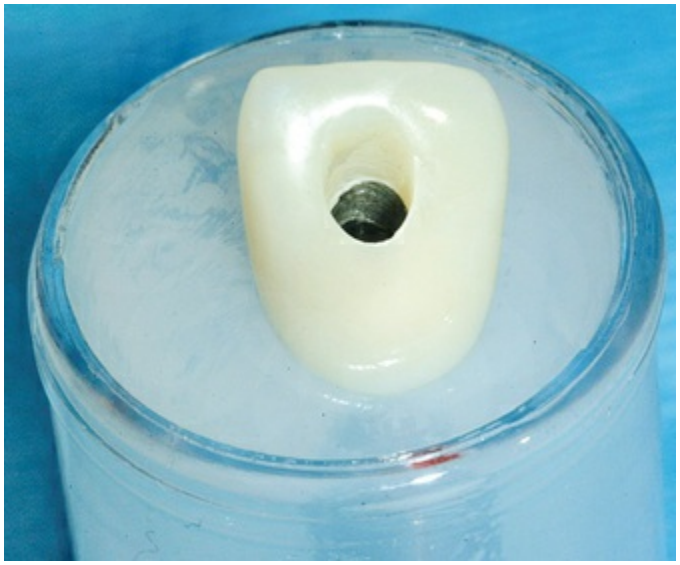

FIG. 82.12 **Clear silicon impression of provisional.**

FIG. 82.13 **Custom impression transfer coping reproducing emergence profile.**

Final Implant Restoration

Final impressions are taken using the custom impression transfer coping. Computer-assisted scanning and machining create a zirconia abutment and zirconia coping for an all-ceramic crown (Fig. 82.14). Zirconia has the benefit of tissue biocompatibility and light translucency. The sequence described ensures a final implant abutment and crown that exactly matches both the provisional emergence profile and the original tooth shape. Working as a team, the surgeon, restorative dentist, and laboratory technician can create a final restoration in harmony with preserved gingival architecture (Fig. 82.15).

microsurgery.

FIG. 82.15 (A) Before microsurgery. (B) Immediately

after microsurgery. (C) Final restoration.

Conclusion

Some of the advantages of microsurgery for extraction and implant placement have been described with an emphasis on tissue management and the ability to enhance visualization of details, which translate into better results. This microsurgery protocol advances dentistry from an era of traumatic tooth extraction to one of seamless immediate tooth replacement using implant microsurgery.

CHAPTER 83

Piezoelectric Bone Surgery

Tomaso Vercellotti, Perry R. Klokkevold, Giuseppe Vercellotti

CHAPTER OUTLINE

Clinical Characteristics of Ultrasonic Cutting
Clinical Applications
Advanced Clinical Applications *(e-only)*
Conclusion

Ultrasound has been used for many years in periodontics to remove tartar, debride root surfaces, and degranulate periodontal defects. In recent decades a novel family of ultrasonic-powered devices has been developed that is revolutionizing oral and maxillofacial bone surgery.

This surgical technique, known as piezoelectric bone surgery, was invented by Vercellotti and developed by Mectron Medical Technology (Carasco, Italy). The Piezosurgery device (Fig. 83.1) consists of a piezoelectric ultrasonic transducer powered by an ultrasonic generator, capable of driving a range of specially

designed cutting inserts.[25,30] The Piezosurgery device employs ultrasonic vibrations to cut mineralized tissues. To this end, a primary frequency at 30 kHz is overmodulated by the superimposition of a sound wave (30 to 60 Hz) to generate a hammering action that effectively cuts bone without harming soft tissues and with minimal heat production. Box 83.1 describes the main cutting properties of Piezosurgery by Mectron, and Box 83.2 describes Piezosurgery inserts. Piezoelectric bone surgery techniques have been developed for clinical applications in dentistry and are becoming state of the art for a variety of procedures.[26–28,30,37,38] Piezosurgery Medical has expanded development of clinical applications to other fields of medicine. The extraordinary cutting properties of piezoelectric bone surgery have been introduced and applied in maxillofacial surgery, facial plastic surgery, otolaryngologic surgery, cranial and spinal neurosurgery, and minute orthopedic surgery.[7–17]

FIG. 83.1 Piezosurgery device by Mectron Medical Technology. (Courtesy Mectron Medical Technology, Carasco, Italy.)

Box 83.1

Description and Cutting Properties of Piezosurgery by Mectron

Piezosurgery is an electronic device that generates ultrasonic microvibrations at variable frequencies. Its dual-wave technology is unique in the world (US patents 6,695,047 B2, 8,002,783 B2) for the characteristic vibrations generated in parallel and variable frequency modulation for precise cutting of bone with different degrees of density.

The unit has a display that allows the operator to select different operating functions that set the ultrasonic modulated frequency to ideal parameters for cutting bone of different density, shaping, debriding, and smoothing root surfaces (both external [periodontal] and internal [endodontic]) and for separating soft tissues from bone.

Function Settings

Implant

The basic ultrasonic frequency is overmodulated by sound waves that are higher than those for cortical bone, ideally suited for perforating bone for implant site preparation.

Cortical

The basic ultrasonic frequency (30 kHz) is overmodulated by sound waves for cutting and removing small cortical bone fragments.

Cancellous

The basic ultrasonic frequency is overmodulated by sound waves that are slower than those for cortical bone, better for cutting and removing cancellous bone fragments.

Special

The basic ultrasonic frequency operates at a frequency that is most effective when working in proximity with soft tissues.

Perio

The basic ultrasonic frequency, without overmodulation, is set at an ideal power level for scaling, debridement, and root planing.

Endo

The ultrasonic frequency, without overmodulation, is set at an ideal power level for retrocanal and intracanal debridement after root canal treatment.

Box 83.2

Description of Piezosurgery Inserts

The mechanical action of bone cutting takes place thanks to the linear microvibrations of inserts with a variable range from 20 to 80 μm, depending on the setting selected. Piezosurgery inserts are classified based on their functional and clinical characteristics.

Functional Classification

Sharp: These inserts have sharp ends for osteotomy and osteoplasty. They are made of nitride titanium steel and are gold in color.

Smoothing: These nitride titanium inserts are diamond coated and gold in color. Their different granulometry produces a smoothing action that is generally used to complete the cut near soft tissue.

Blunt: These steel-colored inserts are characterized by rounded ends and are generally used to refine the cut in contact with soft tissue.

The inserts described in the functional classification as sharp, smoothing, and blunt have clinical classification codes that relate to their specific use.

Clinical Classification

OT: The identification code for inserts used to perform osteotomy is *OT* followed by a number.

OP: The identification code for inserts used to perform osteoplasty is *OP* followed by a number.
EX: The identification code for inserts used to perform extraction is *EX* followed by a number.
IM: The identification code for inserts used to perform implant site preparation is *IM* followed by a number.

Key Fact

Ultrasonic scalers use only one frequency and have insufficient power to cut mineralized tissues. In comparison, Mectron surgical devices rely on the juxtaposition of a sound wave (30 to 60 Hz) to the primary ultrasonic wave (24 to 36 kHz) to cut bone without overheating. This phenomenon is known as frequency overmodulation.

The most compelling characteristics of piezoelectric bone surgery are low surgical trauma, exceptional control during surgery, and a fast healing response of tissues. Clinical studies demonstrate that the specificity of operation and the techniques employed with piezoelectric bone surgery make it possible to exploit differences in hard and soft tissue anatomy advantageously.[7,32,34,36] This not only increases treatment effectiveness but also improves postoperative recovery and healing. Experimental studies on animals have shown faster tissue healing when compared with traditional cutting instruments.[7]

Key Fact

Piezosurgery's cutting action is selective, that is, cuts only mineralized tissues while sparing soft tissues. Selective cutting is made possible by the application of ultrasonic frequencies between 24 and 36 kHz.

Ideally, surgical trauma should be minimized to obtain optimal healing, which depends on gentle management. Surgery, by definition, alters normal physiology by interrupting the vascular

supply of tissues. The degree of surgical invasiveness is extremely important for the quality of tissue healing and may affect whether wounds heal by repair or regeneration. Indeed, when surgical trauma is kept to a minimum, it generates enough stimulation to favor healing mechanisms that lead to regeneration, which is actually promoted by ultrasonic frequencies. Conversely, surgical techniques that are more traumatic often lead to greater inflammatory responses with slow healing that may lead to repair and scarring rather than regeneration. For this reason, it is desirable to choose the least traumatic surgical instruments and techniques for any surgical procedure. Piezoelectric bone surgery was conceived and developed precisely to overcome the limits of traditional bone-cutting instruments and to achieve the most effective treatment with the least morbidity.

From a mechanical standpoint, the effect of burs or twist drills on bone is characterized by lamellar fracturing in areas adjacent to the cut surface and the deposition of large bone fragments and debris in the endosteal spaces. This finding is thought to be, at least in part, responsible for the inflammatory process that takes place in immediate postsurgical wound healing and for the delay of osteogenesis observed in these wounds. In contrast, the micromechanical cutting action of piezoelectric bone surgery results in micronization of the cut bone and does not cause lamellar fracturing in adjacent bone; this feature may favor exposure and release of bone morphogenetic proteins (BMPs) and be responsible for the early onset of osteogenesis at these sites (see later). Furthermore, the inflammatory response may be diminished because little or no need exists to remove damaged bone and surgical debris as compared with conventional rotary-drilled sites (Fig. 83.2).

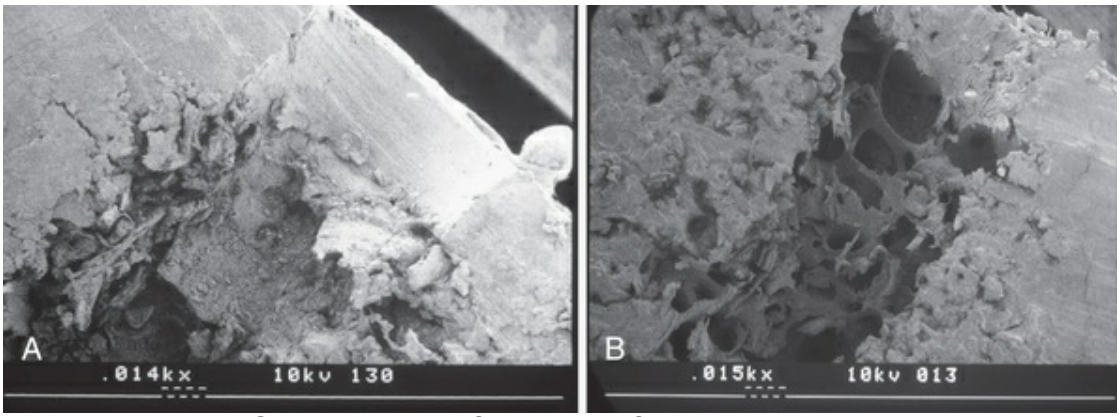

FIG. 83.2 Comparison of bone surfaces prepared with rotary instrumentation and Piezosurgery (Mectron Medical Technology, Carasco, Italy). (A) Rotary technique: in vitro photograph of the implant site following preparation with twist drill of 3.15 mm. The site is ready to receive the implant. Note the compact surface of the cortical bone where no vascular canals are visible. The underlying spongiosa is irregular due to the presence of bone debris in the endosteal spaces. (B) Piezoelectric technique: in vitro image of implant site preparation with 3-mm ultrasonic inserts. The site is ready to receive the implant. Note the cortical bone microporosity where open vascular canals are clearly visible. The underlying spongiosa is intact and free from bone debris. (Courtesy of Dr. Alberto Rebaudi, Genoa, Italy.)

Key Fact

The most compelling characteristics of piezoelectric bone surgery are low surgical trauma, exceptional precision and control, and fast healing. Clinical studies demonstrate that the specificity of operation and the techniques used with piezoelectric bone surgery make it possible to exploit differences in hard and soft tissue anatomy advantageously.

Clinical Characteristics of Ultrasonic Cutting

The primary clinical characteristics of the Piezosurgery cutting action include microprecision, selective cutting, maximum visibility, and excellent healing.

Microprecision

Piezosurgery cuts mineralized tissues with microprecision and extraordinary surgical control. Piezoelectric osteotomies are easy to create, but it is important to recognize that the technique and instrument handling are different from the technique using a traditional handpiece with rotary instruments. The Piezosurgery insert is applied to the bone with a relatively light stroke similar to the smooth precision used to draw a picture. Heavy pressure or force is not required and can, in fact, antagonize the ultrasonic frequency, thus reducing efficiency and transforming mechanical energy into thermal energy (Fig. 83.3). The microprecision of this instrument is made possible by the ultrasonic frequency, which produces mechanical microshock waves at a linear range of approximately 80 μm. The extraordinary surgical control that characterizes Piezosurgery is due to the fact that its microvibrations require only light pressure (approximately 300 g) to be applied to the handpiece. Indeed, the pressure applied by the surgeon to the Piezosurgery handpiece is much lower than the pressure typically applied to a rotary or oscillating type handpiece (approximately 5000 g), which uses mechanical macrovibrations for cutting. This characteristic provides maximum control during surgery and makes this technique unique, especially in areas with delicate anatomy.

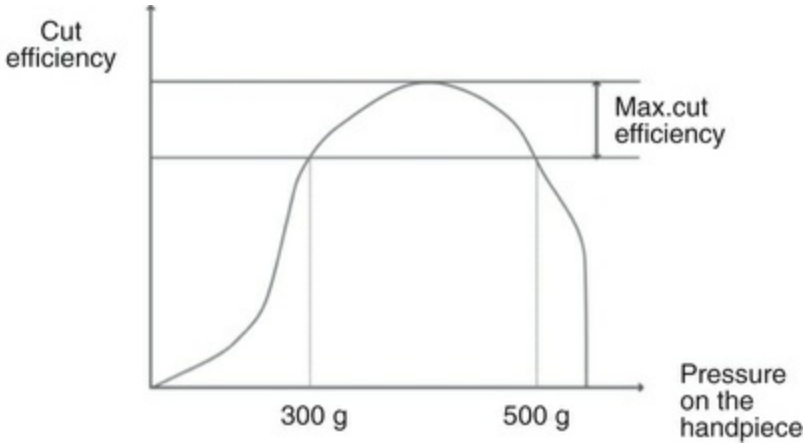

FIG. 83.3 **Graph illustrating the relationship between Piezosurgery (Mectron Medical Technology, Carasco, Italy) cutting efficiency and pressure applied on the handpiece. Note that optimal cutting efficiency is found between 300 and 500 g; pressure in excess of 500 g leads to a sudden and complete loss of cutting efficiency. *Max.*, Maximum.**

Key Fact

Heavy pressure or force is not required to operate the piezoelectric bone surgical handpiece. In fact, forceful handling antagonizes the ultrasonic frequency, thus causing a reduction in the cutting efficiency and transforming mechanical energy into thermal energy.

Selective Cutting

Piezosurgery's cutting action is selective because it cuts only mineralized tissues, which are characterized by greater mechanical resistance to the action of the ultrasonic microvibrations. Indeed, the linear motion of the vibrations, which is in the order of approximately 80 μm, is absorbed and dispersed by the elastic nature of soft tissues. These microvibrations are physically unable to cut soft tissue, where kinetic energy is easily dissipated and—when in low dosage—stimulates tissue healing by promoting mitotic divisions (see later). Clearly, the most significant demonstrated benefit of Piezosurgery selective cutting is the ability to preserve the integrity of soft tissues, such as the alveolar nerve, the infraorbital nerve, the maxillary sinus membrane, blood vessels, and the dura mater, while effectively cutting the mineralized tissue

(bone) in close proximity to these tissues. A study conducted by Schaeren and colleagues[17] revealed that even prolonged contact for up to 5 seconds between Piezosurgery inserts and a peripheral nerve did not dissect the nerve. Combined with maximum operator control, the safety of Piezosurgery's selective cutting dramatically reduces the risk of accidental damage to delicate anatomic structures.

Maximum Visibility

Piezosurgery allows maximum visibility by creating a surgical field that is blood free during cutting because of the cavitation of the cooling irrigation solution. Cavitation is a physical phenomenon that, from a clinical standpoint, happens with the nebulization of the saline solution when it contacts the insert vibrating at ultrasonic frequency. The slight hydropneumatic pressure applied by the nebulized irrigation fluid induces hemostasis in both hard and soft tissues. An important advantage of the cavitation effect is the thorough debridement of the surgical site at the time of the mechanical removal of inflammatory tissue by means of dedicated Piezosurgery inserts. This effect is only temporary, and bleeding resumes shortly after the cutting (and cavitation) action is stopped. Clinically, it is important to ensure proper irrigation and intermittent cutting action to maintain optimal surface microcirculation, especially for long surgical procedures. An added benefit of the temporary hemostasis induced by the cavitation effect is the notably reduced blood loss, especially during longer procedures, which leads to decreased postoperative edema.

Key Fact

The cavitation effect is a physical phenomenon consisting of the implosion of gaseous bubbles within a fluid. In the context of piezoelectric bone surgery, the cavitation of the irrigation solution creates a microspray that cleans the site of debris and provides temporary hemostasis for maximum visibility of the surgical field.

Excellent Healing

Clinical studies comparing use of piezoelectric bone surgery with traditional rotary instruments for third molar extractions[3,6,18] and periodontal surgery[34] have reported better recovery and fewer postoperative symptoms in patients treated with Piezosurgery. Postoperative healing after piezoelectric bone surgery is characterized by minimal swelling and little bleeding, and the rate of postoperative morbidity is lower compared with traditional techniques.[33]

« Flash Back

Piezosurgery's cutting action is selective because it cuts only mineralized tissues, which are characterized by greater mechanical resistance to the action of the ultrasonic microvibrations.

Improved Hard Tissue Healing

The improved healing response observed at Piezosurgery-treated sites may be explained by the stimulation of healing mechanisms promoted by the device's secondary wave, which operates in the range of 30 to 60 Hz. Indeed, research has shown that the application of low-intensity, high-frequency vibrations in the range of 10 to 50 Hz (i.e., the frequency of postural muscle contractions) to bone tissues mimics mechanical loading and induces the release of several growth factors, including BMPs responsible for osteoblast differentiation and new bone formation.[4,5,23] In an animal study comparing the biomolecular profile of sites prepared with piezoelectric bone surgery or rotary drills, BMP-4 increased earlier at implant sites prepared with piezoelectric bone surgery.[7] As compared with drilled sites, the levels of BMP-4 at Piezosurgery-treated sites were 18.5 times higher at 7 days, 15 times higher at 14 days, and 2 times lower at 56 days. The peak levels of BMP-4 were observed at 14 days for Piezosurgery-treated sites. The level of BMP-4 at drilled sites did not reach the same level of BMP-4 achieved at Piezosurgery-treated sites until day 56. A greater increase in the level of transforming growth factor beta 2 (TGF-β2) was also noted at implant sites prepared with piezoelectric bone

surgery techniques. As compared with drilled sites, the levels of TGF-β2 at Piezosurgery-treated sites were 3.5 times higher at 7 days, 19 times higher at 14 days, and diminished below baseline at 56 days. The level of TGF-β2 at drilled sites never exceeded baseline levels.

« Flash Back

Bone morphogenetic proteins (BMPs) are specialized growth factors that promote new bone formation by inducing mesenchymal stem cells to differentiate into osteoblasts. They are fundamental for proper bone physiologic maintenance and repair.

Proinflammatory cytokine tumor necrosis factor alpha, proinflammatory and bone-resorbing cytokine interleukin-1β (IL-1β), and antiinflammatory cytokine IL-10 were also measured. In general, the expression of these proinflammatory cytokines was higher in the early experimental phases of drilled sites only, which also showed more inflammatory cells. The piezoelectric bone surgery–treated sites showed a higher expression of the proinflammatory and bone-resorbing cytokine IL-1β at 56 days. This last finding may be indicative of bone remodeling at day 56 in piezoelectric bone surgery–treated sites (IL-1β is involved in osteoclast differentiation). The lower expression of inflammatory factors following the application of Piezosurgery may be explained in terms of reduced trauma to the cut tissues compared with the use of rotatory instruments; this reduced trauma is made possible by the technology's microvibrations and lack of friction overheating.

Improved Soft Tissue Healing

Research on a novel application of Piezosurgery to detach the periosteum from underlying bone tissue investigated the effect of this technology on the integrity and healing of mucoperiosteal flaps.[21] Periosteal activation following surgical intervention is responsible for chondrogenesis, osteogenesis, and angiogenesis, which ultimately promote vascularization and bone remodeling. Periosteal healing response following trauma is directly related to

the integrity of the periosteum, which provides nourishment to the underlying bone and is essential in osteoinduction and osteoconduction. To ensure proper healing and clinical success, periosteal integrity should therefore be preserved to the maximum extent possible, especially in patients with compromised health. However, the use of manual instrumentation for periosteal elevation has been shown to damage the cells of the osteogenic layer mechanically. Histologically, the periosteum detached with manual elevators shows visible tears, and individual tissue layers are not clearly visible. In contrast, the use of dedicated Piezosurgery inserts specifically designed for periosteal separation from bone was found to be associated with a clean separation of the tissues, with preservation of the outer fibrous layer and the inner cambium layer. Additionally, fat vacuoles and collagenous connective tissue can also be discerned (Fig. 83.4).[21] At the biomolecular level, expression of collagen (II and IV) and osteocalcin in the 8 days following surgery was significantly greater at Piezosurgery-treated sites, thus indicating a more robust healing response. These findings complement the clinical observation that, following piezoelectric bone surgery procedures, gingival tissues show optimal healing and typically appear light in color when compared with the appearance of autogenous gel of platelet-rich plasma.

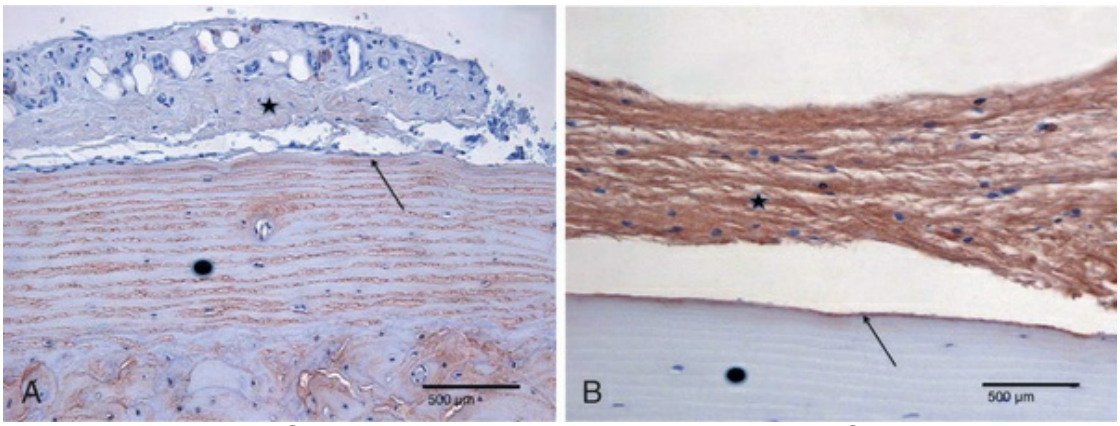

FIG. 83.4 Comparison between periosteal surface elevated with manual instruments and Piezosurgery PR (Mectron Medical Technology, Carasco, Italy) insert tips. (A) Histologic section depicting subperiosteal preparation using manual instrumentation. Note the irregular separation between

periosteum *(star)* and bone *(closed circle)* at the boundary between the two layers *(arrow).* The periosteum shows evidence of mechanical tears. (B) Histologic section showing clear separation between periosteum *(star)* and bone *(closed circle)* at the boundary between the two layers *(arrow)* following preparation with novel piezoelectric inserts. The periosteum is intact and shows no signs of mechanical damage. (Adapted from Stoetzer M, Magel A, Kampmann A, Lemound J, Gellrich NC, von See C. Subperiosteal preparation using a new piezoelectric device: a histological examination. *GMS Interdiscip Plast Reconstr Surg DGPW* 3:Doc18, 2014.)

Clinical Applications

The clinical use of Piezosurgery in osseous surgery advantageously promotes all the benefits of microsurgery, especially when working under optical magnification. Piezosurgery has become an essential instrument in dentistry and in periodontal daily practice to minimize patients' morbidity and increase overall clinical predictability. Piezoelectric bone surgery has many important clinical applications in dentistry. In fact, nearly all techniques previously performed with burs, twist drills, chisels, or oscillating saws have the potential to be performed with Piezosurgery. For 18 consecutive years, one of the authors (T.V.) has used Piezosurgery on a daily basis for oral, periodontal, and implant surgical procedures, thus enabling him to develop techniques and protocols for each. Readers are referred to online materials and other publications for detailed descriptions and step-by-step instructions on these Piezosurgery protocols.[31] A brief overview of basic clinical applications using piezoelectric surgery is described here.

Periodontal Surgery

The use of Piezosurgery in periodontal surgery simplifies and improves both soft and hard tissue management (Table 83.1).[39] In osseous resective periodontal surgery, piezoelectric bone surgery represents a notable evolution from the past because it allows the application of concepts of bone microsurgery. In periodontal soft

tissue management, after raising the primary flap with a traditional technique, it is easier to detach the secondary flap and remove inflammatory granulation tissue by using a scaler-shaped insert (Piezosurgery insert PS2) (Fig. 83.5A) or an insert in the shape of a rounded scalpel (Piezosurgery insert OP3). Contrary to traditional manual techniques, this phase has little bleeding and better visibility as the result of the cavitation of the saline solution (coolant). Hard tissue management is also improved: with the proper inserts and power mode, the ultrasound device facilitates effective scaling, debridement, and root planing (see Fig. 83.5B and C). In particular, debridement with special diamond-coated inserts enables thorough cleaning even for interproximal bone defects, which can therefore be remodeled into even surfaces (see Fig. 83.5D). The mechanical action of ultrasonic microvibrations, together with cavitation of the irrigation fluid (pH neutral; isotonic saline solution) eliminates bacteria, toxins, dead cells, and debris, thus creating clean physiology for healing of the wound. Healing is improved by applying ultrasound to produce micropits at the base of the defect to activate cellular response of healing mechanisms. In hard tissue management, the ostectomy maneuver with Piezosurgery is extremely precise and does not pose any risk of damaging the root surface. Typically, to avoid damaging the radicular cementum, conventional ostectomy techniques are incomplete and leave residual “widow's peaks” that require manual removal using hand chisels. When using Piezosurgery for resective procedures, because it is possible to work on the root surface without damaging it, it is possible to perform thorough ostectomies that do not leave behind more than “micro” widow's peaks. These minimal formations are easily removed when using the final insert for root planing procedures (Piezosurgery insert PP1). When working on reshaping the crestal bone surface, the osteoplasty maneuver at low irrigation allows collecting autogenous particulate bone that can be immediately grafted into small bony defects (see Fig. 83.5E).The use of this technology not only reduces the invasiveness of traditional surgery by making it faster and by ensuring thorough cleaning of the periodontium, but it also favors tissue healing by using bone removed in the osteoplasty procedure to graft small osseous defects, thus

preserving bone architecture.

Clinical Correlation

The clinical use of Piezosurgery in osseous surgery advantageously promotes all the benefits of microsurgery, especially when working under optical magnification. It simplifies and improves both soft and hard tissue management.

It is our opinion that Piezosurgery in periodontal surgery can redefine the guidelines that mark the border between resective treatment and regenerative treatment. Indeed, the choice between a resective technique and a regenerative technique generally depends on the depth of the bone defect, whether it is more or less than 3.5 mm. Thanks to piezoelectric bone surgery, defects greater than 3.5 mm can now be grafted with particulate bone and covered with resorbable membranes.

The ability to work on the bone defect under magnification (e.g., surgical microscope) makes it possible to exploit the benefits of Piezosurgery microprecision in preparing the recipient site and stabilizing micrografts (see Fig. 83.5F to H).

Crown Lengthening

Clinical crown lengthening is the most common periodontal surgical (ostectomy) operation performed in otherwise healthy periodontal conditions. The indication for this procedure is usually associated with a need or desire to expose more tooth structure because of short clinical crowns and/or loss of clinical tooth structure. In general, the goal is to reposition the periodontal bone and soft tissues to a more apical position with appropriate biologic dimensions to avoid periodontal inflammation after tooth restoration.

The clinical crown lengthening technique entails performing a periradicular ostectomy of a few millimeters (1 to 2 mm) combined

with an osteoplasty technique to allow for repositioning of the periodontal flap in a more apical position with favorable periodontal tissue architecture. The positive result obtained is that the health of the treated part is preserved even though the normal gingival morphology is altered. Clinical application must include aesthetic assessment, as well as an assessment of the position and health of the adjacent periodontium.

The traditional surgical technique entails raising of a full-thickness flap, ostectomy with manual instruments, osteoplasty with a bur for crest bone architecture recontouring, periradicular bone removal, root planing, and, finally, replacing the flap in an apical position.

The ostectomy is simple to perform using Piezosurgery in direct contact with the root surface because control of the instrument during surgery is precise, even in very difficult proximity cases (Piezosurgery OP3 insert). The root planing phase can be performed very effectively using blunt ultrasonic inserts (Piezosurgery PP1 insert).

Saline solution cavitation reduces bleeding during surgery and facilitates debridement of the surgical area. This effect is likely responsible for the excellent soft tissue healing result, which is always characterized by a light color and the absence of edema.

A histologic animal study conducted at Harvard University in Cambridge, Massachusetts, showed a better healing response for bone and root cementum in teeth that were crown lengthened using Piezosurgery as compared with teeth that were crown lengthened with traditional rotary instruments.[36] Concerning the latter, the tungsten carbide bur was found to be more favorable than the diamond-coated bur for the bone-healing process.

The crown lengthening technique performed with Piezosurgery using appropriate inserts makes it possible to reduce bone effectively while preserving root surface integrity.

Tooth Extraction

Today, tooth extraction is considered the first step in the preparation for implant placement. Maintaining the integrity of the alveolar bone walls is an essential part of this process.

Consequently, whether an implant is being placed at the time of extraction or not, the selection of instruments and techniques that minimize trauma to socket walls is critical.

Anatomic differences greatly influence the difficulty of extraction and the challenge of maintaining alveolar bone walls. A newer periodontal classification for dental extractions has been developed (Table 83.2) that makes it easier to choose the best surgical tooth extraction technique for different anatomic situations (Table 83.3).[37] The aim is always to preserve the integrity of the alveolar walls and the morphology of soft tissue. This classification divides anatomy into four types depending on the anatomic characteristics of periodontal biotype and anatomy or pathology of the periodontal ligament. Classifying anatomy into type 1, 2, 3, or 4 simplifies the diagnostic process and the subsequent surgical decision. Each type corresponds to a different anatomic issue, which requires a specific extraction technique and determines the most effective surgical instruments.

TABLE 83.2
Periodontal Classification for Dental Extraction

Type 1 anatomy describes a normal periodontal biotype and a normal periodontal ligament (i.e., no pathologic features). This anatomic condition poses little surgical difficulty. A traditional extraction technique using manual instruments is sufficient.

Type 2 anatomy describes a thin periodontal biotype with a normal periodontal ligament. The surgical difficulty for tooth removal is minimal. However, preserving the integrity of the thin alveolar buccal walls makes the extraction more complex. In this situation, the normal displacement operation runs the risk of creating a dehiscence from fracturing the thin buccal cortical plate. To avoid this risk, it is recommended that the surgeon use a root fractioning technique that makes it possible to obtain root mobility inside the alveolus to eliminate the risk of damaging the thin labial and crestal bone is recommended.

Type 3 anatomy describes a normal periodontal biotype with an ankylotic periodontal ligament. The surgical difficulty for tooth removal is high because it is not possible to obtain the mobility necessary for displacement. The traditional technique uses a periradicular osteotomy with burs. This is possible without much consequence for mandibular third molars but often results in serious damage to the buccal alveolar walls. The recommended technique creates the space necessary for extraction by operating only on the root surface through a rootplasty maneuver. The tooth is removed from the socket by consuming the root surface without touching the alveolar bone. This technique is easy to perform with

excellent control using specific Piezosurgery inserts (OP5), used like a bur around the root (eFig. 83.1).

EFIG. 83.1 Case demonstrating use of piezoelectric bone surgery for tooth extraction. (A) Radiograph of mandibular incisors with severe periodontal bone loss that are to be extracted because of a hopeless prognosis. (B) The Piezosurgery (Mectron Medical Technology, Carasco, Italy) insert operates only on the root surface without cutting, damaging, or overheating the surrounding bony walls of the extraction socket. (C) The Piezosurgery insert is directed at cutting the root surface only (rootplasty) without cutting, damaging, or overheating the surrounding bony walls of the extraction socket in this simplified extraction technique. (D) Mobility is obtained with an elevator in a mesiodistal direction. (E) Teeth are extracted with forceps after displacement. (F) Notice the preservation of the alveolar bone. The narrow socket walls are completely intact after this rootplasty extraction technique. (G) Implant placement and particulate bone grafting of extraction socket defects. (H) Flap closure

and suturing.

Type 4 anatomy describes a thin periodontal biotype and an ankylotic periodontal ligament, which is a combination of the challenging aspects of type 2 and type 3 anatomy. The surgical difficulty for tooth removal is the highest. In all cases where aesthetics is important, a root-sectioning technique that divides the root into segments with a mesiodistal cut is recommended. This allows the separate pieces (e.g., buccal and palatal) to be removed internal to the socket with minimal force applied just to the mesiodistal socket walls.

To ensure success of the procedure, it is important for the clinician to master the proper technique to perform extractions with Piezosurgery. As in all other procedures, inserts must never be allowed to rest in one single place when the ultrasonic vibration is active. This is particularly important when working in the periodontal ligament space. To avoid pinching of the insert and consequently having the ultrasonic vibration converted into thermal energy, it is important to keep the insert constantly moving.

Implant Site Preparation

Special Piezosurgery inserts developed for bone perforation have enabled the development of a newer technique for ultrasonic implant site preparation (UISP). Extensive clinical experience has culminated in the development of a protocol with significant clinical advantages. One article described the protocol in detail and reported the results of a multicenter case series study analyzing 3579 implants with a 1- to 3-year follow-up.[41] The preliminary results indicated that implant site preparation with Piezosurgery is a valid alternative to preparation with conventional rotatory instrumentation, with an overall osseointegration percentage of 97.82% (97.14% maxilla, 98.75% mandible) and an overall implant survival rate of 97.74% (96.99% maxilla, 98.75% mandible). These results are extremely encouraging, especially considering that implant placement was often combined with bone regenerative techniques. Given certain specific advantages of UISP, it is preferable to conventional techniques in the presence of soft bone

and limited residual volume, as well as in proximity to delicate anatomic structures such as the inferior alveolar nerve or the schneiderian membrane.

The first advantage of UISP is related to the cutting characteristics of Piezosurgery, which facilitate differential preparation of the cortical and cancellous bone. A surgical classification system of bone quality at the implant site was developed that simplifies the diagnosis and surgical decision-making process by exploiting differences in bone anatomy (Fig. 83.6). The differential implant site preparation (DISP) technique can be used within the initial osteotomy site to correct the implant axis by selectively directing the cutting action in the desired direction.[30] DISP can also be used in combination with twist drills to facilitate preservation of alveolar crestal bone while achieving maximum primary stability.[42]

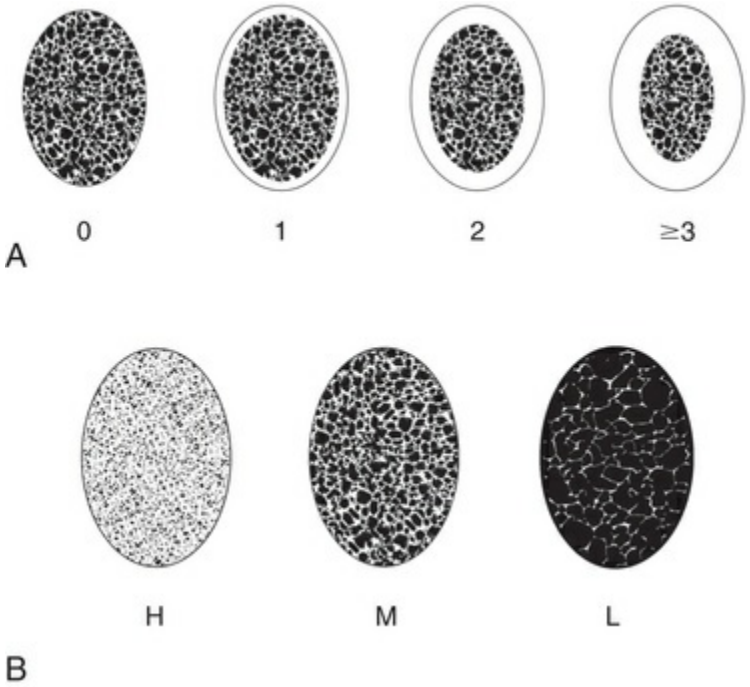

FIG. 83.6 Surgical bone classification by Tomaso and Giuseppe Vercellotti. (A) Cortical crestal thickness in millimeters. (B) Radiographic cancellous bone classification *H,* High; *L,* low; *M,* medium.

The second advantage of UISP is the fast clinical healing of both soft and hard tissue. Animal research demonstrates that new bone

formation (neo-osteogenesis) is active at implant sites prepared with piezoelectric bone surgery earlier than at sites prepared with traditional techniques.[7] A histomorphometric study on mini-pigs showed more bone formation and a greater density of periimplant osteoblasts at implant sites prepared with Piezosurgery as compared with sites prepared with twist drills.[7] Clinically, the minimally invasive nature of the surgery and the stimulation of bone healing translate into better primary stability and likely faster osseointegration compared with conventional instrumentation. In a randomized controlled clinical trial, patients received two identical adjacent implants in the upper premolar area: the test site was prepared with Piezosurgery, and the control site was prepared using twist drills.[19] Resonance frequency analysis (RFA) measurements were taken by a blinded operator on the day of surgery and at scheduled intervals throughout the first 90 days postoperatively. At the end of this time period, following failure of one implant in the control group, 97.5% of implants were osseointegrated. An initial decrease in mean implant stability quotient (ISQ) values was observed in both groups; however, the decrease in the Piezosurgery group was significantly less than in the control group. The Piezosurgery group also exhibited an earlier stability level reversal, indicating that an overall achievement of better primary stability compared with implants placed with twist drills. The surgical technique entails an osteotomy preparation using a series of Piezosurgery inserts. The preparation is initiated with the narrow, pointed IM1 insert (Fig. 83.7A). Parallel pins are used throughout the procedure to check alignment (see Fig. 83.7B). The 2-mm–diameter IM2 insert is used to prepare the osteotomy further (see Fig. 83.7C). The coronal aspect of the preparation is widened with the pilot 2/3 insert (see Fig. 83.7D), and the osteotomy is finished with the IM3 insert (see Fig. 83.7E). Final cortical preparation is accomplished with the IM4 insert (see Fig. 83.7F). After use of the pilot 3/4 insert (Fig. 83.7G), the implant osteotomy is completed (see Fig. 83.7H). If desired, before implant placement, osteoplasty of the crestal bone is possible with the OP3 insert (see Fig. 83.7I). Fig. 83.7J shows a final occlusal view of an implant placed in a narrow ridge.

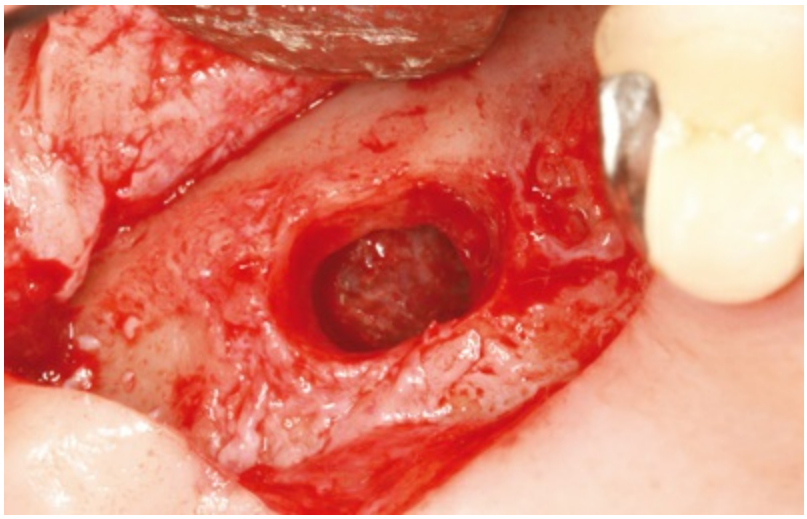
Advanced Clinical Applications

Sinus Lift

Procedures used to lift the floor of the maxillary sinus for bone augmentation make it possible to use dental implants to replace teeth in the atrophied posterior maxilla. Approaches to sinus lift techniques typically involve the use of a lateral window or crestal osteotomy. The lateral window approach enables the surgeon to see and monitor the integrity of the sinus membrane at each step in the process. The crestal osteotomy approach is often a blind technique because it is not possible visually to observe the schneiderian membrane during preparation (i.e., the orifice is limited in size if being used for implant placement). In some cases, when the crestal window is slightly larger (e.g., when simultaneous implant placement is not anticipated), the schneiderian membrane can be observed during the lift procedure (eFig. 83.2).



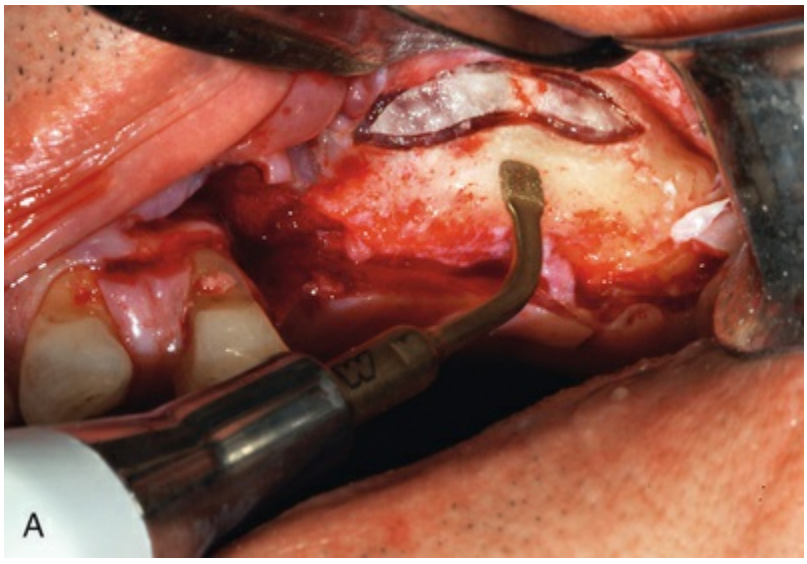
EFIG. 83.2 **Schneiderian membrane observed through the crestal osteotomy prepared for sinus lift with Piezosurgery (Mectron Medical Technology, Carasco, Italy) inserts. Notice the membrane is exposed through the crestal bone and elevated without perforation.**

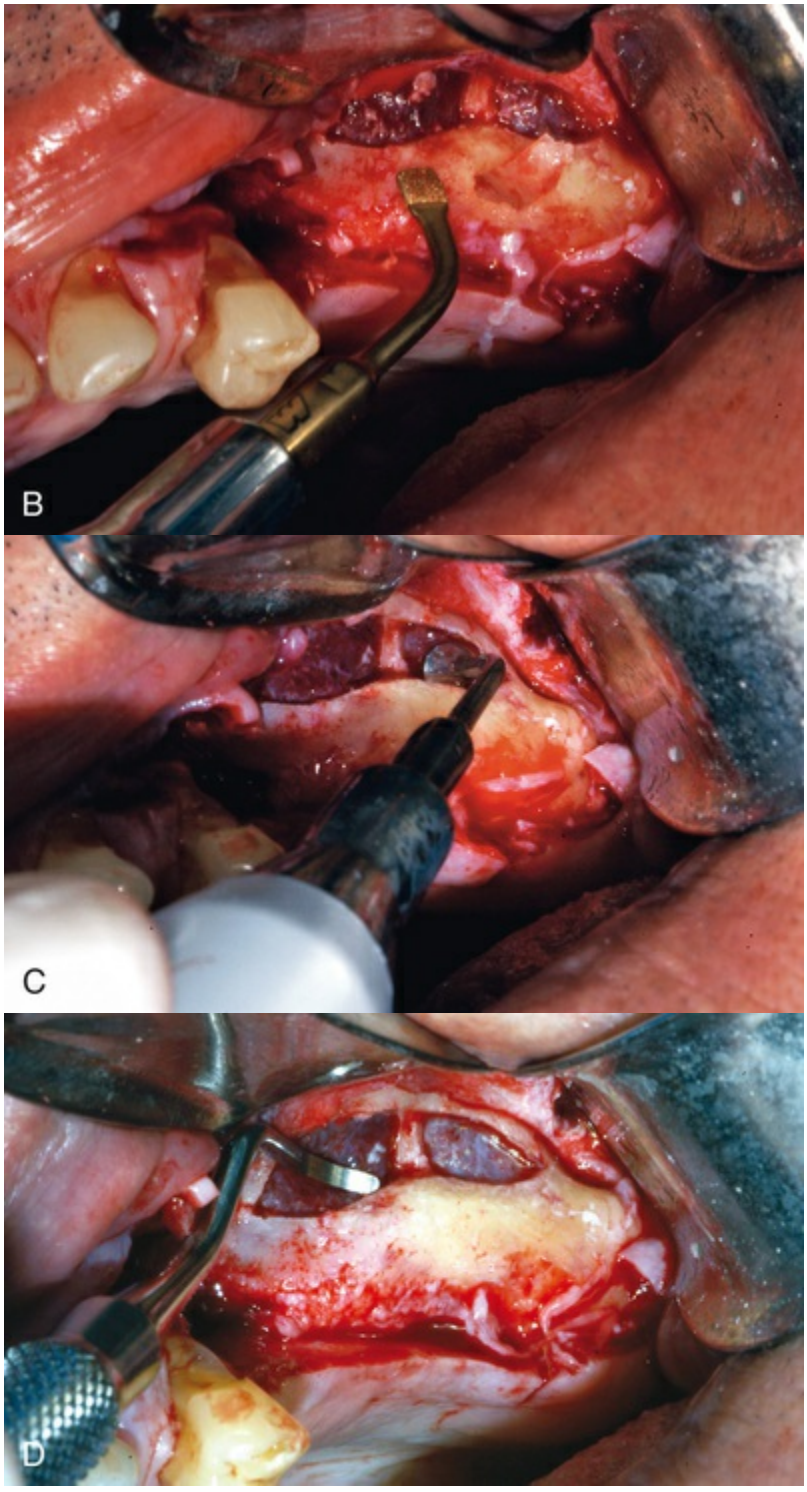
The lateral window approach entails the opening of a bony window through the lateral wall of the maxillary sinus cavity (see Chapter 80). This window is generally prepared in the premolar to first molar area. The traditional technique using a high-speed rotary bur to remove bone runs a high risk of damaging the schneiderian membrane, which often results in membrane perforation (approximately 14% to 56% incidence).[1,22,24]

In 2000, a technique was developed that entails cutting an antrostomy (lateral window) using Piezosurgery. This technique has greatly reduced the risk of membrane perforation (approximately 5% to 7%).[29,33,35,39,43] In a series of 100 consecutive cases, Wallace and colleagues[43] reported that the perforation rate was reduced from the average of 30% with rotary instrumentation to only 7% with Piezosurgery. These investigators stated that all incidences of membrane perforation occurred during hand instrumentation and were not caused by the Piezosurgery inserts. The use of Piezosurgery for lateral window osteotomy has greatly reduced the incidence of membrane perforation even in cases of particularly difficult anatomy with thin schneiderian membranes. A study by Stacchi and colleagues[20] further examined the intraoperative complications of piezoelectric sinus lift procedures by comparing two different techniques. The first technique consisted of outlining the bony window directly (group A), whereas the second technique included lateral wall erosion before

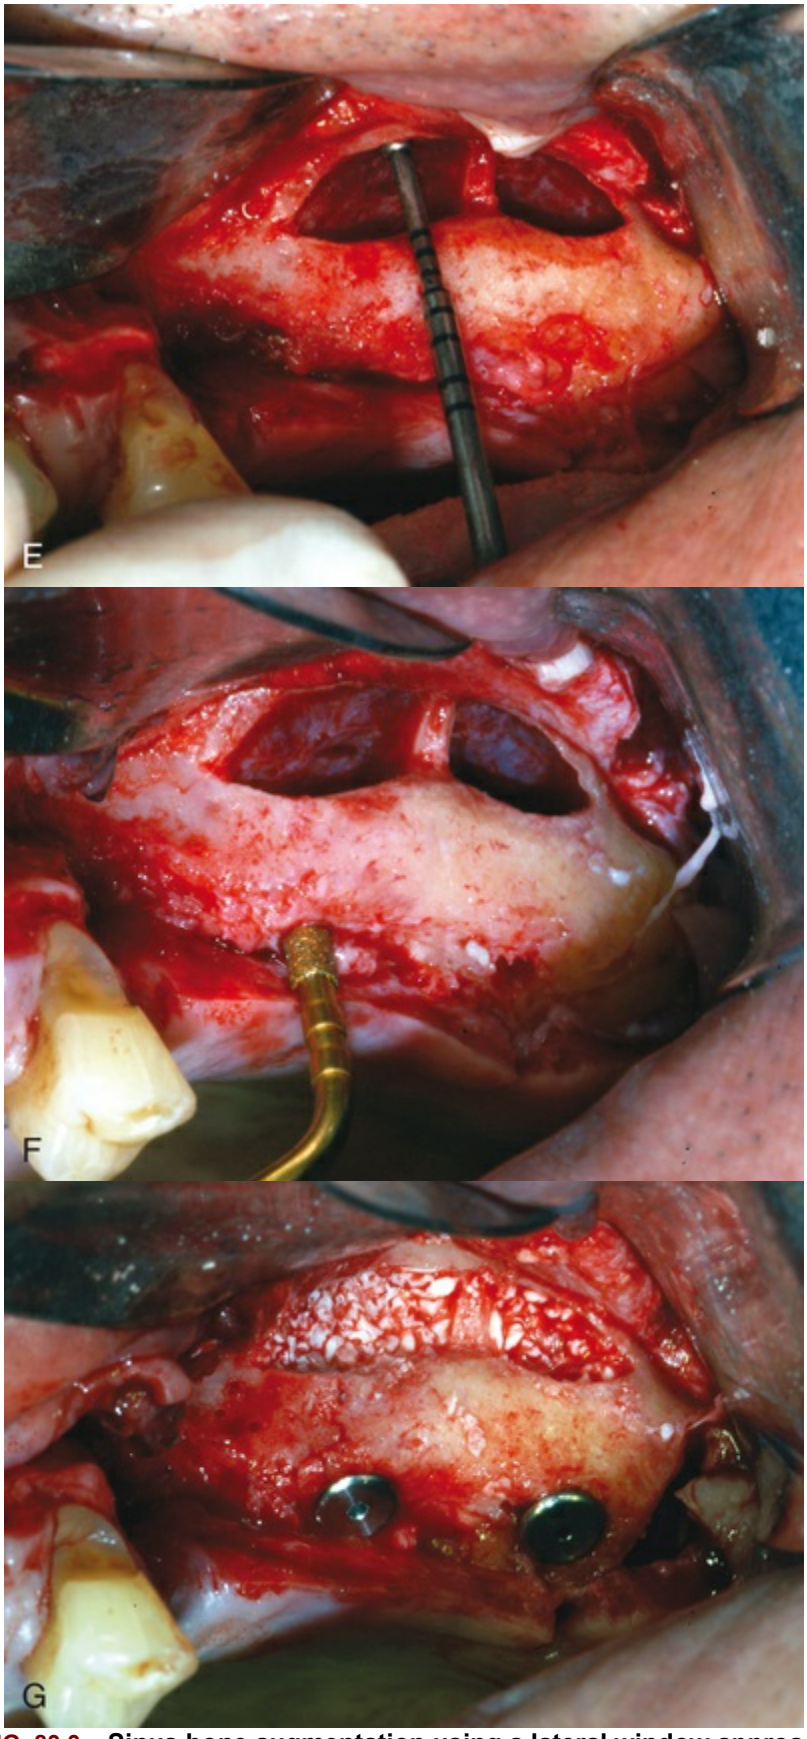
outlining the bony window (group B). Results indicated that the direct approach was associated with a significantly greater number of membrane perforations than the erosion technique (group A: 11.1%; group B: 0%; $P < 0.05$.) Although the erosion technique was found to be slightly (and significantly) more time consuming (group A: 9.2 ± 3.7 minutes; group B: 13.3 ± 2.4 minutes; $P < 0.05$), it appears to be safer and to help prevent accidental perforations of the schneiderian membrane.

The surgical technique entails a lateral window osteotomy that traces the frame of the bony window, which is then removed (eFig. 83.3A and B). If the lateral wall is thicker than 1 mm, piezoelectric erosion is recommended before outlining the bony window. The benefit of the piezoelectric erosion is twofold: the procedure requires less time, and the risk of membrane perforation is reduced further.[20] Separation of the membrane from the inner wall is made using an inverted cone insert that detaches the membrane around the perimeter of the bony window (see eFig. 83.3C). This reduces membrane tension, thus facilitating further separation and lifting with piezoelectric or manual instruments (see eFig. 83.3D to F). Once the membrane is completely elevated, bone augmentation material is inserted and packed, and the bony window is closed with a collagen membrane (see eFig. 83.3G).





B
C
D



EFIG. 83.3 **Sinus bone augmentation using a lateral window approach. (A) Lateral window osteotomy outline created using a Piezosurgery (Mectron Medical Technology, Carasco, Italy) diamond-coated scalpel (OT1). (B) Complete bony wall removal to expose the schneiderian**

membrane. Notice that the membrane is completely intact without damage or perforations. (C) Initial membrane separation from the edges of the lateral window by using a noncutting Piezosurgery insert (EL1). (D) Membrane elevation with a manual instrument. (E) Schneiderian membrane completely elevated. Ball probe used to evaluate adequate height of sinus lift. (F) Implant site is prepared with Piezosurgery inserts after sinus membrane elevation for simultaneous bone augmentation and implant placement. (G) Bone augmentation material is inserted and packed to fill the prepared sinus cavity.

Piezosurgery simplifies the sinus lift technique and increases predictability with its selective cutting action, which enables surgeons to maintain membrane integrity. This has resulted in a considerable reduction in patients' morbidity in maxillary sinus surgery.

Key Fact

The degree of surgical control is typically inversely proportional to the amount of force that must be applied to the surgical instrument being used. Thanks to the high frequency with which ultrasonic systems deliver shock waves, they require less force to be applied to the handpiece, for maximum intraoperative control.

Ridge Expansion

Horizontal alveolar ridge expansion is an extremely useful technique for increasing bone width and simultaneously placing implants in narrow ridges. The great advantage is that both augmentation and implant placement are accomplished in one surgical procedure. A possible disadvantage is that crestal bone loss may be greater in cases that begin with very narrow ridges.

Clinical and radiographic evaluation of the size, shape, and morphologic characteristics of the alveolar bone in the ridge is necessary to determine whether to use a ridge expansion or a traditional bone augmentation technique (eFig. 83.4A). In brief, it can be said that this technique exploits bone elasticity, so it is necessary to know the bone anatomy of each implant site. In particular, the morphology of the crestal bone and the thickness of the buccal cortical and lingual cortical plates in relation to the amount of cancellous bone present in the ridge greatly influence the

ease and ability to prepare an osteotomy and to expand the ridge. The technique requires preservation of periosteum integrity while elevating mucogingival flaps enough for access to create the appropriate osteotomy. Piezosurgery is an indispensable tool used to create a horizontal osteotomy through the alveolar bone crest caused by its precise (narrow) cutting action. In some cases (e.g., areas of dense bone with little elasticity), it may also be necessary to make one or two vertical cuts in the alveolar bone to allow ridge expansion. The horizontal osteotomy is expanded in subsequent steps using piezoelectric inserts for implant site preparation together with screw-type or fan-type expanders for increasing the diameter or section, respectively.

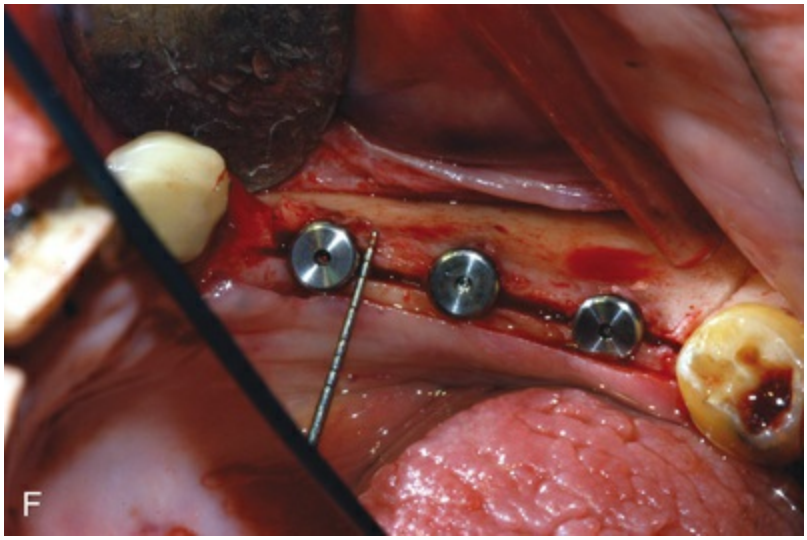
D
E



EFIG. 83.4 **Ridge expansion. (A) Evaluation of narrow (3-mm wide) posterior mandibular ridge with a periodontal probe. (B) Horizontal and vertical osteotomies prepared with a narrow (0.35-mm) Piezosurgery (Mectron Medical Technology, Carasco, Italy) insert (OT7S). (C) Initial implant site preparation started with Piezosurgery insert IM1. (D) Screw expanders used to separate bone segments and begin expanding the alveolar ridge. (E) Differential implant site preparation using Piezosurgery insert OT4. (F) Mandibular ridge expanded, implant sites prepared, and three implants simultaneously placed. Periodontal probe demonstrates final ridge width.**

Expanding a narrow ridge by the entire width (diameter) of the planned implant or implants may be challenging because of the density of cortical bone and limited elasticity. The need to expand or displace the buccal cortical bone can be reduced (i.e., less than the implant diameter) with rigorous application of DISP to the lingual cortical bone (i.e., preferential preparation of the lingual side), which is generally thicker than the buccal cortical. This is difficult to do with traditional twist drills because they cannot limit cutting to one side and tend to become displaced by areas of dense bone into areas of loose or missing bone (i.e., twist drills are deflected away from dense cortical bone). In fact, attempting to prepare the site (between separated cortical plates) with traditional drills can fracture the weaker, inelastic buccal cortical bone, thus making simultaneous implant placement impossible.

Piezoelectric bone surgery has radically simplified the ridge expansion technique in the horizontal osteotomy phase, which can be performed with micrometric precision, and in the site preparation phase, which exploits the different degree of cortical resistance compared with cancellous bone (see eFig. 83.4B to F).[25,40]

Bone Harvesting

The bone harvesting technique using Piezosurgery is effective for harvesting bone fragments and for removing blocks of monocortical-cancellous bone.

Particulate Bone Chip Harvesting Technique

Particulate bone chips are harvested using special osteoplasty inserts to scrape the bone surface. The flow of the irrigation fluid should be reduced to prevent particles from being dispersed after harvesting. The end of the aspirator tip should be kept away from the collecting particles or placed in the opposite direction of the insert movement.

Two Piezosurgery inserts are used for performing this bone chip harvesting technique. Osteoplasty insert 1 (OP1) is the most effective because it is large and quickly harvests bone fragments. However, the size and surgical movement require donor sites with ample surface area. It is generally used in bone grafting techniques for implant surgery. Osteoplasty insert 3 (OP3) is smaller and tends to harvest smaller bone fragments in any anatomic situation. It can be used in any site to collect bone for any bone grafting technique, but it is best used in limited areas to harvest smaller quantities of bone for periodontal osseous defects.

Clinical Note

It is advantageous to use OP1 or OP3 inserts to collect bone (for grafting defects) while performing other procedures (e.g., in maxillary sinus lift surgery while removing bone from the lateral window osteotomy or in periodontal surgery while recontouring bone with osteoplasty/ostectomy).

Block Harvesting Technique

Choosing an appropriate donor site and selecting the best instruments and technique for harvesting block bone are important decisions in the success of bone augmentation with monocortical bone block grafts. Harvesting block bone with Piezosurgery is extremely simple, precise, and fast.

The most common donor sites for harvesting monocortical-

cancellous block bone are the mandibular ramus and symphysis (chin). The surgical operation with Piezosurgery offers considerable precision and operating sensitivity during surgery so that the operator is able to easily recognize differences in cortical and cancellous bone, thereby allowing him or her to preserve the integrity of important structures.

Harvesting a monocortical-cancellous bone block from the mandibular ramus is generally preferable to the symphysis region because of the reduced level of morbidity. Evaluation of presurgical three-dimensional scan images facilitates measurements and determines how much bone can be harvested with respect to the position of the inferior alveolar nerve canal, the position of molar roots, and the width of the mandible in the ramus area. Osteotomies performed with Piezosurgery allow an extremely precise, clean, and smooth vertical cut through bone with excellent visibility.[2] The result is that a cortical block can be removed with a portion of spongy bone, and its surface is extremely regular compared with blocks harvested from the chin.

This technique is very predictable because it facilitates harvesting the maximum amount of bone with respect to the donor site. By comparison, bone blocks harvested using traditional rotary cutting instruments reduce the width of the cortical bone by at least 1 mm circumferentially around the entire graft. Furthermore, traditional cutting instruments are unable to cut the internal cancellous bone effectively. The result is that the block is detached by using scalpels or chisels to break it away, which makes the width irregular. Subsequently, it becomes necessary to reduce the block width further. Finally, because this technology does not have macrovibrations and torque associated with rotary instruments, bone block reshaping can be easily and safely performed extraorally with Piezosurgery.

Conclusion

Piezoelectric bone surgery is a well-known surgical technique for bone surgery with many clinical applications in dentistry. The extraordinary cutting properties and applications of piezoelectric bone surgery are described in this chapter. The most compelling

characteristics of piezoelectric bone surgery are low surgical trauma, exceptional precision, and fast healing response. As a result, Piezosurgery has the ability to increase treatment effectiveness while improving postoperative recovery and healing.

Although a great deal of scientific research focuses on new products for tissue engineering and bone regeneration, the importance of minimal surgical trauma for optimal bone healing and regeneration should not be overlooked. A new appreciation for the effectiveness of Piezosurgery has the potential to redefine the concept of minimally invasive surgery in osteotomy and osteoplasty procedures.

Case Scenario 83.1

Piezoelectric Sinus Lift Technique

Patient:

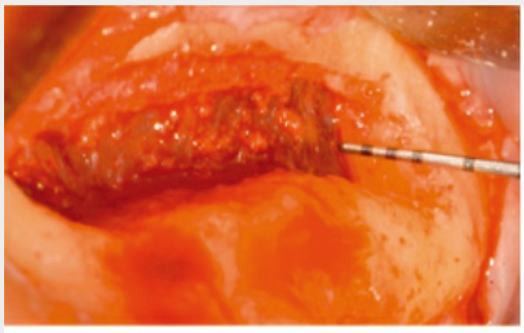
Male patient, 64 years old

Background:

Nonsmoker; edentulism of the upper left arch

Current Findings:

Patient's edentulism can be treated by sinus lift and implant placement. The sinus lateral wall is 3 to 4 mm thick.



CASE-BASED QUESTION	SOLUTION
1. What is the best piezoelectric technique to perform a sinus lift in a patient with a lateral wall thicker than 1 mm? A. Bony window osteotomy B. Lateral wall erosion C. A and B D. None of the above	**Answer: C** **Explanation:** When the lateral wall is thicker than 1 mm, performing the erosion technique before outlining the bony window speeds up the procedure and reduces the risk of membrane perforation.

Case Scenario 83.2

Narrow Crest

Patient:
Female patient, 57 years old

Background:
Former smoker, partially edentulous for more than 20 years

Current Findings:
Residual edentulous crest of average width less than 3 mm

CASE-BASED QUESTION	SOLUTION

1. Which technique is not advisable to treat this patient? A. Bone block harvesting B. Ridge split C. Guided bone regeneration D. All of the above	**Answer: B** **Explanation:** Ridge most likely consists of cortical bone. It is too narrow to split ridge predictably.

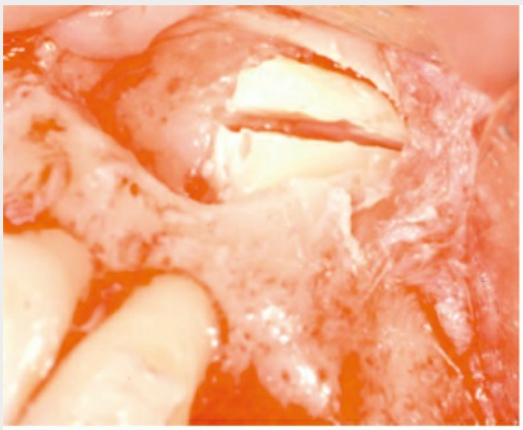
Case Scenario 83.3

Piezoelectric Extraction Technique

Patient:
Female patient, 38 years old

Background:
Non-smoker, permanent canine never erupted.

Current Findings:
Ankylosed, impacted canine



CASE-BASED QUESTION	SOLUTION
1. Which of the following piezoelectric extraction techniques is preferable when aesthetic results are important?	**Answer: A** **Explanation:** Mesiodistal root sectioning allows the removal of the root fragments while applying minimal pressure on the vestibular wall, thus reducing the risk of fracturing it during the procedure.

A. Mesiodistal root sectioning B. Root consumption C. Buccolingual root sectioning D. All of the above

CHAPTER OUTLINE

Digitally Assisted Implant Surgery
Conclusion

The surgical procedures for the placement of implants have more or less remained the same since the introduction of osseointegrated dental implants. Briefly, implant placement surgery involves the elevation of a full-thickness flap to expose bone; a sequential series of drills with increasing diameters is used with profuse irrigation to prepare a precise implant site osteotomy in the bone (see Chapter 78). The site is prepared, and the implant is positioned in a manner that avoids important anatomic structures, such as the inferior alveolar nerve, sinus cavities, and teeth. The ultimate goal is to position the implant for optimal functional support of the planned prosthetic tooth replacement(s) with proper emergence and natural aesthetics.

Clinicians determine implant positions based on presurgical

diagnostic imaging, study models, and the use of a diagnostic wax-up of the planned tooth replacement(s). The final position of the implant(s) results from the surgeon's interpretation of diagnostic information and his or her ability to translate that information to the patient at the time of surgery. A conventional surgical "guide" is typically an acrylic stent, fabricated by a laboratory technician, that is positioned in the mouth and used to direct drills through openings in proposed tooth sites. It may or may not have precise guide channels for implant positioning. The clinician uses the guide along with his or her interpretation of diagnostic information, clinical experience, and surgical skills to place the implant(s). The use of a conventional surgical guide has several limitations and potential sources of error, including inaccuracies in the stent during fabrication, movement of the stent during surgery, and variations in the clinician's use of the stent, which can lead to imprecise implant positioning.

Advances in implant surgical technology include simulation software, computer-generated surgical guides, and real-time digital tracking or guidance.

- Implant planning or simulation software is used preoperatively with the patient's scan data to "simulate" implant placement into a virtual patient. The software allows the clinician to view a three-dimensional (3D) computer image of the patient's jaw created from the computed tomography (CT) or cone beam CT (CBCT) scan data.[46]
- Computer-generated surgical guides with drill sleeves are produced using various techniques from the presurgical "virtual" implant placement data. These guides are used to place implants more accurately based on the "planned" locations.[18,28,38]

- Digitally assisted implant surgery or real-time micro positioning implant surgery (RTMIS) uses simultaneous tracking and "guidance" of the implant instrumentation to follow the planned treatment accurately during surgery.[10] Computer imaging from scan data is observed interactively with implant placement instrumentation during the surgical procedure.

This chapter provides an overview of the terminology, technical requirements, and limitations of digitally assisted implant surgery.

Digitally Assisted Implant Surgery

Real-Time Micro Positioning Implant Surgery: Overview

RTMIS is the most sophisticated and perhaps the most promising of these technologies because it has the greatest potential to reduce surgical time, minimize surgical invasiveness, and result in a more precise translation of implant planning to the actual surgical procedure.[6,22,45] However, as with many newer technologies, conflicting reports regarding its accuracy exist.[24,42] The computerized surgical and prosthetic chain of treatment requires precision at many levels.[33]

Uses and Requirements

Computerized navigation surgery evolved from early applications in neurosurgical procedures and continues to evolve today with applications in many surgical specialties.[36,39] Clearly, the principal advantage of using a computer to assist surgery is the precision it offers. Moreover, real-time safety control is obtained with multiple imaging sources facilitating a minimally invasive approach to surgical procedures. As in medicine, 3D imaging is used in dentistry to facilitate presurgical planning and to guide the surgical

procedure. In the case of implant surgery, this allows precise implant positioning while avoiding injury to nearby important anatomic structures. Computers have been used to enhance dental implant surgery in a variety of ways, from simple imaging software used to visualize implant positions in a 3D virtual patient to more complex, simultaneous image monitoring and instrument navigation used to perform the surgery.[10,19]

As an example, the aerospace industry uses computer assembling software with augmented reality and real-time stock management to reduce complete assembly time of an Airbus A350 aircraft by 30%.[20,21] Similarly, in dentistry, the goals of computer-assisted implant placement are to reduce surgical time, enhance precision, and facilitate prosthetic treatment by combining real-time surgical navigation with computer-aided design (CAD) and computer-aided manufacturing (CAM).

The European Commission (EC) has established a Global Medical Device Nomenclature and an internationally agreed-on classification system for medical devices with four classes from low risk to high risk. The Food and Drug Administration (FDA) in the United States has a Unique Device Identification for the registration of medical devices with three classes from low to middle and high risks.

- Class 1 medical devices are deemed low risk and are therefore subject to the least regulatory control. They do not need to be evaluated by a certified body. In dentistry, a computer-generated surgical guide is considered a class 1 medical device. Regulation committees do not categorize it as an assisting device.
- Class 2 medical devices are a higher risk than class 1. The EC class 2 is subdivided into class 2A and class 2B, where 2A is an assisting device without automation and 2B is a device with automatic assisting. Real-time micro positioning

(RTM) device is a class 2 FDA or class 2A EC. In contrast to a class 1 medical device, a class 2 or 2A medical device must show innovation and improvement of a clinician's decision making and offer new evidence of benefit to the patient.

The use of RTMIS requires an accurate alignment (identification and registration) of the patient anatomy with the patient's volumetric data obtained from radiographic imaging (CT scan, CBCT data) and through a tracking system with a 3D contact probe or ultrasound 3D mapping (Fig. 84.1). The system allows matching between imaging and real patient positions, and it permits tracking of the precise movements of the surgical instrumentation (e.g., handpiece, drills) in relation to the actual patient. Various modalities have been developed to acquire and register image data and to coordinate and track movements.[6]

FIG. 84.1 Dental implant real-time navigation system (Open Pilot System, Stereovision Haptitude) with

infrared stereovision cameras and a monitor display showing the three-dimensional ultrasonic reconstruction of a mandible with the planed implant position in a coronal and a panoramic view. On the panoramic view, a two-dimensional x-ray film is overlaid on the ultrasonic image. (Courtesy Haptitude.)

Sequence of Steps

The clinical sequence of steps (Fig. 84.2) required for conventional RTMIS is as follows:

FIG. 84.2 Assisting data chain with real-time micro positioning implant surgery. The basic setup for a navigation system consists of stereovision cameras with several tools: *(1)* infrared receptor allows real-time patient tracking; *(2)* the contra-angle probe and the ultrasound probe have markers that are tracked in real time by the cameras; *(3)* ultrasound three-dimensional *(3D)* mapping shows bone surface and adjacent root morphology; *(4)* computer-aided design and computer-aided manufacturing *(CAD/CAM)* registered with ultrasound and computed tomography *(CT)* scan; and *(5)* extraoral scanning for matching other 3D imaging.

1. *Data acquisition*. The patient is scanned for image data acquisition with fiducial (artificial) radiographic markers (e.g., stent with markers or intentionally placed pins or screws into jaw) or anatomic (natural) markers such as teeth or bony landmarks. If fiducial markers are placed in a stent, the patient must have the stent in place when scanned.
2. *Identification*. The anatomic or fiducial markers are identified with a probe tracked by the system. If markers were incorporated into a radiographic stent, the stent will again be placed in the mouth, and the markers will be identified by hand with a probe tracked by the stereovision system.
3. *Registration*. After identification of the predetermined markers, the software indicates the best localization or "match" on the arch between the image data and the patient. An invalidated registration may be caused by an improper initialization or CT scan data.
4. *Navigation*. Ultimately, the operator is able to visualize surgical instrument navigation (movement). The drilling instruments are guided to a target point of impact with a 3D spatial orientation.
5. *Accuracy*. Sustained accuracy procedures are critical during surgery and should prove the reliability of the system's overall accuracy. This sustained accuracy procedure is completed by contacting the handpiece or drill on selected teeth while visualizing markers, which can be viewed by the stereovision system.
6. *Feedback*. Variations from the ideal position can be restricted by the software through inactivation of the drill (stop-and-go action) or by an audible or visual cue.

Key Fact

Real-time micro positioning implant surgery requires an accurate alignment of the patient's anatomy with the patient's volumetric data from radiographic imaging (computed tomography scan, cone beam computed tomography data). A tracking system with a three-

dimensional contact probe or ultrasound three-dimensional mapping is used for identification and registration.

Data Acquisition and Registration

CT scans and CBCT scans are widely used for 3D imaging of patients (see Chapter 76). Factors that must be considered when deciding to use a CT scan include radiation exposure, limitations in accuracy, and the possibility of diffracted images as a result of metallic restorations. The evolution of scanner technology (spiral CT scan, CBCT scan) has made it possible to reduce the radiation dose to the level of a conventional panoramic radiograph while maintaining adequate diagnostic quality for preoperative implant planning.[11,15]

Radiographically identifiable markers are important for RTMIS just as they are for implant planning with conventional diagnostic methods. However, unlike conventional planning, in which orientation and simulation of implant positions are related to the planned prosthetic crown positions, RTM markers must relate the image data to the actual patient's anatomy. In other words, the position of the surgical instrumentation (and ultimately the drills and the implant) must be related to the scan image data of the patient's jaw morphology and the image data must be precisely aligned with the actual patient's anatomy. Thus, it is critically important to scan the patient with markers that are identified in the scan and correlated with the patient. Correlation between the scan and the patient's markers is called *registration*. This process is a statistical matching from point to point, point to surface, or surface to surface. CBCT scans present less diffraction with metal, and registration is easier than with CT scans.

A 3D localization of the template is made with different methods of registration. The operator contacts the marker on the template with an instrument that is seen by the system camera. RTM data are obtained when these markers are attached to the patient.

The operator needs to validate whether the template and the patient are correlated in a true position because deviations may result due to mathematic formulations of the data in the registration process. This critical step is used to control the accuracy of the

patient's position. In the absence of a template, anatomic markers such as teeth or specific bony landmarks and/or artificial markers (fiducial) such as small tacks or screws that are secured in the bone can be used. The operator checks the accuracy with a pointer instrument that has its own markers used to touch different sites of the mouth. The precision is visualized by localization of the images on the screen and the real position of the instrument in the patient's mouth.

Key Fact

The orientation of surgical instrumentation (i.e., drills) must be related to the scan image data of the patient's jaw morphology, and the image data must be precisely aligned with the actual patient's anatomy. The critically important correlation between scan data and the actual patient is called *registration*. Markers in the scan are matched with markers in the patient by using a point-to-point, point-to-surface, or surface-to-surface method.

Navigation and Positional Tracking

Numerous commercial products exist for navigation or positional tracking, but few meet the *computer-aided surgery* (CAS) requirements in terms of accuracy[8,48] (approximately 0.1 mm at a distance of 1 m[4]), reliability, and clinical usability. The "real-time" navigational technology is based on global positioning system technology.[41] Some of the technologies used in medical CAS to track movement include mechanical, magnetic, and optical tracking systems.

Mechanical tracking systems use a six-axis coding robot with a passive arm. The system is very reliable and highly accurate but has limitations when more than one instrument or patient marker needs to be located. Thus mechanical tracking is less desirable for implant CAS, which requires the use of several different instruments and multiple markers.

Magnetic tracking systems use a magnetic source and a field receiver. The system loses accuracy in the presence of magnetic field interference. Relative inaccuracies result from changes in the

magnetic field, which may be caused by any metallic mass that may be present, such as a drill motor (with or without activation).[3,4] Thus the obligatory presence of drill motors in the operating room during implant surgery makes magnetic trackers impractical for implant CAS.

Optical tracking systems are recognized for their dependability and accuracy. Positioning is made by intersecting the vision plane between two or three cameras to locate markers with stereovision. A passive system absorbs and processes ambient light, whereas an active system interprets reflected light.

Active markers with infrared light–emitting diodes (IREDs) have been widely used with superb accuracy but are sensitive to reflections and interference with the line of sight between the IRED markers and the cameras.[25,31] Although variations in optical localizers are adequate for medical applications,[1,12] they need to be improved for use in dental implant surgery. This is particularly problematic with the typical seating arrangement of surgeon and assistant (i.e., the direct line of sight to the cameras may be interrupted by the operators). A stereovision with natural-light cameras is a less expensive alternative compared with IREDs. However, natural-light systems are more sensitive to surrounding light, background, and the shape of markers. In comparison, infrared cameras are less sensitive to these light variations.

With optical tracking devices, the surrounding light in the operating room is important, and the choice of an infrared tracking device is more relevant. Patients' motion will be tracked efficiently if the marker is stable during surgery. In case of loose teeth or unstable markers, cortical bone screws should be used.

External Viewer, Augmented Reality, and Three-Dimensional Projection Screens

Once registration between the data and the actual patient has been established, the instrumentation can be coordinated with the system and observed by the surgeon or operator (Figs. 84.3 and 84.4). Instrument movement relative to the image data (and through registration to the patient) may be viewed on an external monitor, visually projected in the surgeon's field of vision (resulting in a

superimposed visual image seen over the surgical field) by using a head-mounted projection system or projected on a 3D projection screen (Fig. 84.5).[47] In this manner, the image on the external monitor (see Fig. 84.4), the surgical field, or the 3D projection screen (Fig. 84.6) guides the surgeon to perform the planned procedure.

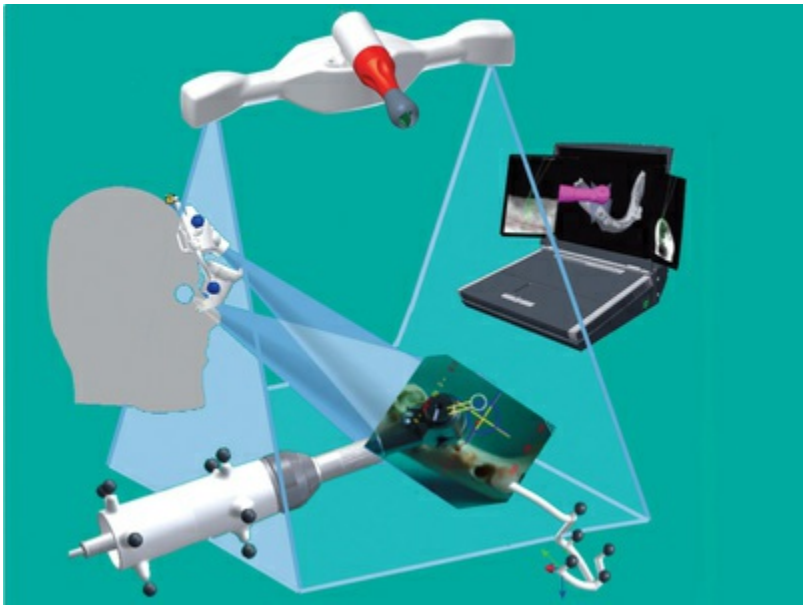

FIG. 84.3 **Global setup for surgical navigation. The basic setup for a navigation system consists of stereovision cameras with several tools. The contra-angle probe, the ultrasound probe, and the patient jig need to have markers, which are tracked by the cameras. The occlusal stent, with markers in the standard process and without markers in ultrasound registration, used during computed tomography scan acquisition will be recognized in its three dimensions for prosthetic planning.**

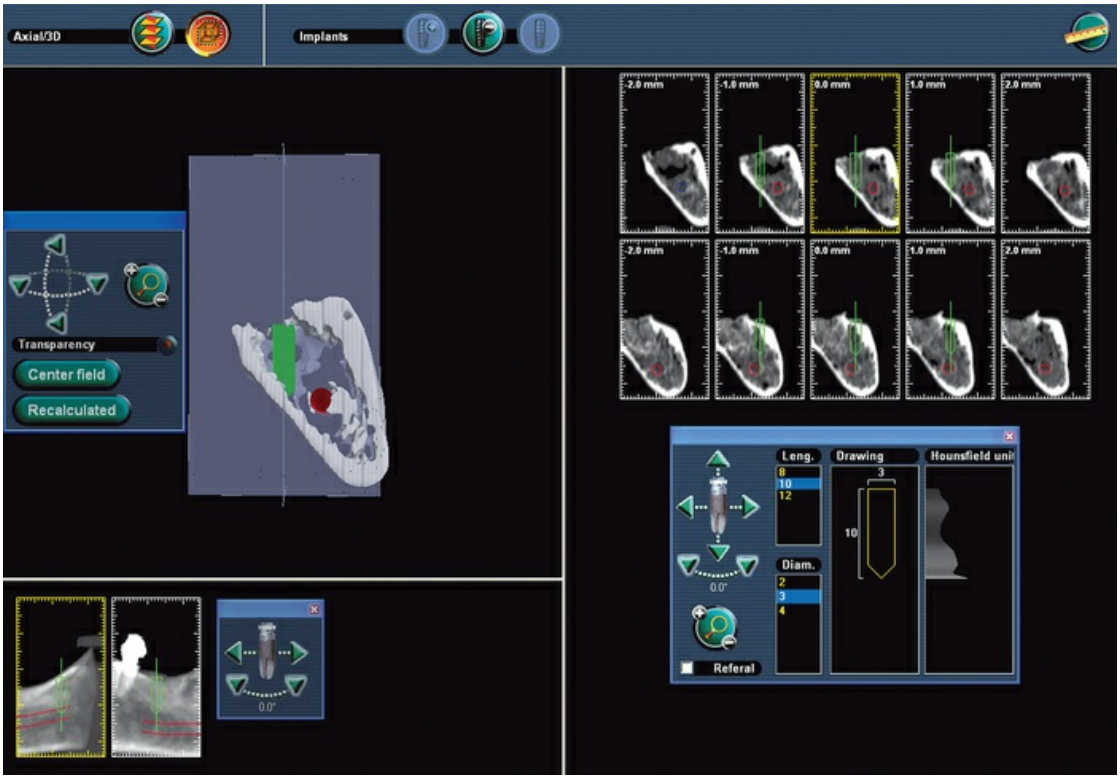

FIG. 84.4 Images of a computer screen and the surgeon's view of computer-aided implant surgery navigation simulated with a dry mandible. During navigation, the surgeon concentrates on visual cues seen on the eye viewer. *(Courtesy Haptitude.)*

FIG. 84.5 Dental implant real-time navigation system with infrared stereovision cameras and a three-dimensional monitor display showing the reconstruction of a computed tomography–scanned mandible.

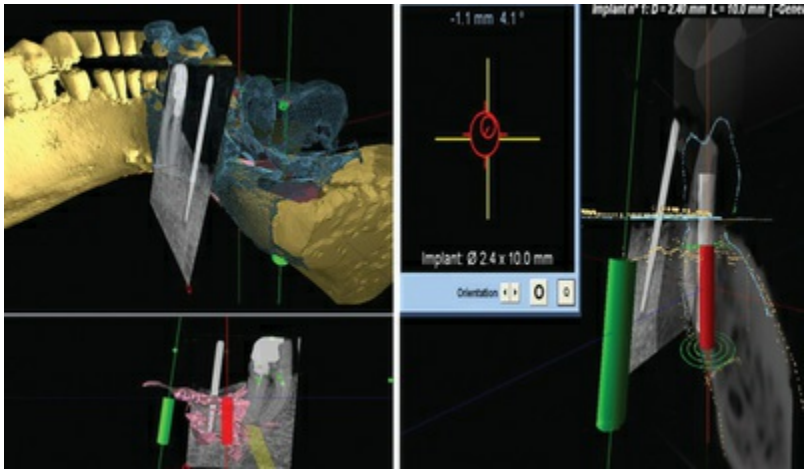

FIG. 84.6 **Screen views available during surgery. *Upper left,* The computed tomography (CT) scan reconstruction of the mandible and**

teeth is observed in *yellow*. Surface mapping of bone and crown morphology *(dark green/blue)* obtained from ultrasound or optical scanner. The computer compares the data from the three-dimensional (3D) topography to the two-dimensional (2D) x-ray film. *Lower left,* The 2D x-ray film is matched to a 3D topography of the patient's "matrix" with the simulated implant positions in *green* and *red. Upper right,* The target and position of the drill and implant are observed. *Lower right,* Real-time navigation with a combination of superimposed images from a 2D x-ray film, optical scanner, CT scan, and 3D ultrasound scan. *(Courtesy Haptitude.)*

Side viewers display target data in two dimensions and require the surgeon to look away from the surgical field. However, see-through viewers display target data transparently in the surgeon's field of view and allow the operator to observe the surgical field continuously. An augmented-reality viewer[26] allows the surgeon to see target data in three dimensions, superimposed over the surgical site through projected images in both eyes.[49] The augmented-reality method allows the operator to adapt to the system more naturally and therefore more rapidly, but it does not appear to have advantages over the use of two-dimensional (2D) side-viewer devices in terms of accuracy.[43] Both systems allow simultaneous viewing of virtual information of the implant (axis and target) and a real vision of the surgical site. Augmented-reality devices are very sensitive to calibration before surgery and require care and monitoring intraoperatively to prevent misalignment during surgery. The relative stability of a headset is critical to maintaining accuracy.

Alternatively, 3D projection screens provide a "real 3D vision" viewed on a specialized monitor (see Fig. 84.5) without the need for viewers (i.e., operator glasses).

Two types of 3D projection screens are available, as follows:

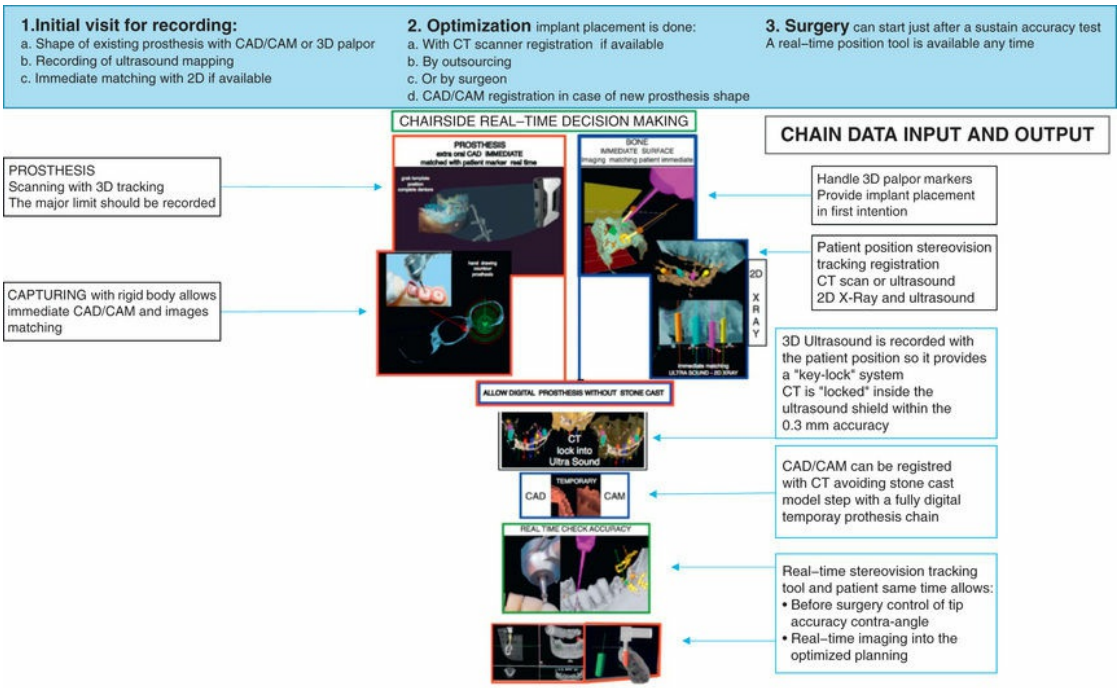
1. The multiplane device has a screen that provides three simulated real-time planes. The object is projected in the screen with a back-field simulated projection. A plane within the screen surface and the forward plane are at a maximum focus of 10 to 20 cm. This device provides a 3D view that is extremely dependent on the shape.
2. A newer-generation device uses nanolenses on each pixel of screen resolution. It provides a natural light-splitting effect similar to the effect of a natural eye separating the three

basic colors. Consequently, it is perceived as a natural view. A lateral displacement of the operator's head provides 8 to 12 simulated views, which together create a natural "volume" effect. No adaptation time is required, and viewing is intuitive.

This 3D projection screen technology cannot provide a true holographic 3D view because of the eye's plane of focus on a flat screen, but it does provide a 3D "real volumetric view." The actual 3D projected screen technology does not provide enough high-quality texture, but it is overviewed with simple shape symbols (e.g., cross, circle). Another difficulty is introduced by the nonlinear depth scale of the screen, which is perceived by the operator's brain as nonlogical and induces a decrease in intuitive hand localization. In addition to this improvement in 3D vision, a 3D sequence of images can be modified for specific applications such as navigation. For example, a 3D sequence of eight views can be modified to facilitate the observation of a projected view of the object at 90 degrees with a minimal head side shift of only 5 degrees. These real-time, 3D front and side views provide intuitive 3D data views in spite of the 2D parameters used to visualize them.

Technical Principles and Limitations

An inaccuracy between the two positions is the *real error* of radio markers transformation (eFig. 84.1).[17] Markers (not radio markers) in the template are localized with the tracking system, which allows measurement of accuracy between registration and the true dimensions. This does not define range, direction, and level of distortion on all parts of the surgical field as a real patient's position (not the template position). To date, no strong test exists to evaluate this error for RTMIS systems or between a computer-guided template and a patient's real position during a CT scan.



EFIG. 84.1 **Sequence of treatment: chain data input and output.**

Cone Beam Computed Tomography and Computed Tomography Scan Limitations

Accuracy in depth at 1 m is around 0.5 mm, even with an optical lens distortion of 1%.[23] If a software treatment is applied at a subpixel level, it will provide a gain of 1/5 of a pixel with an incidence of around 0.1 mm in height and width and around 0.5 mm in depth and after treatment a maximal mean of 0.15 mm. With these characteristics, a 90-degree change in the axis of vision of the cameras between the data of an initial visit and the surgical time may lead to a major inaccuracy >1 to 2 mm in depth or on side positioning by a leverage effect.

The calibration process is temperature-dependant above 25 °C, and could result in several millimeters of deviation. Between long surgical procedures, the system must be stopped to obtain a temperature decrease, and complementary metal oxide semiconductors are more tolerant than charge-coupled devices.

Trackers

The assembly of trackers on each tool is designed to be recognized by the system as rigid bodies. An ultrasound probe is the only

instrument that should be designed for 360-degree tracking capability, but the tracker has to be larger than in other systems, except with RTMIS that is CT based.

The shape should prevent lack of accuracy in depth in all the buccal and palatal positions where we do not need a 360-degree tracker, and it can be smaller on the contra angle. Small trackers with 180-degree efficacy are more convenient in dental implantology or maxillofacial surgery with limited interference from operator's hands and arms.

Deformations of the rigid body may occur with the plastic framework after 100 sterilization cycles. Sensors placed on the tracker may be silicone, they can be disposable, or they can handle a sterilization process if they are protected with a sterile shield. One difficulty during CT scan acquisition with a template is to avoid a shift not seen on the images but observed during surgery where a discrepancy between the real position and the image on the screen is obvious. This is a major level of concern, and with CT-based software the operator has two solutions: perform the surgery in a classic way without any guidance, or cancel the surgery and take a new CT scan, hopefully with a template in a proper position. Localization of radio markers, or a touch pad on a fiducial marker (like a LEGO brick[8]), is operator dependent with infrared stereovision.[14,24,27] CT scan statistical variation after registration is estimated to be between 0.5 and 2 mm.

A moderate level of concern is with full arch acquisition after segmented CBCT. The accuracy of radio markers' template registration will be less than with a full arch CT scan. A large space between radiomarkers in the surgical field is a source of inaccuracy.

A minor concern is the need to elaborate a special template or shape recognition (seen as a marker), with impacts on chair time and cost.

In orthopedics, computer-guided templates, prepositioned with an RTM system, have been used for the last 20 years. RTM in dentistry allows increased control and security by precise positioning of the template without any soft tissue opening and live control of the template position during surgery.[2] If bone fixation of the template is needed, the real-time obtained position is verified after placement of lateral screws or the two or three initial implant

placements in cases of full arch reconstruction as long as the referral abutment supporting the patient's rigid body (markers) is not linked in any way to the guide.

Registration: A Mathematical Complexity

After scan acquisition, the 3D image data of markers or ultrasound bone surface are identified by software as anatomic geometric elements. Then correlation (registration) between marker and surface should be done with the tracking device and the tracked tool. The tracking device gives real-time patient and tool position with its axis. The patient's and localized marker or surface positions could be placed into the patient's referral (fiducial). Several devices have been used to capture the actual patient's anatomy or fiducial marker at surgery, including a touch pointer and an ultrasound probe. The touch pointer allows the operator to touch specific anatomic points (or fiducial markers), whereas an ultrasound tracking device records multiple points of reference on a surface. A hand pointer device is fairly accurate, but if the clinician is not careful, the tendency is to define points that are not in contact with a real surface, thus creating false mapping. The ultrasound probe has a lower accuracy[32] than the touch pointer presenting a maximal (Mx) deviation of 5% of the thickness tissue in the 5 MHz range (i.e., 0.05 mm inaccuracy with 10-mm soft palate tissue), but it has the advantage of capturing continuous data of bone morphology through the mucosa or gingiva.[29,40]

Three registration methods are used to match anatomic points of the preoperative image data and the intraoperative patient's anatomy: (1) point imaging to patient's point, (2) surface to point, and (3) surface to surface. Point-based and line-based methods are described here to illustrate the requirements for adequate registration.

In the point-based method, a few particular points are identified in the preoperative image data (anatomic points) or artificial (fiducial) markers and the patient's anatomy. Points must be well defined and stable so that they can be precisely matched, and the computer calculates a transformation equation that minimizes the mean distance between matched points to complete the registration. The registration accuracy can be predicted, depending on the

distribution of points (e.g., an equilateral tripod gives more accurate results than three colinear points).[16,35]

With specific algorithms, a triangle in the preoperative set of points and a triangle in the intraoperative set of points are computed, compared, and then registered. An average accuracy is around 0.5 to 1 mm with an Mx deviation >2 mm with algorithm type iterative closest point (ICP) modified (most common).

Surface-to-surface methods are derived from point-based methods. All lines and surfaces measured on image planning (after segmentation of anatomic structure of the jawbone in the CT scan) and the points taken on the patient's anatomy by the tracking device are known as a *set of points*. These sets may be dense or sparse; a segmented bone surface may have hundreds or thousands of points. When the segmented surface is dense, one can assume that almost all points measured with the tracking device will be identified as points of the segmented surface. Algorithms have been developed to match preoperative and intraoperative data, but the number of possible errors in the identification process increases dramatically with line-based or curve-based methods.[34] Surface to surface is the most accurate method by far, but it is still a very operative- and experience-dependent process.

Tracking Device

Ideally, a practitioner would like <0.3-mm accuracy due to prosthetic requirements. Without guidance, an operator may attain 0.5-mm accuracy. RTM with magnetic trackers, ultrasound space tracking, and an inertial system shows a mean deviation >0.3 mm. The combination computer-guided template and RTM has 0.3-mm accuracy. Actual stereovision tracking or, in the future, a laser ultrafast scanner will show a mean 0.1 mm accuracy on the contra-angle working tip. Nevertheless, laser scanning real-time systems based on shape recognition will need at least a frame rate of 15 to 20/sec to be compatible with a real-time mode.

In dentistry, cameras sensitive to an infrared range of 800 to 900 nm are used to cope with the surgical light artifacts or the strong contrast in light spots. Two cameras are used, and they have to be synchronized. More have around 4.5 μm of pixel size, with an average dimension of 1600 × 1200. Importantly, camera

specifications have to be adapted for a particular tracking device and the environment where the cameras will be used. A deviation of 0.1 to 2 mm may result from improper use.

To illustrate these considerations, a distance range of 40 to 90 cm from the cameras to the patient's head is required, with the greatest accuracy in the center field. The field of view must be sufficiently large to see most of the markers; if the number of markers is insufficient, a deviation >2 mm may occur. In addition is the issue of dynamics; for example, rapid capture of a point of reference for registration with a CT scan or a poor axis of view for cameras will produce 0.3- to 2-mm inaccuracy. This is due to the speed of frames/second (f/sec). A speed acquisition imaging >40 f/sec appears mathematically favorable (the normal speed of the human eye is 15 f/sec), and algorithms matching CAD frames with other captured images perform more favorably in detecting tool position in a relatively static position.

One difficulty with cameras and real-time monitoring is that the patient and instrument markers have to be seen at the same time without being covered by the contra-angle body, depending on the head position and the surgical site. This situation is avoided when the cameras are placed in front of the patient, above the operator's head, and with the use of a larger camera field.

Cameras are accurate in height and width but less in depth, which is limited by the pixel size of the sensors.

Clinical Advantages of RTMIS

- Improved precision
- Noninvasive implant surgery (without or with limited flap reflection)
- Reduced postoperative complications
- Perspectives for improved prosthetic treatment

Challenges With RTMIS

- Learning curve

- Time spent for preparing simulation (if done by the surgeon)
- Time spent for installation (but overall, surgery is shorter)
- Cost

Benefit of Ultrasound Mapping

- Immediate chairside real-time 3D imaging
- Data obtained at the same time as the patient's position
- Absence of registration
- Bone surface visualization, sinus floor, root morphology
- Same accuracy as CBCT <0.3 mm

Advantages and Limitations of Bone Ultrasound Mapping

The accuracy of a navigation system depends on the accumulated errors due to the different components (eTable 84.1). Three-dimensional ultrasound mapping (bone, root) provides 3D positioning. The advantage of RTM ultrasound is to collect 3D data[30] with an ultrasound probe tracked by cameras simultaneously while splinted to the patient's arch. The patient's collected data are obtained from a known (real) position, and we do not need registration (absence of mathematic errors).

eTABLE 84.1

Overall Technical Characteristics of One Real-Time Ultrasound-Based Micro Positioning System (Open Pilot System)

Specifications	Performances	Comments
Length of time before initial use	15 min	Waiting time needed before the procedure to set up surgical measurements
Volume of the working space (WS)	0.4m × 0.6m ×	Depth: minimal distance

(Depth × Height × Length = WS)	0.6m	WS: maximum tracking depth value
Number of three-dimensional measures/sec	12–30	Avoid speed movement
Temperature	15°–35° C (59°–95° F)	System internally cooled
Humidity resistant	<85% without condensation	
Outside light source impact	Not sensitive	Exception made for other infrared source
Precision of calibration Root mean square (RMS)	0.10 mm (0.12 mm RMS)	10,000 points of measure in the field of view
Marker static statistical accuracy	<0.10 mm (0.04 mm RMS)	60 measures at 75 cm
Rigid body (referral object) static statistical accuracy	<0.10 mm (0.04 mm RMS)	60 measures at 55, 65, 75 cm
Marker dynamic statistical accuracy	<0.1 mm (0.05 mm RMS)	At 65 cm, speed <34 mm/sec
Rigid body dynamic accuracy (with 6 markers)	<0.2 mm (0.05 mm RMS)	At 65 cm, speed <34 mm/sec
Rigid body static absolute stability (Object A / Pointer)	± 0.14 mm	30 measures per 15 mn, for 7 hr of use
Static rigid body differential measure stability (Object A / Object B)	± 0.06 mm	30 measures per 15 mn, for 7 hr of use
Length of time of treatment frame	10 msec	With Intel 2.0 GHz processor
Captor resolution	1024 × 768 pixels	
Optical lens	Focal 4.5 mm	
Cleaning method	Disposable tissue	
Trackers		
Composed with passive spheres	6–9 spheres by tracker	Infrared passive sensors
View of tracking	180–360 degrees	Depending on complexity

Therefore it can be used alone without x-ray download imaging, so global accuracy results only from the stereovision tracking (<0.3 mm). Ultrasound mapping is a measuring device (the patient's fiducial is known, and the tool positioning and axis are known in the same patient's referral).

In other systems, the results of registration are not a measure. They compare the initial position with the final position of a radio template, but you do not know the real position of the initial radio template. We can just appreciate that it is larger or smaller, but we do not know the change in dimension.

The RTM ultrasound accuracy is in the range of a CT scanner (without registration) when using precise monodirectional ultrasound with an Mx of 0.3 mm (identical to CT scan). A 5%

deviation through a 10-mm gingival thickness is demonstrated in vivo in the medical field. The instrument of localization will retain the tracking device precision, and the system is comparable to a metrology system, which is a gold standard of precision. When 3D x-ray films and CAD or CAM are matched with ultrasound, we do not have any impact on the localization tool because the fiducial is always the known patient's position at the initial recording visit and during surgery. An RTM ultrasound error is a unique parallel chain of accuracy.

The control of a patient's position is possible anytime during surgery, and the surgeon can easily verify the match between the actual patient's position and the initial recording time.

The advantage is to overlay CT scan, periapical x-ray study,[13,44] or CAD or CAM images and their potential errors on 3D ultrasound mapping without affecting the accuracy of the localization tool that is linked only to the ultrasound mapping. It can be used for large surgical fields, and an accuracy of 0.3 mm is obtained for zygomatic mapping and registration. We do not have any information on the distance between markers and the surgical field. If the operator is willing to use a computer-guided template, RTM localization can be performed, and displacement of the guide will be known in real time.

RTM ultrasound images are obtained in one visit, and it is possible to obtain another data set of 3D bone imaging in 5 minutes if we have a displacement of markers during surgery or a change in strategy due to a quality in bone anatomy.

One major limitation is that ultrasound surface mapping[7] does not provide internal structure images, except root contours and the sinus floor, but a distance from the alveolar crest to the nerve canal can be measured on 2D x-ray films and evaluated on a 3D mapping image. Matching a CT scan or CBCT and 3D ultrasound mapping may sometimes be challenging because the thin cortical alveolar bone may not be seen on x-ray films, and in these situations we need some expertise to perform the registration process. The operator still has the ability to control the accuracy in real time with pointers and a surgical bur.

Newer ultrasound by liquid cavitation allows measurements of the mandibular canal depth with 0.5-mm accuracy.

Ultrasound 3D mapping is technically sensitive and has a learning curve. Newer technologies are emerging in medicine,[37] such as supersonic ultrasound with a high dynamic frequency for Doppler, bone elastometry, inflammatory tissue applications, and photoacoustic tomography that combines ultrasound and femtosecond laser interferometry for bone and soft tissue Doppler-like applications. These newer techniques are expensive, and the size has to be adapted for dental applications.

Ultrasound is also efficient for prosthetic 3D mapping and crown contouring. The accuracy stays in the limits of the tracking system (mean 0.3 mm).

Similar to 3D ultrasound, a periapical x-ray film can be matched with 3D surface mapping obtained by a palpor instrument (with its markers) directly on teeth or bone surfaces.

System Risk Analysis

The expected potential of computer-based implant surgery is for an inexperienced operator[9] to place an implant with the same accuracy as an experienced surgeon. However, in practice, soft tissue and bone anatomic variations and the prosthetic treatment plan are better managed with more experience. Three parameters are determinants for FDA assisting device approval: safety, availability, and robustness.

Safety

We have mentioned that one difficulty is to appreciate that we are in the patient's real-time position. This consideration applies to a computer-guided template, where the operator can visualize the discrepancy with the ideal position, but the statistical error is unknown. Several studies consider that a comparison between an initial CT scan with a postoperative CT scan evaluates a true position. In fact, we are comparing surface data with other surface data carrying the proper inaccuracy of each data set. With a CT scan obtained before surgery with a fixed computer-guided template, the operator can control the template position by RTM, and some other image technologies are applied, such as 3D ultrasound, palpor tracking, and object scanning in 3D in real time. CAD

imaging is promising, but the computing time is actually not compatible with routine daily use. CAD and CAM (STL files) can integrate an RTMIS chain with specific software and simulate temporary prosthesis without a need for stone casts if the data on implant shape are included in the RTM software planning.

One alternative is to scan with the markers locked on the patient (software learning the shape and orientations of the markers) with the prosthesis in place. CAD imaging, however, should be done with an extraoral scan (and not intraoral) due to the need for more data points obtained from the skin surface. An accuracy of 0.1 mm could be expected with these technologies. The main advantages are a chairtime session lasting around 5 to 10 minutes, avoidance of x-ray studies, and verification that a template is in a true real-time position and a CAD scan will be obtained in occlusion.

We can also register before surgery a CT scan with radiomarkers on the template and on the prosthesis. This is operator dependent, and in the case of CT scan artifacts, these images may be replaced by 3D data obtained with a palpor. The most efficient solution for the final prosthetic framework is still to capture a CAD or CAM implant in place at the end of the surgery.

It appears that at less than 0.5 mm of precision and in totally blind conditions, the operator should use a computer-guided template with real-time micro positioning implant surgery (RTMIS). This accuracy is needed when a risk exists of drill deviation with cortical bone, a narrow ridge, absence of medullar bone, and anatomically challenging proximity.

Availability

An integrated digital chain of treatment is a medical system in which, after validation, a benefit value is obtained for the patient with reduced practitioner operative dependence.

No chairside or real-time limitation exists with 3D ultrasound RTMIS because CT images are not mandatory. Bone 3D mapping can be registered before the surgical session, and CT registration is elaborated automatically by the software. This presurgical time is comparable to the one with shape recognition (i.e., LEGO shape) placed on a standard template. This solution allows the use of a conventional template for CT with, of course, the necessary time for

CT or CBCT capture and data download into the system.

Surgeons are performing operations, and they want to minimize the computing time before and during surgical procedures. A strong demand for simplification has been expressed by clinicians. This is illustrated in daily practice by 3D ultrasound RTMIS users who do not match CT scan and 3D ultrasound data but who prefer, as in conventional surgery, to appreciate the distance between the bone crest and the mandibular canal. So it is not mandatory to download CT data into the system when it is sufficient to appreciate the implant length and a safe distance with the mandibular canal. Real-time control of registration is important, and the positioning of a pointer on a tooth surface is rapid and easy to perform.

Robustness or Accuracy of the Whole System

We have described errors in all segments of the system: CT scan, fiducial x-ray detection, stereovision tracking system (cameras, magnetic captor, inertia system), tracker on contra angle, spread between markers in the surgical field, relative position of patients with stereovision, change in guide position during surgery, and others.

We have also operator errors: 3D mapping (pointer or 3D ultrasound), detection of markers with the pointer by the operator, image matching (CT scan or CBCT, x-ray film, ultrasound, magnetic resonance imaging [IRM]).

All these parameters will affect accuracy,[5] and they may accumulate with some systems. With RTMIS, if images are obtained during surgery by ultrasound or palpor 3D mapping, CD scan errors will not affect the tool position, and the inaccuracy will depend only on the tracking device. *We are dealing with a gold standard measuring system* with a patient marker locked in the jaw, whereas with *CT scan-based systems a mathematic transformation is extracted from radiomarker and image registration data*.

Conclusion

Patient and clinician demand exists for a minimally invasive approach to implant surgery. RTM implant placement secures

implant placement for all operators, but experience is still important for an evaluation of the clinical indication, risk in tissue management, and prosthetic case requirements. The ideal training to obtain a required competence with a digital system needs to be defined, with simplification of all procedures, and it may be an evolution toward a surgical team. With an integration of CAD and CAM prosthetic procedures, laboratory technicians will affect the overall treatment of patients receiving implants by reducing the treatment time and eventually the cost as well.

Case Scenario 84.1

Patient:
A 62-year-old South Asian man

Chief Complaint:
"As a computer programmer, I appreciate precision and technology. I am interested in safer and more precise methods for my implant placement surgery."

Background Information:
Patient is a nonsmoker, has high cholesterol, and does not report any other systemic conditions. Patient is taking simvastatin and has regular medical examinations. He reports brushing and flossing twice a day since losing his upper right molars (caries). He avoided replacement of these teeth until now. Patient seeks a more precise way to place his implants without impinging on the maxillary sinus space.

Clinical Findings:
Examination reveals generalized 2- to 3-mm probing pocket depth with partial edentulism. He has been missing the maxillary right molars (#2 and #3) for a long time. Moderate vertical bone loss is noted in the edentulous area.

CASE-BASED QUESTIONS	SOLUTIONS
1. What are the advantages of real-time micro	**Answer: D** **Explanation:** All of the listed answer choices are the benefits and advantages of using real-time micro positioning implant surgery. It is

positioning implant surgery? A. Potential to reduce surgical time B. Minimized surgical invasiveness C. More precise translation of implant surgical planning to the procedure D. All of the above	a more advanced way of incorporating patient data from computed tomography and cone beam computed tomography scans during implant surgery. It also allows treatment of challenging cases with more comfort and confidence.
2. Real-time micro positioning (or fiduciary) markers must accurately relate the image data to the _____. A. Planned prosthetic crown positions B. Actual patient's anatomy C. Patient's existing opposing dentition	**Answer: B** **Explanation:** Unlike conventional implant planning, where orientation and simulation of implant positions are related to the planned prosthetic crown positions, real-time micro positioning implant surgery markers must relate the image data to the actual patient's anatomy (scan image of patient's jaw morphology).

Complications Related to Augmentation Procedures *(e-only)*
Complications Related to Placement and Loading Protocols *(e-only)*
Prosthetic or Mechanical Complications
Aesthetic and Phonetic Complications
Conclusions

The successful use of osseointegrated dental implants has dramatically changed dentistry and significantly improved dentists' ability to provide tooth replacement options for patients.[3,115] Despite implants' long-term predictability and success, implant-related complications and failures happen in some cases.[4,29] Complications can be surgical, biologic, mechanical, or aesthetic. Some complications are relatively minor and easy to manage, but others are more significant and challenging to resolve. The most serious complications can result in failure of prostheses, loss of implants, and severe loss of supporting bone.

Surgical complications are those problems or adverse outcomes that result from surgery, including procedures used for implant site development, implant placement, implant exposure, and tissue augmentation. Implant complications commonly arise from placement of an implant in a nonideal position. Malpositioned implants, which usually result from poor preoperative treatment planning or errors in surgical technique, can lead to an array of implant problems ranging in severity from minor to major. Surgical complications include compromised aesthetic and prosthetic results, soft tissue and bone dehiscences, impingement on and damage to anatomic structures, and implant failure. Unfortunately, the problems that arise from implant malposition are often not recognized until after osseointegration, when the prosthesis is being fabricated.

Biologic complications involve the hard and soft tissues that support the implant. Peri-implant tissue changes can be limited to inflammation of surrounding soft tissues or be more significant, such as progressive loss of supporting bone. The ultimate biologic complication is implant loss or failure, which can produce soft and hard tissue defects. Loss of implants can be caused by failure to achieve osseointegration in the early stages before restoration or by loss of osseointegration as a result of destruction of supporting bone after the restoration is installed and functioning.

Prosthetic or *mechanical complications* and failures typically occur in the form of material failure, such as abutment and prosthetic screw loosening or fractures. The prosthesis can be rescued from many mechanical problems if they are minor and recognized early. However, some complications, such as implant fractures, are

devastating and not salvageable.

Aesthetic complications arise when the patient's expectations are not met. Satisfaction with the aesthetic outcome of the implant prosthesis varies from patient to patient. The risk of aesthetic complications is increased among patients with high aesthetic expectations and suboptimal patient-related factors, such as a high smile line, thin gingival tissues, or inadequate bone quantity and quality.

This chapter reviews common implant-related complications. A summary of the literature offers some insight into the prevalence of implant-related complications. Implant failure and surgical complications related to site development and variations in implant placement protocols are discussed.

Definitions of Implant Survival and Success

The criteria used to define and report implant success or failure can vary substantially among publications. Selection of success criteria can be based on the author's preference, study population, or some other study objective. Because the level of success reported in an article is based on the criteria used to define success, recognizing the tremendous variation in the way investigators measure and interpret success is crucial. Sometimes, outcomes are measured by the presence or absence of implants at the time of the last examination, which is a measure only of implant survival and should not be confused with implant success. In contrast to this simplified reporting, some investigators use detailed criteria to measure implant success and failure, with variations of successful outcomes separated and defined by additional criteria.

Implant survival is defined as an implant that remains in place at the time of evaluation, regardless of any untoward signs, symptoms, or history of problems. There is a difference between implants that are functioning under an implant-retained restoration and those that are not connected to a restoration and not providing support or function. These implants are sometimes referred to as *sleepers*, and they should not be considered successful merely

because they remain osseointegrated. Sleeper implants instead should be included in the discussion as surviving but counted as *failures* because they did not fulfill the originally intended treatment objective.

Implant success is defined by the presence of the implant and the criteria evaluating its condition and function at the time of examination. Various criteria for implant success and failure have been published, but not all investigators agree with or use them. In the classic definition, Albrektsson and colleagues[6] defined success as an implant with no pain, no mobility, no radiolucent peri-implant areas, and no more than 0.2 mm of bone loss annually after the first year of loading. Roos-Jansaker and associates[157] added to this by defining a successful implant as one that loses no more than 1 mm of bone during the first year of function.

Sometimes, the criteria are used as proposed, but in other cases, they are used by investigators with modifications and additional criteria. This makes it difficult to compare studies and draw conclusions about any aspect of implant success or failure based on one or a few studies.

Strictly defined, implant success is any implant-retained restoration in which (1) the original treatment plan is performed as intended without complications, (2) all implants that were placed remain stable and functioning without problems, (3) the peri-implant hard and soft tissues are healthy, and (4) the patient and treating clinicians are pleased with the results. When these strict criteria are used, the rate of implant success (i.e., absence of complications) is only about 61% after 5 years for implant-supported fixed partial dentures (FPDs) and 50% after 10 years for combined tooth–implant FPDs.[113]

An additional criterion of implant success that is not typically reported but should be considered is the aesthetic success or patient satisfaction with the outcome. Several methods have been proposed to evaluate aesthetic results. A restorative index was proposed by Jensen and coworkers[95] to appraise the aesthetics of the final restoration. The index uses a scale of 1 to 10, with 1 being an extremely poor result and 10 being a superlative aesthetic result. Based on subjective and objective criteria, the index evaluates the size and shape of the implant restoration compared with the

equivalent contralateral tooth, how well it blends into the arch, and the papillae, gingival form, color, and other factors considered essential in determining an aesthetic result. The pink aesthetic score is an index proposed by Furhauser and colleagues[72] that considers seven soft tissue parameters, including evaluation of the color, contour, and texture of the surrounding soft tissues (i.e., papilla and facial mucosa). Each parameter is given a score of 0, 1, or 2, which allows the best score of 14 to determine the highest level of aesthetics.

Other indices were proposed for single-tooth implant restorations in the aesthetic zone.[23,122] Proposed by Belser and colleagues,[23] one index combines a modified pink aesthetic score with a white aesthetic score that focuses on the visible part of the implant restoration. Scoring includes five parameters: general tooth form, hue, value, surface texture, and translucency. The maximum white aesthetic score is 10. These indices are aimed at quantifying the aesthetic result, which can provide an objective method of judging implant aesthetic success.

Key Fact

Implant survival indicates that the implant has become osseointegrated but does not consider associated problems. An implant that is not restored can be included in survival percentages while failing to fulfill its intended purpose. *Implant success* is defined by criteria evaluating the condition and function of the implant. Because different criteria have been used to define implant success, it is difficult to make comparisons between studies and often impossible to make conclusions about implant success or failure based on only one or a few studies.

Types and Prevalence of Implant Complications

The prevalence of implant-related complications has been reported in several reviews. However, a systematic review of the incidence of complications in studies of at least 5 years' duration revealed that

biologic complications were considered in only 40% to 60% and technical complications in only 60% to 80% of the studies. The review found that the incidence of technical complications related to implant components and suprastructures was higher for overdentures than for fixed restorations.[24]

In a systematic review of reports on the survival and complication rates of implant-supported FPDs, Lang and associates[113] found that the most common technical complication was fracture of veneers (13.2% after 5 years), followed by loss of the screw access hole restoration (8.2% after 5 years), abutment or occlusal screw loosening (5.8% after 5 years), and abutment or occlusal screw fracture (1.5% after 5 years and 2.5% after 10 years). Fracture of implants occurred infrequently (0.4% after 5 years and 1.8% after 10 years).

A retrospective evaluation of 4937 implants by Eckert and colleagues[54] found that implant fractures occurred more frequently in partially edentulous restorations (1.5%) than in restorations of completely edentulous arches (0.2%), and all observed implant fractures occurred with commercially pure, 3.75-mm diameter threaded implants.

In a literature review that included all types of implant-retained prostheses, Goodacre and colleagues[77] found that the most common technical complications were loosening of the overdenture retentive mechanism (33%), resin veneer fractures with FPDs (22%), overdentures needing to be relined (19%), and overdenture clip or attachment fracture (16%). With the inclusion of edentulous patients having overdentures, their review seemed to indicate a significantly higher percentage of complications than Pjetursson's systematic review[145] of patients with implant-supported FPDs. Goodacre and associates[76] found it impossible to calculate an overall prosthesis complication rate because most studies included in their review did not report several of the complication categories.

The most common complication reported for single crowns was abutment or prosthesis screw loosening. The rate of abutment screw loosening varied dramatically from one study to another, ranging from 2% to 45%.[77] The highest rate of abutment screw loosening was associated with single crowns, followed by overdentures. The rate of prosthesis screw loosening was similar,

ranging from 1% to 38% in various studies. A higher frequency was reported for single crowns in the posterior areas (i.e., premolar and molar) than in the anterior region.

Implant fracture is an uncommon but significant complication. Goodacre and colleagues[76] reported a 1.5% incidence in their literature review. The incidence of implant fracture was higher in FPDs supported by only two implants. Consistent with this finding, Rangert and coworkers[149] reported that most implant fractures occurred in single- and double-implant–supported restorations. They also found that most of these fractures were in posterior partially edentulous segments, in which the generated occlusal forces can be greater than in anterior segments (Fig. 85.1).

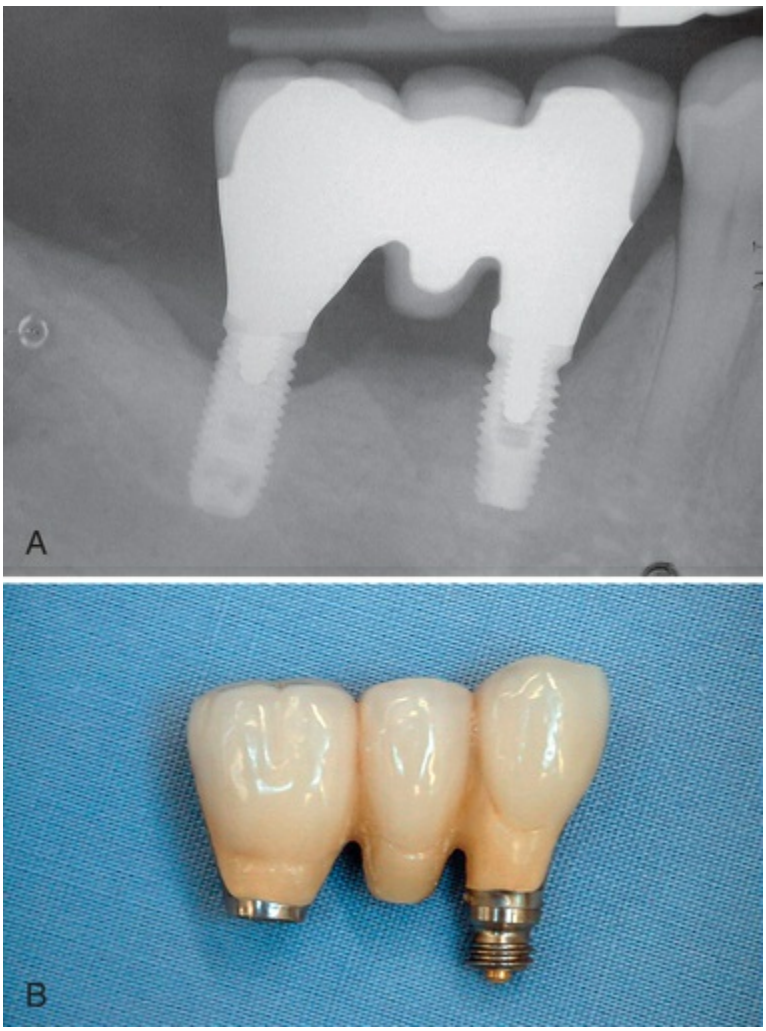

FIG. 85.1 (A) Radiograph of a three-unit, posterior, fixed partial denture supported by two standard-diameter, screw-shaped threaded implants. Notice the

long crown height, relatively short implant length, and bone loss around the posterior implant. (B) Photograph of the ultimate implant-supported restoration failure. The anterior implant fractured between the second and third threads, which resulted in loss of the restoration.

In a systematic review of prospective longitudinal studies (i.e., minimum of 5 years' duration) reporting biologic and technical complications associated with implant therapy (i.e., all restoration types included), Berglundh and collegues[24] found that the incidence of technical complications was consistent with Pjetursson's findings, with implant fracture occurring in less than 1% (0.08% to 0.74%) of cases. Consistent with the findings in Goodacre's review, technical complications were higher for implants used in overdenture therapy than implants supporting fixed prostheses.

In Lang and associates' systematic review[113] of survival and complication rates for implant-supported FPDs, biologic complications such as peri-implantitis and soft tissue lesions occurred in 8.6% of patients after 5 years. In a later literature review of the prevalence of peri-implant diseases, Zitzmann and Berglundh[191] reported that although cross-sectional studies were rare, data from the only two studies available showed that peri-implant mucositis occurred in 80% of patients and 50% of implant sites. Peri-implantitis was identified in 28% and 56% or more of patients and in 12% and 43% of implant sites in the two studies that followed patients with functional implants for at least 5 years.

A critical review of the literature by Esposito and associates[64] included 73 publications reporting early and late failures of Brånemark implants; biologically related implant failures were relatively low at 7.7%. Treatments involved all anatomic areas and all types of prosthetic design. The study authors concluded that the predictability of implant treatment was especially good for partially edentulous patients compared with totally edentulous patients; failures in the latter population were twice as high as those in the other group. The incidence of implant failure was three times higher for the edentulous maxilla than for the edentulous mandible, whereas failure rates for the partially edentulous maxilla were similar to those for the partially edentulous mandible.

Risk factors such as smoking, diabetes, and periodontal disease

can contribute to implant failure and complications. Several studies with numerous implants and years of follow-up have concluded that smoking is a definite risk factor for implant survival.[13,50,51,56,134] A systematic review of the effect of risk factors on implant outcomes concluded that smoking had an adverse effect on implant survival and success; the effects were more pronounced in areas of loose trabecular bone (i.e., posterior maxilla).[107] The review suggested that type 2 diabetes could have an adverse effect on implant survival rates but did not have enough studies to permit a definitive conclusion.[107] The same review concluded that although patients with a history of treated periodontitis did not show a decrease in implant survival, they did experience more biologic implant complications and lower success rates, especially with longer-term follow-up.[107]

Types of Dental Implants

Analysis of the data on the prevalence of implant complications (i.e., failure, fracture, and peri-implantitis) in published systematic reviews should consider the fact that many of these studies reported on implants with earlier designs (i.e., machined surfaces and external connections). Most current implant systems feature surfaces with an altered microtopography (i.e., rough), and many have internal connections. The prevalence and type of complications associated with the newer implant designs may be different.

Many modifications have been developed to try to improve the long-term success rates of implants. More than 1300 types of dental implants are available with different materials, shapes, sizes, lengths, and surface characteristics or coatings. Although it has been suggested that machined surfaces are more resistant to plaque accumulation and peri-implantitis, there is limited evidence to show that implants with relatively smooth surfaces (i.e., machined) are less prone to bone loss from chronic infection than implants with rough surfaces. To date, there is no evidence showing that any particular type of dental implant has superior long-term success.[59]

Different implant designs and surfaces must be studied in prospective human trials over long periods. Until those data

become available, clinicians should be aware that historical data reporting success rates for earlier implant designs may not reflect the outcomes for current implants. Moreover, new implant surfaces and designs are commonly introduced with limited or no data available on potential complications.[a]

Surgical Complications

As with any surgical procedure, implant surgery has risks. Proper precautions must be taken to prevent injuries, including (1) a thorough review of the patient's medical history, (2) a comprehensive clinical and radiographic examination, (3) establishment of a comprehensive interdisciplinary treatment plan, and (4) good surgical techniques.

Surgical complications include perilous bleeding, damage to adjacent structures such as teeth, injury to nerves, and iatrogenic jaw fracture. Postoperative complications include bleeding, hematoma, and infection. They may be minor, transient, and easily managed or more serious and require postoperative treatment.

Hemorrhage and Hematoma

Bleeding during surgery is expected and usually easily controlled. However, if a sizable vessel is incised or otherwise injured during surgery, the hemorrhage can be difficult to control. Smaller vessels naturally constrict or retract to slow the hemorrhage. If bleeding continues, it may be necessary to apply pressure or suture the hemorrhaging vessel. Cauterizing the hemorrhaging vessel also may be warranted. This can be especially difficult if there is a vascular injury to an artery that is inaccessible, such as in the floor of the mouth or posterior maxilla. Serious bleeding from an inaccessible vessel can be life-threatening, not by exsanguination but rather as a result of airway obstruction. This is most problematic when the point of bleeding is inaccessible and internal (i.e., in connective tissues and soft tissue spaces).

Postoperative bleeding is an equally important problem to manage (Fig. 85.2). Patients should be given postoperative instructions on normal expectations for bleeding and how to

prevent and manage minor bleeding. Historically, standard practice is that they should be advised, with their physician's approval, to discontinue or reduce medications that increase bleeding tendency 3 to 10 days before surgery. However, recent evidence suggests that this may not be necessary and may increase the risk of hematologic or cardiovascular problems[96,97,134,159] (see Chapter 39).

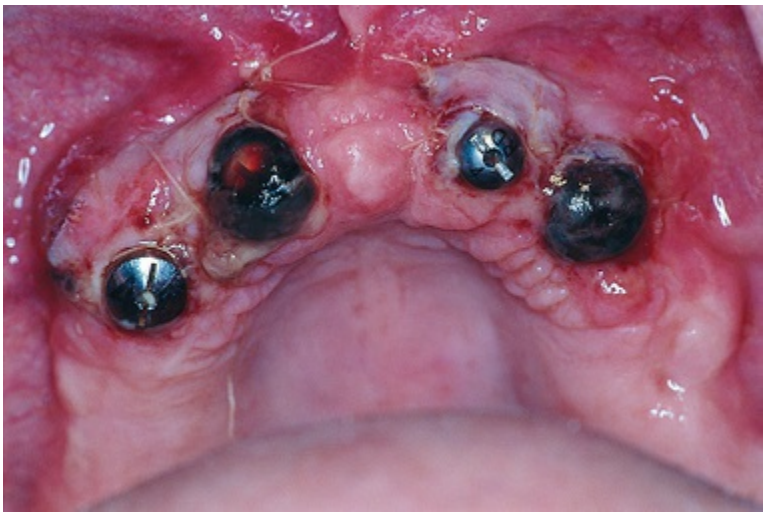

FIG. 85.2 Clinical photograph of postoperative bleeding around healing abutments after second-stage implant exposure surgery.

Dental health care providers should consult with medical health care providers regarding the best management for each patient. Dental health care providers and patients should always include the treating medical practitioner in management decisions if postoperative bleeding is excessive or persistent.

Submucosal or subdermal hemorrhage into the connective tissues and soft tissue spaces can result in hematoma formation. Postoperative bruising is a typical example of minor submucosal or subdermal bleeding into the connective tissues (Fig. 85.3). Bruising and small hematomas typically resolve without special treatment or consequence. However, larger hematomas or those that occur in medically compromised individuals are susceptible to infection as a result of the noncirculating blood that sits in the space. It is prudent to prescribe antibiotics for patients who develop a noticeably large hematoma. Referral to the appropriate medical physician may be warranted for nonresolving hematomas.[88]

FIG. 85.3 Clinical photograph of postoperative (extraoral) bruising indicative of subdermal bleeding into connective tissue spaces. This is a normal expectation that resolves in 7 to 14 days.

Although the incidence of a life-threatening hemorrhage from implant surgery is extremely low, the seriousness of the problem warrants the attention of everyone who participates in this type of surgery. Potentially fatal complications have been reported for implant surgical procedures in the mandible, especially the anterior region.[b] Massive internal bleeding in the highly vascular region of the floor of the mouth can result from instrumentation or implants that perforate the lingual cortical plate and sever or injure the arteries running along the lingual surface. Depending on the severity and location of the injury, bleeding may become apparent immediately or only after some delay. In either case, the progressively increasing hematoma dissects and expands to displace the tongue and soft tissues of the floor of the mouth, ultimately leading to upper airway obstruction.

Emergency treatment includes airway management (primary importance) and surgical intervention to isolate and stop the bleeding. Clinicians must be aware of this risk and be prepared to act quickly. It is important to recognize that bleeding, although considered a complication at the time of surgery, can become a serious complication in the hours and days after surgery.[47]

Clinical Correlation

Although the incidence of a life-threatening hemorrhage from

implant surgery is extremely low, it is a serious problem that can occur. Implant surgical procedures in the anterior mandible have been associated with potentially fatal complications. Massive internal bleeding in the floor of the mouth from inadvertent injury to lingual arteries can cause an expanding hematoma that displaces the tongue and soft tissues, obstructing the upper airway. Emergency treatment includes airway management and surgical intervention to isolate and stop the bleeding. Clinicians must be aware of this risk and be prepared to act quickly.

Neurosensory Disturbances

One of the more problematic surgical complications is an injury to nerves. Neurosensory alterations caused by damage to a nerve can be temporary or permanent. Neuropathy can be caused by a drilling injury (i.e., cut, tear, or puncture of the nerve) or by implant compression or damage to the nerve (Fig. 85.4; see Fig. 76.18). In either case, the injury causes neuroma formation, and two patterns of clinical neuropathy may follow. *Hypoesthesia* is a neuropathy defined by impaired sensory function that is sometimes associated with phantom pain. *Hyperesthesia* is a neuropathy defined by pain with minimal or no sensory impairment.[79] Some neuropathies resolve, whereas others persist. The type of neuropathy does not indicate the potential for recovery.

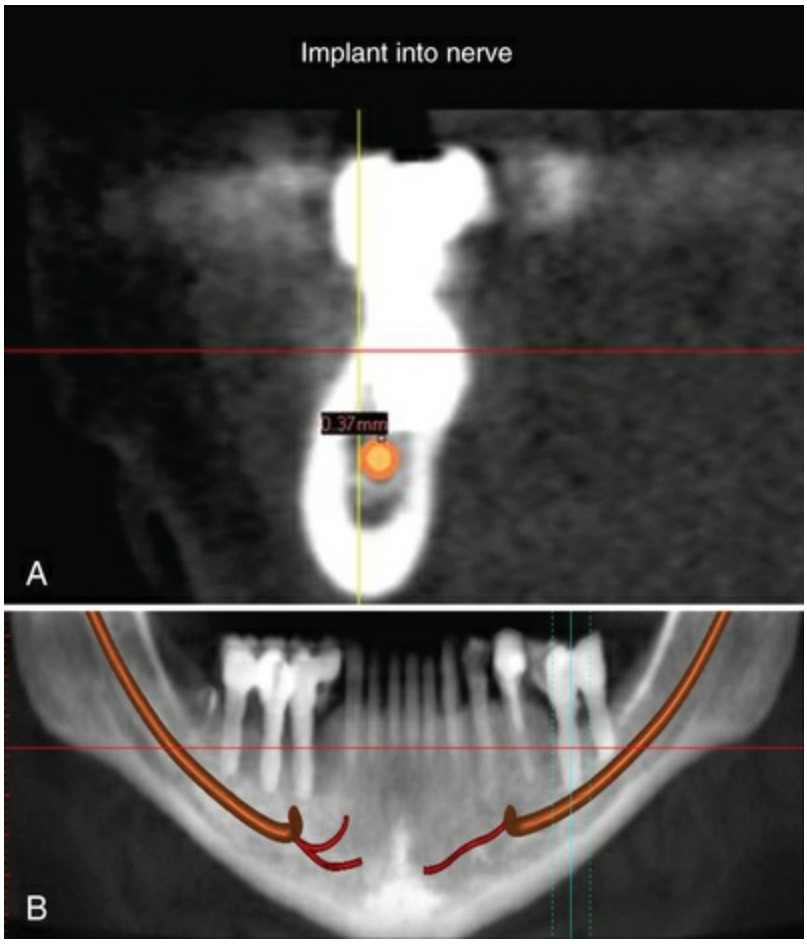

FIG. 85.4 (A) Cross-sectional computed tomography (CT) image shows the implant impinging on the inferior alveolar nerve canal. (B) Panoramic CT scan shows the implant in the lower left first molar area impinging on the inferior alveolar nerve canal. The nerve is marked by tracing with software.

For several reasons, it is likely that neurosensory disturbances occur more frequently after implant surgery than is reported in the literature. First, many of the changes are transient in nature, and most patients recover completely or at least recover to a level that is below a threshold of annoyance or daily perception. Second, wide variation exists in the postoperative evaluation of patients by clinicians. Some clinicians do not assess or inquire about postsurgical neurosensory disturbances, allowing this complication to go unnoticed. Likewise, some patients expect altered sensation as part of surgery and may never acknowledge or comment on its presence, especially if the disturbance is minor. It is therefore likely that minor neuropathies exist but go unrecognized and unreported.

According to a systematic review of inferior alveolar nerve injuries after implant placement, the importance of early diagnosis and treatment is considered essential for preventing long-term, permanent neurologic problems. If a diagnosis is established and treatment is rendered within the first 36 hours, a high percentage of successful outcomes can be achieved. An estimated 25% of patients with iatrogenic paresthesia suffer permanent effects.[104] Several researchers and clinicians proposed that early implant removal (i.e., within the first 24 to 36 hours after implant placement) may lead to better healing with the return of sensation.[104,105]

Neurosensory disturbances reported in the literature are most prevalent and significant when they are more serious and occur more frequently, such as those associated with lateral transposition of the mandibular nerve.[93,101] This relatively uncommon procedure is used to reposition the nerve and allow longer implants to be placed in the atrophic posterior mandible. Lateral nerve transposition procedures are associated with an almost 100% incidence of neurosensory dysfunction immediately after surgery. More than 50% (range, 30% to 80%) of these neurosensory changes are permanent.[101] Several articles have been written on the treatment of neurosensory disturbances.[7,128,151]

Implant Malposition

Many of the complications that arise during implant surgery can be attributed to the dental implant being placed in an undesired or unintended position. Malpositioning of dental implants is usually the result of poor treatment planning before surgery, lack of surgical skill, or poor communication between the implant surgeon and the restorative dentist. Optimal implant aesthetics and the avoidance of positional complications can be achieved by placing the implant in a prosthetically driven manner.[123,140] The implant should be placed with reference to the three dimensions dictated by the position of the final restoration and not by the availability of bone.

Angulation is another important determinant of implant position that affects outcome aesthetics. The ideal implant position entails an accurate preparation, insertion, and placement into the alveolus in a

proper three-dimensional geometry according to apicocoronal, mesiodistal, and buccolingual parameters and implant angulation relative to the final prosthetic restoration and gingival margins[108,160] (see Chapter 78).

Apicocoronally, the implant should be placed so the platform is about 3 mm apical to the gingival margin of the anticipated restoration.[28] The implant position varies slightly from one implant system to another, depending on abutment design and space requirements. If the implant platform is placed too far coronally, there will not be sufficient room to develop a natural-looking emergence profile, and the tooth may have a boxy, unaesthetic appearance. If the platform is placed at or above the level of the gingival margin, metal collar or implant exposure can occur, yielding an unaesthetic result (Fig. 85.5). If the implant platform is placed too far apically, a long transmucosal abutment will be necessary to restore the implant. This can lead to a deep pocket and difficult hygiene access for the patient and clinician.

FIG. 85.5 Clinical photograph of gingival recession around a maxillary anterior implant (left central incisor) resulting in exposure of the crown margin, the implant collar, and several threads of the implant.

The implant should be placed at a distance of 1.5 to 2 mm from an adjacent natural tooth and 2 to 3 mm from an adjacent implant to maintain an adequate biologic dimension.[81] Similar to natural teeth, violation of biologic width around an implant can lead to

bone loss.[87] Implants that are placed too close to each other (Fig. 85.6) or to natural teeth can be difficult to restore. Impression copings and impression-taking techniques must be modified. Improperly spaced implants invariably lead to chronic inflammation and peri-implantitis.[57,181] Conversely, an implant placed at an excessive distance from an adjacent tooth or implant may require prosthetic compensation in the form of mesial or distal cantilevers, which can predispose the implant to biologic (i.e., bone loss) and mechanical (i.e., screw loosening,[77] screw fracture,[179] and implant fracture[149]) complications and difficulties with hygiene.[181]

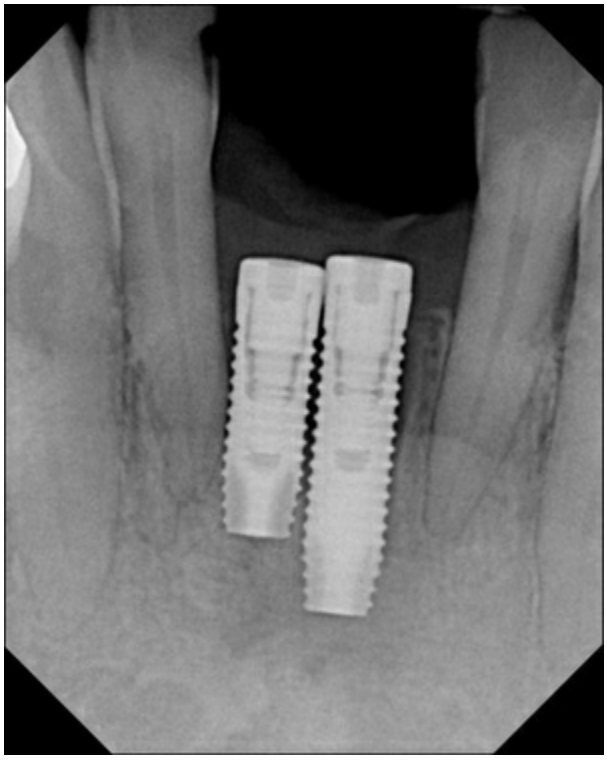

FIG. 85.6 Radiograph of two mandibular anterior implants placed too close together (i.e., no proximal space), resulting in implants that are impossible to restore.

Ideally, an implant should be placed buccolingually so there is at least 2 mm of bone circumferentially around it.[172] Implant exposure through the lingual or buccal cortex can predispose an individual to abscess and suppuration.[38] Implants that are placed too palatally or lingually require prosthetic compensation in the form of a buccal ridge lap, which may be difficult for the patient to clean and can

lead to tissue inflammation.[22]

To obtain ideal aesthetics, to avoid potential aesthetic complications, and to correct bodily placement of the dental implant, it must be correctly angulated on insertion. In most anterior cases, it is desirable to have the long axis of the implant directed so it is emerging toward the cingulum. In the posterior region, the implant axis should be directed toward the central fossa or the stamp cusp of the opposing tooth. Implants that are placed with mild to moderate misangulations can often be corrected prosthetically with implant abutments. Minor misangulations (i.e., 15 to 20 degrees) can be corrected with prefabricated or customized angled abutments; moderate misangulations (i.e., 20 to 35 degrees) can usually be managed with customized UCLA-type abutments; and extreme errors in implant angulations (>35 degrees) may make an implant unrestorable and require it to be left submerged (i.e., a sleeper) or be removed (Fig. 85.7).

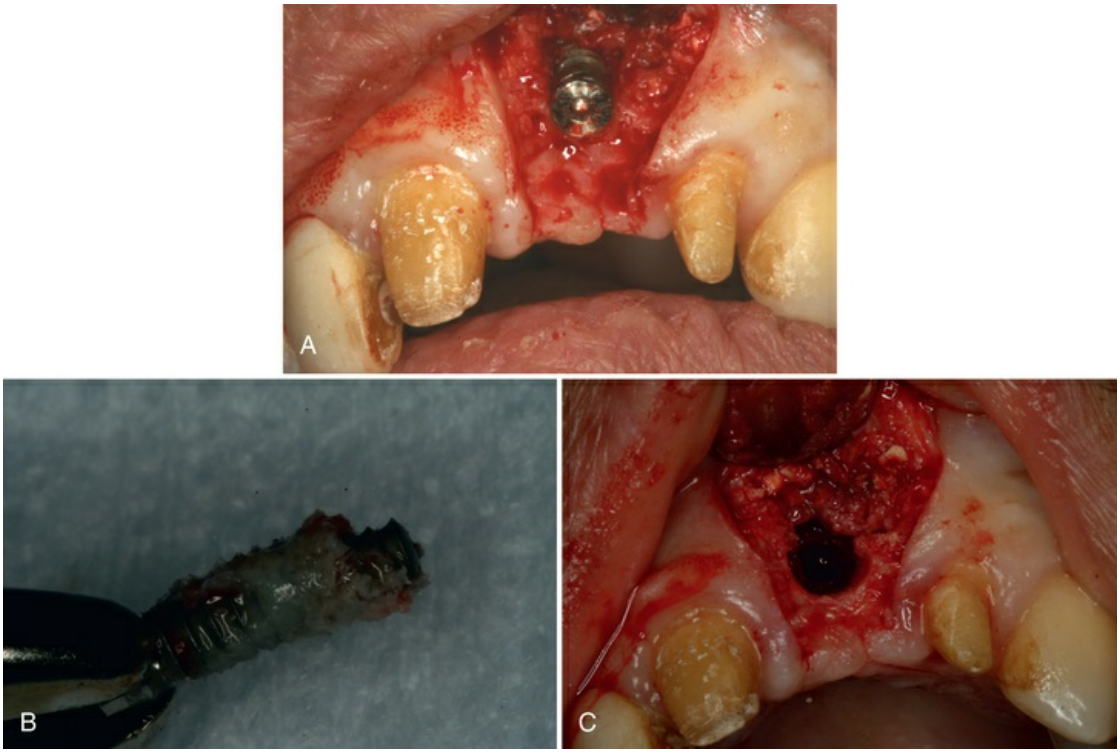

FIG. 85.7 Clinical photograph of a maxillary anterior implant (i.e., left central incisor) placed with an extreme facial angulation, resulting in an implant that emerges through the gingiva at a level that is more apical than the adjacent natural tooth gingival margins. (A)

Surgical exposure of the malpositioned implant. (B) Surgically removed implant. (C) Alveolar defect resulting from surgical removal of the malpositioned implant.

The ultimate complication of malpositioning is implant or instrument invasion into vital structures. The most common violation of neighboring anatomy is placement of the dental implant into the adjacent tooth root. Surgical procedures used to prepare osteotomy sites and place implants adjacent to teeth can injure them by directly cutting into the tooth structure or by damaging nearby supporting tissues and nerves. Instrumentation (e.g., drills) directed at or near the adjacent tooth can injure the periodontal ligament, tooth structure, and nerve of the tooth. Depending on the extent of the injury, the tooth can require endodontic therapy or extraction.

On insertion, dental implants follow the trajectory of the osteotomy prepared by the drill. Care must be taken when preparing the osteotomy to stay true to the planned path of insertion. Radiographs taken periodically during implant surgery with a guide pin in the osteotomy site can greatly reduce the potential for damaging adjacent teeth (see Fig. 76.15). Radiographic analysis before implant surgery should include detection of curved, convergent, or dilacerated root structures of adjacent teeth that can limit implant placement.

Particular care must be taken when placing implants in the mandible so as to not encroach on the inferior alveolar canal or the mental foramen (see Chapter 58 for a description of the anatomy). Encroachment on the mandibular canal or mental foramen during osteotomy or implant placement by direct contact or mechanical compression of bone can injure nerves and blood vessels. Paresthesia, hypoesthesia, hyperesthesia, dysesthesia, or anesthesia of the lower lip, skin, mucosa, and teeth can result, as can arterial or venous bleeding.[78] The reported incidence of sensory disturbances after mandibular implant placement is 0% to 40%.[18,104]

In the maxilla, care must be taken to avoid dental implant perforation into the maxillary sinus or nasal cavity. Displacement of the entire dental implant into the maxillary sinus cavity may require a Caldwell-Luc procedure for retrieval. The online section

on Sinus Bone Augmentation provides further information about complications related to the maxillary sinus.

The risks of surgery always exist, but the complications can be minimized by an understanding of the causes and with proper diagnosis and treatment planning. Three-dimensional imaging (i.e., computed tomography [CT] and cone beam CT [CBCT]) provides the surgeon with useful preoperative information for diagnosis and treatment planning (see Chapter 76). Careful surgical exposure for direct visualization and identification of the mental nerve are indicated. The surgeon should establish a *zone of safety* and keep instrumentation and implants a safe margin (≥2 mm) away from the nerve.[78]

Key Fact

Malpositioned implants can be avoided by proper planning, good communication, and meticulous surgical skills. Radiographs taken periodically during implant surgery with guide pins in the osteotomy site can greatly reduce damage to adjacent teeth. Radiographic analysis before implant surgery should include detection of curved, convergent, or dilacerated root structures of adjacent teeth that can limit implant placement.

Biologic Complications

Biologic complications involve pathology of the surrounding peri-implant hard and soft tissues. Frequently, soft tissue problems are an inflammatory response to bacterial accumulation around implants. Bacteria can accumulate at the junction of an ill-fitting implant–abutment or abutment–crown connection. Some of the highly textured, macroscopically rough implant surfaces (e.g., titanium plasma–sprayed [TPS] or hydroxyapatite [HA] coating) may also perpetuate the accumulation of bacteria on the implant surface.

Inflammation and Proliferation

Because inflammation of the peri-implant soft tissues is similar to the inflammatory response in gingival and other periodontal tissues, the clinical appearance also is similar. Inflamed peri-implant tissues demonstrate the same erythema, edema, and swelling around teeth. Occasionally, the reaction of peri-implant soft tissues to bacterial accumulation is profound and unusual, with dramatic inflammatory proliferation (Fig. 85.8). This type of lesion is somewhat characteristic around implants and indicates a loose-fitting implant-to-abutment connection or trapped excess cement that remains buried within the soft tissue space (i.e., pocket).

FIG. 85.8 Inflammatory proliferation caused by a loose-fitting connection between the abutment and the implant. (Courtesy Dr. John Beumer, UCLA Maxillofacial Prosthetics, Los Angeles, CA.)

The precipitating local factor ultimately becomes infected with bacterial pathogens, leading to mucosal hypertrophy or proliferation and possible abscess formation (Fig. 85.9). Correction of the precipitating factors (e.g., loose connection, retained cement) can effectively resolve the lesion. Another type of lesion resulting from a loose abutment connection is a fistula (Fig. 85.10), and correcting the etiologic factor can quickly resolve it.

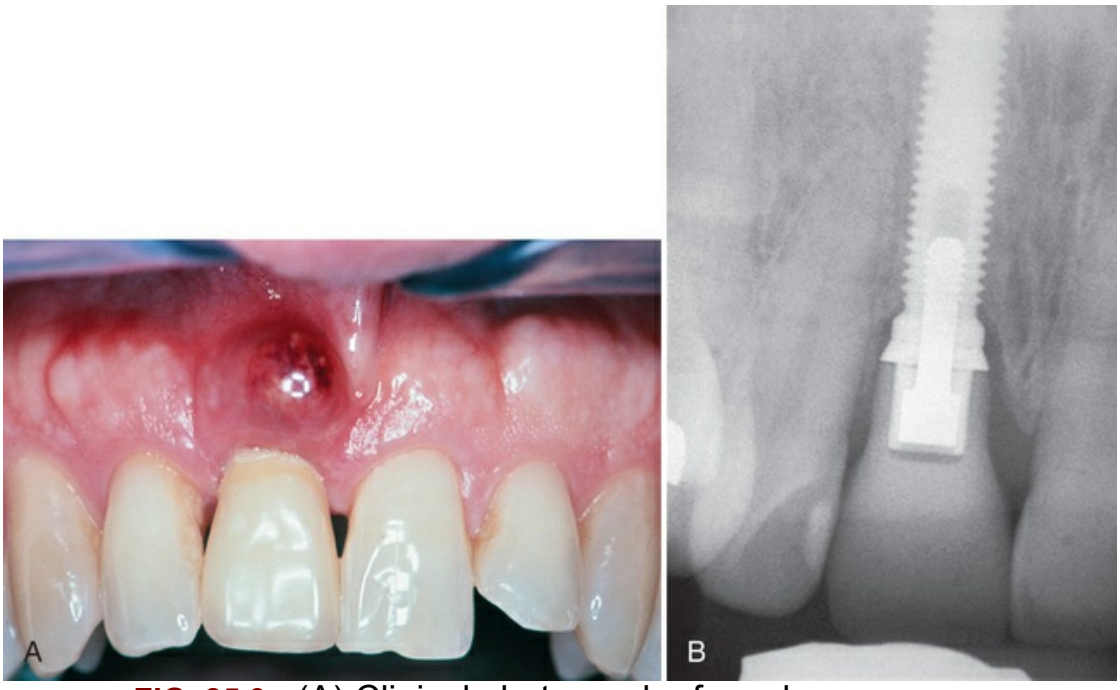

FIG. 85.9 (A) Clinical photograph of an abscess caused by excess cement trapped within the soft tissues. (B) Radiograph of an implant with a cemented crown (same patient as in A). Notice the subgingival depth of the crown–abutment (cement line) junction, which is below the level of the adjacent interproximal bone and therefore impossible to adequately access with an explorer to remove the excess cement. (Courtesy Dr. John Beumer, UCLA Maxillofacial Prosthetics, Los Angeles, CA.)

FIG. 85.10 Fistula caused by a loose implant–abutment connection (i.e., maxillary left lateral incisor).

Dehiscence and Recession

Dehiscence or recession of the peri-implant soft tissues occurs when support for the tissues is lacking or has been lost. Recession is a common finding after implant restoration and should be anticipated, especially when soft tissues are thin and not well supported (Fig. 85.11). Improper implant positioning also predisposes peri-implant tissues to recession. Placement or angulation of the implant too far buccally causes the buccal plate to resorb, resulting in greater recession.[171]

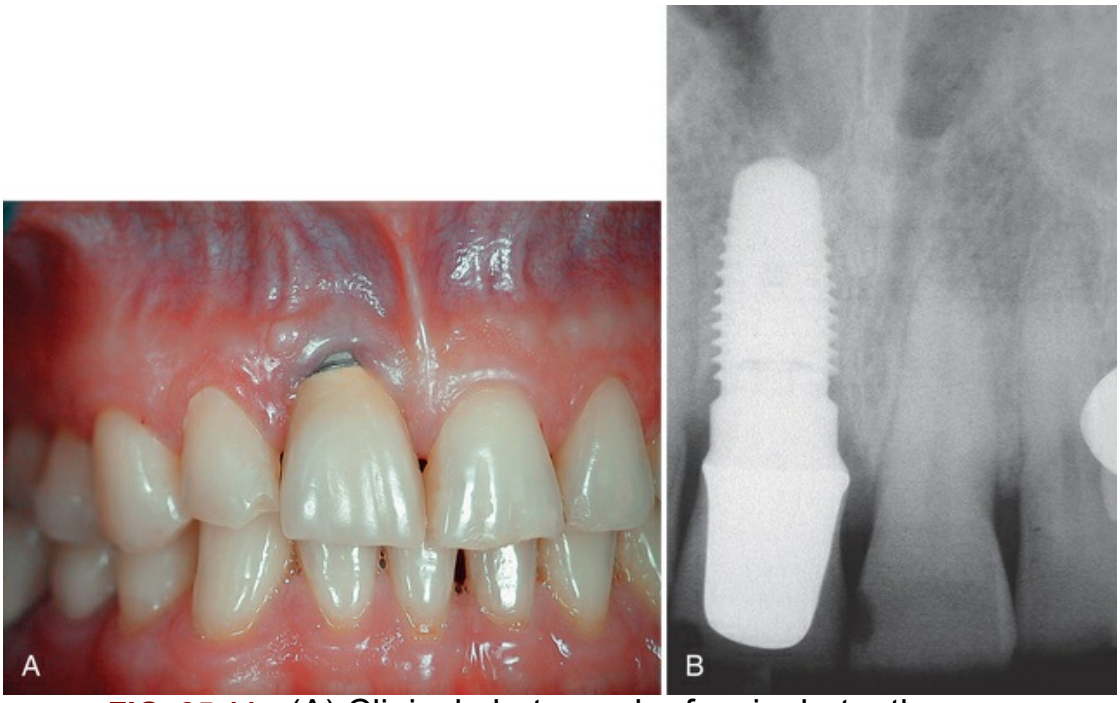

FIG. 85.11 (A) Clinical photograph of a single-tooth implant crown (maxillary right central) with moderate recession that occurred 1 year after the final restoration. In this case, recession most likely occurred because the labial bone around this wide-diameter implant was very thin or nonexistent. (B) Radiograph of a wide-diameter (6-mm) implant supporting a maxillary central incisor crown (same patient as in A).

Another factor is the thickness of the buccal plate of bone. Spray and colleagues[172] recommended a buccal bone thickness of 2 mm or greater to support the buccal soft tissue. If it is insufficient, preoperative or simultaneous site development using guided bone

regeneration is indicated. Recession is a problem that is particularly disconcerting in anterior aesthetic areas. Patients with a high smile line or high aesthetic demands consider recession a failure (Fig. 85.12).

FIG. 85.12 Poor aesthetics resulting from gingival recession and exposure of the crown margins, implant collars, and threads of several maxillary and mandibular implants supporting full-arch, fixed partial dentures. Notice the thin labial tissues and erythema, especially around the mandibular implant sites.

The anatomy and soft tissue support around implants are different from those around teeth. Periodontal tissues have the advantage of soft tissue support supplied by circumferential and transseptal connective tissue fibers that insert into the cementum at a level that is more coronal than the supporting bone. In the absence of inflammation, these fibers support periodontal soft tissues far above the level of crestal bone. As a result, gingival margins and interdental papillae are supported and maintained higher around teeth than around implants, even when the periodontal tissues are very thin.

Peri-implant soft tissues, however, depend entirely on the surrounding bone for support. Soft tissue thickness accounts for some soft tissue height, but there are no supracrestal inserting connective tissue fibers to aid the soft tissue support around an implant. The soft tissue height around implants is typically limited

to about 3 or 4 mm, and bone loss around implants often leads to recession.

« Flash Back

The peri-implant soft tissue seal is weaker than the periodontal soft tissue seal. The soft tissue seal around implants depends on tissue thickness and a long junctional epithelial attachment with hemidesmosomes. It is inferior to the periodontal attachment around natural teeth because it lacks the inserting connective tissue fibers (i.e., Sharpey fibers) of the periodontium. Periodontal papillae and gingival margins are also supported at a higher supracrestal level compared with peri-implant soft tissues. Periodontal soft tissues are supported by circumferential and transseptal connective tissue fibers that insert into the cementum at a level that is more coronal than the supporting bone.

Peri-Implantitis and Bone Loss

Peri-implantitis is an inflammatory process that affects the tissues around an osseointegrated implant and results in the loss of supporting bone.[129] The reported prevalence of peri-implantitis varies from less than 7% to 37% of implants.[106] The variation can be attributed to differences in studied populations, length of follow-up time, implant variables, and the criteria used to define peri-implantitis.[109,158] Two systematic reviews concluded that peri-implantitis affected 10% of implants and 20% of patients during the 5 to 10 years after placement.[11,131]

A classification for early, moderate, and advanced peri-implantitis based on the degree of bone loss was proposed to improve communication when describing prevalence and treatment.[71] Soft tissue measurements using manual or automated probes have been suggested to diagnose a compromised implant site.[71a] Although some reports state that probing is contraindicated, careful monitoring of probing depth over time seems useful in detecting changes of the peri-implant tissue.[44,148,174,175] Standardized radiographic techniques, with or without computerized analysis, have been useful in evaluating peri-implant bone levels.[4,25,29,99,148]

Periodic evaluation of tissue appearance, probing depth changes, and radiographic assessment are the best means of detecting changes in bone support.

Clinicians should monitor the surrounding tissues for signs of peri-implant disease by observing changes in probing depth and radiographic evidence of bone destruction, suppuration, calculus buildup, swelling, color changes, and bleeding.[130,136] Peri-implantitis can be perpetuated by bacterial infection that has contaminated a rough (e.g., TPS- or HA-coated) implant surface and by excessive biomechanical forces.[188,189] The classic trough-type defect is typically associated with peri-implantitis (Fig. 85.13). In cases with severely reduced bone support extending into the apical half of the implant (Fig. 85.14) or in cases demonstrating mobility, implant removal should be considered.[6,135]

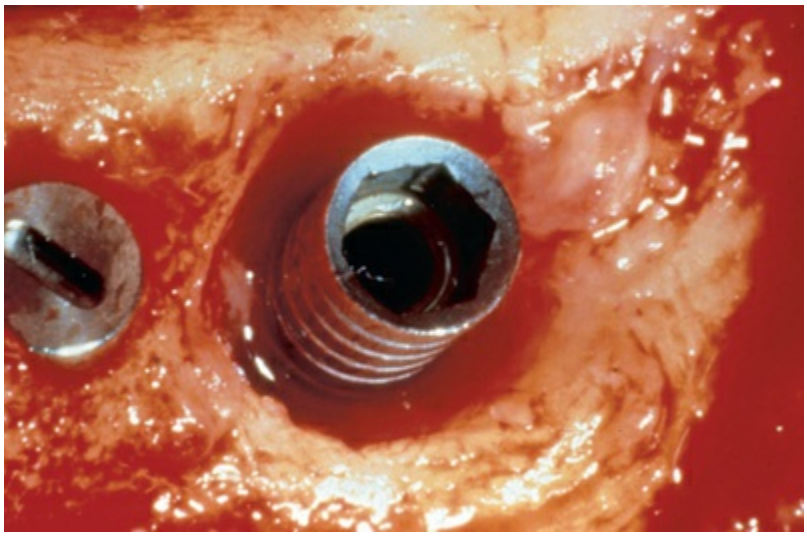

FIG. 85.13 Moderately advanced bone loss around an implant with the typical circumferential trough type of bony defect. (From Garg AK: *Implant dentistry: a practical approach,* ed 2, Mosby, St. Louis, 2010.)

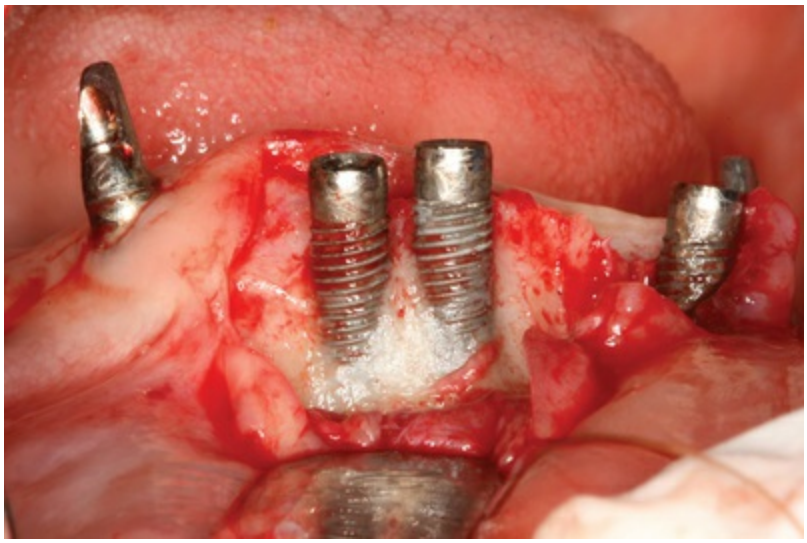

FIG. 85.14 Severe horizontal and vertical bone loss around several mandibular implants.

The number and distribution of implants and the occlusal relationships influence the biomechanical forces applied to implants.[147,153] A review by Lindhe and Meyle from the Consensus Report of the Sixth European Workshop on Periodontology concluded that risk indicators for peri-implantitis included (1) poor oral hygiene, (2) a history of periodontitis, (3) diabetes, (4) cigarette smoking, (5) alcohol consumption, and (6) implant surface.[117] Risk factors 1 to 4 have been recognized and reported in the literature.[107] The report suggests that although data for risk factors 5 and 6 are limited, they appear to be relevant to peri-implantitis.[117] One study found little evidence to support smoking as a risk factor for peri-implantitis.[167] Another proposed risk factor involves individual genetic polymorphisms.[33,112] More research is needed to study the relation of this risk factor to the development of peri-implantitis.

Other risk factors, including excess and retained cement, have been implicated in peri-implantitis. One article said that excess dental cement was associated with signs of peri-implant disease in 81% of cases evaluated using a dental endoscope.[187] The radiopacity of some commonly used cements affects their detectability.[183] This emphasizes the importance of proper cementation, use of screw-retained rather than cemented restorations when possible, and careful clinical examination after final crown cementation on implants.

Other proposed peri-implantitis predisposing factors include the

presence of aggressive bacteria, excessive mechanical stress, and corrosion. Each was documented as a factor that could act synergistically with biofilm or existing peri-implantitis to worsen the condition.[133]

Nine systematic reviews[c] concluded that no predicable method of treatment for peri-implantitis could be recommended. However, a clinical study of 170 consecutively treated implants with peri-implantitis using a regenerative protocol reported a more than 98% success rate.[70]

Implant Loss or Failure

Implant loss or failure is considered relative to the time of placement or restoration. Early implant failures occur before implant restoration. Late implant failures occur after the implant has been restored. When an implant fails before restoration, it probably did not achieve osseointegration, or the integration was weak or jeopardized by infection, movement, or impaired wound healing (Fig. 85.15). Late implant failures occur after prosthesis installation for a variety of reasons, including infection and implant overload (Fig. 85.16). In a review of the literature to evaluate biologic causes for implant failure, Esposito and colleagues[63] found that infections, impaired healing, and overload were the most important contributing factors. Two systematic reviews of the literature concluded that a single dose of preoperative antibiotic therapy could decrease the failure rate of dental implants.[60,168]

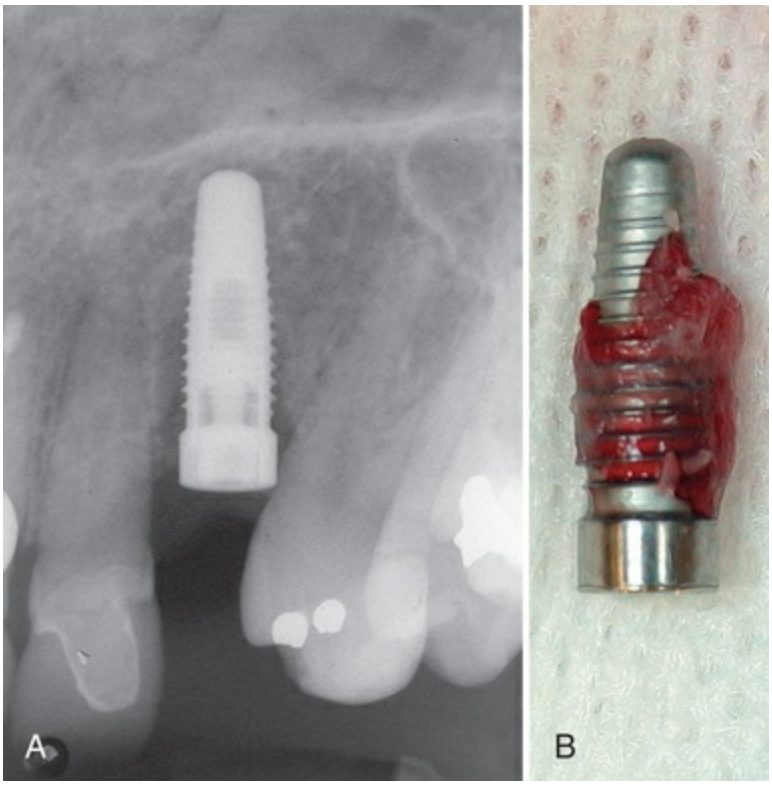

FIG. 85.15 (A) Radiograph of an early failed implant caused by lack of osseointegration. In addition to the crestal bone loss, notice the radiolucency along the sides of the implant. (B) Photograph of the failed (nonintegrated) implant (shown in A) that was easily removed along with surrounding connective tissue.

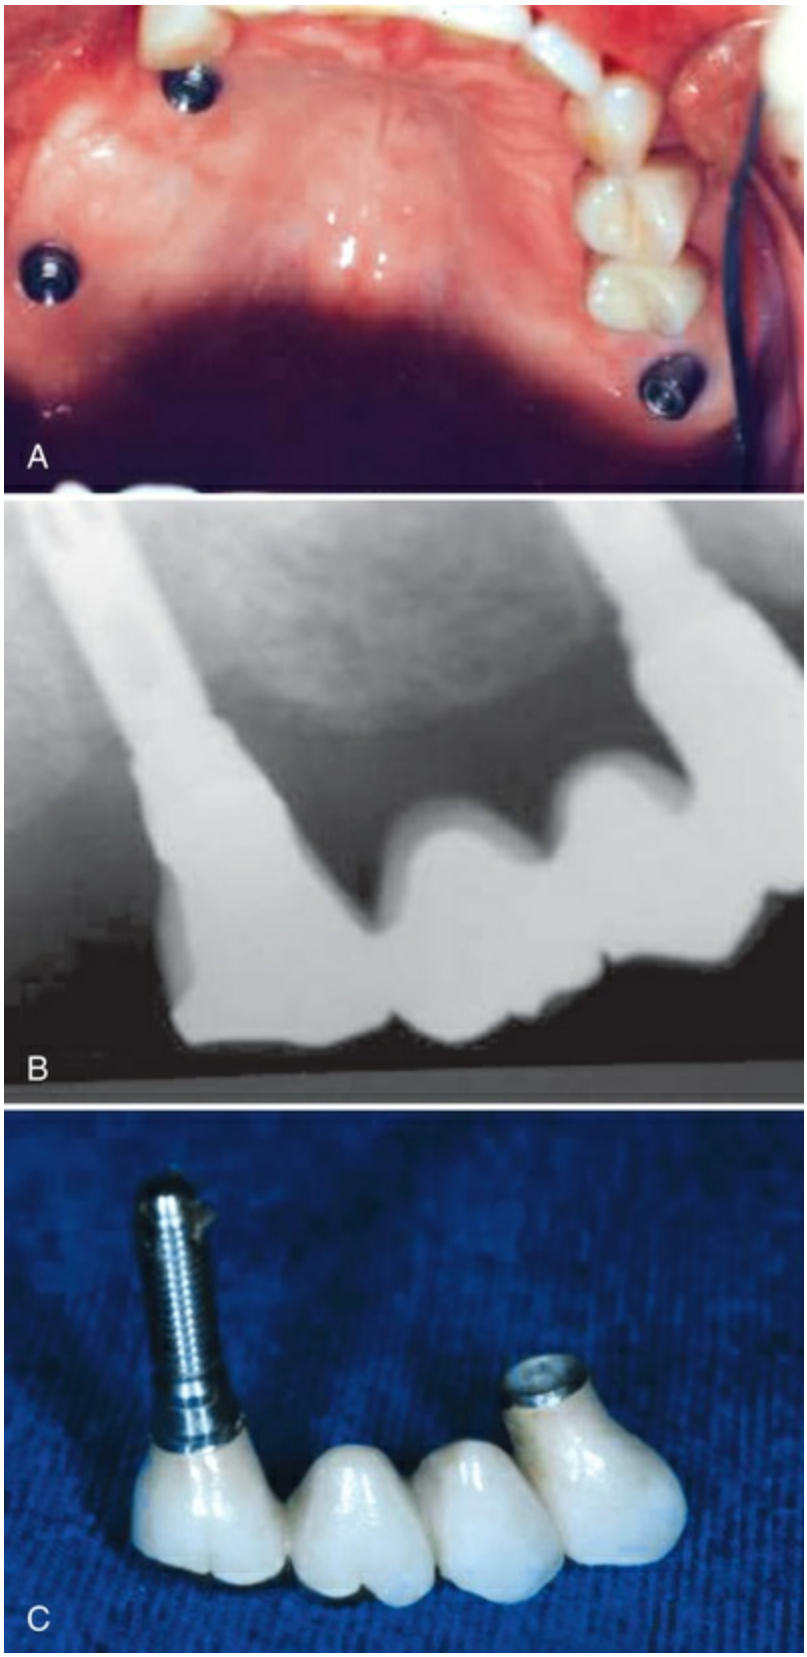

FIG. 85.16 A four-unit fixed partial denture in the posterior maxilla was supported by only two implants. (A) Clinical photograph of implant abutments in the posterior maxilla. (B) Radiograph taken 30 months

after restoration. Notice the bone loss around the distal implant. (C) Failed distal implant attached to a failed prosthesis. The biologic failure of one (posterior) implant resulted in a long-span cantilever extension from the other (anterior) implant that ultimately led to its mechanical failure (i.e., abutment screw fracture).
(Courtesy Dr. John Beumer, UCLA Maxillofacial Prosthetics, Los Angeles, CA.)

A review of the reasons for failure of oral implants concluded that several situations increased the failure rate: a low insertion torque on immediately placed or early loaded implants, inexperienced surgeons, implants inserted in the maxilla and posterior regions of the jaws, implants placed in heavy smokers, implant insertion in poor-quality (i.e., type III and IV) bone, lack of initial stability, and prosthetic rehabilitation with implant-supported overdentures.[39]

The risk of implant failure varies among patients, but patterns of loss tend to cluster. A second attempt at dental implant placement should be approached cautiously if placing the implant in the same site as the one that previously failed. It is often challenging to achieve adequate diameter, length, and stability of replacement implants due to the residual defect created by removal of the failed implant. In 2007, Grossmann and Levin reported an overall survival rate of 71% for dental implants that were placed in sites of previously failed single implants. In that study, all of the original implants failed during the early healing phase (mean of 2.3 to 3.2 months after placement).[80] In a 2008 study, Machtei and colleagues[119] reported an overall survival rate of 83.5% for the second attempt at dental implants. They concluded that replacing failed implants resulted in a lower survival rate compared with that for implants placed in pristine sites. This could not be associated with conventional implant- or patient-related factors. They suggested that a site-specific negative effect might be associated with this phenomenon.[119]

In 2011, Machtei and coworkers reported a lower survival rate (60%) for third reimplanted sites.[118] This outcome represents a further diminished prognosis compared with implants in original sites or after a second attempt.[43] Replacement of a failed implant poses a challenge in achieving osseointegration in a healed bone

site and can reduce the implant survival rate.[118]

Complications Related to Augmentation Procedures

A common problem encountered in implant dentistry is insufficient bone quantity to allow implant placement according to standard procedures. Deficiencies in alveolar bone result from developmental defects, periodontal disease, tooth loss, or trauma.[9,32,164] For most cases with alveolar ridge resorption, bone regeneration procedures are required to correct the defects before or simultaneously with implant placement.

The success of bone augmentation procedures has been assessed by experienced clinicians in several workshops.[5,38,66,83,84] One systematic review of the literature (2003 Workshop on Contemporary Science in Clinical Periodontics) found that survival rates of dental implants in augmented bone achieved a high level of predictability and showed that these rates were similar to those for implants placed in natural bone.[66] However, another systematic review of the literature (2008 Consensus Report of the Sixth European Workshop on Periodontology) concluded that bone augmentation procedures could fail and that implants placed in these areas did not enjoy the high long-term survival rates of dental implants placed in pristine sites.[182] Research is needed to answer questions concerning (1) the long-term performance of dental implants placed in augmented bone, (2) the clinical performance of dental implants placed in augmented or pristine sites, and (3) the clinical benefits of bone augmentation with respect to alternative treatments.

The procedures most often used to regenerate bone include autogenous bone harvesting and grafting, guided bone regeneration, and sinus bone augmentation (see Chapters 79 and 80). The following is a brief review of the most common complications related to these three augmentation procedures.

Autogenous Bone Harvesting and Grafting

Histologically and biologically, autogenous bone has been considered the gold standard for osseous reconstruction. Bone block grafts of autogenous bone from extraoral and intraoral sources are predictable sources for reconstruction of defective or atrophic alveolar ridges.[127] Complications can occur at the donor or recipient sites.

The most common extraoral donor sites include the ilium and tibia. Complications related to extraoral donor sites are beyond the scope of this chapter. The most common intraoral donor sites include the mandibular symphysis, mandibular ramus, and maxillary tuberosity. Although each donor area has specific associated complications, the most common complications of intraoral autogenous harvesting and grafting concern donor tissue from the mandibular symphysis.

The ramus donor site is associated with a much lower incidence of complications compared with the symphysis area.[82,126] Potential complications associated with surgical harvesting of bone from the ramus include damage to the inferior alveolar nerve and trismus after surgery. Damage to the buccal nerve, although rare, has been reported. Surgical harvesting of bone from the mandibular symphysis region is associated with a higher incidence of altered neurosensory disturbances to the mandibular anterior teeth and soft tissues of the chin area. The incidence of mental nerve paresthesia after symphysis grafts is as high as 43%.[146] Many paresthesias are temporary.

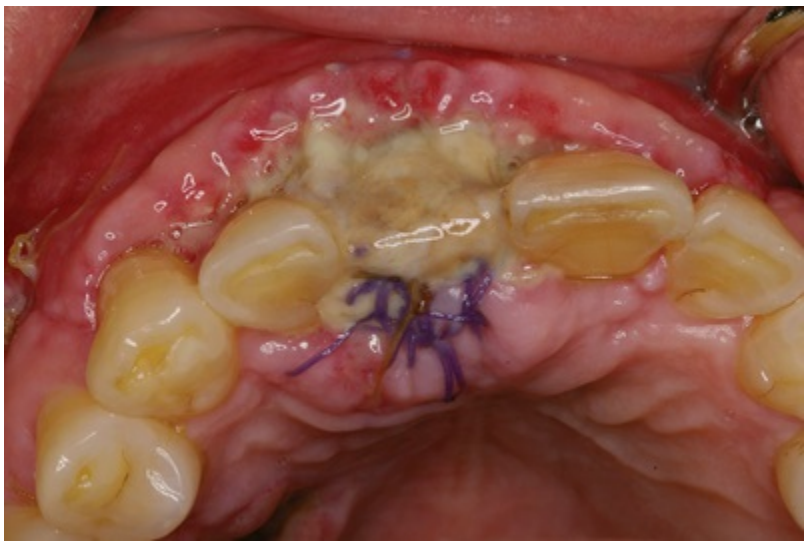
Fracture of the mandible has been reported after bone graft harvesting from the symphysis.[42] Many complications can be avoided by proper surgical technique, good planning, and an experienced operator.

Recipient site complications include wound dehiscence, flap necrosis, graft exposure, graft contamination, infection, and problems with bone graft incorporation and resorption. Proper flap reflection, intimate fixation of the graft, and flap coverage without tension can avoid many postoperative complications. Bone graft material, including barrier membranes, should be immobilized (i.e., fixated). Provisional restorations should be adjusted to prevent pressure over grafted areas. Block grafts and other augmentation procedures require experience in handling hard and soft tissues and

a clinician who is prepared to recognize and treat complications when they arise.[53,150]

Guided Bone Regeneration

Guided bone regeneration (GBR) is a procedure that uses a barrier membrane to isolate an area for bone growth. The technique has been well documented for horizontal and limited vertical ridge augmentation[27,44,100] (see Chapter 79). The most common complication associated with GBR is premature exposure of the barrier membrane and necrosis of the overlying flap (eFig. 85.1). Exposure rates of expanded polytetrafluoroethylene (ePTFE) membranes during various GBR procedures range from 41% when the technique was first introduced in the early 1990s for horizontal ridge augmentation[27] to 12.5% after surgical techniques improved and clinicians became more familiar with handling the material.[169]



EFIG. 85.1 Clinical view of flap necrosis over area treated with a guided bone regeneration procedure.

After it is exposed to the oral environment, the membrane becomes colonized with bacteria in 3 to 4 weeks, and the potential for bone regeneration under the membrane is limited to an area that is at least 2 to 3 mm from the contaminated surface.[20,170] Topical application of chlorhexidine to the exposed membrane has been advocated as a method of reducing the amount of bacteria, but it

does not solve the problem, and removal of the exposed membrane is necessary.

Other complications associated with GBR procedures include soft tissue or bone graft infection, failure to regenerate adequate bone volume, and mucogingival problems, including loss of keratinized tissue and decrease in the vestibule.[27] Most of these complications are related to insufficient soft tissue healing after tooth extraction, inadequate flap design, movement of the membrane or graft caused by transmucosal loading and improper provisionalization, flap suturing under tension, poor surgical technique, contamination of the membrane or surgical site, compromise of the vascular supply, and flap advancement for graft coverage that reduces the keratinized tissue and vestibular depth. To prevent complications associated with GBR procedures, proper surgical technique should be employed.[69,92,111,124]

Sinus Bone Augmentation

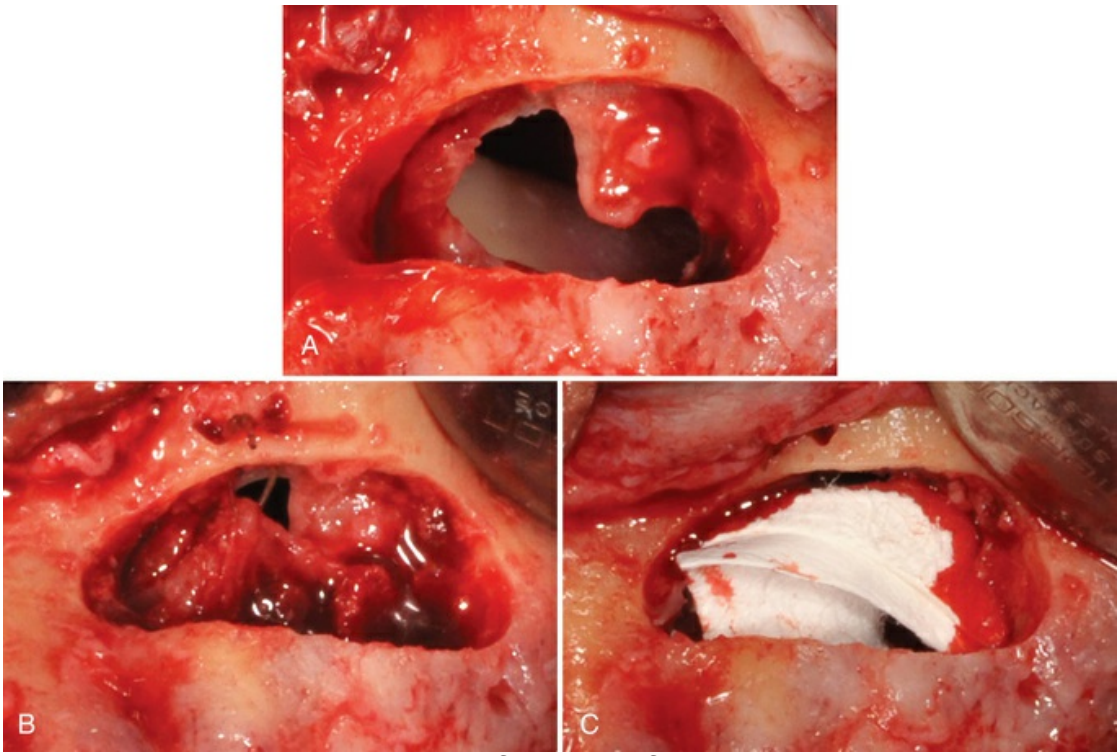
Lateral Window Sinus Lift

The lateral window sinus lift and bone augmentation procedure has been well documented and evaluated in three systematic reviews.[5,48,185] Although survival rates of implants placed in sinus-grafted areas have been high (95%), there are intraoperative and postoperative complications associated with this procedure.

The most common intraoperative complications include bleeding and perforation of the schneiderian membrane. Bleeding usually occurs when the vascular supply to the lateral wall of the sinus is severed or damaged.[55] In most cases, if the patient does not have an underlying bleeding problem and is not taking anticoagulants, the bleeding is usually minor and relatively easy to control with local measures. Perforation of the schneiderian membrane has an incidence that varies from 11%[190] to 56%,[103] with most clinicians reporting an incidence of 20% to 30%.

Minor membrane perforations can be treated by reflection of the membrane that folds on itself, whereas medium or large membrane perforations require the use of an absorbable membrane placed over the perforation to patch the opening (eFig. 85.2). Very large membrane tears may be too big to repair intraoperatively and

require aborting the procedure. Careful surgical technique and the use of newer instruments (e.g., piezoelectric surgery) have significantly reduced this complication[186] (see Chapter 83).



EFIG. 85.2 (A) Large perforation of the schneiderian membrane during a sinus elevation procedure. (B) Attempt to close or reduce the size of the perforation with resorbable sutures. (C) Use of resorbable barrier membranes to cover the perforation.

The most common, although still infrequent, postoperative complication associated with sinus bone augmentation is infection.[17,103,127] The incidence of infection varies from 2% to 5.6%. Careful surgical techniques, adherence to sterility, and judicious use of antibiotics can minimize the risk of postoperative infections. Some infections resolve with antibiotic treatment alone, whereas others require surgical debridement of the infected area. Consultation with or referral to a specialist may be indicated for persistent infections.

The Sinus Consensus Conference of 1996 was revisited in 2016 and reaffirmed the validity of the sinus graft. It concluded that noninductive materials with slow resorption might be superior in

forming and maintaining bone compared with inductive materials. The consensus also questioned the need for biologic enhancement with growth factors and morphogenic proteins.[94]

Crestal (Osteotome) Sinus Lift

Another method of sinus elevation and bone augmentation involves the use of osteotomes. This technique is indicated when there is enough native bone to stabilize the implant and a minimal need for sinus floor elevation. Bone is added through the crestal osteotomy by means of osteotomes and a mallet, the floor of the sinus is fractured, and the schneiderian membrane is lifted by the bone graft (see Chapter 80).

This method is thought to be a relatively less invasive technique of great utility in certain patients. However, it has been associated with the complication of benign paroxysmal positional vertigo (BPPV),[143] which is a consequence of working the implant bed with osteotomes. During the osteotomy preparation and sinus floor elevation using the osteotome technique, the trauma induced by percussion with the surgical hammer, along with hyperextension of the neck during the operation, can displace otoliths in the inner ear and induce BPPV. It has been reported that 1.25% of the patients treated suffered vertigo when trying to sit up immediately after surgery and were diagnosed with BPPV. Because implant treatment is increasingly being carried out on older patients and because of the widespread use of bone expansion technique with osteotomes, the incidence of BPPV can be expected to increase.[144] In suspected cases of BPPV, the patient should be informed about the condition and then referred to an otoneurologic specialist to determine which semicircular canal is affected and to carry out the appropriate otolithic reinstatement maneuver.

To prevent this complication, care should be taken when using the osteotome technique. The application of manual force instead of hammer percussion and the use of a surgical fraise in combination with osteotomes can minimize the trauma to the craniofacial area, especially in older patients. Many alternative methods for a crestal approach to sinus elevation and bone augmentation have been developed, including inflatable balloon techniques, selective drill systems, and piezoelectric surgical instruments that cut bone while

leaving the schneiderian membrane intact (see Chapters 80 and 83). These newer methods should be considered to avoid BPPV. The effectiveness of the procedure can be affected by the level of experience in implant dentistry.[68]

Complications Related to Placement and Loading Protocols

The traditional implant placement protocol required a healed edentulous ridge into which implants were placed and allowed to integrate for 3 to 6 months without occlusal loading. In contrast to the early standards, some current protocols advocate dramatically different approaches, including (1) implant placement immediately after tooth extraction, (2) implant loading immediately after placement, and (3) flapless implant placement surgery. Each of these approaches has distinct advantages but also have specific risks of complications.

Immediate Implant Placement

Immediate implant placement is a protocol that places an implant in an extraction socket immediately after tooth removal and socket debridement. This procedure, which was originally described by Schulte and associates[165] and Lazzara,[114] has survival rates similar to those of implants placed into healed ridges,[36,120] with long-term survival rates of approximately 94%.[184] The advantages of this protocol include fewer surgical procedures, decreased morbidity, decreased time of treatment, decreased cost, and decreased soft tissue healing time by avoiding flap reflection and advancement.[166] However, as with any surgical protocol, complications are possible, and specific complications are associated with immediate implant placement, including implant failure, poor implant position, bone loss, recession of the peri-implant marginal soft tissues, and compromised aesthetic outcomes.

After tooth extraction, there may be a compromised socket as a result of the predisposing pathology (i.e., periodontal, endodontic, or root fracture) of the hopeless tooth. Proper implant position may

be difficult to establish when the socket walls are missing or deficient. For example, the implant osteotomy for extracted maxillary anterior teeth should be made on the lingual incline of the lingual wall of the socket. The burs often slip buccally, causing the osteotomy to be made too far buccally or at an undesired angulation. Careful use of a surgical stent, round bur, sharp initial bur, or side-cutting bur can avoid slipping and improve the accuracy of implant site preparation. Although success rates of immediately placed implants are excellent, failure to attain primary stability in native bone apical or lateral to the socket can increase failure rates. Inability to debride or incomplete debridement of an infected or compromised socket (e.g., tooth with an apicoectomy) can increase the risk of failure.[116]

Buccal plate resorption and gingival margin recession after implant placement can expose the implant surface after integration of the implant (see Figs. 85.5 and 85.11). This can compromise the aesthetic results or necessitate hard and soft tissue augmentation procedures to improve the aesthetic outcome.[103] A published case series documented this problem for immediate implant placement in extraction sites without flap elevation.[65] The risk of complications can be decreased with proper case selection, proper procedures, and experience in using this protocol. Until clinicians have the knowledge and experience to use an immediate implant placement protocol, they should avoid using it in the aesthetic zone.

Immediate Loading After Implant Placement

Bränemark established the concept and predictability of osseointegrated dental implants based on a requirement for an unloaded healing period of 3 to 6 months.[26] The original protocol purported that premature loading would cause micromotion of the dental implant, leading to fibrous encapsulation and implant failure. However, several studies in the literature showed that immediately loaded dental implants can have success rates similar to those of conventionally loaded dental implants.[d] Whether restoring a single tooth or a complete dentition, there are many advantages to early or immediate loading, although these advantages may come with increased risks of complications. The

most significant complications are failure to achieve primary stability and implant failure.

Studies have shown that using longer and wider implants can produce increased success rates when immediately loading the dental implant.[162,163] When placing multiple implants in an edentulous area, the implants should be placed in a fashion that maximizes the anterior-to-posterior spread, leading to a greater distribution of forces over a wider area and a reduction in cantilever forces. Implants placed around the arch can lead to *cross-arch stabilization*, which can decrease the individual force and motion experienced by any individual implant.[156,177] For the fully edentulous case, a minimum of four to six implants of adequate size and good stability that are properly spaced throughout the ridge is recommended to improve success with immediate loading.[46] Mandibular cases may require fewer implants than maxillary cases because of greater bone density, especially in the interforaminal region. If the opposing arch is restored with a removable prosthesis, fewer implants may be needed to immediately support a restoration because of a decreased opposing occlusal force.

Other factors associated with increased failure rates of immediately loaded implants are implant surface and implant design. Lower success rates with immediately loaded implants have been reported with smooth (i.e., turned or machined) surface implants, especially in cases of single-tooth, immediately loaded restorations.[90,154,161] The macrodesign features of an implant (e.g., threaded vs. cylindrical) can affect initial stability and success rates in immediately loaded cases.[35,102] Some newer macrothread designs can overcome the transient loss of stability in the early postinsertion healing phase.[121] Two studies concluded that bruxism, clenching, and sites in the posterior maxilla can reduce the likelihood of implant success under an immediate loading protocol.[21,74]

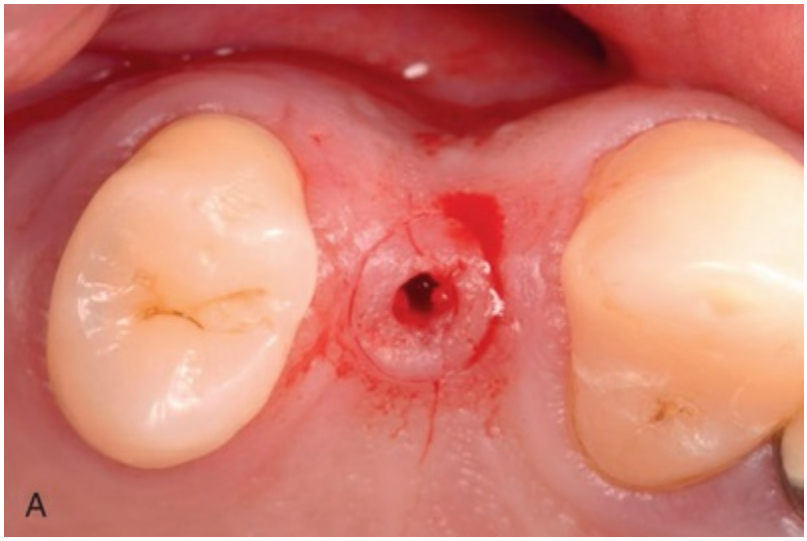
Complications of immediately loaded implants can arise from a poorly constructed or inserted restoration despite all things going well with surgical placement. Extreme care must be taken to achieve a passive fit of the restoration and to eliminate nonworking or balancing contacts on the restoration. In full-arch cases that are immediately loaded, the restoration must be designed to withstand the direct occlusal force. This can be accomplished by a rigid

connection and by splinting the implants together in cross-arch fashion. Loosening or unseating of the provisional restoration usually indicates mismanagement of occlusal forces and can be an early predictor of failure.

Immediately loading dental implants is a technique that offers many advantages but can also increase the incidence of complications and failure. This technique should be performed only by an experienced operator who is prepared and informed. Controlling micromotion after loading is paramount to success. Meticulous case selection, which incorporates stabilizing the cross-arch, controlling occlusal overload, minimizing cantilevers, and increasing the anterior-posterior distribution of implant placement, can significantly increase the success rate of loading dental implants immediately after placement.

Implant Placement Using a Flapless Approach

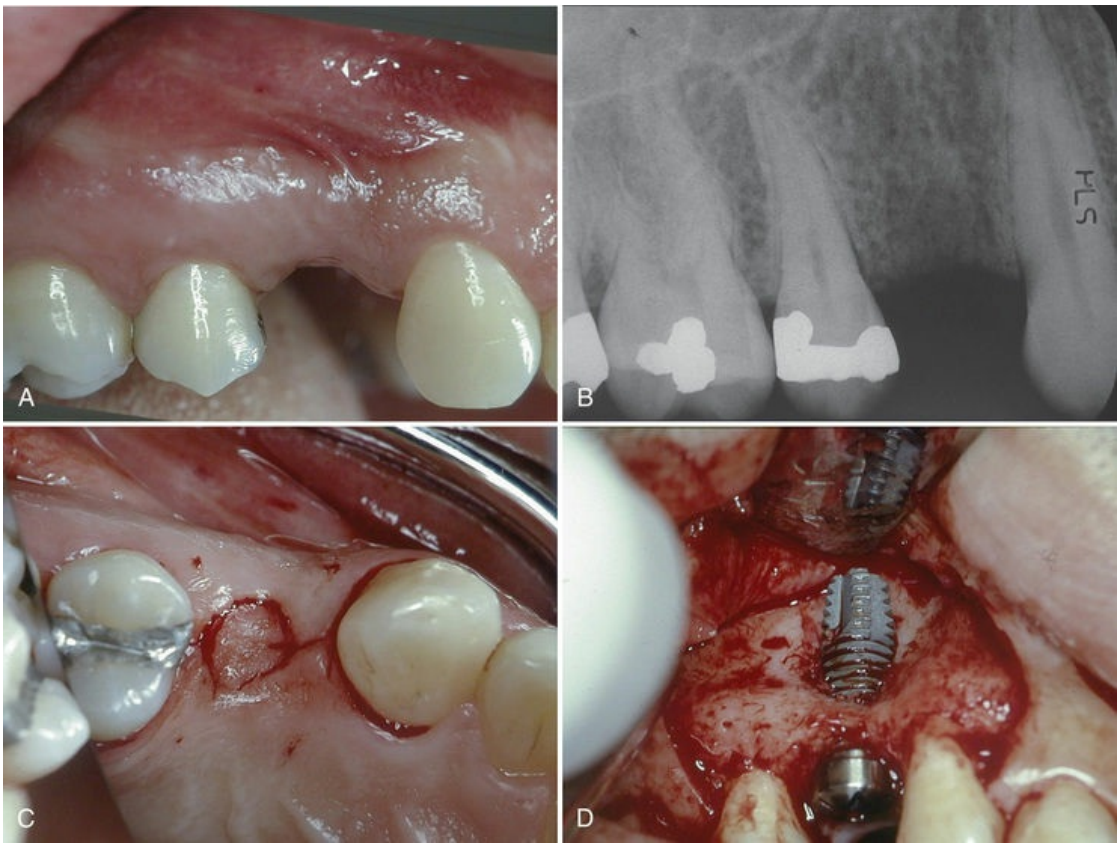
In flapless implant surgery, the dental implant is placed without elevation of the epithelium, connective tissue, and periosteum covering the alveolar bone. It is performed by drilling through the soft tissue with twist drills or by first removing a small circular section of the soft tissue (eFig. 85.3A), preparing the osteotomy, and placing the implant (see eFig. 85.3B) without reflecting a full-thickness flap.[1]



EFIG. 85.3 (A) Removal of a small circular section of tissue before osteotomy. (B) Dental implant in place.

Flapless surgery has been successful and has many advantages because it is minimally invasive.[30,31] The benefits of flapless surgery include a decrease in associated surgical morbidity, including postoperative pain, ecchymosis, and swelling, and a reduction in surgical time and intraoperative bleeding.[143] Studies show that when a full-thickness mucoperiosteal flap is raised, there is loss of bone volume,[75] whereas a flapless approach results in less bone resorption.

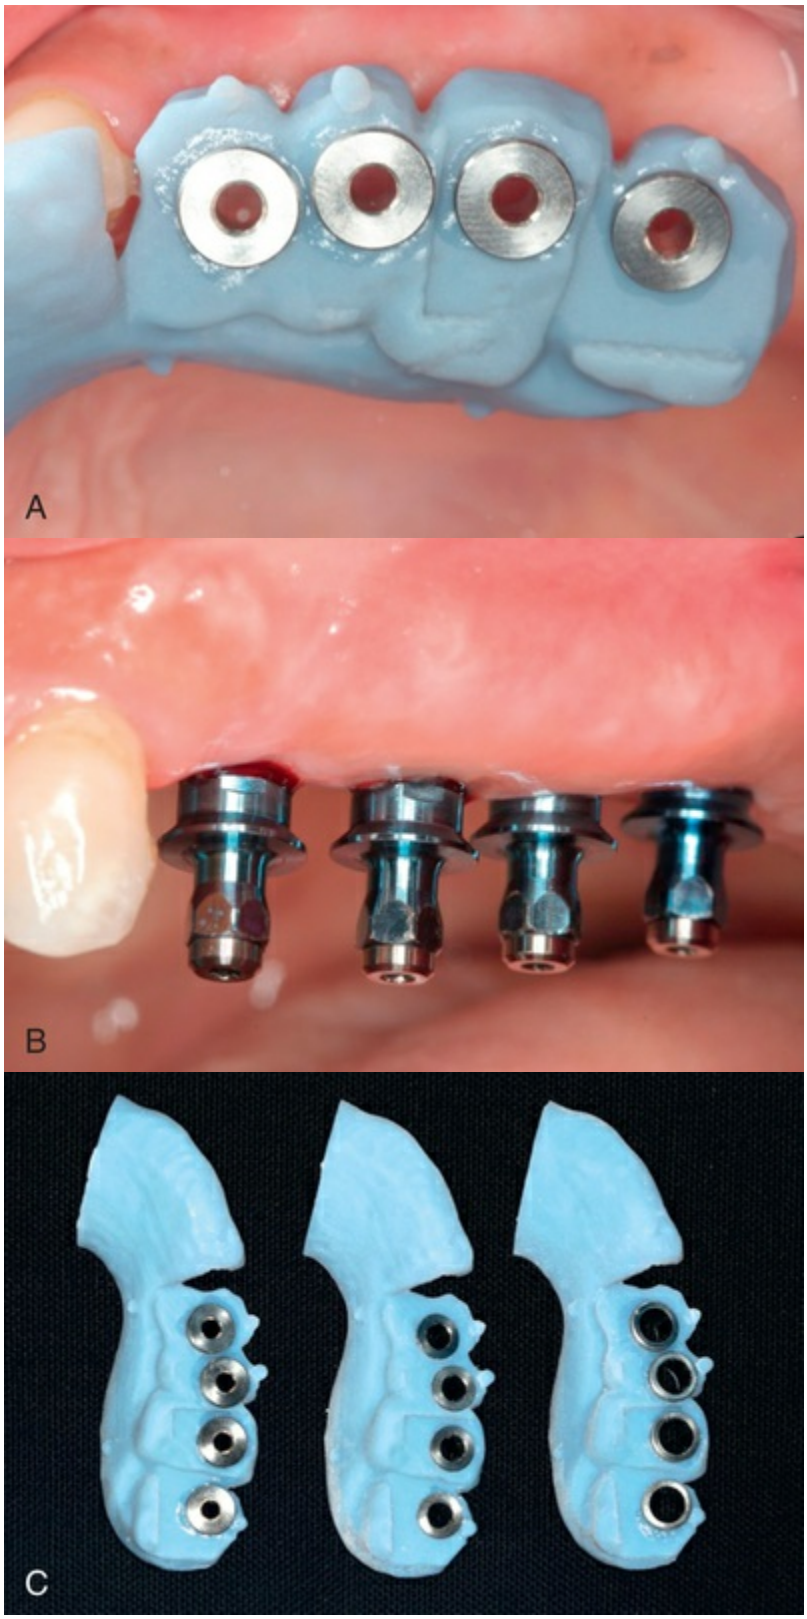
The lack of operator visualization of the alveolus when preparing osteotomies and placing implants can increase the potential for complications. The most common problems associated with flapless surgery are loss of keratinized tissue when excising the crestal circle of soft tissue and improper positioning of the dental implant in the bone resulting from a lack of direct vision. Improper positioning can result in a dehiscence or fenestration defect (eFig. 85.4) or damage to adjacent vital structures.

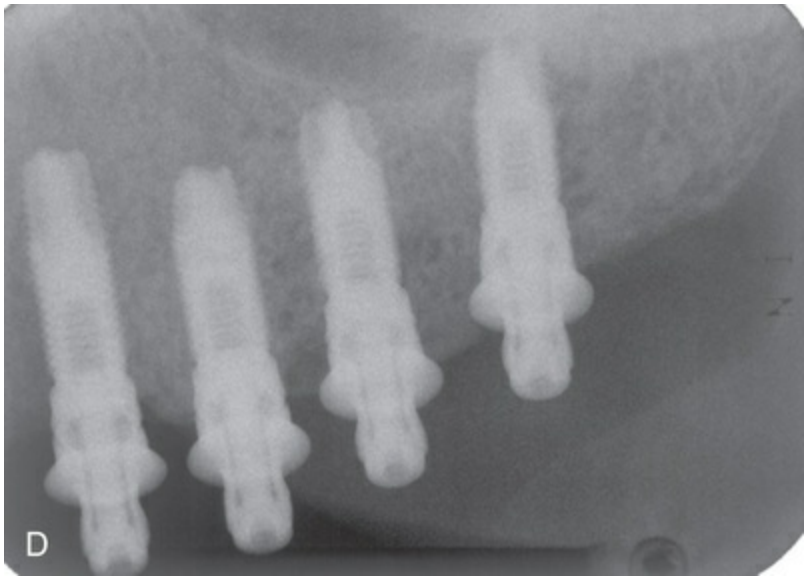


EFIG. 85.4 (A) Preoperative clinical view of a single missing tooth, #5. There appears to be a good alveolar ridge shape with adequate keratinized gingiva. (B) Radiograph shows good bone height and mesial-distal space available for a single tooth implant. (C) Occlusal view of the circular punch incision used to access bone and prepare the implant osteotomy. (D) Full-flap reflection (after noticing a suspicious protrusion in the labial vestibule) revealed an implant protruding from the alveolar bone on the buccal surface.

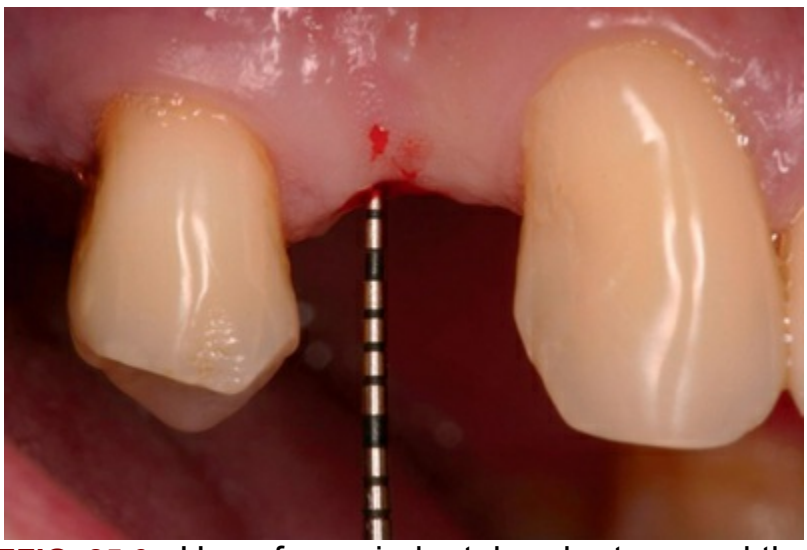
An anatomically correct, computer-generated surgical guide fabricated from a three-dimensional CT or CBCT scan is recommended when performing flapless surgery to reduce potential implant malposition complications. Several systems (Nobelguide, Materialize SurgiGuide) can generate a precise surgical guide with metal sleeves of the exact dimensions that can direct the implant into the proper position (eFig. 85.5). These guides typically are used in fully edentulous arches and have fixation screws that keep them in place. When using a flapless approach, before initiating the osteotomy, the operator should sound the soft tissue with a periodontal probe to ascertain the tissue thickness and

account for this dimension when determining the final position of the implant platform in the apical–coronal dimension (eFig. 85.6).





EFIG. 85.5 (A) Clinical view of a computer-generated surgical guide shows metal drill sleeves in the position of the planned implants. (B) Clinical buccal view of the implant mounts emerging from gingival tissue shows accurate placement of four implants in the posterior maxilla using the computer-generated surgical guide. (C) Photograph of three surgical guides with increasing sleeve diameter that are used in the sequence of implant site preparation. (D) Radiographic view of four implants placed in the planned position using the computer-generated surgical guide.



EFIG. 85.6 Use of a periodontal probe to sound the bone and measure the soft tissue thickness over the bone in the proposed implant site.

A common complication is placement of implants apical to the crestal bone because it is difficult, even with a punch, to visualize the alveolar bony crest in relation to the platform of the implant. If this occurs, it is difficult to fully seat the abutment. The relationship between implant and abutment connection must be verified by periapical radiographs. If bone prevents abutment seating, the implant must be backed out until it is at the crest, or the bone must be removed with a profile drill. If a fenestration occurs when placing the dental implant, full-flap reflection is required, and a GBR procedure should be performed to augment the bone and cover the fenestration.

Although flapless implant surgery has many beneficial features, it is a technique-sensitive procedure that requires surgical experience, an accurate surgical guide, and knowledge of the anatomy surrounding the planned implant site.

Prosthetic or Mechanical Complications

Prosthetic or mechanical complications occur when the strength of materials is no longer able to resist the forces that are being applied. As materials fatigue, they begin to stretch and bend. Ultimately, depending on the applied forces, they will fracture. Material failures lead to prosthetic complications such as loose, broken, and failed restorations.

Screw Loosening and Fracture

Screw loosening has occurred frequently in screw-retained FPDs. Screw-retained single crowns attached to externally hexed implants (i.e., those with narrow- or standard-diameter restorative interface connection surfaces) are particularly prone to this type of mechanical complication. Screw loosening has been reported for 6% to 49% of cases at the first annual checkup.[91,132] Screw loosening was a more prevalent problem with earlier designs. For example, abutment screws were previously made with titanium, which did not offer the clamping forces of current materials. Newer abutment

designs and improved abutment screws enable an increased clamping force to be achieved without excessive torque, which has helped to reduce the rate of screw loosening.

Abutment or prosthesis screw loosening is often corrected by retightening the screws, but if screws continue to be stretched over time, they become fatigued and eventually fracture. This problem is evident in the patient with a loose single crown. In the patient with a prosthesis retained by multiple implants, the ability to detect a loose screw is greatly diminished, and the problem may go unnoticed until additional screws stretch, fatigue, and fracture. In either case, the biomechanical support (and resistance) for the restoration must be evaluated and, if possible, changed to prevent recurrence of the problem.

Implant Fracture

The ultimate mechanical failure is implant fracture because it results in loss of the implant and possibly of the prosthesis (Fig. 85.17). Removal of a fractured implant creates a large osseous defect. Factors such as fatigue of implant materials (Fig. 85.18) and weakness in prosthetic design or dimension are the usual causes of implant fractures.[4,16] Balshi[16] listed three categories of causes that may explain implant fractures: (1) design and material, (2) nonpassive fit of the prosthetic framework, and (3) physiologic or biomechanical overload. Patients with bruxism seem to be at higher risk for these events and therefore need to be screened, informed, and treated accordingly.[15,16] These patients should be fitted with occlusal guards in conjunction with placement of the final prostheses.

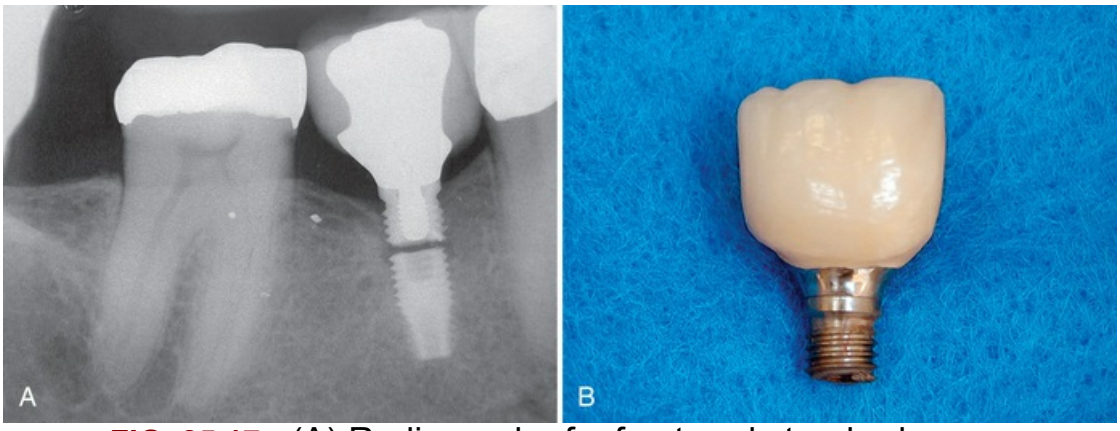


FIG. 85.17 (A) Radiograph of a fractured standard-diameter implant used to support a molar-sized single crown in the posterior mandible. (B) Crown and coronal portion of the implant (same as shown in A) that fractured between the third and fourth threads.

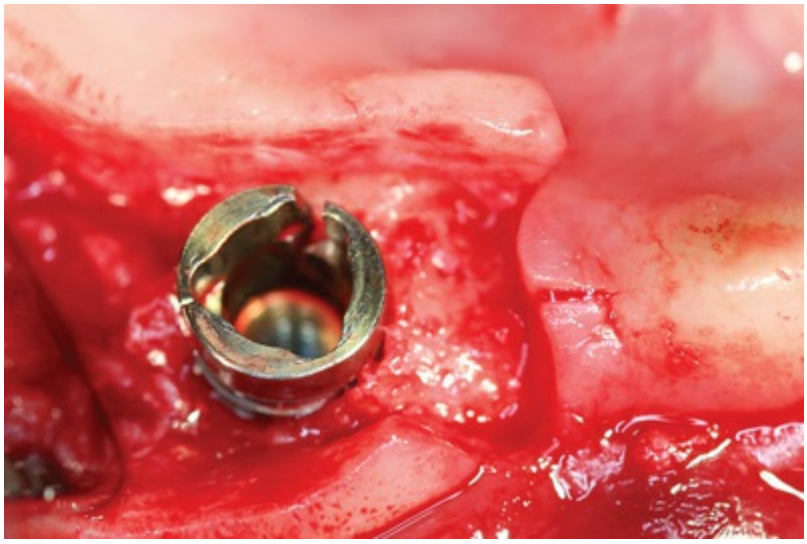

FIG. 85.18 The implant fractured at the internal connection collar. Fracture was caused by rotational forces applied to the implant at the time of placement into dense bone and was likely the result of combined material weakness and density of the prepared site.

Fracture of Restorative Materials

Fracture or failure of materials used for implant-retained restorations can be a significant problem. This is particularly true for veneers (i.e., acrylic, composite, or ceramic) that are attached to

superstructures (Fig. 85.19).

FIG. 85.19 Fractured porcelain from incisal edges of an implant-supported fixed partial denture.

Aesthetic and Phonetic Complications

Aesthetic Complications

The challenge of modern implant dentistry is achieving an aesthetic and functional implant restoration. Harmonious tooth shape and size and ideal soft tissue contours are key factors for successful aesthetic outcomes.[108]

Aesthetic complications arise when patient expectations are not met. Patients' degree of satisfaction with the aesthetic outcome of implant prostheses varies. The risk of aesthetic complications is increased for patients with high aesthetic expectations and suboptimal patient-related factors such as a high smile line, thin periodontal soft tissues, or inadequate bone quantity and quality. In addition to the appearance of the final restoration, factors such as a patient's perception and desires determine the acceptance of the results. Aesthetic complications can result from poor implant position, deficiencies in the existing anatomy of edentulous sites that were reconstructed with implants, and prosthetic-related factors such as color mismatch.[14]

Important prerequisites for achieving optimal gingival tissue contour are sufficient peri-implant bone to support the soft tissues

and a sufficient zone of keratinized tissue. Soft and hard tissue defects can be treated by a variety of augmentation procedures.

Implant placement in the aesthetic zone requires precise three-dimensional tissue reconstruction and ideal implant placement.[81,160] This reconstructive procedure enables the restorative dentist to develop a natural emergence profile of the implant crown. If the amount of available bone does not allow for ideal implant placement and the implant is positioned too far apically or buccally or in the proximal space, an unaesthetic emergence profile can result (Fig. 85.20).

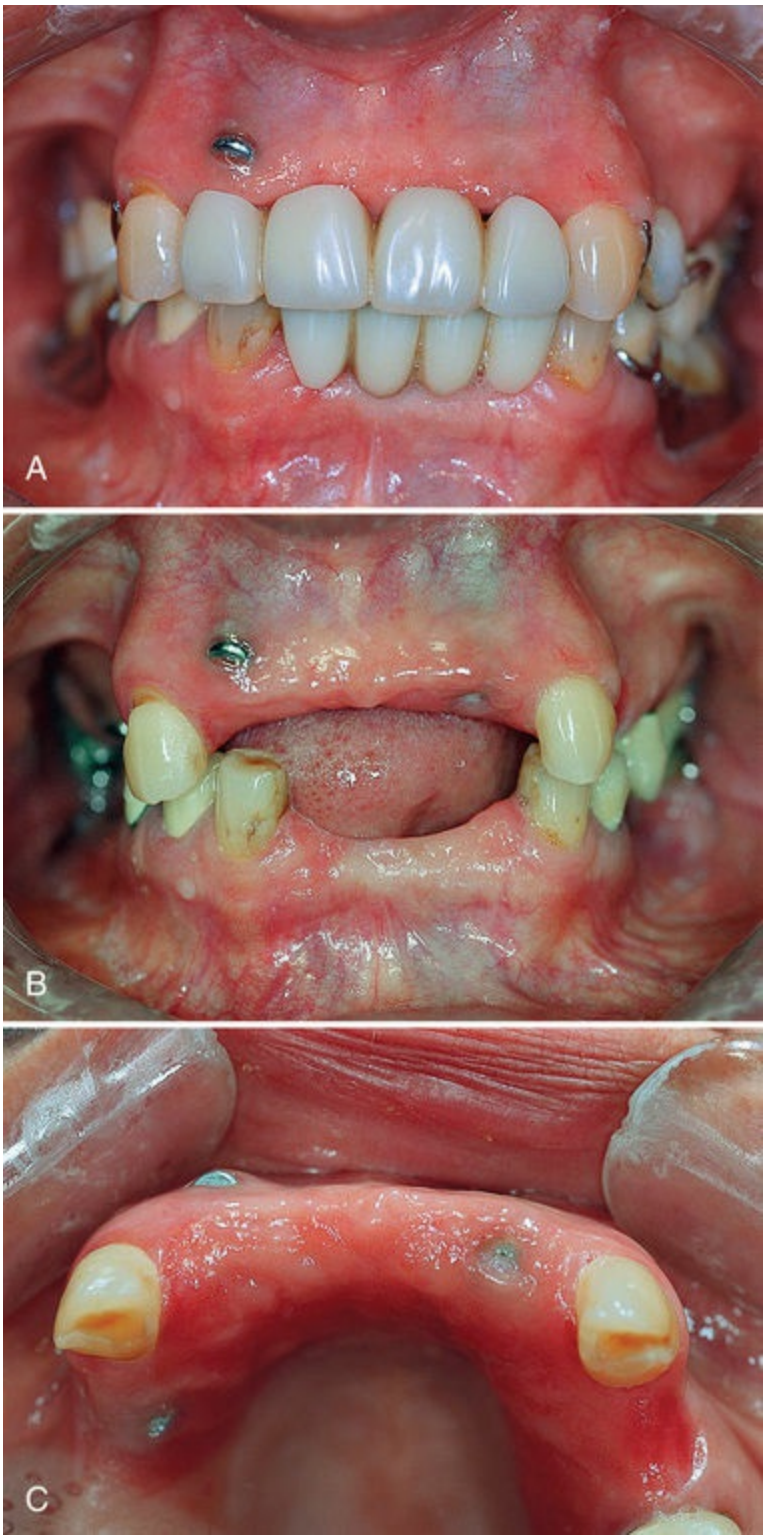

FIG. 85.20 Poor implant position makes it impossible to correct the problem with an aesthetic, natural-appearing restoration. (A) Anterior view with the removable partial dentures inserted. (B) Anterior view without the removable partial dentures. Notice the high level of implant cover screw/head exposure (maxillary right lateral incisor) that is significantly apical to the

level of the adjacent natural tooth (cuspid) gingival margin. (C) Occlusal view of the same patient. Notice the labial projection of the same implant (maxillary right lateral incisor) and the palatal position of the implant in the premolar area. Any attempt to restore the anterior implants would not be aesthetically acceptable.

If crown contours and dimensions are not ideal or gingival harmony around the implant restoration is unaesthetic, the patient may consider the implants or restorations to be failures because the outcome does not represent a natural appearance (Fig. 85.21). Gingiva-colored materials used to replace lost gingival anatomy offer an alternative to surgical augmentation in patients undergoing implant therapy (Fig. 85.22). These restorations provide numerous advantages over conventional restorations, including improved lip support, masking of interproximal spaces, and restoration of gingival symmetry in selected cases.[85]

FIG. 85.21 High gingival margin on single-tooth implant crown in the maxillary lateral incisor position, showing the discrepancy between gingival margin levels of the implant and the adjacent natural teeth.

FIG. 85.22 Pink porcelain was used on an implant-supported fixed restoration to mask the high gingival margin and long implant crowns resulting from an uncorrected alveolar ridge defect.

If the patient is truly dissatisfied with the aesthetic result and there is a problem with the position of the implants that can be corrected (i.e., the patient's expectations are reasonable), the implants can be removed. The case can be reevaluated and possibly retreated. However, the clinician should consider prosthetic solutions before implant removal. Using angulated abutments, superstructures, or gingiva-colored materials, or submerging the implant with a conventional fixed partial denture may result in an acceptable aesthetic result, avoiding multiple operations to rebuild hard and soft tissues if an integrated implant is removed.

Careful patient evaluation and treatment planning with a solid understanding of and appreciation for the predictability and limitations of implant procedures can minimize aesthetic complications. Patients with a high smile line, high aesthetic demands, thin periodontium, or lack of hard and soft tissue support in the anterior aesthetic region should be treated only after extensive interdisciplinary treatment planning by experienced clinicians.

Key Fact

Aesthetic complications arise when a patient's expectations are not met. Satisfaction with the aesthetic outcome varies tremendously

among patients, and the increased risk of aesthetic complications correlates with high aesthetic expectations and less than optimal patient-related factors, such as a high smile line, thin periodontal soft tissues, or inadequate bone quantity and quality. Risk factors should be carefully evaluated and discussed with the patient before initiating therapy, and the ability to meet the patient's expectations should be carefully considered.

Phonetic Problems

Implant prostheses that are fabricated with unusual palatal contours (i.e., restricted or narrow palatal space) or that have spaces under and around the superstructure can create phonetic problems for the patient. This is particularly problematic when full-arch, implant-supported, fixed restorations are fabricated for patients who have a severely atrophied maxilla. Horizontal bone loss in the premaxilla often causes palatal positioning of the dental implants, resulting in the prosthesis covering the incisive papilla region. Because some sounds are formed when the tip of the tongue lightly touches the palate at the incisive papilla region, covering this area can interfere with proper enunciation. Titanium-framed full restorations allow a thinner bulk of material in this region and can minimize phonetic complications.

These complications are exacerbated when using an immediate fixed provisional restoration. Phonetic problems can be common in full-denture cases. However, with dentures, the clinician can figure out many of the speech issues in wax before the final restoration, making it easier to focus on the specific problem area. Ideal tooth setup and multiple adjustments are needed to minimize phonetic problems. These patients are probably best served with an implant-assisted maxillary overdenture because the design facilitates replacement of missing alveolar structure and avoids creating spaces that allow air to escape during speech.

Conclusions

Although implants offer a highly predictable treatment option for the replacement of single and multiple missing teeth, surgical,

biologic, mechanical, prosthetic, and aesthetic complications can occur. Careful diagnosis and treatment planning with the use of diagnostic imaging, surgical guides, meticulous techniques, and adherence to proven principles can prevent many of the problems discussed in this chapter.

A thorough understanding of anatomy, biology, and wound healing can reduce the incidence of complications. There is no substitute for good training, knowledge, and clinical experience. The clinician who places or restores implants must be well prepared to diagnose, prevent, and manage complications.

Case Scenario 85.1

Patient:
53-year-old male

Chief Complaint:
"I want implants to replace my teeth."

Background Information:
The patient lost most of his posterior teeth more than 10 years ago due to periodontal disease. He has an upper partial denture but does not wear it. He has diabetes that is controlled with diet and oral medication (metformin) and hypertension controlled with medication (lisinopril). He has smoked 1 to 1.5 packs of cigarettes per day for the past 30 years.

Current Findings:
The examination reveals generalized probing pocket depths of 2 to 4 mm with localized depths of 5 to 6 mm. There is generalized mild to moderate plaque (i.e., biofilm), minimal gingival recession, and slight marginal gingival erythema. He is missing all maxillary molars and the mandibular third molars. Radiographic examination reveals pneumatized sinuses and loose trabecular bone in the posterior maxilla.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Is this patient a candidate for implant replacement of his	**Answer: B** **Explanation:** This patient has several risk factors that may

maxillary posterior dentition? A. Yes, he is an ideal candidate. B. Yes, but there are concerns. C. Maybe, maybe not. D. No, absolutely not.	reduce the likelihood of implant survival and implant success. Smoking may be the most significant factor, especially for implants in the posterior maxilla.
2. Which of the following options is a surgical complication of the lateral window sinus bone augmentation procedure? A. Hemorrhage from inferior alveolar vessels B. Neuropathic injury to the inferior alveolar nerve C. Hemorrhage from the posterior superior alveolar vessels D. Neuropathic injury to the incisive nerve	**Answer: C** **Explanation:** Several arteries supply the maxillary sinus, including the posterior-superior alveolar artery, which can be encountered during the lateral window approach to sinus elevation and bone augmentation procedure.

Case Scenario 85.2

Patient:
64-year-old white male

Chief Complaint:
"My implant feels loose, and it hurts to brush the area."

Background Information:
The patient reports having implant #4 placed and restored with a single crown 5 years ago.

Current Findings:
Examination reveals that implant #4 is mobile (i.e., class 1). The implant moves with the crown. The buccal soft tissue consists primarily of unattached mucosa. The apical end of the implant is directed toward the palate. The implant crown is screw retained, with the screw access from the buccal cusp. The natural dentition shows evidence of bruxism (i.e., severe wear facets).

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. The palatal position of the implant contributed to	**Answer: D** **Explanation:** If any implant is mobile regardless of the

nonaxial occlusal loads, most likely causing what result? A. Fracture of the veneer B. Loosening of the prosthesis C. Screw loosening D. Loss of osseointegration	cause, it has lost osseointegration, is no longer connected to the bone, and should be removed.
2. What prosthetic parameters are thought to reduce occlusal load on the implant? A. Narrow occlusal table B. Increased buccal cantilever C. Maximized working contacts D. Maximized centric contacts	**Answer: A** **Explanation:** A narrow occlusal table is favorable. A large cantilever would lead to unfavorable distribution of occlusal forces. It is preferable to have no balancing and minimal working and centric contacts.
3. What type of tissue surrounding the implant can decrease the risk of peri-mucositis or peri-implantitis? A. A minimum of 2 mm of keratinized gingiva B. A minimum 1 mm of keratinized gingiva C. An entire border of detached mucosa D. The tissue type or quality does not affect the risk of disease around the implant.	**Answer: A** **Explanation:** The quality (i.e., thickness and density) of tissue surrounding the coronal aspect of implants affects the established peri-implant seal and resistance to attachment and bone loss.

CHAPTER OUTLINE

Rationale for Supportive Implant Treatment
Examination of Implants
Assessment of Peri-implant Health
Implant Maintenance
Treatment of Peri-implant Diseases
Referral of Patients to the Periodontist

Dental implant therapy does not end with the final prosthetic restoration of the implant. Predictability and long-term success of a dental implant and its restoration require sound treatment planning, precise surgical and restorative execution, and impeccable long-term maintenance, which depend on patient compliance with home care and professional supportive implant treatment.

Peri-implant maintenance begins as the implant becomes exposed

to the oral cavity and continues at regular intervals during the life of the implant. The recall interval is determined by the patient's oral hygiene and susceptibility to biofilm-induced inflammatory diseases. For the first year after treatment, recall maintenance visits should be scheduled at 3-month intervals and then adjusted to suit the patient's needs. Patients who have good oral hygiene, minimal deposits, and disease resistance require infrequent professional hygiene maintenance, whereas those who have poor oral hygiene, heavy deposits, and disease susceptibility require more frequent follow-up care.

Rationale for Supportive Implant Treatment

Although dental implants are not vulnerable to dental caries, they are susceptible to mechanical complications and peri-implant, biofilm-induced inflammatory tissue changes. A 10-year retrospective study[48] of 397 fixed-implant reconstructions in 300 patients observed a mechanical complication rate of 24.7%. The most frequent complication was ceramic chipping (20.31%), followed by occlusal screw loosening (2.57%) and loss of retention (2.06%). Although relatively infrequent, occlusal screw loosening can result in a subgingival gap at the implant–abutment junction that retains plaque and stimulates an inflammatory reaction in soft and hard tissues.

Biologically, biofilm accumulation due to inadequate or no access for oral hygiene can result in peri-implant mucositis and peri-implantitis. Peri-implant mucositis is characterized by inflammation confined to the soft tissue and is reported to affect up to 80% of patients with dental implants.[25] Peri-implantitis is characterized by peri-implant inflammation with progressive crestal bone loss beyond the initial remodeling. The prevalence of peri-implantitis among patients is 11.2% to 53%.[27,37,38-40] Poor oral hygiene, residual cement, current or history of periodontitis, cigarette smoking, and diabetes mellitus are risk factors for peri-implant diseases.[1,9]

The relationship between peri-implant mucositis and peri-

implantitis is similar to that between gingivitis and periodontitis. Although peri-implant mucositis does not necessarily progress to peri-implantitis, it is likely the precursor to peri-implantitis.[1] The inflammatory response in peri-implant disease appears to be similar to that in periodontal disease.[41] However, the severity and rate of disease progression appear to be more pronounced around implants. This may be caused by the absence of a self-limiting process, which is observed in periodontitis, around implants that separates the inflammatory cell infiltrate from the bone.[6] Experimental models demonstrated that peri-implant mucositis was reversible at the biomarker level (i.e., matrix metalloproteinase 8 [MMP-8] and interleukin-1β [IL-1β]).[41]

A review of the literature[36] reported that peri-implant mucositis could be effectively treated with nonsurgical mechanical therapies, but these modalities tended to be ineffective against peri-implantitis. Results of surgical treatment for peri-implantitis are not predictable. Prevention, early detection, and early treatment of peri-implant diseases are therefore crucial. Periodic and well-regimented supportive implant treatment is essential to the long-term success of dental implant therapy.

Key Fact

Implants are susceptible to mechanical complications and biofilm-induced inflammatory diseases, such as peri-implant mucositis and peri-implantitis.

Examination of Implants

The supportive implant treatment appointment should include: an inquiry about new concerns, problems, or pain; review of changes in the patient's medical and oral status; evaluation and reinforcement of oral hygiene; examination and evaluation of soft and hard tissue health; evaluation of implants and the associated implant restorations' stability and integrity; and professional supportive treatment. Assessment should determine the appropriate recall interval and plan for the next visit.

Examination begins with visual inspection for biofilm and calculus accumulation; signs of inflammation and swelling; peri-implant soft tissue quality, color, consistency, and contour; and aberrations in the implant prosthesis. Peri-implant soft tissue can be digitally palpated to detect edema, tenderness, exudation, or suppuration. Peri-implant probing can be done to assess the condition and level of soft and hard tissues surrounding implants. When indicated, radiographic images can be obtained to help verify the level of the peri-implant crestal bone. Determination of implant stability or mobility and percussion testing can help verify implant osseointegration (Fig. 86.1).

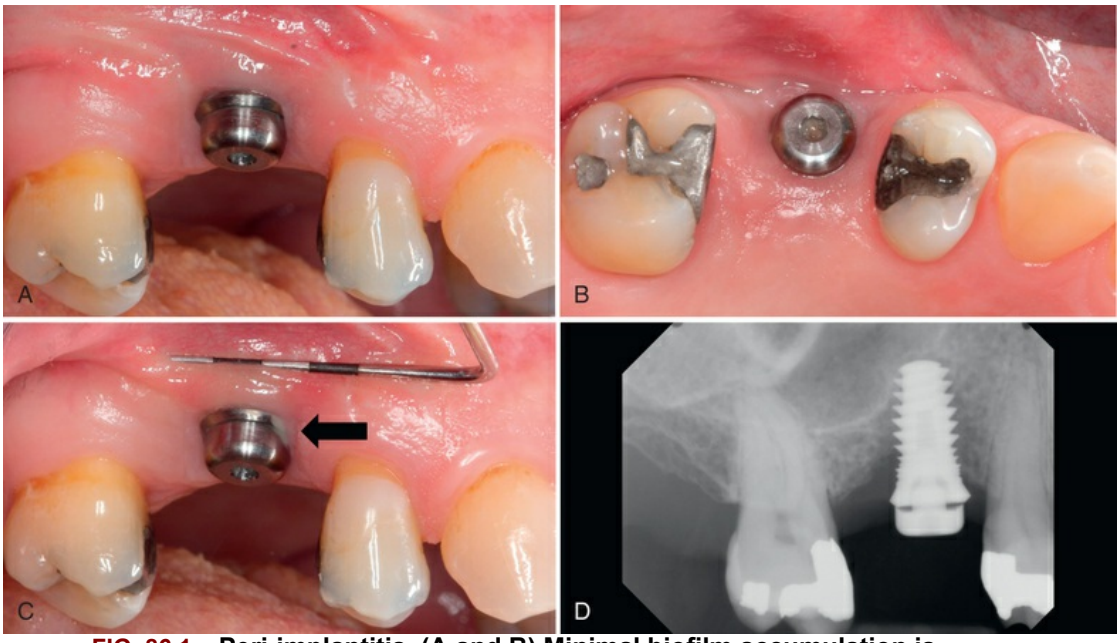

FIG. 86.1 Peri-implantitis. (A and B) Minimal biofilm accumulation is seen. The peri-implant mucosa exhibits minimal erythema and edema. Notice the buccal placement of the implant in B. (C) Manipulation of tissue indicates a lack of buccal keratinized attached gingiva and exudation from the peri-implant sulcus *(arrow)*. (D) The periapical radiograph shows peri-implant bone loss to the apex of the implant.

Clinical Correlation

Implant examination includes evaluation of biofilm control, visual and tactile assessment of peri-implant tissue for inflammatory changes and changes in probing depths, and radiographic

examination of the mesial and distal bone level.

Peri-implant Probing

Probing of implants can be done with light force (i.e., 0.25 N) using a traditional steel probe without adverse effects to the peri-implant mucosa.[15] Implant probing should be recorded at the time of final restoration as the baseline measurement and done at least annually thereafter.[25]

Clinicians should use caution when evaluating peri-implant probing because these measures cannot be interpreted the same as probing depths around teeth. Although periodontal probing around natural teeth is useful for assessing the health of periodontal tissues, the sulcus or pocket depth, and the level of attachment, probing around implants may not provide comparable results.[7] Due to distinct differences in the tissues that surround and support teeth compared with those that surround and support implants, the probe inserts and penetrates differently. Around teeth, the periodontal probe is resisted by the health of the periodontal tissues and importantly by the insertion of supracrestal connective tissue fibers into the cementum of the root surface. These fibers, which are unique to teeth, are the primary source of resistance to the probe.[3] There is no equivalent fiber attachment around implants. Connective tissue fibers around implants usually run parallel to the implant or restorative surface and do not have perpendicular or inserting fibers (see Chapter 74). The primary source of resistance to the probe depends on the conditions around the implant.[12,24] At noninflamed sites, the most coronal aspect of connective tissue adhesion to the implant resists the probe. At inflamed sites, the probe tip consistently penetrates farther into the connective tissue until less inflamed connective tissue is encountered, which is often close to or at the level of bone.

The value of peri-implant probing is different from periodontal probing and offers comparatively limited information. Probing around implants can measure the level of the mucosal margin relative to a fixed position on the implant or restoration and can also measure the depth of tissue around the implant. The peri-implant probing depth is often a measure of the thickness of the

surrounding connective tissues and correlates most consistently with the level of surrounding bone. However, peri-implant probing is affected by several conditions, including the size of the probe, the force and direction of insertion, the health and resistance of peri-implant tissues, the level of bone support, and the features of the implant, abutment, and prosthesis design (Fig. 86.2).

FIG. 86.2 Buccal probing of the implant is impeded by the implant restoration.

A comparison[45] of probing pocket depth of implants with peri-implantitis before and after the removal of the prosthetic restorations reported similar probing depths in only 37% of sites. In 39% of sites, the difference was ±1 mm; in 15% of sites, it was ±2 mm; and in 9% of sites, it was ±3 mm. Probing measurements can be an accurate measure of soft tissue thickness around an implant (i.e., peri-implant soft tissue above the bone level), but in many cases or sites, the inability to properly angle and direct the probe along the implant can lead to inaccurate assessment of soft tissue thickness. In these situations, the clinician must appreciate the limitations and know that other clinical parameters and radiographs are required to help evaluate the peri-implant's condition.

Probing around implants is likely to vary more than around teeth. Studies have shown that a change in probing force around implants results in more dramatic changes than a similar change in probing force around teeth.[29] The probing depth around implants presumed to be healthy (and without bleeding) has been

documented as about 3 mm around all surfaces.[2,8] The absence of bleeding on probing around teeth has been established as an indicator of health and a predictor of periodontal stability.[21] Studies comparing bleeding on probing around teeth and implants in the same patient have reported that bleeding around implants occurs more frequently.

Bleeding on probing at implant sites can indicate inflammation in the peri-implant mucosa. However, the ability to use bleeding on probing as an indicator for assessing diseased or healthy sites around implants has not been established. Due to the potential for false-positive bleeding (i.e., provoked bleeding) with probing, the use of marginal bleeding, which is a more sensitive indicator of inflammation and is less likely to elicit false-positive bleeding, has been proposed to assess peri-implant inflammation.[50] Marginal bleeding can be evaluated by running a probe circumferentially along the coronal portion in the implant sulcus. Overall, the value of peri-implant probing is in monitoring changes in the probing pocket depth over time rather than the initial value because some implants are placed apically for aesthetics.[1]

Clinical Correlation

Probing of implants can be accomplished with a traditional steel probe. It is valuable for detecting tactilely inflammatory changes in the tissue, such as loss of tissue to resistance to probe penetration, sponginess of peri-implant mucosa, and bleeding on probing, and for monitoring changes in probing depth over time.

Microbial Testing

Studies in animals and humans have demonstrated the development of peri-implant mucosal inflammation in response to the accumulation of bacterial plaque.[5,33,41,51] Microbiologic studies suggest that greater probing depths (i.e., pockets) around implants harbor higher levels of pathogenic microorganisms.[30,35,43] Studies have also documented similarities in the microbial composition of plaque in healthy periodontal sites compared with healthy peri-implant sites.[31] Evidence indicates that the microbiota of diseased

periodontal pockets harbor the same pathogenic microorganisms as those observed in inflamed peri-implant sites (i.e., peri-implantitis).[31,43] However, there is no evidence to prove that periodontal pathogens cause peri-implant disease, and the pathogenesis of inflammatory disease around implants has not been defined.[10]

One report[1] accepted the idea that peri-implant disease, like periodontal disease, occurs primarily as a result of an overwhelming bacterial insult and subsequent host response. Human biopsies indicate that peri-implantitis and periodontitis exhibit similar histologic features, including an inflammatory cell infiltrate in the connective tissue dominated by B lymphocytes and plasma cells and by up-regulation of inflammatory biomarkers. No evidence indicates that laboratory tests for the identification of suspected periodontal pathogens are of use in the evaluation of implants.[14] The usefulness of microbial testing may be limited to the evaluation of peri-implant sites that are showing signs of infection and bone loss, allowing the clinician to prescribe appropriate antibiotics.

Stability Measures

The assessment of implant stability or mobility is an important measure for determining whether osseointegration is being maintained. Important as it is, however, this measure has extremely low sensitivity but high specificity. An implant can exhibit significant bone loss and remain stable; the stability measure in this case has a low sensitivity for the detection of bone loss. Conversely, if implant mobility is detected, it is likely that the implant is not surrounded by bone; mobility is highly specific for the detection of implant failure or lack of osseointegration. Mobility demands differentiation of loss of implant osseointegration from a loose implant restoration.

There is great interest in evaluating the stability of bone-to-implant contact in a noninvasive manner. Two noninvasive techniques for evaluating implant stability are impact resistance (e.g., Periotest) and resonance frequency analysis (RFA). Originally designed to evaluate tooth mobility quantitatively, the Periotest

(Gulden, Bensheim, Germany) is a noninvasive electronic device that provides an objective measurement of the reaction of the periodontium to a defined impact load applied to the tooth crown. The Periotest value depends to some extent on tooth mobility but mainly on the dampening characteristics of the periodontium. Despite dependence on the periodontium, the Periotest has been used to evaluate implant stability. However, unlike teeth, the movement of implants and surrounding bone is minuscule, and Periotest values therefore fall within a much smaller range compared with those for teeth. Detection of horizontal mobility may be a significant advantage of the Periotest because it is much more sensitive to horizontal movement than similar detection by other means, such as manual assessment.[14]

Another noninvasive method used to measure the stability of implants is RFA,[28] which uses a transducer that is attached to the implant or abutment. A steady-state signal is applied to the implant through the transducer, and the response is measured. The RFA value is a function of the stiffness of the implant in the surrounding tissues. The stiffness is influenced by the implant, the interface between the implant and the bone and soft tissues, and the surrounding bone itself. The height of the implant or abutment above the bone influences the RFA value. Unlike the Periotest, the RFA does not depend on movement in only one direction. The absolute RFA values vary from one implant design to another and from one site to another, but there is high consistency for any one implant or location.

The value of RFA is most appreciated with repeated measures of the same implant over time because it is very sensitive to changes in the bone–implant interface. Small changes in tissue support can be detected using this method. An increase in RFA value indicates increased implant stability, whereas a decrease indicates loss of stability. However, this is a relative measure, and it has not been determined whether RFA is capable of detecting impending failure before the implant fails.

Much interest and research have focused on the use of noninvasive methods to evaluate implant stability. Mobility remains the cardinal sign of implant failure, and detecting mobility is therefore an important parameter.

Implant Percussion

Tapping an implant's healing abutment or restoration with an instrument produces a sound that can help determine its osseointegration. A solid resonating sound and the absence of pain usually indicate osseointegration. A dull sound can indicate that the implant is fibrous encapsulated; radiographic and other clinical findings are needed for diagnosis.

Radiographic Examination

Perpendicular intraoral periapical radiographs should be taken at implant placement, at abutment connection, and at final restoration for baseline documentation of bone levels and annually[11] thereafter to monitor marginal or peri-implant bone changes. In the setting of peri-implant inflammation, a periapical radiograph is indicated for peri-implant bone evaluation and disease diagnosis. Periapical radiographs have excellent resolution and, when taken perpendicular to an implant, can provide valuable details of the implant-abutment junction, mesial and distal crestal bone level relative to the implant platform, and bone-to-implant interface along the length of the implant (Fig. 86.3). Periapical radiographs are difficult to standardize and great variation is inherent in the acquisition process, but they are relatively simple, inexpensive, and readily available in the dental office. It is diagnostically important to obtain images that clearly show implant threads (i.e., not blurred by nonperpendicular angulation) and the restorative implant–abutment connection.

FIG. 86.3 (A) A periapical radiograph captures the whole implant. (B) A second perpendicular periapical radiograph is necessary to assess the crestal bone level. Platform switching is seen at the implant–abutment junction.

The objective of the radiographic examination is to measure the height of bone adjacent to the implant, evaluate the quality of bone along the length of the implant, and detect peri-implant radiolucencies. Although the predictive value of assessing implant stability with radiographs is low, films do offer a reasonable method to measure changes in bone levels.[46] The predictive value of detecting implant failure or loss of stability is good when radiolucent lesions are discovered with periapical radiographs. Identification of unstable implants is reliable when radiographs are obtained as part of an annual examination and when examining patients on a routine long-term basis.[19]

The radiographic examination remains one of the primary tools for detection of failed or failing implants in routine clinical evaluations, although it is not as accurate as mobility tests. In one study designed to evaluate the accuracy and precision of radiographic diagnosis of mobility, the probability of predicting implant mobility in a population with a low prevalence of implant failures was low.[46] Other studies, however, have demonstrated a much higher predictive value for radiographic diagnosis of implant mobility.[18,19] Investigators concluded that the most important factors for making an accurate radiographic diagnosis are the quality of the radiograph and the experience of the clinician.[19,46]

« Flash Back

Intraoral periapical radiographs of implants must be taken with the x-ray beam perpendicular to the implant fixture to enable clear visualization of implant threads and the mesial and distal crestal bone levels.

Assessment of Peri-Implant Health

Evaluation of Biofilm Control

Impeccable biofilm control is crucial to peri-implant tissue health. Poor biofilm control is associated with peri-implant disease (odds ratio =14.3).[25] It is advantageous to evaluate biofilm control before tissue manipulation. The amount and location of biofilm and calculus accumulation should be assessed visually. Poor control is typically associated with biofilm and calculus retention and with erythematous and edematous gingival tissue. When biofilm control is inadequate, the patient should be asked to demonstrate his or her oral hygiene routine in front of a mirror so that the clinician can evaluate the patient's technique. If the patient fails to remove biofilm in any areas, the patient's attention should be directed to the location of the biofilm. An instrument can be used to remove the biofilm, with the patient paying attention so that he or she can see its color and consistency. At this time, oral hygiene instruction should be demonstrated and reinforced.

Evaluation of Peri-Implant Health and Disease

Peri-implant mucosal health is characterized by pink, firm, and well-adapted gingival tissue. Peri-implant disease is associated with clinical erythema, edema, and loss of tissue tightness around the implant. Peri-implant mucosa can be nonkeratinized and unattached (see Fig. 86.1C) or keratinized and attached (Fig. 86.4C). In the setting of keratinized, attached mucosa, a gingival seal or gingival cuff is established around the implant.[4] The gingival cuff can protect the underlying bone and reduce subgingival plaque formation. Due to the mobile nature of oral mucosa, the protective function of nonkeratinized, unattached peri-implant mucosa may not be as effective. However, the presence of keratinized, attached gingiva, which can facilitate oral hygiene, is not a requisite for peri-implant health if biofilm is well controlled.[44,49] Nonetheless, sites deficient in keratinized, attached tissue typically exhibit vertical or horizontal ridge deficiencies, shallow vestibular depths, and long or bulky restorations. All of these factors can impede oral hygiene access and contribute to biofilm accumulation and peri-implant

inflammation.

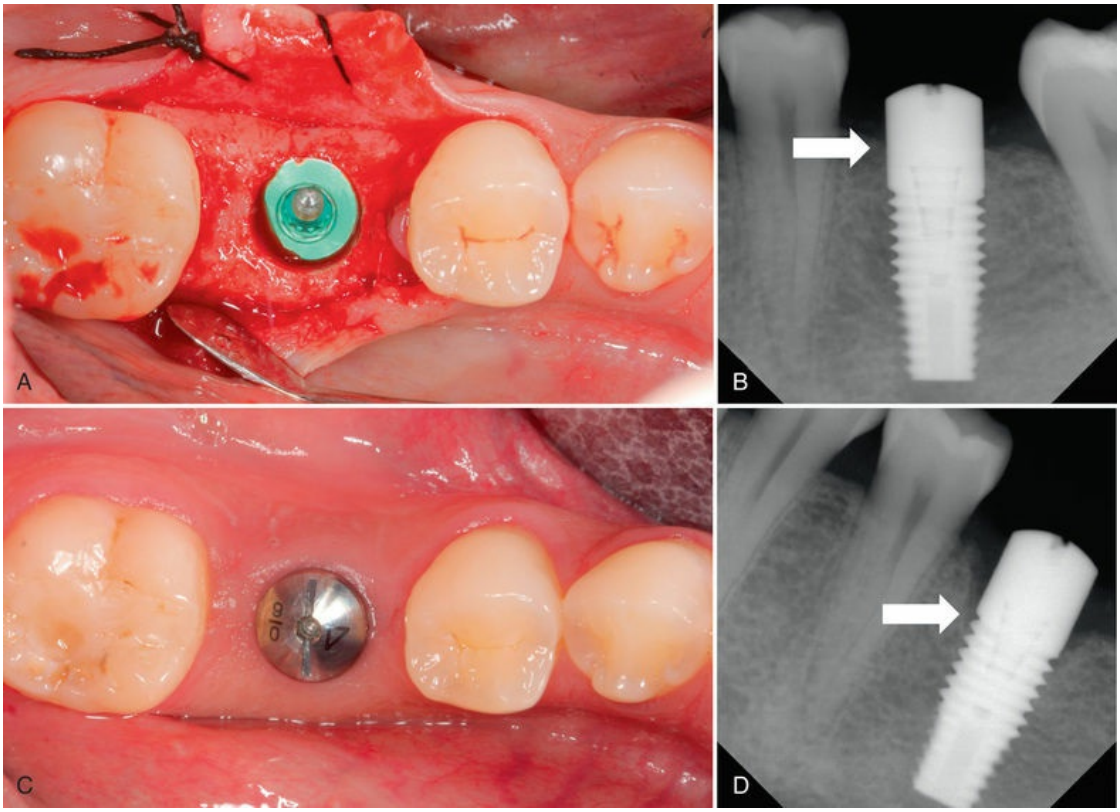

FIG. 86.4 (A) Subcrestal placement of an implant with adequate buccal and lingual bone thickness. (B) Periapical radiograph at the time of implant placement. (C) Implant at the 5-month osseointegration check exhibits adequate peri-implant keratinized attached tissue. (D) It also shows crestal bone remodeling to the first thread. *Arrows* indicate the mesial crestal bone level.

Key Fact

Peri-implant health is characterized by pink, firm, and well-adapted peri-implant mucosa. Peri-implant disease is associated with erythema, edema, and loss of tissue tightness around the implant.

In cases of inflammation, the peri-implant tissue must be palpated for tenderness and suppuration, the implant must be

probed, and periapical radiographs must be obtained and compared with baseline images to determine peri-implant bone loss. Suppuration often indicates peri-implantitis.[25] Radiographic crestal bone loss beyond the implant baseline level at the time of final prosthesis delivery in conjunction with bleeding on probing is characteristic of peri-implantitis.[22] Due to potential measurement errors, a threshold of detectable bone loss of 1.0 to 1.5 mm is recommended for the diagnosis of peri-implantitis.[42] In the absence of a baseline radiograph, a vertical distance of 2 mm from the expected marginal bone level after the initial crestal bone remodeling is recommended as the threshold for diagnosing peri-implantitis.[42]

The amount of initial marginal bone remodeling depends on the design of the implant–abutment junction. Platform-switched implants (Fig. 86.5C; see Fig. 86.3), in which the abutment is internally offset relative to the implant fixture at the implant–abutment junction, may exhibit less crestal bone remodeling than non–platform-switched implants (see Fig. 86.4), in which the abutment is flush or even with the implant fixture at the implant–abutment junction.

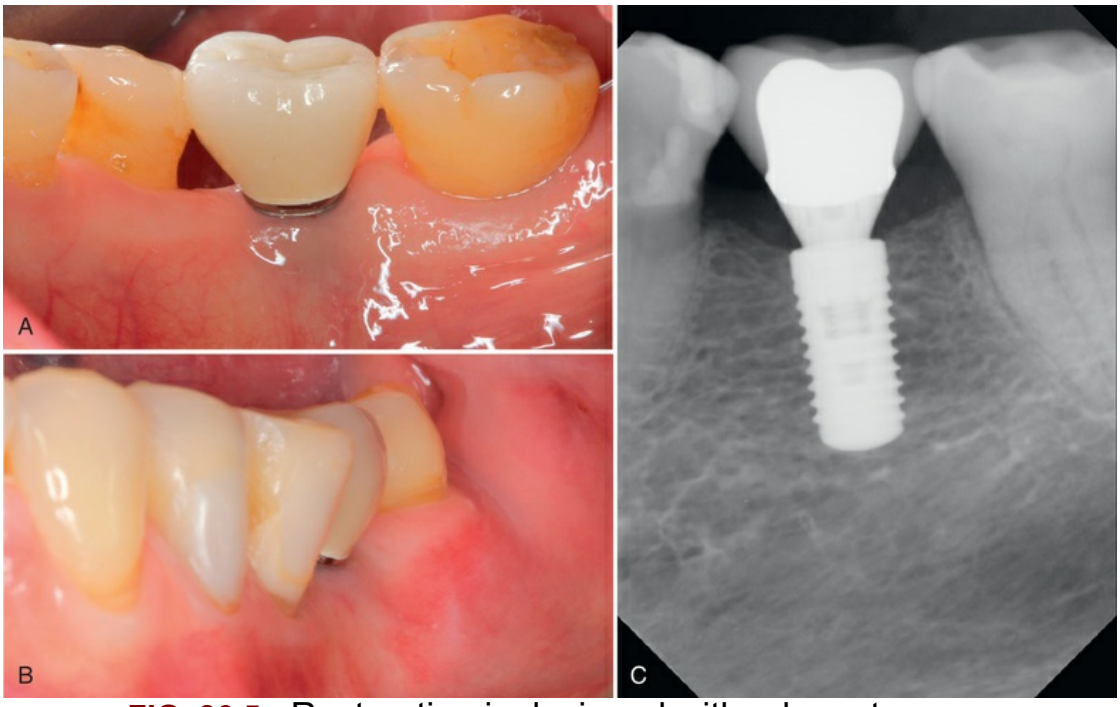

FIG. 86.5 Restoration is designed with adequate hygiene access. (A) Lingual view. (B) Mesial view of

the buccal contour. (C) The periapical radiograph shows a gradual transition from the implant fixture to the restoration. Platform switching is seen at the implant–abutment junction.

Evaluation of Implant Osseointegration

Implant osseointegration must be determined before fabrication and delivery of the final implant prosthesis. Implant osseointegration can be definitively determined only histologically, which requires the implant and the surrounding bone to be removed. A combination of radiographic and clinical parameters are used to assess implant osseointegration or to rule out lack of osseointegration. They include absence of peri-implant inflammation and pain in response to palpation and percussion, a solid resonating sound in reaction to percussion, complete radiographic bone-to-implant contact along the implant surface (i.e., absence of radiolucencies along the bone–implant interface), and implant stability.

Evaluation of Implant Restorations

Implant superstructures, frameworks, and restorations should be fabricated to accommodate and facilitate oral hygiene (e.g., embrasure spaces made to allow passage of a proxy brush) (see Fig. 86.4). Occlusal schemes of implant restorations should provide adequate posterior support, maximize axial loading, and minimize incline contacts, nonaxial loading, and interferences in excursive movements.

During delivery, radiographs perpendicular to the implant should be obtained for baseline documentation and to verify complete seating of the restorations. After delivery, cement-retained implant restorations should be thoroughly evaluated for residual excess cement, which must be removed. During follow-up visits, implant restorations should be carefully examined for heavy contacts, fractures, loose screws, and in removable prostheses, worn-out retentive components (i.e., Hader clips and locator attachment inserts). Occlusion should be adjusted accordingly to

prevent implant overload and fractures of implant parts. Loose abutment and set screws must be evaluated, possibly replaced, and properly torqued down. Worn-out retentive components must be replaced periodically to ensure proper retention, stability, and function of the removable prosthesis. Occlusal wear of teeth and fit of tissue-borne surfaces of an implant prosthesis should be assessed and corrected as indicated. In patients with oral parafunctions and heavy occlusal forces, occlusal guards are recommended to protect implants and restorations.

Implant Maintenance

Methods for Patient Oral Hygiene

The importance of good oral hygiene should be stressed even before implants are placed, and peri-implant oral hygiene for biofilm control should begin as early as possible after the implant is exposed to the oral cavity. A cotton tip, cotton gauze, or soft toothbrush can be used to gently remove biofilm from healing abutments or provisional restorations during the early postoperative phase of healing. Before implant osseointegration, the use of powered toothbrushes should be avoided.

After implant osseointegration has been achieved and verified, brushing with dentifrice can help remove deposits and increase smoothness of exposed implant and restoration surfaces.[32] Other dental hygiene aids, such as dental floss, rubber tips, and interdental brushes, can be employed (Fig. 86.6). Oral hygiene should emphasize removal of biofilm and deposits along the gingival margin. Evidence for the use of a powered oral irrigator around implants is limited. One study reported that subgingival irrigation of 0.06% chlorhexidine gluconate with a Waterpik device (Water Pik, Inc., Fort Collins, CO) was more effective at reducing biofilm and gingival inflammation and produced fewer stains than rinsing with 0.12% chlorhexidine gluconate once daily.[16]

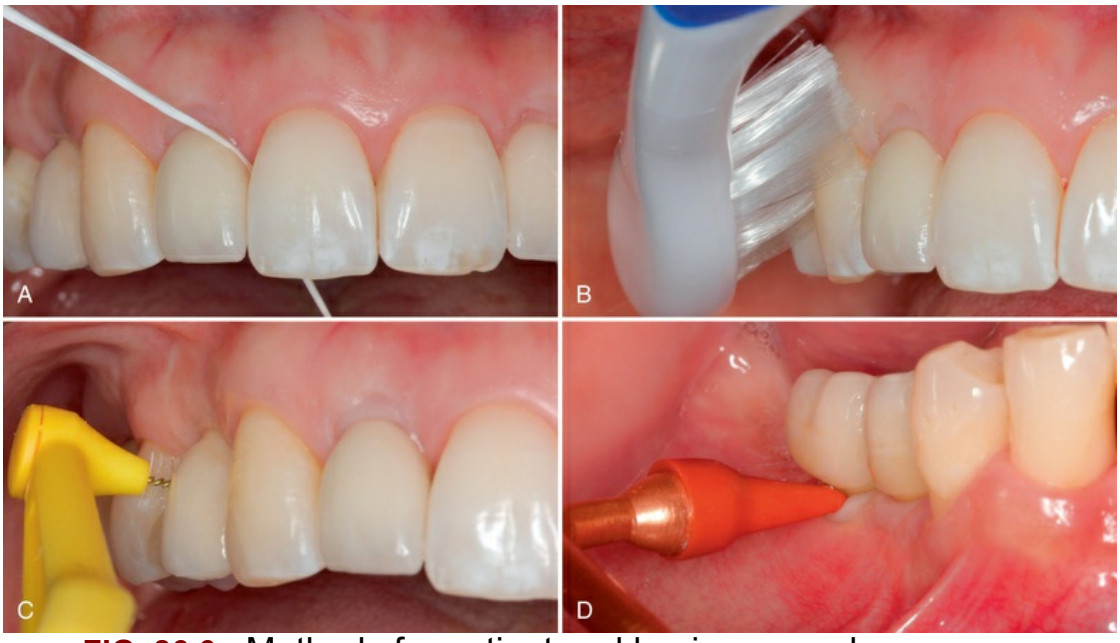

FIG. 86.6 Methods for patient oral hygiene are shown. (A) Flossing. (B) Bass method of brushing with an extra-soft toothbrush. (C) Interproximal brushing. (D) Removal of biofilm with a rubber tip. Hygiene methods remove biofilm along the gingival margin.

Methods for Professional Recall Maintenance

Professional maintenance consists of the removal of dental biofilm and calculus from implant components exposed to the oral environment.[26] Like root surfaces, the transmucosal surfaces of implants should be smooth to minimize plaque accumulation and to facilitate oral hygiene practices.[23] At sites with excellent biofilm control and peri-implant health, the need for professional instrumentation is minimal, and instrumentation should be limited to prevent iatrogenic damage to implant components that can contribute to plaque and calculus accumulation. In the setting of biofilm, calculus, and tenacious deposits, care should be taken to minimize damage to transmucosal implant surfaces. However, priority should be placed on the complete removal of implant surface deposits.

All metal instruments, including metal curettes and scalers, and ultrasonic scalers increase the surface roughness of polished titanium.[26] The use of plastic, Teflon-coated, and carbon and gold-

coated curettes and nonmetal ultrasonic tips have been advocated to protect the titanium implant surface and the titanium abutment from contamination by other metals and to reduce the likelihood of scratching the surface. Unfortunately, the large size and flexibility of nonmetal curettes may not allow effective biofilm and calculus removal,[34] and Teflon- and gold-coated curettes cannot be sharpened.

Most implant prostheses are made with gold alloys or ceramic materials, which are usually identical to the materials used in restorations for the natural dentition. The location of the connection between the restorative material and the implant is typically below the mucosa and often near the crest of bone; most calculus removal is done above this level. The fear of contaminating the titanium implant is therefore unwarranted. Gold alloy or ceramic surfaces can be debrided with most scalers and curettes (e.g., plastic, gold-coated, stainless steel) without damaging the surface. Rubber cups and polishing paste can be used to remove biofilm and to enhance the smoothness of machined and polished surfaces. Magnetostrictive and piezoelectric ultrasonic instruments with metal tips (e.g., Cavitron) should be used with caution because of irregularities that can easily be created in the surface.

Treatment of Peri-Implant Diseases

The goals of treatment are elimination of all peri-implant infectious and inflammatory processes, prevention of disease progression, and preservation and restoration of function and aesthetics. Treatment begins with patient education about the causes, pathogenesis, and prevention of peri-implant diseases, along with oral hygiene instruction. Although bacteria are the main etiologic factor, systemic (e.g., smoking, poorly controlled diabetes) and local factors (e.g., residual excess cement, poorly designed restorations that inhibit hygiene access) should be identified and modified.

Peri-Implant Mucositis

Peri-implant mucositis can be effectively treated with nonsurgical mechanical therapy.[36] Treatment requires complete removal of

supramucosal and submucosal biofilm, calculus, and deposits using curettes, ultrasonic scalers, and polishing cups with prophy paste. Antimicrobials (e.g., chlorhexidine irrigation, mouthrinse) can be used with mechanical debridement to enhance treatment outcome.[36]

Peri-Implantitis

The treatment of peri-implantitis includes nonsurgical and surgical interventions, which can be combined with the adjunctive use of antimicrobials. Nonsurgical interventions consist of antimicrobial rinse and irrigation, local antibiotics, ultrasonic debridement, mechanical debridement with air-abrasive devices, and laser therapy. Surgical treatment includes full-thickness flap elevation for access, followed by degranulation, surface debridement by laser or mechanical instruments, surface decontamination with laser or antimicrobials, and bone augmentation. The data from two systematic reviews[13,47] are insufficient to suggest which intervention for peri-implantitis is most effective or to allow specific recommendations for the use of locally or systematically administered antibiotics.

Implant surface decontamination or disinfection remains challenging, especially for implants with roughened surfaces. For some treatment modalities, recurrence of peri-implantitis appears to be high (up to 100%) after 1 or more years of treatment, and retreatment may be necessary. Surgical access appears to be necessary to arrest peri-implant bone loss. Surgical treatment can result in gingival recession and compromised aesthetics. At sites with high aesthetic demands, definitive treatment of peri-implantitis can include the removal of the implant, grafting of the site, and placement of another implant.

Key Fact

Treatment of peri-implant mucositis is effective, whereas treatment of peri-implantitis is unpredictable. Prevention, early detection, and treatment of peri-implant inflammatory diseases are essential for successful outcomes.

Referral of Patients to the Periodontist

The previously described guidelines allow many implants to be maintained quite well by primary dental care providers (i.e., general dentists). Referral to a periodontist should be considered if peri-implantitis or peri-implant mucositis is diagnosed and cannot be resolved with improved oral hygiene and professional maintenance care. Early referral is advantageous to stop progression and limit the extent of bone loss.

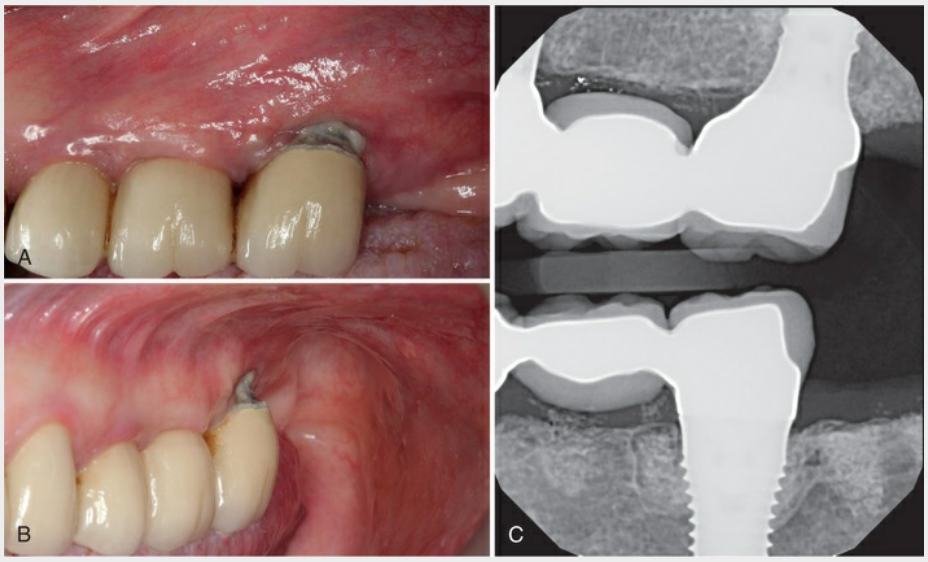
Case Scenario 86.1

Patient:
73-year-old woman

Chief Complaint:
Patient reports pain and bleeding in the back upper left whenever she brushes.

Background Information:
The patient has hypertension, hypothyroidism, depression, and anxiety. She has smoked half to three-quarters of a pack per day on and off since age 17. Medications include lisinopril, levothyroxine, and duloxetine. She had a 12 × 14 fixed dental prosthesis restored 10 years ago. She reports no pain or discomfort associated with implants.

Current Findings:
The #14 implant is a Straumann tissue-level implant that is 4.8 mm in diameter. The patient has mild to moderate erythema and edema. There is no buccal keratinized tissue, and there is 3 mm of buccal recession. Buccal mucosa is loose and poorly adapted. Peri-implant probing depths are 4 to –5 mm. The first implant thread on the buccal aspect is detectable with the periodontal probe. There is heavy biofilm.



CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. The clinical and radiographic information is adequate for diagnosis and treatment. A. True B. False	**Answer: B** **Explanation:** Although a vertical bitewing is shown and the mesial and distal crestal bones on implant #14 are visible, an additional periapical radiograph is required to enable complete visualization of the implant before a diagnosis can be made.
2. Based on the information provided, what is the likely diagnosis? A. Peri-implant mucositis B. Peri-implantitis C. Health	**Answer: B** **Explanation:** Radiographically, it does not appear there is mesial or distal bone loss, but the presence of biofilm, inflammation, recession, and buccal bone loss as detected by probing support the diagnosis of peri-implantitis.
3. Treatment must begin with which of the following? A. Patient education and oral hygiene instruction B. Implant debridement with implant scalers C. Soft tissue augmentation D. Bone augmentation	**Answer: A** **Explanation:** The cause of peri-implant mucositis and peri-implantitis is biofilm. For therapy to be successful, the patient must effectively control biofilm. After biofilm control is effective and inflammation is resolved, the implant can be assessed for the need for soft tissue augmentation.

CHAPTER 87

Results of Implant Treatment

Perry R. Klokkevold

CHAPTER OUTLINE

Defining Implant Outcomes
Factors That Influence Implant Outcomes
Aesthetic Results and Patient Satisfaction
Conclusions

The landmark Göteborg study and the replica study at the University of Toronto supported expectations for the success and predictability of root-form dental implants. The study, conducted over a 15-year period at the University of Göteborg, Sweden, by P.I. Bränemark and coworkers, began in 1965 and concluded in 1980. The results, which were reported in several articles, defined the concept of osseointegration, described protocols for success, and shared clinical experiences.

The most significant article from the study, published in 1981, was on osseointegrated implants in the treatment of the edentulous

jaw.[2] The Göteborg study included 2768 root-form implants placed into 410 edentulous jaws in 371 consecutive patients. The data were most often reported in subsets according to the three study phases (i.e., initial, developmental, and routine). Cases treated in the routine period with standardized procedures and an observation time of 5 to 9 years were thought to reflect the potential of the method and were the basis of data reported in that historic publication. The subset consisted of 895 implants placed in 130 jaws. The implant survival rate was 81% in the maxilla and 91% in mandible. The prosthesis survival (i.e., continuous stability) rate was 89% in the maxilla and 100% in the mandible.

The replica study, which was conducted at the University of Toronto, demonstrated that comparable results could be predictably achieved using the same implant design and treatment protocols.[5,78–80] Together, these studies demonstrated that implant survival of 81% or more and prosthesis survival of 89% or more could be expected in the edentulous patient.

In the decades since the landmark discovery of osseointegration and the documentation of its clinical effectiveness, clinicians have had tremendous success in replacing missing teeth with endosseous root-form dental implants in both partially edentulous and edentulous patients.[1,48] Despite the high level of success and long-term predictability, a 100% success rate cannot be achieved. Complications and implant failures do occur.[2,12] Some implants fail to achieve osseointegration; some achieve osseointegration but lose bone progressively over time, leading to failure; and other implants rapidly lose bone and fail in a short time. Some implants achieve and maintain osseointegration but fail because they do not meet the aesthetic expectations of the patient or clinician.

The reporting of implant success varies widely in the literature, which makes defining an absolute implant success rate impractical. This chapter considers implant treatment results in light of the factors that influence implant survival and success. The intent is to outline important aspects that need to be considered in evaluating implant outcomes and offer guidelines for understanding published results.

Defining Implant Outcomes

Implant outcomes are reported in a variety of ways in the literature. Various levels of implant success and failure are described in case reports, case series, retrospective studies, controlled studies, and prospective studies. The type of study and method of reporting are decided by the authors and often influenced by the data collected and the study objectives. Each type of study or report has recognized limitations, but because of tremendous variation that exists in the ways individual investigators measure, interpret, and report implant outcomes, differences in the results from one study to another may not be obvious.

Some implant outcomes are reported as the presence or absence of the implant at the time of the last examination, regardless of whether the implant was functional, suffered from bone loss, or had other problems. This type of assessment is a measure of implant *survival* and should not be confused with implant *success.* In contrast to such an overly simplified assessment, some investigators report implant outcomes using specific criteria to determine implant success.

Implant success is defined by specific criteria used to evaluate the condition and function of the implant. Criteria for implant success have been proposed in the literature but have not been used consistently. The problem is that a universally accepted definition of implant success has not been established. In the classic definition, Albrektsson and colleagues[3] defined success as an implant with no pain, no mobility, no radiolucent peri-implant areas, and less than 0.2 mm of bone loss annually after the first year of loading.[3] Bone loss in the first year was recognized, but it was not defined or quantified as part of the success criteria until later in a separate definition by Roos and associates.[61]

The challenge in comparing reported data between studies is that investigators use different criteria for success in their work. As a result, it is difficult or impossible to make comparisons between studies, and drawing conclusions about implant success or failure from data reported in different studies is tenuous.

Success rates are dramatically affected by variations in the criteria used to define them. In strict terms, if implant success is considered

to be an outcome without adverse effects or problems, the treatment would be performed as planned, implants would remain stable and functioning without problems, peri-implant tissues would be stable and healthy, and the patient and treating clinician would be pleased with the outcome (Fig. 87.1). Use of strict criteria would produce implant success rates lower than those determined using less stringent criteria.

FIG. 87.1 Clinical implant success was demonstrated when a single implant was placed in the mandible to replace the lower second premolar (as planned). The implant osseointegrated, and function was successfully restored. The patient and clinicians were pleased with the outcome. (A) Photograph of the dentition in occlusion (from the left side). (B) Close-up photograph of the dentition in occlusion. The mandibular second premolar is an implant-supported crown. (C) Occlusal view of an implant-supported crown in the second premolar position. Replacement of the mandibular second premolar with an implant is a conservative treatment, obviating the need to prepare adjacent

teeth. (D) Periapical radiograph of the posterior mandibular teeth and implant in the second premolar position. Bone support is good, and bone loss is minimal and consistent with expectations for this implant design.

Table 87.1 illustrates the powerful effect that small changes in success criteria have on reported success rates. The data demonstrate that changing the criteria of success to include a probing pocket depth (PPD) of 5 mm or less to 6 mm or less changed the implant success rates from 52.4% to 62% and from 79.1% to 81.3% for patients with and without a history of periodontitis, respectively.[42] This also shows that implant survival is quite different from implant success.

TABLE 87.1

Effect of Slight Modifications of Implant Success Criteria on Successful Outcomes[a]

Group	PPD ≤5 mm, No BOP, BL <0.2 mm/yr (%)	PPD ≤6 mm, No BOP, BL <0.2 mm/yr (%)	PPD ≤5 mm, No BOP (%)	PPD ≤6 mm, No BOP (%)	Implant Survival (%)
Group A	52.4	62	71.4	81	90.5
Group B	79.1	81.3	94.5	96.7	96.5

[a]The initial success criteria at 10 years were set as a PPD ≤5 mm, no BOP, and BL <0.2 mm annually. The implant success rates for group A (i.e., patients with a history of periodontitis) and group B (i.e., patients with periodontal health) using these initial criteria are listed in the first column. Notice how dramatically the success rates change when the criteria used to define success are modified to include PPD ≤6 mm (i.e., second column). The next two columns show the success rates for each group using PPD ≤5 mm and ≤6 mm when the criteria are modified to omit bone loss as a determinant. The last column shows the implant survival rate for each group, which demonstrates that the survival rate is different than the success rate.

PPD, Probing pocket depth; *BOP,* bleeding on probing; *BL,* bone loss.

Data from Karoussis IK, Salvi GE, Heitz-Mayfield LJ, et al: Long-term implant prognosis in patients with and without a history of chronic periodontitis: a 10-year prospective cohort study of the ITI Dental Implant System. *Clin Oral Implant Res* 14:329–339, 2003.

Key Fact

Implant success is defined by specific criteria used to evaluate the condition and function of the implant. Criteria for implant success have been proposed in the literature but not used consistently. Depending on the criteria used, the rates of implant success reported in studies can vary substantially.

Implant survival is defined as an implant that remains in place at the time of evaluation, regardless of untoward signs and symptoms or a history of problems. Extant implants that are healthy and functioning under an implant-retained restoration are different from those that are suffering from peri-implant bone loss or those that are not connected to a restoration and not functioning (Fig. 87.2), but these operational differences do not affect calculations of implant survival. Implants that are osseointegrated but not functional are referred to as *sleepers* and should not be considered successful merely because they are present and osseointegrated.

FIG. 87.2 Panoramic radiograph shows an implant placed in the position of a missing maxillary right central incisor. The implant appears to be placed in a nonrestorable position. It is osseointegrated and could technically be counted as a surviving implant, but it must be considered a failure because it does not meet the intended goal and function has not been restored.

Implant survival and implant success are different outcome measures. Consider the dramatic difference between survival and success rates for implants reported in a systematic review (21 studies included) of implants supporting fixed partial dentures.[59] The 5-year implant survival rate was 95.4%, whereas the overall 5-year success rate (individual implant success rates were not calculated), defined as free of complications, was only 61.3%.[59]

In a 10-year retrospective study of 397 fixed implant reconstructions in 300 patients, the observed mechanical complication rate was 24.7%.[77] The most frequent complication was ceramic chipping (20.31%), followed by occlusal screw loosening (2.57%) and loss of retention (2.06%).[77] Although relatively uncommon, occlusal screw loosening can result in a subgingival gap at the implant–abutment junction that retains plaque and stimulates an inflammatory reaction in the soft and hard tissues, leading to bone loss around the implant. Although surviving, these implants would fail to meet optimal success criteria.

Defining implant results in absolute terms is difficult and confusing. Implant survival, which typically is reported in studies, can overestimate good implant outcomes. Implant success, which is less often reported, could offer a better measure if specific success criteria were universally defined, accepted, and used. Implant success is difficult or impossible to compare across studies because of differences in evaluation criteria used by investigators. Implant success in a single study or series of studies using the same success criteria is meaningful only in the context of that study or series.

Currently, the usefulness of implant success rates from different studies is limited. Implant survival is important but is only an indicator of surviving implants and does not reveal whether they are functioning or had problems associated with them over time. The incidence of peri-implant problems is more significant than once thought. A systematic review of the literature evaluating the prevalence of peri-implant disease reported that peri-implant mucositis and peri-implantitis occurred in 19% to 65% and 1% to 47% of cases, respectively.[22]

Factors That Influence Implant

Outcomes

Many issues influence implant outcomes, including available bone, implant design, placement and loading protocols, and host-related factors.

Anatomic Location

Osseointegration depends on the availability of an adequate quantity and quality of bone at the implant site. Areas with abundant bone volume in the desired location are better than those with deficient bone volume. Areas with good bone density provide more predictable outcomes than those with poor bone density.

The bone classification system described by Lekholm and Zarb[49] defines bone with different levels of support for implants and the likely impact on survival and success. The quality of bone support is greatly influenced by the anatomic location, and implant outcomes are sometimes categorized according to location. Extreme examples are the anterior mandible and the posterior maxilla. The anterior mandible typically consists of dense cortical bone, which offers great support and high bone-to-implant contact, whereas the posterior maxilla is often limited in volume because of alveolar resorption and sinus pneumatization and typically consists of a loose, trabecular structure and a thin cortical bone shell.

Implants placed in the posterior maxilla are less well supported compared with implants placed in the anterior mandible. Jaffin and Berman[36] demonstrated the significance of bone quality on implant survival in a report of 1054 Bränemark implants. Ninety percent of the implants were placed in type I, II, or III bone, with a failure rate of only 3%. Of the 10% that were placed in type IV bone, 35% failed.[36] Excluding those placed in the mandible, 23 (44%) of 52 implants placed in type IV bone in the maxilla failed, for a dismal survival rate of 56%. The study authors concluded that bone quality was the single greatest determinant of implant loss.

Anatomic location has a significant effect on implant outcome, particularly for the posterior maxilla. The implants used in the study by Jaffin and Berman[36] had machined surfaces, and current implants with altered microtopography are thought to perform

better in the posterior maxilla due to increased bone-to-implant contact. When all 1054 implants (placed in all types of bone) are considered together, the combined implant survival rate (93.9%) in the study is within or slightly higher than the reported range in the Göteborg study (done with similar implants).

Implant Design

Implant design influences outcome. Hundreds of companies manufacture and market dental implants worldwide, and the number continues to grow. Implant dimensions, geometries, and surface characteristics vary tremendously and continue to evolve as innovation and research findings pave the way for changes that are thought to improve outcomes. Very few implant designs have been studied. They instead rely on being clinically similar to researched and approved designs without additional studies or documentation to support their effectiveness. In most cases, it is impossible to appreciate the effect of a particular implant design features on outcomes. Nonetheless, novel implant designs are being used, and outcomes are being reported in studies that evaluate other aspects of treatment that are not specific to the design, which makes comparisons and assessments more confusing and unreliable.

The studies that have documented the success of dental implants based on design characteristics have shaped current standards for selection and use. For example, many clinicians adhere to the premise that longer implants, threaded implants, and rough-surfaced implants are better than shorter, unthreaded, and smooth designs. As changes in design and use have evolved over time, some beliefs have been disproved, and continued advances and research will undoubtedly refute other firmly held beliefs.

Clinicians would like to know whether one implant design performs better than the rest, but it is almost impossible to determine which design characteristics are important, because there are many variables to consider and implants are successful most of the time. Given the generally high rate of success, it appears that subtle differences in implant design are probably not significant for most patients and situations.[24,28] However, in patients with inadequate sites or challenging circumstances, certain implant

designs may perform better than others. An example is the effect of implant surface characteristics. Implants with altered surface microtopography (i.e., acid-etched or blasted) enhance the bone-to-implant interface[44,45] and can improve outcomes, especially in compromised sites.[71,72] Lower success rates have been associated with smooth-surface (i.e., machined) implants.[37,60,64]

Implant length is another consideration. Many studies have supported the dogma that longer is better for implant success,[65,66] but later studies have challenged it.[31] Another important feature is the macro-thread design of implants. Clinical research[52] evaluating the stability (assessed by resonance frequency analysis) of a novel implant designed with a wide thread depth and increased pitch found that it did not cause the typical decrease in stability in the early postoperative healing period. This finding may have an impact on early and immediate loading protocols.

Key Fact

Many features influence outcomes, including available bone, implant design, placement and loading protocols, and host-related factors. Defining implant results in absolute terms can be difficult and confusing.

Placement and Loading Protocols

The traditional placement protocol required a healed edentulous ridge into which implants were placed and allowed to osseointegrate for a period without occlusal loading (see Chapter 78). The nonloading period after implant placement was empirically determined to be 3 to 4 months in the mandible and 6 months in the maxilla.[10] A strongly held belief was that early loading would lead to higher failure rates.[11]

In contrast to the early standards, some current protocols advocate dramatically different approaches, including implant placement immediately after tooth extraction and implant occlusal loading immediately or shortly after placement. Each of these approaches has distinct advantages, but they are accompanied by challenges that have the potential to adversely affect outcomes.

Immediate Implant Placement

The immediate implant placement protocol describes the procedure in which an implant is placed in an extraction socket after tooth removal and socket debridement. This procedure, described by Schulte and colleagues[68] in 1978 and by Lazzara in 1989,[47] has been reported with survival rates equivalent to those of implants placed into healed ridges.[14,51] The advantages of immediate placement include decreased surgery, cost, and healing time.[69] Immediate implant placement introduces an additional risk of complications, including poor implant position, compromised aesthetic outcome, and implant failure (see Chapter 85). Despite the increased risk, a high long-term (1- to 16-year) survival rate of 96% has been reported for implants immediately placed into extraction sockets.[74]

Immediate Occlusal Loading

Bränemark established the concept of the osseointegrated dental implant as a predictable treatment modality for the edentulous patient on the empirically based requirement that the implant remain submerged and unloaded for a healing period of 3 to 6 months.[10] This original protocol, requiring the implant to remain stress free, was based on the concern that premature loading would cause micromotion of the dental implant, leading to fibrous encapsulation and implant failure. However, studies have shown this assumption to be incorrect, demonstrating that immediately loaded implants can achieve success rates (>90%) similar to those for conventionally loaded dental implants.[15,19,29,33,40] The long-term predictability of immediately loaded implants requires strict surgical and prosthodontic protocols.[7]

Bone Augmentation

A common problem encountered in implant dentistry is insufficient bone quantity to allow implant placement. Deficiencies in alveolar bone result from developmental defects, periodontal disease, tooth loss, or trauma.[6,13,67] For most cases with alveolar ridge resorption, bone regenerative procedures are required to correct the defects before or simultaneously with implant placement (see Chapters 79 and 80). The question is whether implants placed in sites that are

reconstructed with bone augmentation procedures can achieve the same survival and success rates as implants placed in native bone sites.

The results of implants and bone augmentation procedures reported in the literature have been assessed by expert clinicians in several workshops.[16,30,34,35] One systematic review of the literature (2003 Workshop on Contemporary Science in Clinical Periodontics), including 13 studies (i.e., guided bone regeneration) with 1741 patients and 5 studies (i.e., distraction osteogenesis) with 92 patients, found that survival rates of dental implants in augmented bone achieved a high level of predictability that was similar to that for implants placed in natural (nongrafted) bone.[30]

Another systematic review of the literature (2008 Consensus Report of the Sixth European Workshop on Periodontology[73]) pointed out that bone augmentation procedures can fail and that implants placed in these areas do not enjoy the high long-term survival rates of dental implants placed in pristine sites.[73] The 2003 systematic review did not include an assessment of whether bone augmentation procedures failed; it intentionally focused on implants placed in sites that were successfully treated with bone augmentation. More research is needed to determine the long-term performance of dental implants placed in augmented bone and the clinical benefits of bone augmentation with respect to alternative treatments (e.g., use of short implants).

Risk Factors

Most patients enjoy similar rates of survival and success with dental implants. Only a few patients experience implant failure.

In addition to the factors previously discussed, host-related factors can adversely affect healing, osseointegration, and maintenance of dental implants. Smoking, diabetes, and periodontitis have been identified as risk factors that can adversely affect implant outcomes. In a systematic review of the literature, Klokkevold and Han[43] evaluated the influence of smoking, diabetes, and periodontal disease on outcomes and found that smoking has an adverse effect on implant survival and success, with the effects being more pronounced in areas of loose trabecular bone (e.g.,

posterior maxilla).

The review also suggested that type 2 diabetes had an adverse effect on implant survival rates, but the limited number of included studies did not permit a definitive conclusion.[43] The review did conclude that although patients with a history of treated periodontitis did not show a decrease in implant survival, they did experience more complications and lower success rates, especially when the implants were followed over longer periods (10+ years).[43]

Smoking

Above all other risk factors, smoking has a significant negative impact on implant survival and success. In a study of 2194 implants, Bain and Moy reported a significantly greater rate of failure among smokers (11.28%) than nonsmokers (4.76%).[8] De Bruyn and Colleart reported an early failure rate of 9% among smokers compared with 1% among nonsmokers.[18] Two other studies, one of 10 years[25] and the other with follow-up assessment of 6 months to 21 years,[56] concluded that smoking was a definite risk factor for implant survival.[20,21]

Diabetes

The role of diabetes mellitus as a risk factor for implant outcomes is less clear. Although a metabolic disease such as diabetes was expected to have an adverse effect on bone healing[75] and tissue support for implants, the research has not definitively determined that diabetes has a negative impact on implant survival or success.[4]

Moy and coworkers[56] reported a significantly lower success rate (68.7%) for patients with diabetes compared with the success rate (85.1%) for the entire study population (1140 patients with 4680 implants); individual implant survival and success rates were not reported. However, the low success rate (i.e., high failure rate) may be an overestimate of the actual implant failure rate for patients with diabetes, because it counts the number of patients with failures regardless of how many implants they had (i.e., implants successfully inserted and maintained in these patients are not counted). There were 48 patients with diabetes in the study, 4.2% of the 1140 total. Of these, 15 patients experienced implant failures.

Conversely, in a systematic review of the literature (33 studies),

Javed and Romanos found that patients with good metabolic control (i.e., glycated hemoglobin [HbA1c] levels in the normal range) achieve success rates with osseointegrated implants that are similar to those for patients without diabetes.[38] Dowell and coworkers[23] also found similar success for implants placed in patients with controlled diabetes.

Periodontitis

A limited number of studies have assessed the prognosis of implant treatment in patients with a history of periodontitis.[41] Most of these studies suggest that implants are equally successful in patients with a history of chronic periodontitis. Short-term studies demonstrate 90% to 100% implant survival in patients with a history of chronic periodontitis.[53,55] Long-term studies report 90% to 97% implant survival rates for patients with a history of chronic periodontitis.[42,50,62,76] Short-term implant survival rates for patients treated for aggressive periodontitis are 95% to 100%.[53,54] One long-term study reported an 88.8% implant survival rate over 5 years for patients treated for aggressive periodontitis.[55]

Implant survival in patients with a history of periodontitis appears to be highly predictable. However, the lack of long-term studies to support implant survival in patients treated for aggressive periodontitis leaves the prognosis for these patients open to question.[41]

Long-term studies evaluating implant treatment in periodontally compromised patients suggest that they may experience more peri-implant problems.[42] When these patients are followed for extended periods, there appear to be more complications (i.e., peri-implantitis) associated with implants than in periodontally healthy patients. In a 10-year prospective study of patients with and without a history of chronic periodontitis, the rate of biologic complications (i.e., peri-implantitis) was higher for those with a history of chronic periodontitis (28.6%) than those with periodontal health (5.8%).[42] This controlled study by Karoussis and coworkers[42] found a statistically significant difference in mean peri-implant bone loss between patients with a history of chronic periodontitis and patients who were periodontally healthy.

Peri-implant problems may be attributed to a continuous increase

in the percentage of implants exhibiting probing pocket depths of 4 mm or deeper over time.[26] A systematic review of implant outcomes in patients treated for periodontitis concluded that these individuals had a greater incidence of biologic complications and lower success and survival rates compared with periodontally healthy subjects.[70]

Key Fact

Smoking, diabetes, and periodontitis are risk factors that can adversely affect implant outcomes.

Aesthetic Results and Patient Satisfaction

The ultimate goal of treatment is to achieve natural-appearing, optimally functioning, implant-supported tooth replacements. Proper tooth dimensions and contours, and ideal soft tissue support are key factors for successful aesthetic outcomes.[46] If crown form, dimension, and shape and gingival harmony around the implants are not ideal, the patient may consider the implant restoration unacceptable, because the result does not represent a natural dental profile (Fig. 87.3). For some patients, such as those with severe alveolar deficiency, an ideal aesthetic outcome may be impossible because reconstructive surgical procedures are complex, require extensive time, and remain unpredictable. For others, a less-than-ideal aesthetic outcome may be acceptable (see Chapter 81).

FIG. 87.3 Clinical photograph shows a maxillary anterior fixed restoration supported by two malpositioned implants in the central incisor positions. The patient was dissatisfied with the aesthetic outcome. The left implant was positioned between the central and lateral incisor and angled toward the facial surface at a level above the gingival margin. A tooth-colored material was used to mask the exposed framework in the gingival area.

Aesthetic problems and patient dissatisfaction happen when results are inferior to what was expected. Satisfaction with the aesthetic outcome of the implant prosthesis varies from patient to patient, depending on a number of factors. The risk for aesthetic failure is increased for patients with high aesthetic expectations. The risk is also higher when patients present with patient-related risk factors such as a high smile line, thin periodontal soft tissues, and compromised bone support. Two recent systematic reviews reported that the patient's perceptions and desires greatly influence and determine how well he or she accepts the implant outcome.[17,57]

Although infrequently reported, aesthetic success and patient satisfaction need to be included when considering the results of implant therapy. Despite several proposed methods for evaluating aesthetic results, reports of aesthetic parameters in the scientific literature are scarce.[9] A restorative index appraises the white aesthetics of the final restoration,[39] a soft tissue or pink aesthetic score considers soft-tissue parameters,[32] and an aesthetic index uses a combination of pink and white aesthetic scores, focusing on the

visible part of the implant restoration.[8] These indices quantify the aesthetic result, providing an objective method of judging aesthetic success.

In a survey of patient satisfaction, more than 90% of patients were completely satisfied in terms of function and aesthetics.[58] A questionnaire was given to 104 patients 5 to 15 years (mean, 10.2 years) after implant placement to assess subjective perceptions of treatment. Of these patients, 48% were treated with single implant crowns and 52% were treated with fixed partial dentures. The survival rate for all implants was 93%. Most patients had favorable responses to the questions regarding function, aesthetics, hygiene, and cost. Table 87.2 lists the percentage of patients responding as highly satisfied or satisfied for each category. Comparing chewing comfort for teeth or implants, 72.1% perceived no difference, 17.3% felt more secure chewing on teeth, and 7.7% felt more secure chewing on implants.

TABLE 87.2

Patient Satisfaction With Implant Treatment

Implant Experience	Highly Satisfied or Satisfied (%)[a]
Function or chewing	97
Phonetics	96
Aesthetics	97
Oral hygiene ease	93
Complete fulfillment	92
Would do treatment again	94
Would recommend to friend or relative	89
Reasonable or justified cost	87

[a]Percentage of patients subjectively responding with *highly satisfied* or *satisfied* to survey questions about their implant experience. More than 90% responded favorably and thought implant treatment was a positive experience.

Data from Pjetursson BE, Karoussis I, Burgin W, et al: Patients' satisfaction following implant therapy. A 10-year prospective cohort study. *Clin Oral Implants Res* 16:185–193, 2005.

In another survey, patient satisfaction with implant-supported prostheses in totally edentulous jaws was evaluated.[63] Experience with an implant-supported prosthesis was assessed over a period of 10 years, and 97% of the 135 patients reported overall satisfaction with treatment. Chewing satisfaction was reported as good or very good by all but one patient (99.3% positive response rate).

Improved lifestyle and greater self-confidence in public were reported by 75% and 82% of patients, respectively.

A systematic review of the literature, which included all randomized controlled trials published in English or French up to April 2007 comparing conventional mandibular dentures and implant overdentures in adult edentulous patients, identified eight publications for meta-analysis.[27] The study reported that patients were more satisfied with implant overdentures than with conventional mandibular dentures. However, there was a lack of evidence to show a patient's perception of the impact of mandibular implant overdentures on general health.

Clinical Correlation

Aesthetic problems and dissatisfaction happen when results do not match a patient's expectations. Satisfaction with the aesthetic outcome of an implant prosthesis varies among patients. The risk of failure is greater among those with high aesthetic demands and risk factors such as a high smile line, thin periodontal soft tissues, or compromised bone support.

Conclusions

The use of dental implants to replace missing teeth is highly predictable, advantageous, and beneficial for patients. Because of variations in implant designs, study protocols, and populations studied, results are difficult to compare and an absolute definition of implant success remains elusive. The results of implant treatment are reported using a wide range of criteria from being present (i.e., survival) to being functional without complications (i.e., success).

It is challenging to compare the results of studies because the number of variables continues to change. Clinical research suggests that certain risk factors can decrease success rates for some patients. Understanding what is being reported in the literature helps patients and clinicians appreciate implant treatment results.

Case Scenario 86.1

Patient:
57-year-old male

Chief Complaint:
"My front tooth is loose. It bothers me, and I want an implant."

Background Information:
The patient reports a history of trauma to his front teeth as a young teenager. Both central incisors were fractured. Multiple restorations were done over the years. Tooth #9 had root canal treatment and a crown. Later, it became infected and required an apicoectomy. It is now loose and migrating.

Current Findings:
Tooth #9 has severe localized gingival recession. Tooth mobility is class 2/3. It has drifted in a coronal and facial direction. There are no significant probing pocket depth measurements around tooth #9 or the remaining dentition. The patient is healthy and has no systemic illnesses.

CASE-BASED QUESTION	SOLUTION AND EXPLANATION
1. Is it possible to replace tooth #9 with an implant? A. Yes. Implants can successfully replace failing teeth. B. No. There is too much gingival recession. C. No. Implants are not successful in the anterior maxilla. D. Maybe. It depends on the patient's aesthetic demands.	**Answer: A** **Explanation:** There will likely be a need for bone and soft tissue augmentation. Implant placement in the anterior maxilla has been a successful option for replacement of a single tooth.

CHAPTER OUTLINE

Plaque-Induced Gingival Diseases
Causes of Periodontal Diseases
Gingival Diseases Modified by Systemic Factors
Gingival Diseases Associated With Blood Dyscrasias
Drug-Induced Gingival Diseases
Non–Plaque-Induced Gingival Lesions
Gingival Lesions of Genetic Origin
Gingival Manifestations of Systemic Conditions
Traumatic Lesions: Factitious, Iatrogenic, and Accidental
Cysts and Tumors
Chronic Periodontitis
Aggressive Periodontitis
Periodontitis as a Manifestation of Systemic Diseases
Genetic Disorders
Necrotizing Periodontal Diseases

Abscesses of Periodontium

This chapter provides additional illustrations for Chapter 27 and the chapters in Part 2 and in Sections 1 and 2 of Part 3. The presentation of cases follows the classification of periodontal diseases and conditions developed by the 1999 International Workshop for the Classification of Periodontal Diseases, which was organized by the American Academy of Periodontology (see Chapter 4). All illustrations are from the Archives of the Department of Periodontology, School of Dentistry, Cukurova University, Adana, Turkey (Box 88.1).

Box 88.1

Gingival Diseases

Plaque-Induced Gingival Diseases

I. Gingivitis associated with dental plaque only
- A. Without local contributing factors
- B. With local contributing factors (see Figs. 88.1 to 88.32)

II. Gingival diseases modified by systemic factors
- A. Associated with endocrine system
  1. Puberty-associated gingivitis (see Fig. 88.33)
  2. Menstrual cycle–associated gingivitis (see Fig. 88.34)
  3. Pregnancy-associated gingivitis (see Figs. 88.35 to 88.37)
     - a. Gingivitis
     - b. Pyogenic granuloma
  4. Diabetes mellitus–associated gingivitis
- B. Associated with blood dyscrasias
  1. Leukemia-associated gingivitis (see Figs. 88.38 to 88.40)

2. Other (see Figs. 88.41 to 88.46)

III. Gingival diseases modified by medications
- A. Drug-induced gingival diseases
  - 1. Drug-influenced gingival enlargement (see Figs. 88.47 to 88.51)
  - 2. Drug-influenced gingivitis
    - a. Oral contraceptive–associated gingivitis
    - b. Other

IV. Gingival diseases modified by malnutrition
- A. Ascorbic acid–deficiency gingivitis
- B. Other

Non–Plaque-Induced Gingival Lesions

I. Gingival diseases of specific bacterial origin
- A. *Neisseria gonorrhoeae*
- B. *Treponema pallidum*
- C. *Streptococcus* species (see Fig. 88.52)
- D. Other

II. Gingival diseases of viral origin
- A. Herpesvirus infection (see Fig. 88.53)
  - 1. Primary herpetic gingivostomatitis
  - 2. Recurrent oral herpesvirus infection
  - 3. Varicella zoster
- B. Other (see Fig. 88.54)

III. Gingival diseases of fungal origin
- A. *Candida* species infections: generalized gingival candidiasis (see Figs. 88.55 and 88.56)
- B. Linear gingival erythema
- C. Histoplasmosis
- D. Other (see Figs. 88.57 and 88.58)

IV. Gingival lesions of genetic origin
- A. Hereditary gingival fibromatosis (see Figs. 88.59 to 88.61)
- B. Other

V. Gingival manifestations of systemic conditions

A. Mucocutaneous lesions
    1. Lichen planus (see Figs. 88.62 to 88.65)
    2. Pemphigoid
    3. Pemphigus vulgaris (see Fig. 88.66)
    4. Erythema multiforme
    5. Lupus erythematosus
    6. Drug induced
    7. Other (see Figs. 88.67 to 88.73)
B. Allergic reactions
    1. Dental restorative materials
        a. Mercury
        b. Nickel
        c. Acrylic
        d. Other
    2. Reactions attributable to the following
        a. Toothpastes or dentifrices
        b. Mouthrinses or mouthwashes
        c. Chewing gum additives
        d. Foods and additives (see Fig. 88.74)
    3. Other

VI. Traumatic lesions: factitious, iatrogenic, or accidental (see Figs. 88.75 to 88.92)
A. Chemical injury
B. Physical injury
C. Thermal injury

VII. Foreign body reactions

VIII. Not otherwise specified
A. Cysts and tumors (see Figs. 88.93 to 88.102)

Chronic Periodontitis (see **Figs. 88.103 to 88.108**)

I. Localized

II. Generalized

III. Chronic periodontitis modified by systemic disorders
A. Diabetes mellitus (see Figs. 88.109 to 88.113)

Aggressive Periodontitis (see **Figs. 88.114 to 88.119**)

I. Localized
II. Generalized

Periodontitis as a Manifestation of Systemic Diseases

I. Hematologic disorders
    A. Acquired neutropenia
    B. Leukemias (see Figs. 88.120 to 88.122)
    C. Other
II. Genetic disorders
    A. Familial and cyclic neutropenia (see Fig. 88.123)
    B. Down syndrome
    C. Leukocyte adhesion deficiency syndromes (see Figs. 88.124 and 88.125)
    D. Papillon-Lefèvre syndrome (see Figs. 88.126 and 88.127)
    E. Chediak-Higashi syndrome
    F. Histiocytosis syndromes
    G. Glycogen storage disease
    H. Infantile genetic agranulocytosis
    I. Cohen syndrome
    J. Ehlers-Danlos syndrome (types 4 and 8)
    K. Hypophosphatasia (see Fig. 88.128)
    L. Other
III. Not otherwise specified

Necrotizing Periodontal Diseases

I. Necrotizing ulcerative gingivitis (NUG) (see Figs. 88.129 to 88.131)
II. Necrotizing ulcerative periodontitis (NUP) (see Fig. 88.132)
III. Bisphosphonate-related osteonecrosis (see Figs. 88.133 and 88.134)

Abscesses of the Periodontium

I. Gingival abscess
II. Periodontal abscess (see Figs. 88.135 to 88.137)
III. Pericoronal abscess (see Fig. 88.138)

Periodontitis Associated With Endodontic Lesions

I. Endodontic-periodontal lesions (see Figs. 88.139 and 88.140)
II. Periodontal-endodontic lesions
III. Combined lesions

Developmental or Acquired Deformities and Conditions

I. Localized tooth-related factors
II. Mucogingival deformities around teeth
III. Mucogingival deformities on edentulous ridges
IV. Occlusal trauma

Plaque-Induced Gingival Diseases

Clinical Features of Gingivitis

Bleeding
Color Changes
Consistency
Surface Texture
Position
Contour

FIG. 88.1 In the healthy gingiva of a 17-year-old girl, notice the demarcation (mucogingival line) (*arrows*) between the attached gingiva and the darker alveolar mucosa.

FIG. 88.2 Two views show prominent stippling of healthy gingiva in a 21-year-old man.

FIG. 88.3 Bright-red color and loss of stippling of the gingiva is seen in a 21-year-old woman with gingivitis.

FIG. 88.4 Two views show bleeding on probing in a 24-year-old man with gingivitis and inflammatory enlargement.

FIG. 88.5 Plaque accumulation and red color of the gingiva are seen in a 17-year-old girl with gingivitis.

FIG. 88.6 Bluish red color of the gingiva is seen in a 46-year-old man with advanced chronic periodontitis.

Melanin Pigmentation

FIG. 88.7 Two views show melanin pigmentation that caused aesthetic problems in a 21-year-old woman and the gums 6 months after treatment with a carbon dioxide laser.

FIG. 88.8 Two views show diffuse melanin pigmentation that caused aesthetic problems for a 34-year-old woman and the gums 2 months after treatment with conventional gingivectomy.

FIG. 88.9 Two views show localized melanin pigmentation in a 26-year-old woman and the result 1 month after treatment with a carbon dioxide laser.

FIG. 88.10 Two views show diffuse localized melanin pigmentation in a 33-year-old woman and the result 1 month after carbon dioxide laser treatment.

Causes of Periodontal Diseases

Microbial Dental Plaque
Calculus
One-Sided Chewing
Malocclusion

FIG. 88.11 Severe plaque accumulation and gingivitis occurred in a 13-year-old boy with neglected hygiene.

FIG. 88.12 Extensive plaque formed in a 46-year-old man with chronic periodontitis. Darker shades of gingiva are seen in areas with subgingival calculus.

FIG. 88.13 Three views show extreme plaque formation and periodontitis in a 52-year-old woman with prolonged neglect of oral hygiene procedures.

FIG. 88.14 Plaque formation was caused by habitual

one-sided chewing in a 9-year-old boy. The patient had avoided chewing on the right side because of the mobility of deciduous teeth.

FIG. 88.15 There is extensive plaque accumulation and severe inflammation in a 35-year-old male smoker.

FIG. 88.16 Advanced plaque and calculus formed around implants in a 72-year-old woman.

FIG. 88.17 Plaque and calculus formed around implants in a 55-year-old man.

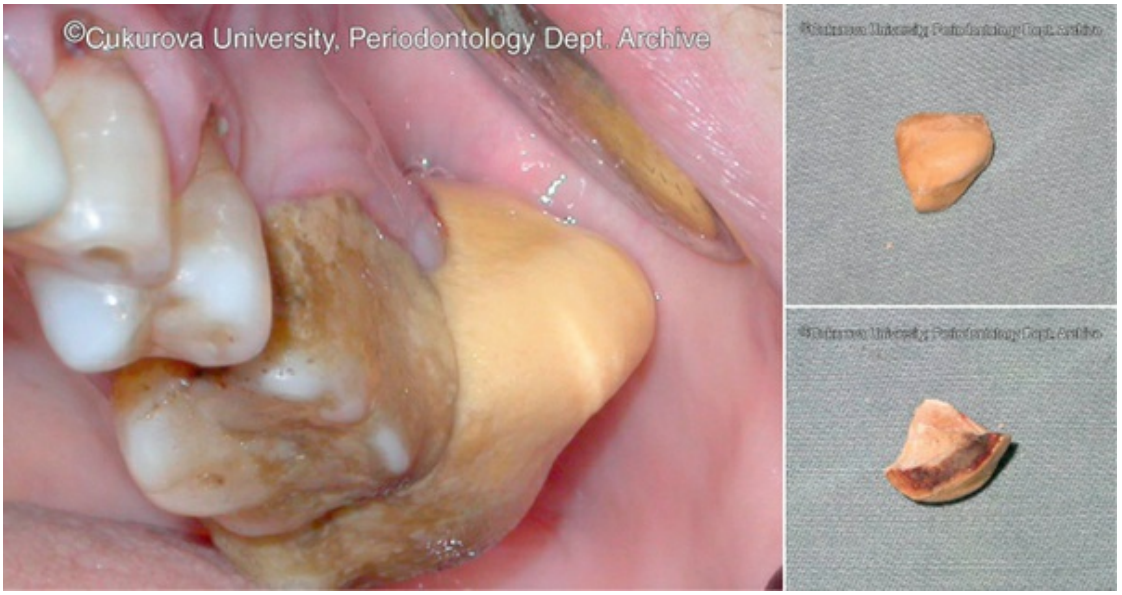

FIG. 88.18 Three views show calculus formation on teeth #26 and #27 where the parotid gland duct (i.e., Stensen duct) opens in a 47-year-old man. These teeth had lost their functional antagonists. Calculus also covered the occlusal surfaces.

FIG. 88.19 Calculus formed on upper molars adjacent to the Stensen duct in a 44-year-old man. Notice the divergence of the roots of the first molar.

FIG. 88.20 Anterior open-bite malocclusion and the loss of functional antagonist teeth caused extensive calculus formation on the left maxillary teeth in this 35-year-old woman.

FIG. 88.21 Bridge-like formations of calculus resulted from malocclusion, loss of an antagonist tooth, tilting of the remaining teeth, and avoidance of chewing on the affected site in a 49-year-old woman.

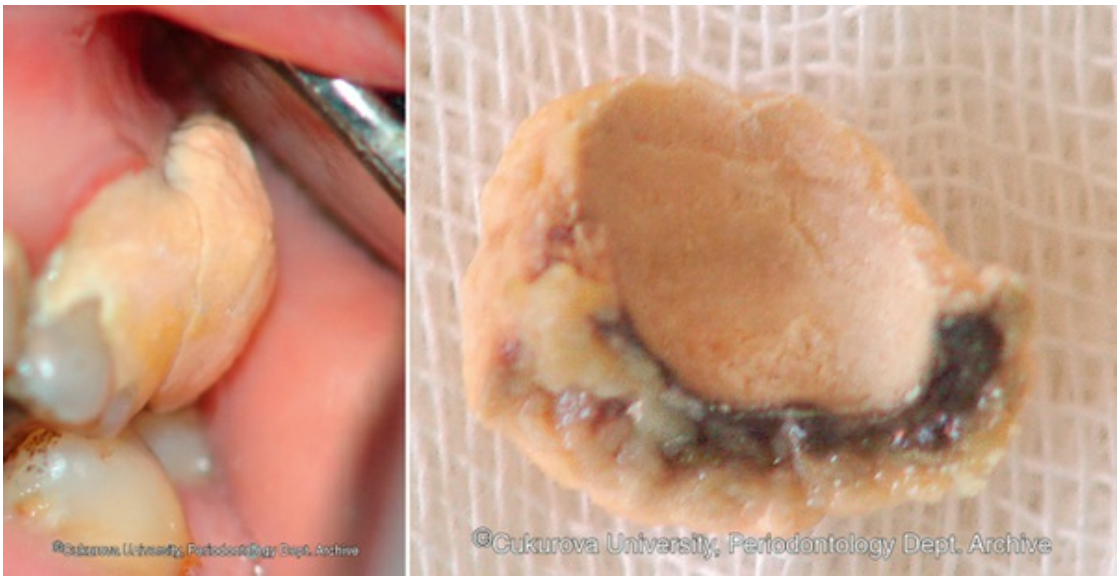

FIG. 88.22 Two views show extensive calculus that formed adjacent to the Stensen duct in a 53-year-old man.

FIG. 88.23 Extensive bridge-like calculus formed on the lingual surfaces of the lower anterior teeth where the Wharton and Bartholin ducts empty in a 36-year-old man.

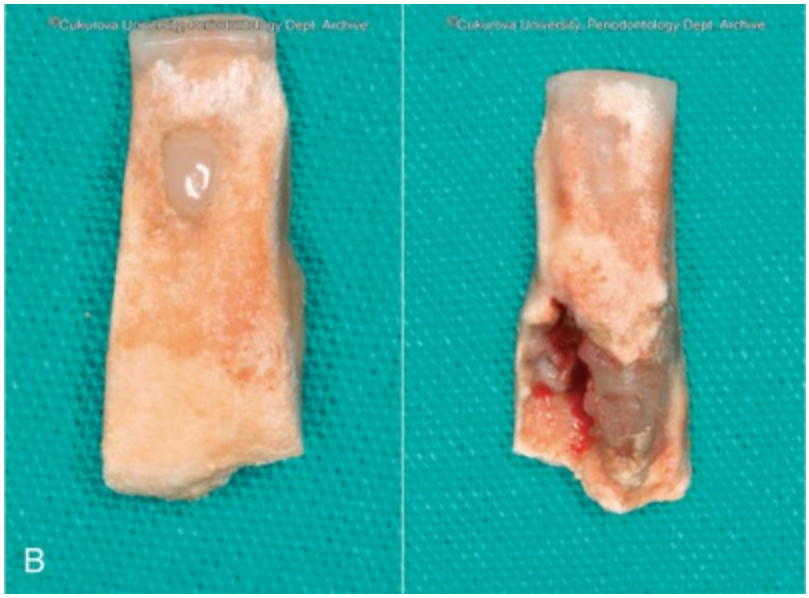

FIG. 88.24 (A) Extensive bridge-like calculus formed on the lingual surfaces of the lower anterior teeth where the Wharton and Bartholin ducts empty in a 42-year-old woman. (B) In the same patient seen in A after extraction of the left central incisor, calculus has covered almost all surfaces of the tooth.

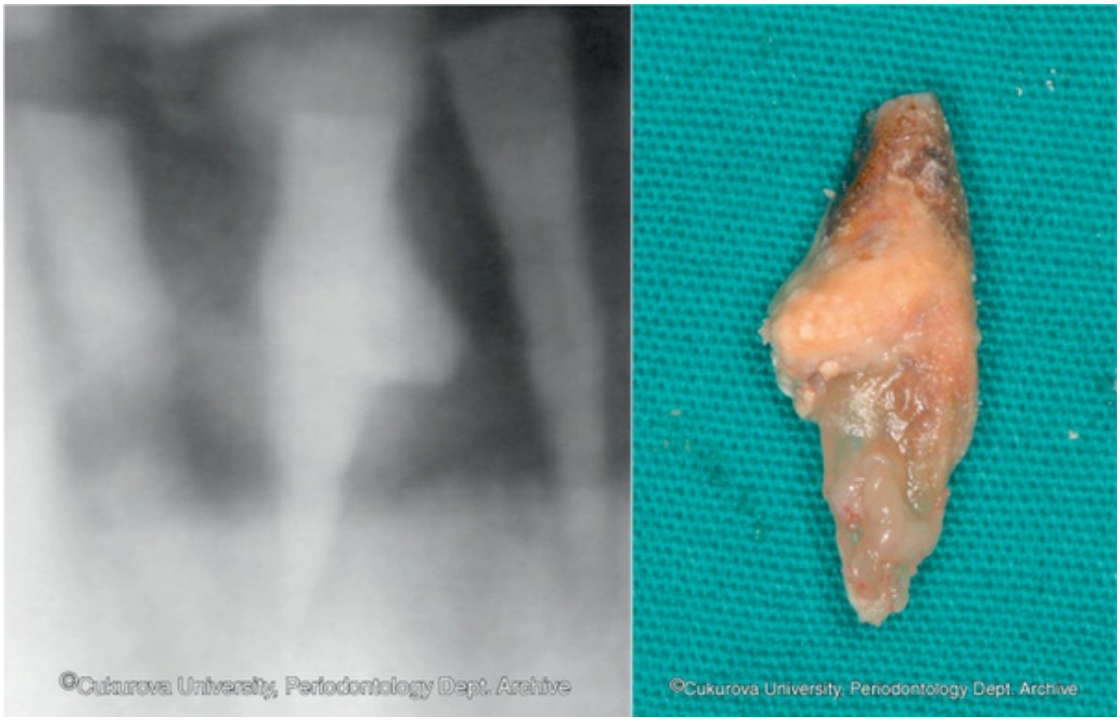

FIG. 88.25 A radiograph shows the radiopaque projection of extensive calculus, which is compared with its appearance after extraction in a 62-year-old

man.

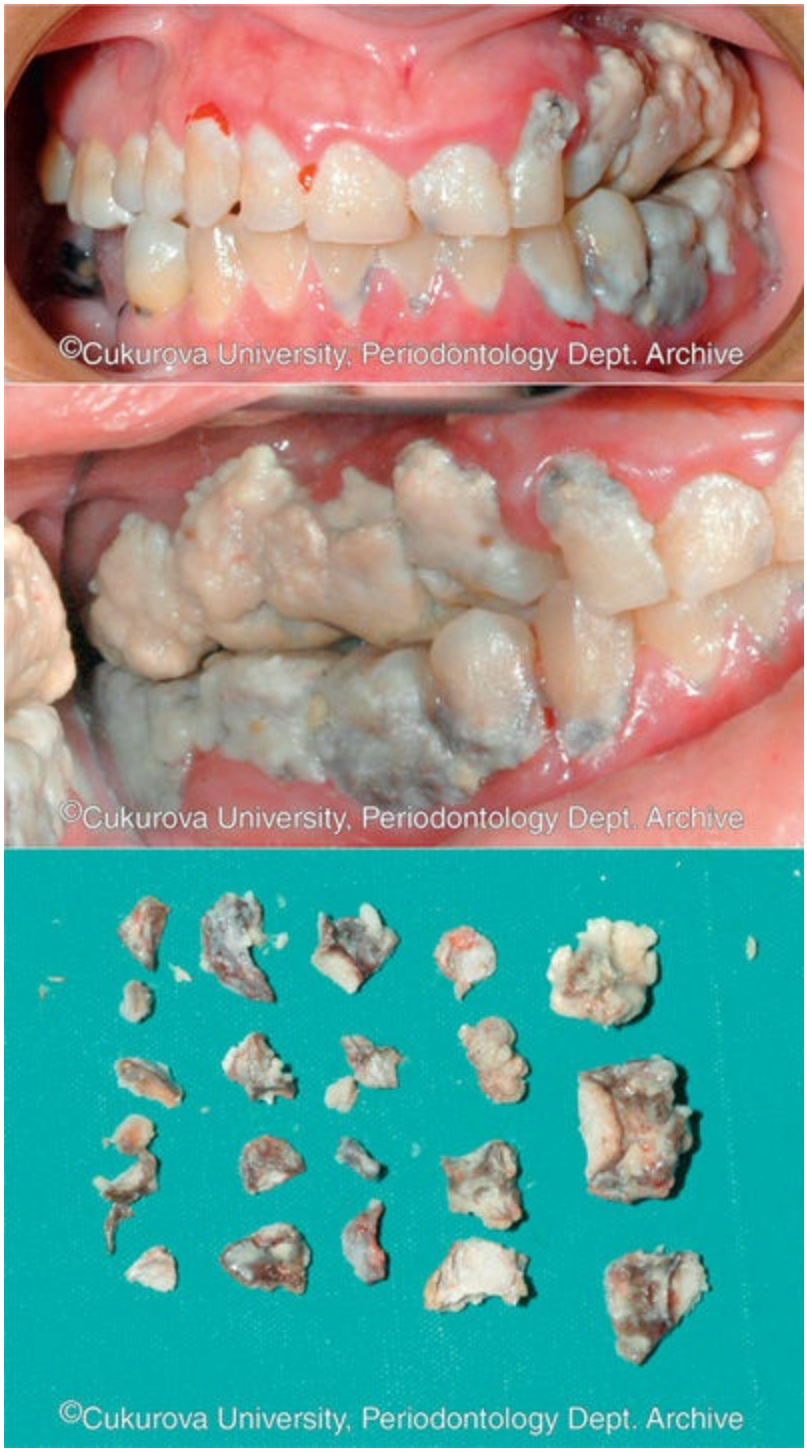

FIG. 88.26 Three views show the extreme plaque and calculus formation that was caused by habitual one-sided chewing in a 35-year-old woman. The patient had avoided chewing on the left side for 10 years.

FIG. 88.27 Extensive plaque and calculus formation was associated with crowding of the teeth in a 21-year-old woman.

FIG. 88.28 Periodontal destruction was associated with class III malocclusion in a 35-year-old man.

FIG. 88.29 Four views show extensive calculus formation in a 9-year-old child with an open bite and lack of hygiene.

FIG. 88.30 Two views show plaque formation and gingival inflammation with crowding and supernumerary teeth in a 14-year-old boy.

FIG. 88.31 Gingival inflammation and enlargement was

associated with chronic habitual mouth breathing in a 16-year-old boy. There is clear demarcation of the affected gingiva.

FIG. 88.32 Two views show extensive plaque and calculus formation in a 27-year-old woman and the same patient after 2 months of receiving initial debridement and oral hygiene instruction. Although the patient still has hygiene problems, the inflammation, redness, and contour of the gingiva are greatly reduced.

Gingival Diseases Modified by Systemic Factors

Endocrine System

Sex Hormones

FIG. 88.33 Puberty gingivitis in a 14-year-old girl was associated with poor hygiene, crowding of teeth, and mouth breathing. Gingival hyperplasia was confined to the anterior regions.

FIG. 88.34 Periodic localized color changes of the gingiva around maxillary anterior teeth were associated with menstruation in a 29-year-old woman.

FIG. 88.35 Localized gingival enlargement occurred in a 24-year-old woman who was in the seventh month of pregnancy. The lesion was first noticed in the fourth month by the patient.

FIG. 88.36 Severe gingival enlargement occurred in a 29-year-old woman who was 8 months pregnant.

FIG. 88.37 Gingival enlargement in a 32-year-old woman in the (A) seventh, (B) eighth, and (C) ninth months of pregnancy and (D) at 1 month after delivery. Notice the progression of the dimensions and the increase of the vascularization of the lesion. (E) The extraoral view shows the lesion interfering with occlusion and aesthetics.

Gingival Diseases Associated With Blood Dyscrasias

Leukemia

FIG. 88.38 Two views show gingival hyperplasia and spontaneous bleeding *(left)* in a 6-year-old boy with newly diagnosed acute myelogenous leukemia and after one course of chemotherapy and periodontal treatment *(right)*.

FIG. 88.39 Enlargement of the gingiva and floor of the mouth occurred in an 8-year-old boy with acute myelogenous leukemia.

FIG. 88.40 Severe gingival inflammation, hyperplasia, and the results of poor hygiene are seen in a 46-year-old man with chronic myelogenous leukemia.

Anemia

FIG. 88.41 Pale gingiva and apparent vascular structures are seen in a 22-year-old woman with iron deficiency anemia.

FIG. 88.42 Severe malocclusion and gingival recession occurred in an 18-year-old boy with thalassemia.

FIG. 88.43 Skeletal disturbance of the thumb *(left)* and severe gingival inflammation with spontaneous bleeding (right) occurred in a 12-year-old boy with Fanconi anemia.

FIG. 88.44 Localized bleeding occurred in the tissue in a 24-year-old woman with Glanzmann thrombasthenia.

FIG. 88.45 Plaque accumulation and spontaneous bleeding occurred in a 28-year-old patient with hemophilia A who neglected oral hygiene procedures due to severe bleeding.

FIG. 88.46 Spontaneous bleeding and clot formation occurred in a 22-year-old man with von Willebrand disease.

Drug-Induced Gingival Diseases

FIG. 88.47 Gingival enlargement was associated with phenytoin use in a 20-year-old patient with epilepsy.

FIG. 88.48 Amlodipine-associated gingival enlargement was seen in a 47-year-old man with hypertension.

FIG. 88.49 Gingival enlargement occurred in a 44-year-old man receiving cyclosporine after kidney transplantation.

FIG. 88.50 (A) In a case of cyclosporine-associated gingival enlargement, the clinical crowns are covered and enlargement reaches up to the occlusal plane. (B) Intraoperative view of the enlargement. Views of the patient after (C) 6 and (D) 12 months. (From Haytac CM, Ustun Y, Essen E, Ozcelik O: Combined treatment approach of gingivectomy and CO2 laser for cyclosporine-induced gingival overgrowth. *Quintessence Int* 38(1):e54-e59, 2007.)

FIG. 88.51 Gingival thickening and hyperplasia occurred in a 25-year-old male bodybuilder who had been using steroid injections for 3 years.

Non–Plaque-Induced Gingival Lesions

Streptococcus Species Infections

FIG. 88.52 Lesions on the lip and gingiva are seen in a 7-year-old child with acute streptococcal gingivostomatitis.

Herpesvirus Infections

FIG. 88.53 Ruptured and unruptured herpetic vesicles *(arrows)* are seen in a 19-year-old male with herpetic gingivostomatitis.

FIG. 88.54 Two views show recurrent aphthous ulcers in a 27-year-old woman.

Gingival Diseases of Fungal Origin

FIG. 88.55 Four views show severe mucositis on the gingiva, cheek, palatal mucosa, and tongue of a 7-year-old boy with acute myelogenous leukemia after remission induction chemotherapy. These lesions are very prone to candidal infections.

FIG. 88.56 Candidal infection of the oral cavity occurred after chemotherapy in a 3-year-old boy with acute myelogenous leukemia.

FIG. 88.57 Mucormycosis caused soft and hard tissue destruction in a 9-year-old patient with acute myelogenous leukemia.

FIG. 88.58 (A) Two views show rapid gingival and alveolar bone destruction caused by mucormycosis infection in a 14-year-old boy with acute myelogenous leukemia. The lesions started on the third day of chemotherapy, and breakdown occurred within 1 week. (B) Histologic analysis used Gomori methenamine silver staining, which showed fungal hyphae. (Courtesy Dr. M. Cem Dogan and Dr. M. Cenk Haytac.)

Gingival Lesions of Genetic Origin

Hereditary Gingival Fibromatosis

FIG. 88.59 Hereditary gingival fibromatosis occurred in a family. Intraoral views of the father were obtained in (A) 2000, (B) 2003, and (C) 2005.

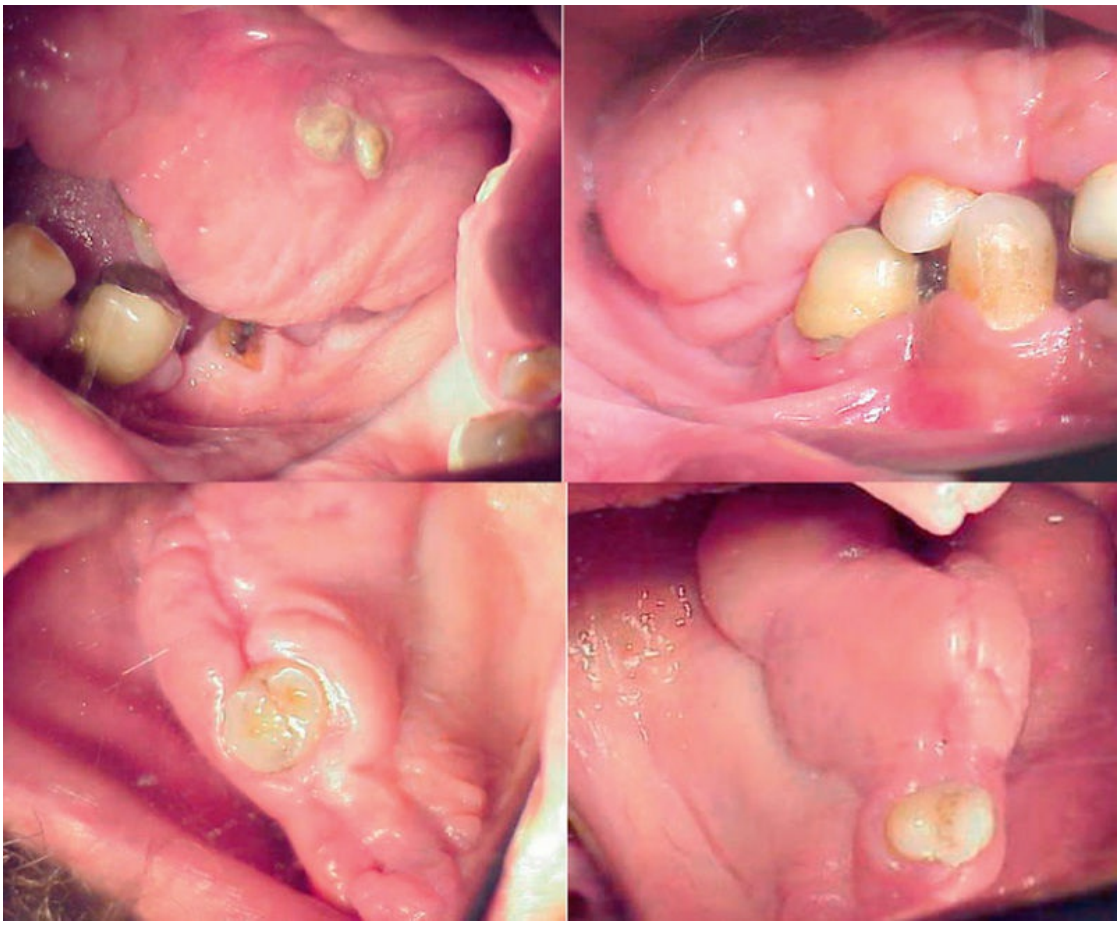

FIG. 88.60 Hereditary gingival fibromatosis occurred in a family. In four views of the father in 2000, notice the severe enlargement of the tuberosities contacting the mandibular ridges and the root fragments in the overgrown tissue.

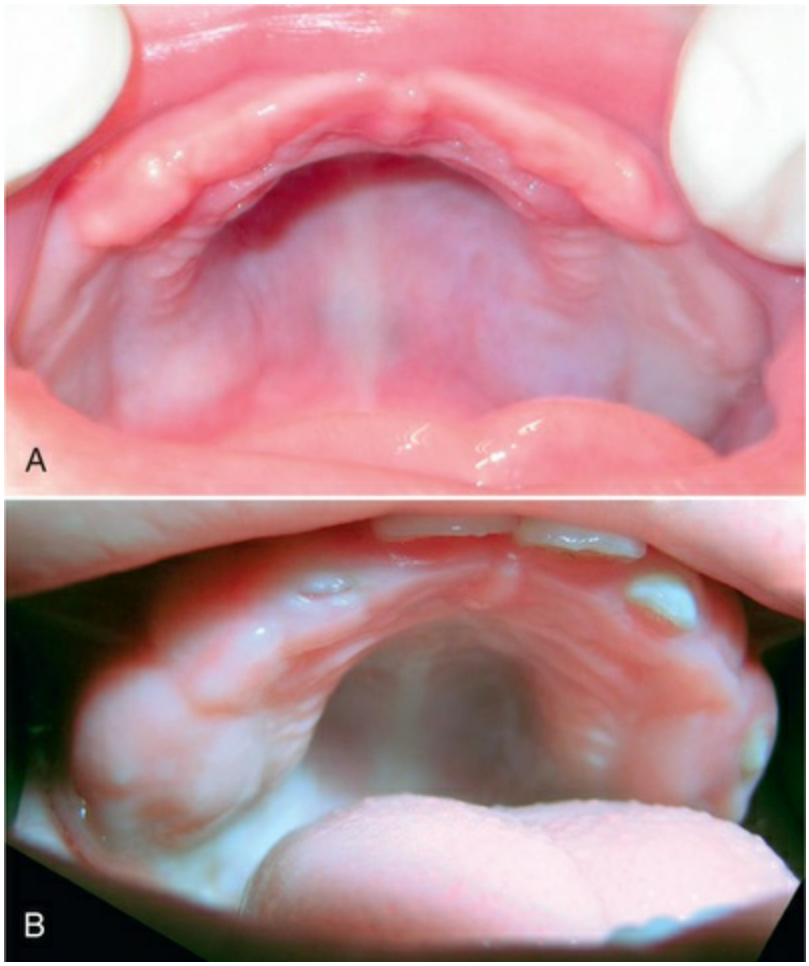

FIG. 88.61 Hereditary gingival fibromatosis occurred in a family. Intraoral views of the younger son show his condition when he was (A) 10 days and (B) 2 years old. (From Haytac MC, Ozcelik O: The phenotypic overlap of syndromes associated with hereditary gingival fibromatosis: follow-up of a family for five years. *Oral Surg Oral Med Oral Pathol Oral Radiol Endodontol* 103:521–527, 2007.)

Gingival Manifestations of Systemic Conditions

Mucocutaneous Lesions

FIG. 88.62 Severe desquamation and positive Nikolsky sign were seen in a 56-year-old woman with lichen planus. Desquamation leaves the connective tissue exposed and painful in response to stimulant agents.

FIG. 88.63 Two views show reticular lichen planus in a 63-year-old woman who was referred because of a complaint of a burning sensation in her mouth.

FIG. 88.64 Two views show desquamation and spontaneous bleeding in a 62-year-old woman with erosive lichen planus. The patient was extremely sensitive to temperature changes and foods.

FIG. 88.65 Two views show atrophic lichen planus that exposed connective tissue in a 62-year-old man.

FIG. 88.66 Three views show pemphigus vulgaris characterized by desquamation, pain, and bleeding in a 56-year-old woman. The suprabasal and subepithelial separation of cells can be detected in the histologic analysis.

Other Systemic Diseases

FIG. 88.67 Four views show developmental deformities of the fingers and limited mouth opening in an 18-year-old boy with scleroderma. Insufficient attached gingival width complicates oral hygiene procedures, and advanced gingival recession is seen on the lower central incisor.

FIG. 88.68 Gingival enlargement occurred in a 9-year-old boy with juvenile hyaline fibromatosis.

FIG. 88.69 Four views show atopic dermatitis characterized by pruritic lesions on the extremities and lips of a 22-year-old woman. Notice the inadequate vestibular depth and gingival recession.

FIG. 88.70 Five views show fibrous dysplasia characterized by unilateral fibroosseous expansion of the bones in a 17-year-old girl. Notice the facial asymmetry, advanced malocclusion, migration of teeth starting from the midline, and gingival enlargement in accordance with expansion of the underlying bones. The radiograph shows unilateral increases of the dimensions of mandible and maxilla.

FIG. 88.71 Three views show Sturge-Weber syndrome characterized by unilateral cavernous hemangiomas on the face and neck of a 35-year-old man. Notice the unilateral soft tissue and easily bleeding gingival enlargement with high vascularization on the affected site.

FIG. 88.72 Three views show Rothmund-Thomson syndrome characterized by photosensitivity and hypopigmentation and hyperpigmentation on the skin of a 16-year-old girl. Notice the decreased keratinization and spontaneous bleeding of the gingiva. Histologic analysis showed discontinuity of the basement membrane. (From Haytac MC, Oztunç H, Mete UO, Kaya M: Rothmund-Thomson syndrome: a case report. *Oral Surg Oral Med Oral Pathol Oral Radiol Endodontol* 94:479–484, 2002.)

FIG. 88.73 Four views show recurrent major aphthous lesions on the cheek and lip mucosa, tongue, and alveolar mucosa in a 42-year-old man with Behçet disease.

Allergies

FIG. 88.74 Four views show results of the oral challenge test for the diagnosis of an allergic reaction of the gingiva to apples in a 48-year-old woman. Notice the formation of blisters, desquamation, and subepithelial bleeding. (From Haytac MC, Ozcelik O: Oral challenge test for the diagnosis of gingival hypersensitivity to apple: a case report. *Oral Surg Oral Med Oral Pathol Oral Radiol Endodontol* 101:317–321, 2006.)

Traumatic Lesions: Factitious, Iatrogenic, and Accidental

FIG. 88.75 Inadequate margins, design, and shape of the restoration violating the biologic width caused severe gingival inflammation in a 32-year-old woman.

FIG. 88.76 Overhanging margins and injury were caused by the self-curing acrylic used for restoration in a 49-year-old woman.

FIG. 88.77 Three views show extensive calculus formation and an ill-fitting restoration on the lower anterior teeth of a 51-year-old man. Notice the trauma caused by the deposits on the sublingual soft tissue seen after the restoration was removed.

FIG. 88.78 Two views show extensive calculus formation under the restoration on the lower anterior teeth of a 44-year-old man. Notice the trauma caused by calculus on the sublingual soft tissue seen after removal.

FIG. 88.79 Subgingival margin locations and lack of

interproximal embrasures of the crowns caused gingival inflammation in a 29-year-old man.

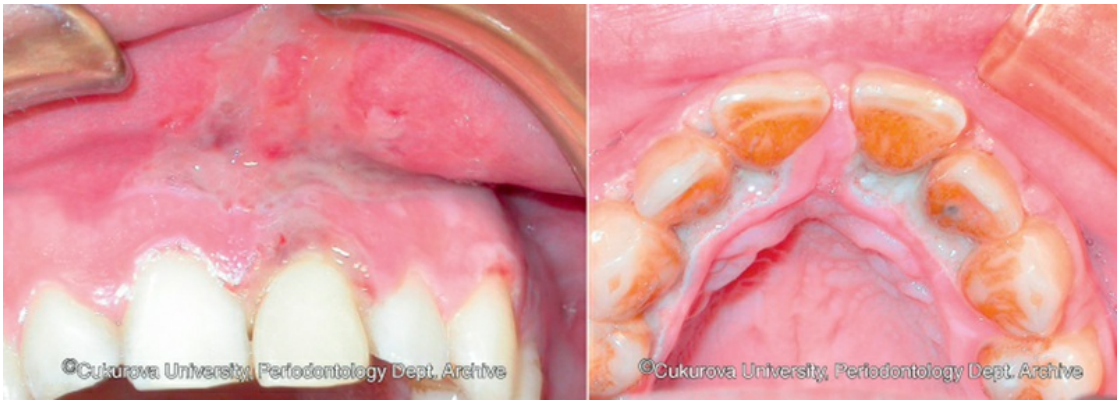

FIG. 88.80 Two views show the results of misuse of ferric sulfate during gingival retraction, which caused burns and desquamation in a 30-year-old man.

FIG. 88.81 Two views show iatrogenic use of a bonding agent for the treatment of dentinal hypersensitivity, causing gingival recession in a 32-year-old woman.

FIG. 88.82 Trauma and inflammation of the soft tissues was caused by the brackets in a 14-year-old orthodontic patient.

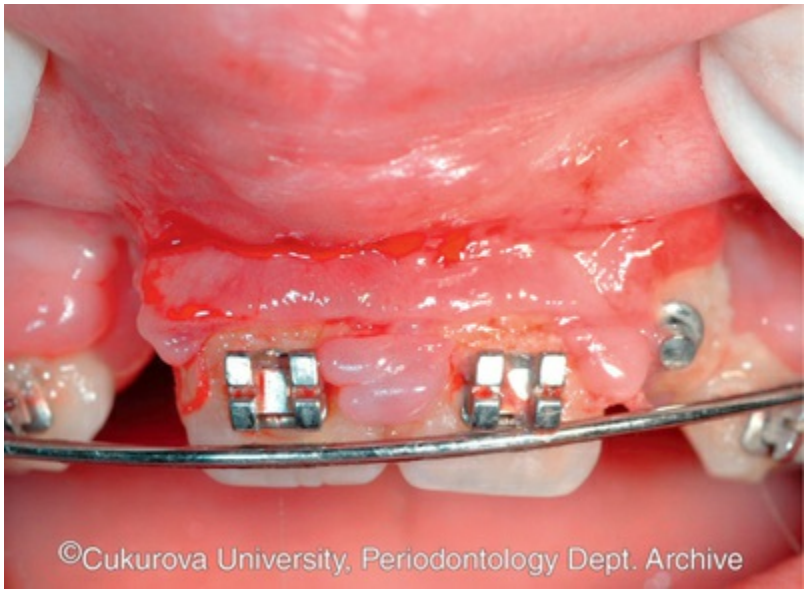

FIG. 88.83 Gingival trauma was caused by the ligature wire in a 12-year-old girl.

FIG. 88.84 Gingival recession was associated with vigorous toothbrushing in a 48-year-old man.

FIG. 88.85 Gingival desquamation after a 21-year-old woman rinsed with cologne.

FIG. 88.86 Hyperkeratosis was associated with smokeless tobacco use in a 42-year-old man.

FIG. 88.87 Desquamation was associated with toothbrushing with soap in a 55-year-old man.

FIG. 88.88 Trauma and desquamation occurred after placing plant seeds on the gingiva for a toothache in a 41-year-old man.

FIG. 88.89 Gingival recession was associated with habitual scratching of the gingiva with a nail in a 26-year-old woman.

FIG. 88.90 Gingival recession was associated with habitual cleansing with tissue in a 42-year-old woman.

FIG. 88.91 Desquamation and burn occurred after a 50-year-old man rinsed with raki, a Turkish drink with a 40% to 50% alcohol content.

FIG. 88.92 A traumatic lesion resulted from placing fresh garlic onto the aching third molar in a 26-year-old man.

Cysts and Tumors

FIG. 88.93 A fibroma in a 45-year-old man had a firm and nodular character.

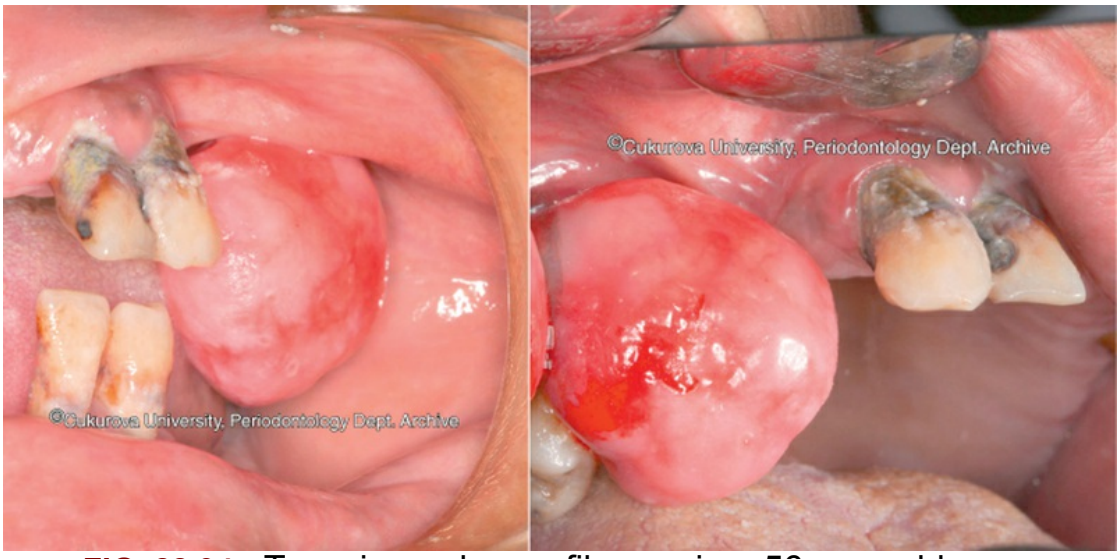

FIG. 88.94 Two views show a fibroma in a 56-year-old man. (Courtesy Dr. Burcu Cam and Dr. Onur Ozcelik.)

FIG. 88.95 A papilloma occurred in a 27-year-old woman.

FIG. 88.96 A papilloma developed on the palatal tissue in a 42-year-old woman.

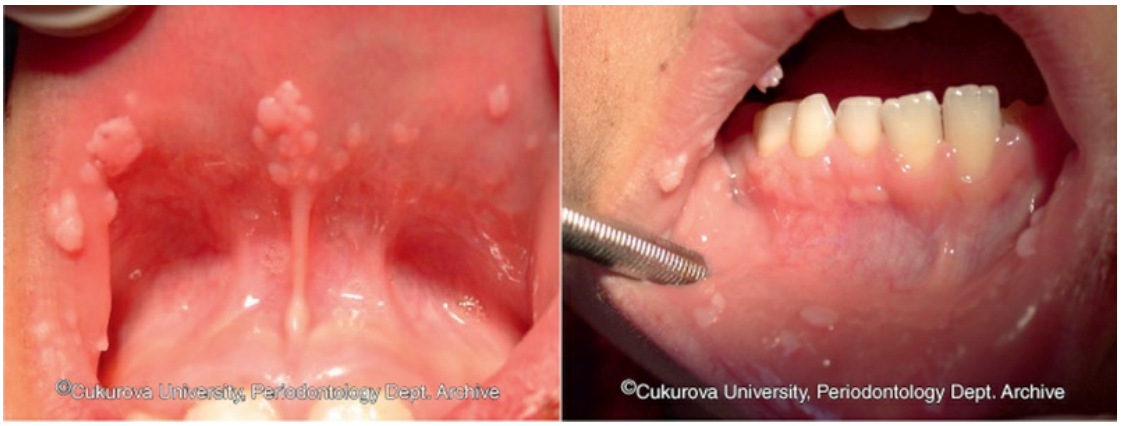

FIG. 88.97 Two views show severe, generalized human papillomavirus–associated warts in a 7-year-old child.

FIG. 88.98 A peripheral giant-cell granuloma was seen in a 31-year-old woman.

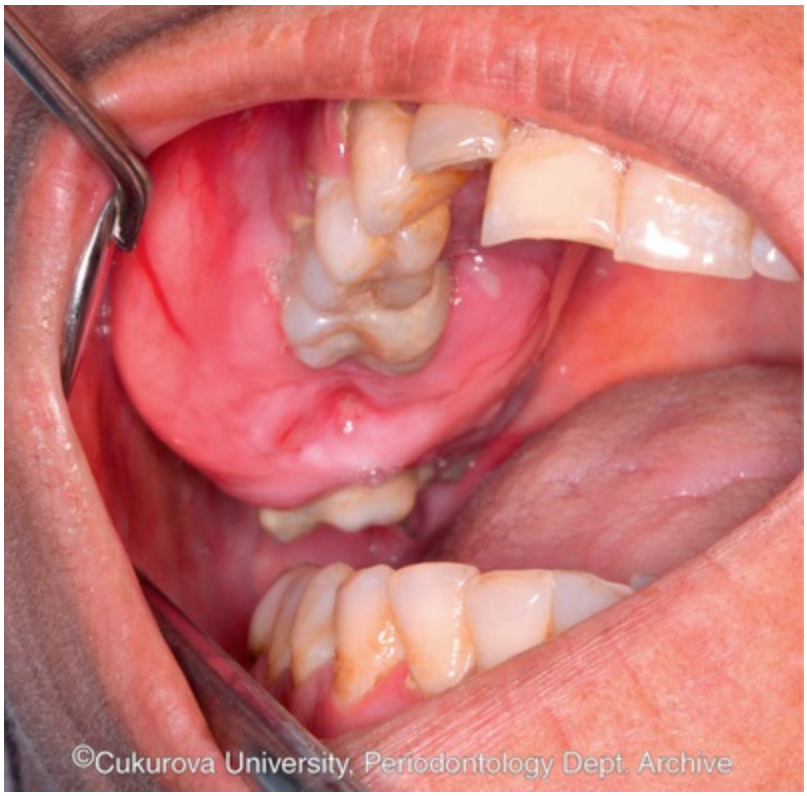

FIG. 88.99 An ameloblastoma occurred in a 54-year-old woman.

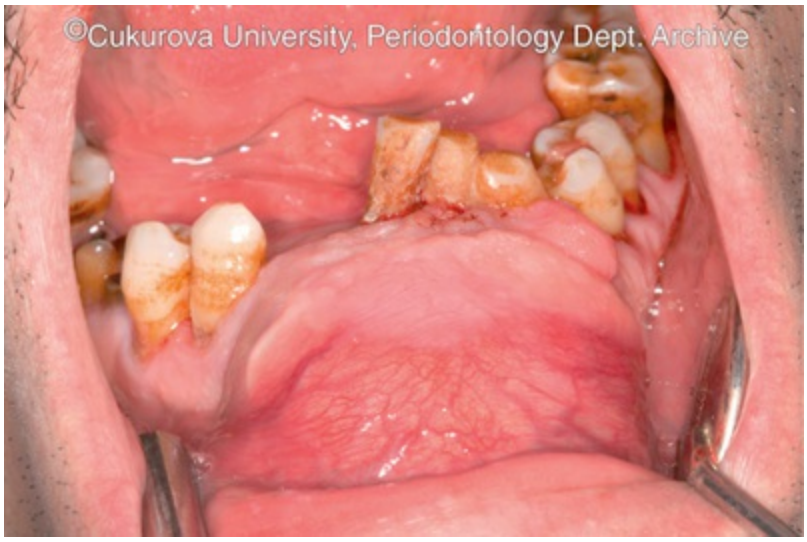

FIG. 88.100 An ameloblastoma was seen in a 49-year-old patient.

FIG. 88.101 Squamous cell carcinoma was detected in a 62-year-old patient.

FIG. 88.102 Malignant melanoma was seen in a 52-year-old woman.

Chronic Periodontitis

FIG. 88.103 Two views show plaque and calculus that caused chronic periodontitis in a 42-year-old man without any systemic diseases. Notice the generalized radiographic bone loss.

FIG. 88.104 Two views show gingival recession, mobility, migration, and extrusion of teeth due to alveolar bone loss in a 48-year-old man with chronic periodontitis.

FIG. 88.105 Advanced chronic periodontitis was seen in a 54-year-old man who had hygiene neglect and smoking as contributing factors.

FIG. 88.106 Generalized bone loss occurred in a 38-year-old woman with moderate chronic periodontitis.

FIG. 88.107 Two views show generalized bone loss that occurred in a 45-year-old male smoker with advanced chronic periodontitis.

FIG. 88.108 (A) Cone-beam computed tomography shows generalized bone loss in a 39-year-old man with advanced chronic periodontitis. (B) Two views show the patient before and 4 months after initial periodontal therapy and extraction of mandibular incisors (*bottom*). There is closure of the diastema between the maxillary central incisors after therapy.

Chronic Periodontitis Modified by Systemic Factors

Diabetes Mellitus

FIG. 88.109 Severe gingival inflammation and periodontal abscess occurred in a 26-year-old woman with type 1 diabetes mellitus. Notice the extrusion of the maxillary left central incisor caused by alveolar bone loss.

FIG. 88.110 Severe inflammation, pus formation, and

periodontal breakdown occurred in a 34-year-old man with uncontrolled type 1 diabetes mellitus.

FIG. 88.111 Two views show the dentition of a 14-year-old girl who was referred with a complaint of tooth mobility. She had spontaneous loss of teeth #11, #31,

#41, and #46 in the past 2 years. The patient had advanced bone loss despite a minimal amount of bacterial plaque and degree 3 mobility of many teeth. She was diagnosed with type 1 diabetes mellitus on consultation.

FIG. 88.112 Three views show alveolar bone loss and severe inflammation with spontaneous bleeding, pus formation, and abscess in a 56-year-old man with type 2 diabetes mellitus who used external insulin for 12 years.

FIG. 88.113 A 28-year-old woman with uncontrolled type 1 diabetes mellitus was referred with complaints of rapid mobility of teeth, severe pain, spontaneous pus, and several abscesses. Her fasting glucose level was 486 mg/dL on the day of referral. (A) Although the lesions resembled abscesses of periodontal origin, the pocket depths and attachment levels were within normal levels. (B) The computed tomography findings and consultation with the infection department confirmed the diagnosis of osteomyelitis. (C) View of the patient after 1 week of blood glucose control in the intensive care unit and hyperbaric oxygen therapy. (D) Although the lesions healed uneventfully, severe malocclusion was evident at the 1-year follow-up examination.

Aggressive Periodontitis

FIG. 88.114 Three views show aggressive periodontitis in a 3-year-old boy without systemic diseases. There is severe alveolar bone destruction of deciduous molar teeth.

FIG. 88.115 Two views show extrusion of the left central incisor in a 21-year-old man with localized aggressive periodontitis. There is severe breakdown of alveolar bone of the incisor and mandibular first molar.

FIG. 88.116 Three views show advanced bone loss in an 18-year-old boy with aggressive periodontitis.

FIG. 88.117 Two views show intrabony defects in a 24-year-old woman with aggressive periodontitis.

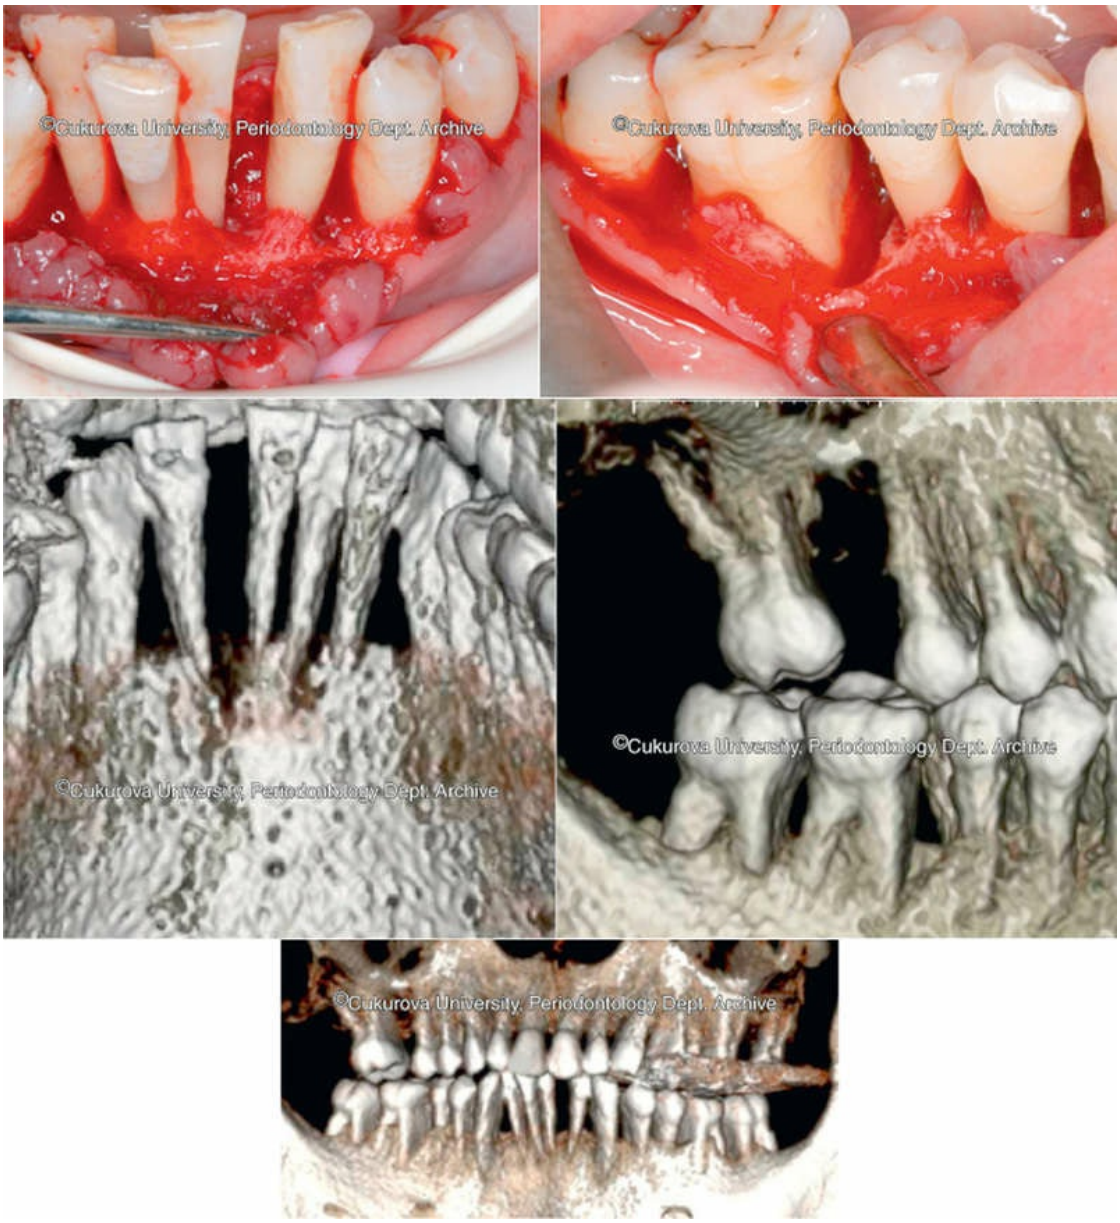

FIG. 88.118 Five clinical and cone-beam computed tomography views show advanced alveolar bone resorption around the incisors and first molar in a 24-year-old man with aggressive periodontitis.

FIG. 88.119 Clinical and radiographic views of a 27-year-old man show generalized aggressive periodontitis at (A) the initial visit and (B) the 5-year follow-up examination after therapy. Cone-beam computed tomography views show (C, D, and F) advanced alveolar bone resorption around incisors, (E) premolars, and (G) first molar.

Periodontitis as a Manifestation of Systemic Diseases

Leukemias

FIG. 88.120 A 12-year-old girl was referred with complaints of rapid swelling on (A) the face and (B) the gingiva, and (C) spontaneous bleeding. The patient also had persistent fever and general malaise for 2 weeks. (D) Radiographic analysis revealed alveolar bone loss and separation of the roots of the maxillary right lateral and canine. Consultation with the hematology department and histologic analysis of the lesion confirmed the diagnosis of granulocytic sarcoma, which can precede acute myelogenous leukemia. (E) Histologically, infiltration of atypical myeloid cells into the gingival tissues was evident (hematoxylin and eosin; original magnification ×100). (F) The lesion regressed significantly after two courses of chemotherapy. (From Antmen B, Haytac MC, Sasmaz I, Dogan MC, Ergin M, Tanyeli A: Granulocytic sarcoma of gingiva: an unusual case with

aleukemic presentation. *J Periodontol* 74:1514–1519, 2003.)

FIG. 88.121 A 14-year-old boy was referred with complaints of rapid mobility of teeth, gingival swelling, persistent fever, and joint pain. (A) Clinical examination

revealed gingival hyperplasia in accordance with the expansion of jawbones and third-degree mobility in many teeth despite minimal bacterial plaque. (B) Bone marrow aspiration biopsy revealed cytoplasmic vacuolization of lymphoblasts specific for acute lymphoblastic leukemia type L3 (May-Grünwald Giemsa stain; original magnification ×100). (C) Radiographically, there was severe bone loss, abnormal trabeculation, and radiolucent areas around roots, which was more prominent on the molar teeth.

(From Haytac MC, Antmen B, Dogan MC, Sasmaz I: Severe alveolar bone loss and gingival hyperplasia as initial manifestation of Burkitt cell type acute lymphoblastic leukemia. *J Periodontol* 74:547–551, 2003.)

FIG. 88.122 Two views show alveolar bone destruction and gingival enlargement around teeth #41, #42, and #43 in a 15-year-old boy with acute lymphocytic leukemia.

Genetic Disorders

FIG. 88.123 A 16-year-old girl who had been receiving treatment for neutropenia for 8 years was referred for gingival inflammation. Two views show severe malocclusion and gingival inflammation, spontaneous bleeding, deep periodontal pockets up to 15 mm, and advanced radiographic alveolar bone loss.

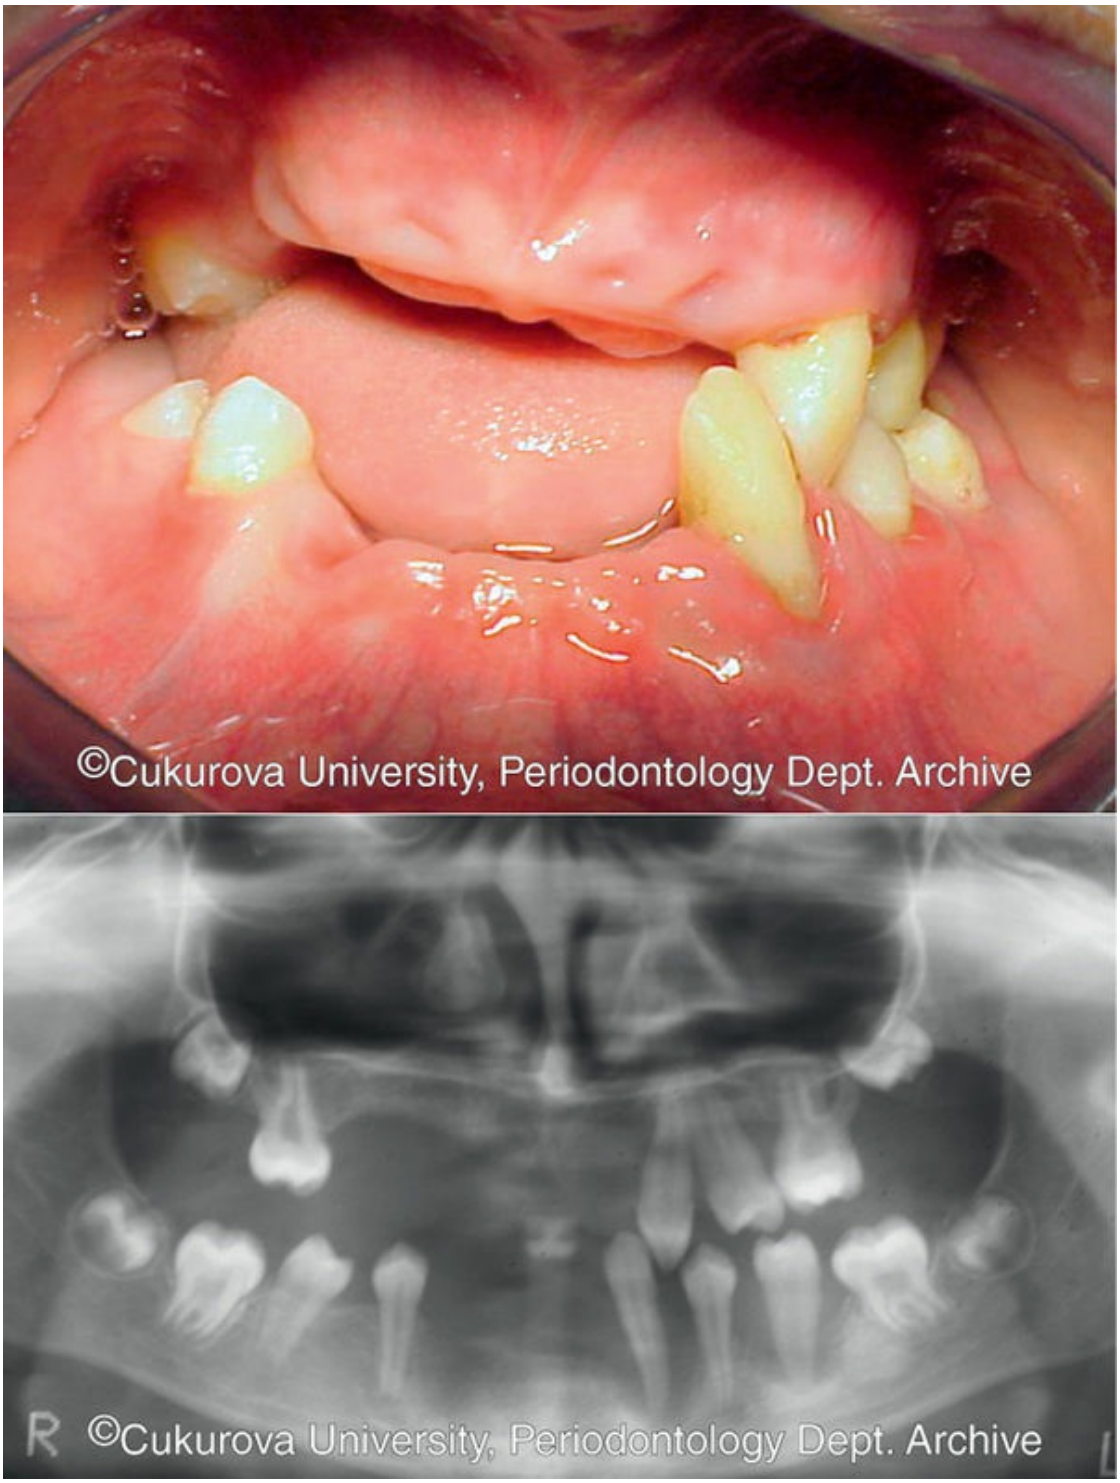

FIG. 88.124 An 11-year-old girl with leukocyte adhesion deficiency was referred to the periodontology department. She had recurrent skin, ear, upper respiratory tract, and lung infections since early childhood and was diagnosed with leukocyte adhesion deficiency (LAD) 4 years earlier. She had one kidney surgically removed due to infection. Two views show severe periodontal breakdown with spontaneous loss of many teeth and advanced bone loss, deep pockets

up to 15 mm, and mobility for the remaining teeth. The patient's elder sister, who was 14 years old, also had LAD and was diagnosed during the same period. The elder sister's periodontal status is shown in Fig. 88.125.

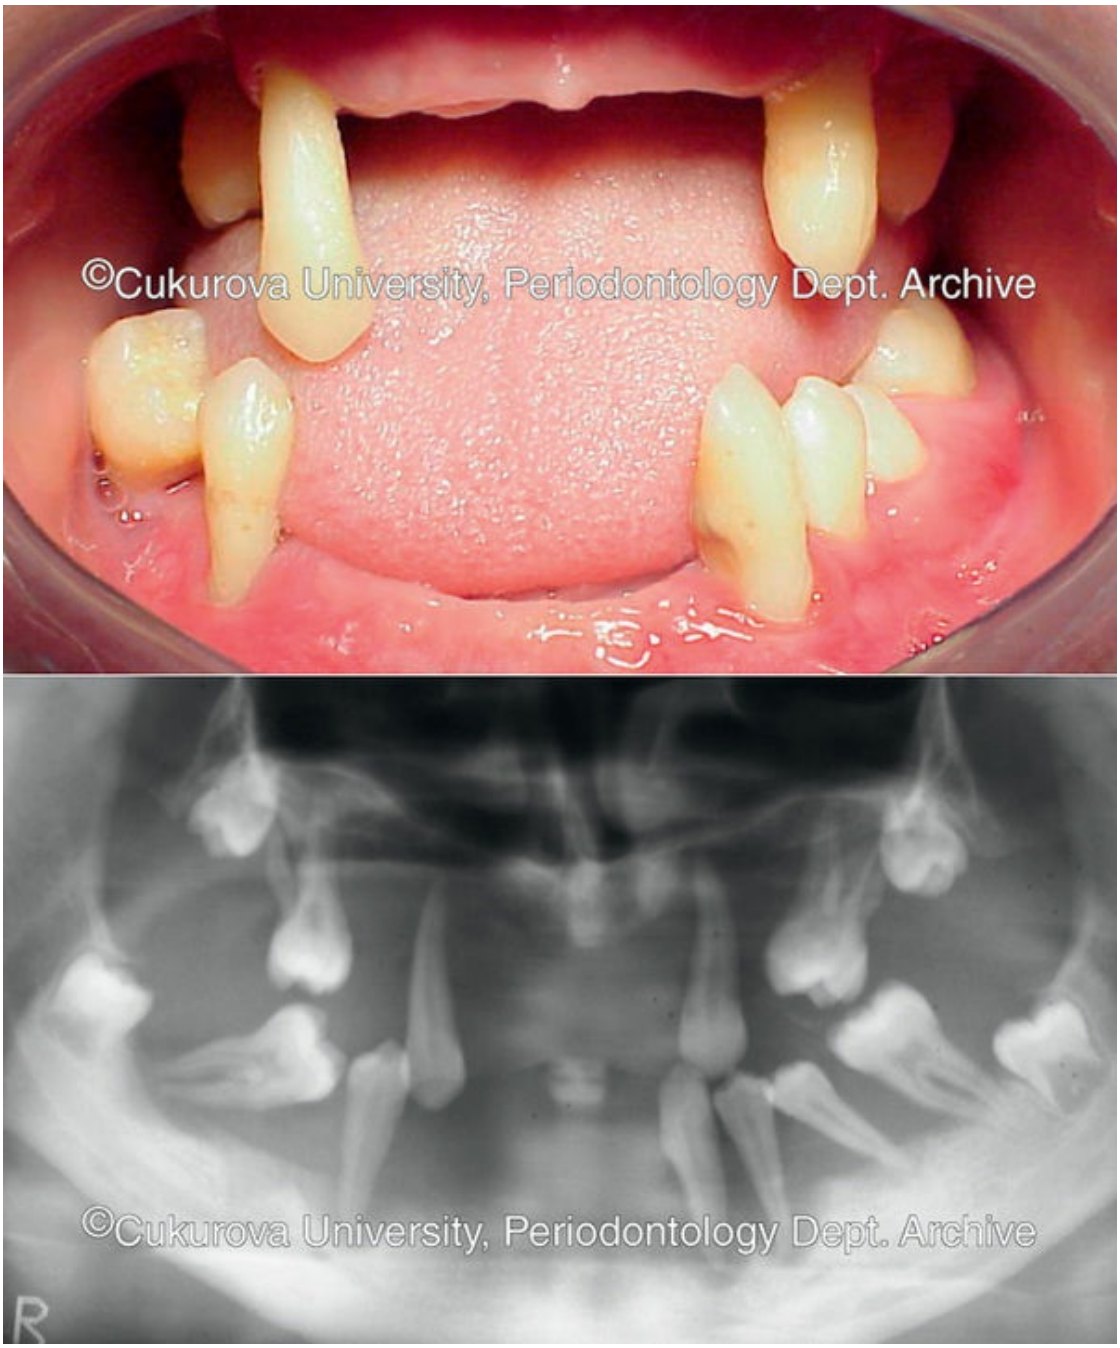

FIG. 88.125 Two views show leukocyte adhesion deficiency in a 14-year-old girl.

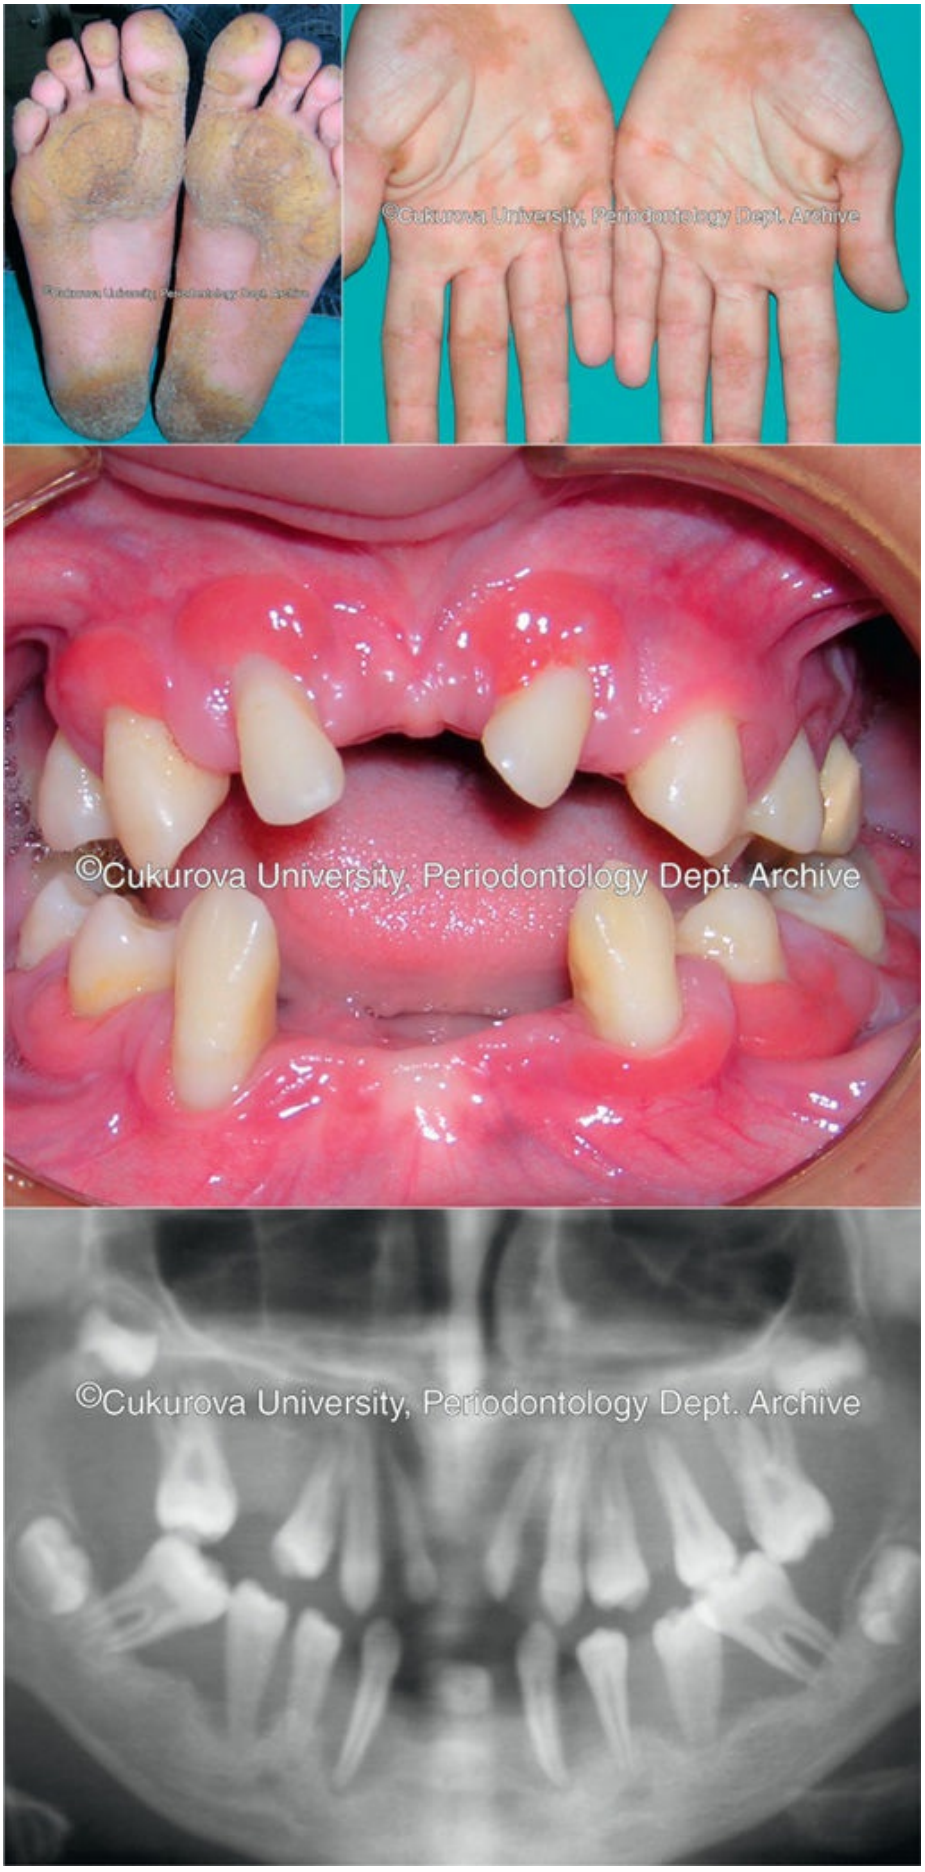
FIG. 88.126 Three views show hyperkeratosis of the palms, loss of anterior teeth, gingival recession, and extensive radiographic alveolar bone loss of deciduous teeth in a 3-year-old boy with Papillon-Lefèvre syndrome.



©Cukurova University, Periodontology Dept. Archive
©Cukurova University, Periodontology Dept. Archive
©Cukurova University, Periodontology Dept. Archive

FIG. 88.127 Three views show effects of Papillon-Lefèvre syndrome in a 12-year-old girl, including hyperkeratosis of the palms and soles. The patient had spontaneous loss of many teeth and deep pockets ranging from 4 to 12 mm on the remaining teeth. Severe alveolar bone destruction is seen in the panoramic radiograph.

FIG. 88.128 Three views show skeletal deformities and gingival inflammation in a 14-year-old girl with hypophosphatasia.

Necrotizing Periodontal Diseases

FIG. 88.129 Typical punched-out appearance of the gingiva *(arrow)* in necrotizing ulcerative gingivitis (NUG) is seen in a 25-year-old man.

FIG. 88.130 Two views show a necrotizing ulcerative gingivitis lesion before and after removal of pseudomembrane in a 27-year-old woman.

FIG. 88.131 Two views show a crater-like lesion and pseudomembrane formation on the palatal gingiva in a 31-year-old man with necrotizing ulcerative gingivitis.

FIG. 88.132 Three views show severe necrotizing ulcerative gingivitis (NUG) and a necrotizing ulcerative periodontitis (NUP) infection that caused extreme pain in a 22-year-old woman on the first, third, and seventh day of referral. Rapid soft tissue destruction exposed the alveolar bone.

Bisphosphonates

FIG. 88.133 Zoledronic acid–related osteonecrosis occurred in a 54-year-old woman who had been using the drug intravenously for breast cancer. The lesion occurred 1 month after extraction of tooth #36.

FIG. 88.134 Three views show rapid gingival and bone necrosis 1 month *(top left)*, 2 months *(top right)*, and 7 months *(bottom)* after scaling and root planing in a 52-year-old woman receiving intravenous zoledronic acid after breast cancer treatment.

Abscesses of Periodontium

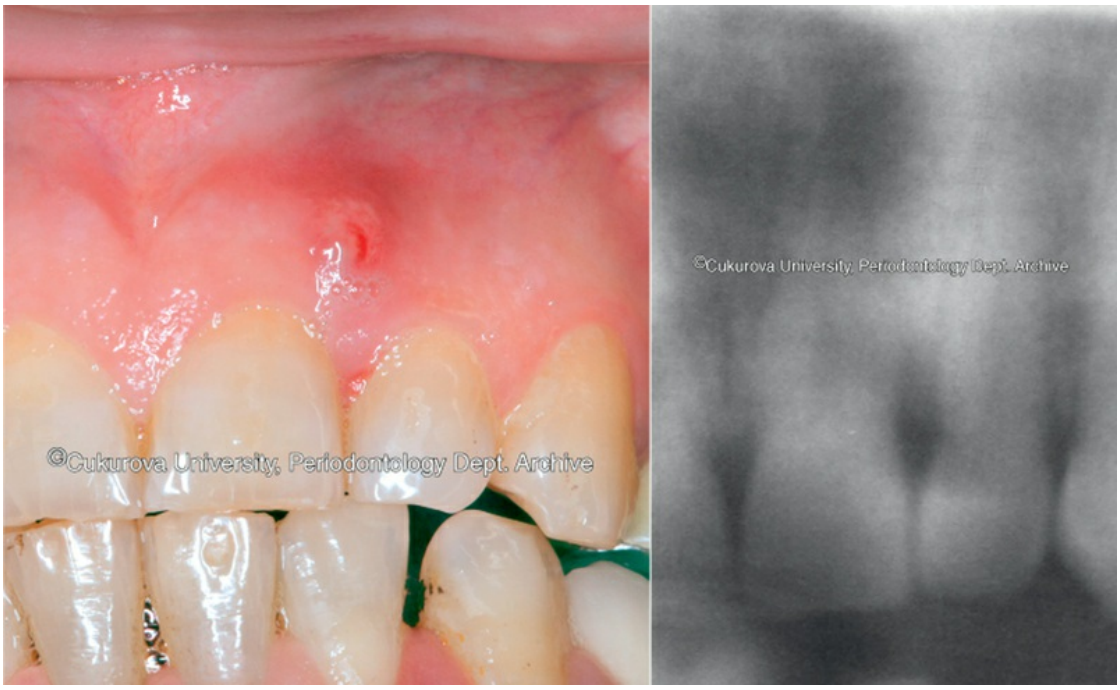


FIG. 88.135 Two views show a periodontal abscess of the left central incisor in a 21-year-old woman with aggressive periodontitis.

FIG. 88.136 Periodontal abscess of the maxillary first molar occurred in a 35-year-old man with chronic periodontitis.

FIG. 88.137 Two views show a periodontal abscess in a 39-year-old woman before and after treatment.

FIG. 88.138 Pericoronitis is seen around a partially erupted mandibular third molar in a 19-year-old girl.

Endodontic-Periodontal Lesions

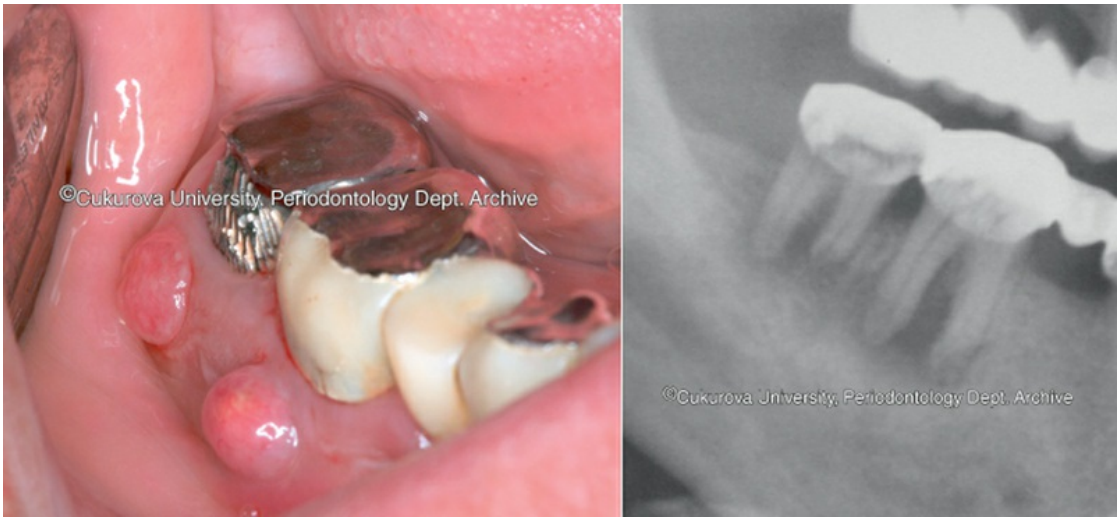

FIG. 88.139 Two views show an endodontic-periodontal lesion in a 36-year-old man.

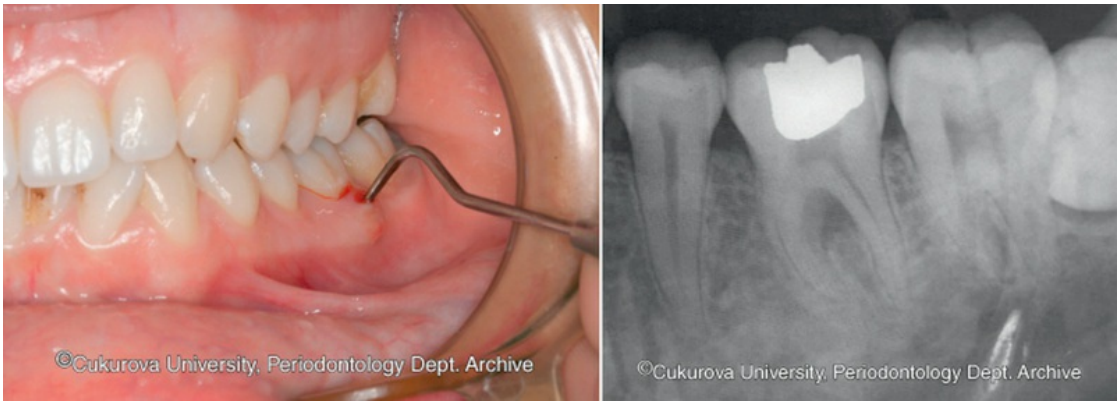

FIG. 88.140 Two views show an endodontic-periodontal lesion in an 18-year-old girl.

periodontal abscess and, 390.*e*3
Gingival augmentation
apical to recession, 663.*e*1–663.*e*7, 663.*e*2*f*
coronal to recession, 663.*e*7–663.*e*17, 663.*e*8*b*, 663.*e*8*f*
Gingival bleeding
acute episodes, 251
chronic bleeding, 250–251
hemorrhagic disorders, 251
increase, 467*b*
local factors, 250–251
medications (relationship), 250*b*
presence of, 381
probing
appearance, 250*f*
usage, 249–250
recurrent bleeding, 250–251
severity, factors, 251
spontaneous bleeding, 251
systemic changes, impact, 251
variation, 249
Gingival cauterization, *e*ii*f*
Gingival connective tissue, 27–30
aging, impact, 52
repair, 28–29
Gingival contour

changes, 255
irregularity, 246*f*
Gingival crevice, tactile examination of, 387–390, 387*b*
Gingival crevicular fluid (GCF), 91, 105, 193, 310*b*
amount, 238
analysis of, 239
cellular elements of, 239, 242*b*
cellular/humoral activity in, 239
chlorhexidine, release, *e*7
circadian periodicity, 239
clinical significance of, 239, 239*b*
collagenase
presence, 568–569
SDD (effect), 571*f*
composition of, 238–239
diagnostic tests of, 238*t*
drugs in, 239–240
electrolytes in, presence of, 239
flow, increase, 186–187
levels of, 235.*e*3
measurement, electronic device, 238*f*
mechanical stimulation of, 239
organic compounds of, 239
periodontal therapy, 239
PGE_2 levels, 469
presence of, 237
sex hormones, 239
smoking and, 239
total protein content of, 239
Gingival curettage, 615.*e*1
Gingival cysts, 267
Gingival desquamation, cologne, impact, *e*81*f*
Gingival discrepancies, orthodontic treatment, 583.*e*9–583.*e*11

Gingival diseases, 55–61, 57*b*
atlas of, *e*48*b*–*e*49*b*
bacterial origin, 59–60
dental-plaque-induced gingival diseases, 55–59
drug-induced, *e*64
fungal origin, 60–61, *e*67, *e*67*f*–*e*68*f*
genetic origin, 61
malnutrition, impact, 423
modification
malnutrition, impact, 59
medications, impact, 58–59
systemic factors, impact, 58
non-plaque-induced, *e*48*b*–*e*49*b*, *e*65–*e*67
plaque-induced, *e*48*b*–*e*49*b*, *e*49–*e*51
prognosis, 422–423
systemic factors, impact, *e*59
viral origin, 60
Gingival disturbances, blood dyscrasias (association), 213
Gingival embrasures
correction, 703.*e*1, 703.*e*1*f*
with gingival recession, management of, 703.*e*1–703.*e*2
volume, papillary form (relationship), 703*f*
Gingival enlargement, 256–267, 422, 267.*e*1*b*–267.*e*2*b*, 267.*e*1*f*–267.*e*2*f*
acute lymphocytic leukemia, *e*98*f*
antibiotics administration, 629*b*
cyclosporine and, *e*64*f*
drug-associated gingival enlargement, 628–631
false, 265
flap surgery, 631*b*
forms of, 265–267
inflammatory, 257–259
involvement, impact, 260*f*
juvenile hyaline fibromatosis, *e*74*f*
microscopic view of, 261*f*

in mouth breather, 258*f*
phenytoin therapy in, impact of, 261*f*
pregnancy and, *e*60*f*–*e*61*f*
recurrence, 632–635
substitute drug, prescribing, 629*b*
treatment, 628–635, 635.*e*1*b*–635.*e*2*b*, 635.*e*1*f*–635.*e*2*f*

cleaning, 528
coating, 522, 522*f*, 523*b*
of dorsum, 382, 383*f*
crenulations (scalloped borders), 458
dorsum, 113
intraoral habitats, 117*t*
left lateral border, oral hairy leukoplakia, 368*f*
Miyazaki tongue coating index, 528*f*
pressure, pathologic migration (association), 336*f*
Tongue surface
free energy, clinical impact (photographs), 127*f*
irregularities, 127*f*
microorganism, adherence, 125*f*
microroughness, 127, 128*f*
plaque-bacteria association, depiction, 120*f*
roughness, clinical impact (photographs), 127*f*
Tongue thrusting, 200, 201*f*
Tonsils, 113
Tooth aspiration, potential danger, 476.*e*5*f*
Tooth-associated cervical plaque, root cementum (adherence), 121
Tooth-blade relationships, 545.*e*6
Tooth extraction, 802
example, 417*f*
microsurgical tooth extraction, 824, 825*f*
Piezosurgery for, 836–837, 836*t*, 839.*e*6*b*, 839.*e*6*f*, 837.*e*1*f*
site, implant drilling, 824–825, 825*f*
Tooth loss
advanced periodontal disease, 727*f*–728*f*
predictors, 188
prolongation of, 764
untreated periodontal disease, 730*f*

Tooth mobility, 391–392, 391*f*, 392*b*, 419, 419*b*, 605
causes, 419
complaint, *e*89*f*, *e*98*f*
increased, 333
tactile/visual testing for, 578*f*
testing for, 577, 577*b*, 579*b*
Tooth mortality, 726–729, 726*t*
average tooth loss, 728*f*–730*f*
periodontal treatment, 727*f*
posttreatment, 727*t*
therapy initiation, 728*f*
untreated periodontitis patients, 731*t*
Tooth pain, mandibular repositioning devices and, 463.*e*2
Tooth surface, 587
microbial populations, 119
Toothbrush, 512–513
design, 512*b*, 513, 513*f*
options, 513*f*
manual, 512*f*
powered, 513–514
recommendation, 512–513, 513*b*
use of, instruction and demonstration on, 520.*e*5–520.*e*6
Toothbrushing
abrasive dentifrice, with, 514*f*
impact, 253
importance of, 528
methods, 514–516, 516*b*
soap toothbrushing, desquamation and, *e*82*f*
Trackers, 844.*e*1–844.*e*2
Tracking device, 845
Tranexamic acid, 452
Transalveolar approach, L-PRF and, for sinus augmentation,

671.e2f, 671.e3b, 671.e5f
Transcription, 168t–169t
Transforming growth factor-β(TGF-β) superfamily, 815.e1
Transfusion-transmitted virus (TTV), 456.e3
Transgingival interdental probing depth, usage, 611
Transgingival probing, 390.e1, 390.e3f
usage, 641
Transgingival sounding, 653
Translation, 168t–169t
Transmandibular implants, 733.e2
Transseptal fibers, 27
interproximal extension, 34
reformation, 318f, 320b
Trauma from occlusion, 321, 392, 405–406
clinical and radiographic signs of, 333–334
definition of, 328–330, 328b, 333b
impact, 47
injury phase, 406
repair phase, 406
Trauma, site, irrigation (usage), 3f
Traumatic forces, occurrence of, 330f
Traumatic lesions, 61, 253–254
evolution of, 332f
result, 406
reversibility of, 331
types, e79
Traumatic occlusion, 328
Treatment
benefit, obtaining (likelihood), 375
biologic mechanisms, understanding, 375–376

clinical relevance, determination, 376
clinical significance, assessment, 375
effect, size, 375, 375*b*
phase, 439.*e*4
success, 179, 179*f*
Treatment plan, 426–430, 426*b*, 430*b*
explanation, 427–429
overall, 427
therapy, sequence of, 427, 427*b*–428*b*, 428*f*–429*f*
Treponema denticola (spirochete), 195, 349
culture difficulty, 114*f*–115*f*
Treponema microdentium (cultivated strains), 269
Treponema pallidum (syphilis), 59–60
Triacylated lipoproteins, 154
Triangular wooden tips, 519*f*
Triazolam, 439.*e*1, 439.*e*1*t*
anxiolytic dosing guidelines for, 439.*e*2*t*
precautions and drug interactions, 439.*e*1*b*
prescription, sample, 439.*e*3*f*
Tricalcium phosphate (TCP), 647.*e*1
Trichomonas tenax, 136
Triclosan, 529, 520.*e*3
Trimethylaminuria, 523.*e*1
True endpoints, 83
TTV, Transfusion-transmitted virus
Tuberculosis, 456.*e*3
Tumor-like inflammatory enlargements, 628
appearance, 629*f*
Tumor necrosis factor, 175
Tumor necrosis factor alpha, 98–99

Tumors, *e*83
Twin studies, 171*t*
2-mm twist drill, 788
Two-phase oil-water rinse, 529
Two-stage implant placement, 785–792
flap closure and suturing for, 789
flap design, incisions, and elevation for, 785*f*, 786–788, 787*f*
implant site preparation for, 786*f*, 788–789, 788*b*, 788*f*
one-stage implant placement *versus*, 784–785, 785*f*
postoperative care for, 790
second-stage exposure surgery for, 790–792, 790*b*
Two-wall angular defects, 636
Two-walled defects/craters, 638–639
Tx methods, 179
Type 1 anatomy, 836
Type 1 diabetes
abscess, presence, 212*f*
medical management, interindividual variability, 234
Type 1 diabetes mellitus, 208–209
gingival inflammation/periodontal abscess, impact, *e*88*f*
Type 2 anatomy, 837
Type 2 diabetes, 163.*e*1
longitudinal study of, 234
long-term history of, 211*f*
Pima Indians, 210–211
therapeutic actions for, 164*t*
Type 2 diabetes mellitus, 209
alveolar bone loss/inflammation, *e*90*f*
Type 3 anatomy, 837
Type 4 anatomy, 837

Type I error rates, 13
control, *e*27
Type II error rates, 13

U

U15/30 scaler, 533
ends, 533*f*
UISP, Ultrasonic implant site preparation
Ulcerated lateral pocket wall, view, 307*f*
Ulcerated suprabony periodontal pockets, interdental papilla, 310*f*
Ulcerative lesions (erosive lesions), 291
Ulcerative stomatitis, chronic, 289*t*, 291*t*, 298–299, 299*b*
appearance, 298*f*
diagnosis, 298–299
direct immunofluorescence, 298*f*
histopathology, 298
immunofluorescence, 298
oral lesions, 298
treatment, 299
Ultrasonic cutting
clinical characteristics, 831–833
healing, 833, 833*b*
microprecision, 831, 832*f*
selective cutting, 831–832
visibility, 832–833, 833*b*
Ultrasonic implant site preparation (UISP), 837
advantages, 837–839
Ultrasonic instrumentation, 546–554, 545.*e*21–545.*e*23, 545.*e*21*b*–545.*e*22*b*
technique, 545.*e*22–545.*e*23, 545.*e*22*b*
Ultrasonic scalers, 555, 830*b*

Ultrasound, usage, 830
Ultra-thin ceramic veneers, 700*f*
Unattached plaque zone, 311
Uncontrolled type 1 diabetes mellitus
appearance, *e*88*f*
complaints, *e*91*f*
Undisplaced flap, 619–620
internal bevel incision, initiation, 619, 619*f*
Unfavorable prognosis, 413
Unilateral fibroosseous expansion, *e*76*f*
United States, *e*vi
periodontal education in, *e*vii–*e*viii
periodontitis (prevalence) in, 348*f*–349*f*
Universal curettes, 534, 534*b*, 535*f*–536*f*, 545.*e*8, 545.*e*8*b*, 545.*e*8*f*
area-specific curettes, comparison, 536*t*
Gracey curettes, differences, 535
types, 534*f*
Unmounted stones, 545.*e*24
Unreplaced missing teeth, 334–335
Unruptured herpetic vesicles, *e*66*f*
Upper molars, calculus formation, *e*54*f*
Upper premolar, circumferential vertical defect, 321*f*
Upper right central incisor, periodontal abscess, 314*f*
Upper second premolar/molars, facial aspect, 321*f*
Urea, 528.*e*1
Urinary tract infections (women), 116
Urticaria, 224.*e*3
Uvula, ulcerations, 371*f*
Uvulopalatopharyngoplasty, 460

V

Valproic acid, 260

Varenicline, usage, 185*b*

Varicella zoster virus (VZV), 60*b*, 134*t*–135*t*

Vascular cell adhesion molecule-1 (VCAM-1), 231

Vascular supply, inflammation and, 738–739, 739*f*

Vasoconstrictor, usage, 601

VCAM-1, Vascular cell adhesion molecule-1

VDR, Vitamin D receptor

Veillonella parvula (anaerobic gram-negative small cocci), 114*f*–115*f*

Veneers, 700*f*

Venous drainage, 49

Venous leg ulcers, L-PRF application for, 668.*e*1, 668.*e*2*f*–668.*e*3*f*

Vertical bite-wing films, usage, 399*f*

Vertical bone augmentation, 813–815

  guided bone regeneration for, 813–815, 814*f*

Vertical bone height deficiency, 806

Vertical bone loss, 648*f*

  mandibular implants, impact, 855*f*

Vertical defects (bone), 322–325, 323*f*

Vertical grooving, 641.*e*2

  advantages, 641.*e*2

Vertical incisions, 612

  avoidance, 612, 613*f*

Vertical maxillary excess, 663.*e*20–663.*e*23

Vertical orthodontic tooth repositioning, 582, 583*b*

Vertical ridge, sinus bone augmentation and, 815*b*, 813.*e*1*f*–813.*e*2*f*

Vesalius, Andreas, *e*ii

Vesicular lesions (bullous lesions), 291
Vestibular depth, 663.*e*17
inadequacy, *e*75*f*
reestablishment, 78*f*
Vestibular fornix, mucogingival ridge defect, 78*f*
Veterans Affairs Dental Longitudinal Study, 228
Vienna school, *e*v
Vincent angina, 271, *e*v
Vincent, Hyacinthe Jean, *e*v
Viruses, presence, 133–136
Viscoelastic system theory, 36
Visibility, 545.*e*1–545.*e*2
Visual acuity, microsurgery and, 677, 677*f*
Visual periodontal examination, 383
Vital root resection, 658.*e*2
Vitamin A deficiency, 220.*e*1
Vitamin C deficiency, 263, 264*f*, 220.*e*2–3
epidemiologic studies of, 220.*e*2
etiologic factors of, 220.*e*2
gingivitis in, 220.*e*2
periodontitis in, 220.*e*2–220.*e*3
Vitamin D deficiency, 220.*e*1
Vitamin D receptor (VDR), 175
Vitamin E deficiency, 220.*e*1
Volatile sulfur compounds (VSCs), 522, 523*b*
conversion of, 529–530
von Recklinghausen disease, Neurofibromatosis
von Willebrand disease, 450
spontaneous bleeding/clot formation, *e*64*f*

von Willebrand factor antigen, increase, 230
VPro5, 583.e21
VSCs, Volatile sulfur compounds
VZV, Varicella zoster virus

W

Waerhaug, Jens, evii*f*
Wasting, definition, 390
Wasting disease, of teeth, 390–391
Water-soluble vitamin deficiency, 220.e1–220.e3
WBCs, White blood cells
Weakness, feeling of, 604
Wegener granulomatosis, 264, 264*f*, 302.e1
  appearance, 302.e1*f*
Wells, Horace, eiii–eiv
Weski, Oskar, ev
Western blot (WB), for HIV, 365.e3–365.e4
Wettability, 733.e6
Wharton duct, e55*f*
White aesthetic score, 847
White blood cells (WBCs)
  count, reduction, 216
  involvement, 213
Wide-diameter implants, 747*f*
  case presentation, 823.e4
  dental history and complaints, 823.e4
  examination and diagnosis, 823.e4–823.e6, 823.e5*f*
  surgical procedure, 823.e6
  treatment

objectives, 823.e6
options, 823.e6
plan and rationale, 823.e6
sequence, 823.e6
Widow's peaks (line-angle inconsistencies), removal, 639
Wilckodontics, 583.e20
Window technique, L-PRF and, for sinus augmentation, 671.e1f, 671.e2b, 671.e5f
"Witch's chin", 794.e4
Women, urinary tract infections, 116
Wooden toothpick, 518–519, 519f
Woodson periosteal elevator, 607f
Working side, 576
Woven bone, 734, 734b, 734f
characterization of, 733.e7f

X

Xenografts, 645–646, 651.e2t
Xerostomia, 206, 242b, 476.e7, 476.e7f
complaint, 470
HIV and, 369
mandibular repositioning devices and, 463.e1
screening
sialometry, 476.e9t
tongue blade to measure saliva for, 476.e10f

Y

Yeasts, 136

Z

Zaleplon, 439.e1, 439.e1t

anxiolytic dosing guidelines for, 439.e2, 439.e2t
precautions and drug interactions, 439.e1b
prescription, sample, 439.e2f
Zene Artzney, eii
Zidovudine, drug-induced hyperpigmentation, 369f
Zinc, 529
Zinc oxide-eugenol dressing, 602
Zirconia abutments, 773f, 778, 779f
Znamensky, eiv
Zoledronate (Zometa), 221t
Zoledronic acid-related osteonecrosis, e106f–e107f
Zonae occludens, 22.e1
Zygomatic process, 593

About the Book 69
About The Authors 71
Michael G. Newman, DDS, FACD 71
Henry H. Takei, DDS, MS, FACD 72
Perry R. Klokkevold, DDS, MS, FACD 74
Fermin A. Carranza, DR ODONT, FACD 75
Preface 77
Acknowledgments 79
Video Contents 83
Introduction: The Historical Background of Periodontology 85
Chapter Outline 85
Early Civilizations 86
The Classical World 86
The Middle Ages 87
The Renaissance 89
The Eighteenth Century 91
The Nineteenth Century 93
The Twentieth Century 98
The History of This Book 108
References 109
Part 1 Evidence-Based Practice 113
Chapter 1 Evidence-Based Decision Making 114

Background and Definition 115
Principles of Evidence-Based Decision Making 117
Evidence-Based Decision-Making Process and Skills 119
Conclusion 138
References 138
Chapter 2 Critical Thinking 142
Twelve Tools for Assessing Evidence 143
Conclusion 171
References 171
Part 2 Biologic Basis of Periodontology 179
Section I Normal Periodontium 180
Chapter 3 Anatomy, Structure, and Function of the Periodontium 181
Oral Mucosa 182
Gingiva 182
Periodontal Ligament 228
Cementum 244
Alveolar Process 258
Development of the Attachment Apparatus 273
External Forces and the Periodontium 276
Vascularization of the Supporting Structures 279
References 282
Chapter 4 Aging and the Periodontium 306
Effects of Aging on the Periodontium 308
Effects of Aging on the Progression of Periodontal Diseases 316
Aging and the Response to Treatment of the Periodontium 317
References 320
Section II Classification and Epidemiology of Periodontal Diseases 325
Chapter 5 Classification of Diseases and Conditions Affecting the Periodontium 326
Gingival Diseases 330
Periodontitis 346

Medication-Related Osteonecrosis of the Jaw 370
Necrotizing Periodontal Diseases 373
Abscesses of the Periodontium 376
Periodontitis Associated With Endodontic Lesions 376
Developmental or Acquired Deformities and Conditions 379
References 396
Chapter 6 Fundamentals in the Methods of Periodontal Disease Epidemiology 400
The Need for Epidemiology 400
Epidemiologic Study Designs 414
Causes 418
Diagnosis 422
References 426
Section III Etiology of Periodontal Disease 433
Chapter 7 Periodontal Disease Pathogenesis 434
Histopathology of Periodontal Disease 438
Inflammatory Responses in the Periodontium 451
Linking Pathogenesis to Clinical Signs of Disease 472
Resolution of Inflammation 477
Immune Responses in Periodontal Pathogenesis 479
Concept of Host Susceptibility 501
References 510
Chapter 8 Biofilm and Periodontal Microbiology 528
The Oral Cavity From a Microbe's Perspective 534
Bacteria and Their Biofilm Mode of Living 542
Characteristics of Biofilm Bacteria (Life in “Slime City”) 579
Bacterial Transmission and Translocation 587
Nonbacterial Inhabitants of the Oral Cavity 591
Microbiologic Specificity of Periodontal Diseases 606
The Transition From Health to Disease 619
Virulence Factors of Periodontopathogens 639
Future Advances in Periodontal Microbiology 647
References 652
Chapter 9 Practical Molecular Biology of Host–Microbe 692

Interactions 692
Microbe-Associated Molecular Patterns 693
Toll-Like Receptors 697
Nucleotide-Binding Oligomerization Domain–Like Receptors 703
Complement System 707
Antimicrobial Peptides 711
Immunomodulatory Therapies 713
References 714
Chapter 10 Resolution of Inflammation 734
Inflammation 735
Acute Inflammation Is Self-Limited 738
Unresolved Chronic Inflammation in Periodontal Diseases 744
Systemic Link 746
Therapeutic Actions of Resolution Mediators 753
Final Remarks 756
References 759
Chapter 11 Precision Dentistry 769
Genomic Advances in the 21st Century 1098
Genetic Basis for Individual Differences in Disease Risk 1113
Precision Dentistry: Using Genetics for Personalized Treatment 1132
Acknowledgments 1136
References 1138
Chapter 12 Smoking and Periodontal Disease 1145
The Smoking Epidemic 1145
Effects of Smoking on the Prevalence and Severity of Periodontal Diseases 1150
Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease 1161
Effects of Smoking on the Response to Periodontal Therapy 1166
Effects of Smoking Cessation on Periodontal Treatment 1171

References 1176
Chapter 13 The Role of Dental Calculus and Other Local Predisposing Factors 1189
Calculus 1189
Other Predisposing Factors 1208
References 1244
Section IV Relationship between Periodontal Disease and Systemic Heath 1262
Chapter 14 Influence of Systemic Conditions 1263
Endocrine Disorders and Hormonal Changes 1264
Hematologic Disorders and Immune Deficiencies 1283
Genetic Disorders 1303
Stress and Psychosomatic Disorders 1309
Nutritional Influences 1315
Medications 1324
Other Systemic Conditions 1335
Conclusion 1345
References 1347
Chapter 15 Impact of Periodontal Infection on Systemic Health 1370
Pathobiology of Periodontitis 1371
Focal Infection Theory Revisited 1375
Evidence-Based Clinical Practice 1376
Subgingival Environment as a Reservoir for Bacteria 1380
Periodontal Disease and Mortality 1380
Periodontal Disease, Coronary Heart Disease, and Atherosclerosis 1382
Periodontal Disease and Stroke 1397
Periodontal Disease and Diabetes Mellitus 1399
Periodontal Disease and Pregnancy Outcome 1405
Periodontal Disease and Chronic Obstructive Pulmonary Disease 1415
Periodontal Disease and Acute Respiratory Infections 1416
Periodontal Disease and Asthma 1419
Periodontal Medicine in Clinical Practice 1419

Periodontal Medicine in Clinical Practice 1419
Conclusions 1421
References 1425
Section V Gingival Pathology 1442
Chapter 16 Defense Mechanisms of the Gingiva 1443
Sulcular Fluid 1443
Leukocytes in the Dentogingival Area 1452
Saliva 1454
References 1461
Chapter 17 Gingival Inflammation 1471
Stage I Gingival Inflammation: The Initial Lesion 1473
Stage II Gingival Inflammation: The Early Lesion 1478
Stage III Gingival Inflammation: The Established Lesion 1480
Stage IV Gingival Inflammation: The Advanced Lesion 1484
References 1485
Chapter 18 Clinical Features of Gingivitis 1490
Course and Duration 1491
Description 1492
Clinical Findings 1495
References 1516
Chapter 19 Gingival Enlargement 1523
Terminology and Classification 1524
Diagnosis 1526
Types of Gingival Enlargement 1527
Other Forms of Gingival Enlargement 1553
References 1562
Chapter 20 Acute Gingival Infections 1573
Necrotizing Ulcerative Gingivitis 1573
Primary Herpetic Gingivostomatitis 1589
Pericoronitis 1595
Conclusions 1596
References 1598
Chapter 21 Gingival Disease in Childhood 1605
Periodontium of the Primary Dentition 1606

Development 1609
Gingival Diseases of Childhood 1613
Periodontal Diseases of Childhood 1622
Gingival Manifestation of Systemic Disease in Children 1626
Oral Mucosa in Childhood Diseases 1628
Therapeutic Considerations for Pediatric Patients 1628
Conclusions 1631
References 1634
Chapter 22 Desquamative Gingivitis 1641
Chronic Desquamative Gingivitis 1641
Diagnosis of Desquamative Gingivitis: A Systematic Approach 1643
Diseases That Can Manifest as Desquamative Gingivitis 1650
Drug-Related Eruptions 1687
Miscellaneous Conditions That Mimic Desquamative Gingivitis 1689
References 1692
Section VI Periodontal Pathology 1708
Chapter 23 The Periodontal Pocket 1709
Classification 1710
Clinical Features 1712
Pathogenesis 1714
Histopathology 1720
Periodontal Disease Activity 1738
Site Specificity 1739
Pulp Changes Associated With Periodontal Pockets 1739
Relationship of Attachment Loss and Bone Loss to Pocket Depth 1739
Area Between Base of Pocket and Alveolar Bone 1741
Relationship of Pocket to Bone 1741
Periodontal Abscess 1745
Lateral Periodontal Cyst 1748
References 1750
Chapter 24 Bone Loss and Patterns of Bone Destruction 1757

Bone Destruction Caused by the Extension of Gingival Inflammation 1759
Bone Destruction Caused by Trauma From Occlusion 1772
Bone Destruction Caused by Systemic Disorders 1773
Factors Determining Bone Morphology in Periodontal Disease 1774
Bone Destruction Patterns in Periodontal Disease 1778
Conclusion 1792
References 1796
Chapter 25 Periodontal Response to External Forces 1801
Adaptive Capacity of the Periodontium to Occlusal Forces 1801
Trauma From Occlusion 1803
Stages of Tissue Response to Increased Occlusal Forces 1808
Effects of Insufficient Occlusal Force 1814
Reversibility of Traumatic Lesions 1815
Effects of Excessive Occlusal Forces on Dental Pulp 1815
Relationship Between Plaque-Induced Periodontal Diseases and Trauma From Occlusion 1816
Pathologic Tooth Migration 1821
Summary 1828
References 1829
Chapter 26 Masticatory System Disorders That Influence the Periodontium 1835
Temporomandibular Joint 1836
Muscles and Nerves of the Masticatory System 1838
Centric Relation 1840
Biomechanics of the Masticatory System 1842
Dysfunction and Deterioration 1844
Orofacial Pain 1849
Comprehensive Evaluation 1854
Diagnostic Decision Making 1861
Acknowledgments 1862
References 1864
Chapter 27 Chronic Periodontitis 1880

Clinical Features 1882
Risk Factors for Disease 1894
References 1905
References 1907
References 1907
